In summary, although the precise mechanism of action is unknown, some common features of investigation have emerged. The potential targets, widely found and disparate in function, all seem to be inhibited by lithium in an uncompetitive fashion, most commonly through displacement of a divalent cation, usually  $\text{Mg}^{2+}$ . The systems affected by this inhibition vary widely. Downstream targets modulate secondary cell messengers and intracellular

signal transduction, transcription factors and gene expression, and neuronal plasticity and cellular differentiation. Further study is needed to elucidate the complex interaction of these pathways with the action of lithium to form an integrated hypothesis, along with the disruption that occurs in cases of lithium toxicity.

## PHARMACOKINETICS AND TOXICOKINETICS

Lithium has a volume of distribution of between 0.6 and 0.9 L/kg. It has no discernible protein binding and distributes freely in total body water, with the exception of the cerebrospinal fluid (CSF), from which it is actively extruded.<sup>72,98,198</sup> The extrusion is believed to occur through active transport mechanism involving sodium-lithium exchange at the arachnoid processes.<sup>70</sup> Immediate-release preparations of lithium are rapidly absorbed from the gastrointestinal (GI) tract, and peak serum concentrations are achieved within 1 to 2 hours. Sustained-release products demonstrate variable absorption, with a delay to peak of 4 to 5 hours.<sup>98,223</sup> In overdose, a longer delay to peak concentrations and multiple peaks are reported.<sup>69,98</sup> Chronic therapy prolongs the elimination of lithium, as does advancing age.<sup>98</sup> Although lithium is rapidly absorbed, tissue distribution is a complex phenomenon, with a significant delay to achieve steady state, similar to digoxin. Lithium exhibits preferential uptake into the kidney, thyroid, bone, and other organs and tissues such as the liver and muscle. Lithium distribution into the brain can take up to 24 hours to reach equilibrium. Lithium is concentrated in red blood cells (RBCs) by both passive diffusion and active transport. Although the RBC concentration correlates closely with the brain concentration, this does not appear to be clinically useful.<sup>48</sup> The pharmacokinetic profile of lithium is described as an open, two-compartment model.<sup>72,98</sup>

Each 300-mg lithium carbonate tablet contains 8.12 mEq of lithium.<sup>98</sup> Ingestion of a single 300-mg tablet is expected to increase the serum lithium concentration by approximately 0.1 to 0.3 mEq/L (assuming a volume of distribution of approximately 0.6–0.9 L/kg and a patient weight of 50–100 kg).

Lithium is not metabolized and is eliminated almost entirely (95%) by the kidneys, with a small amount eliminated in the feces.<sup>72</sup> Lithium is also found in sweat, saliva, and breast milk.<sup>68,228</sup> In an adult with normal kidney function, lithium clearance varies from 10 to 40 mL/min.<sup>98,222</sup> Given the elimination of lithium being primarily renal, when at steady state, total body clearance equals renal clearance.

Lithium is handled by the kidneys much in the same way as sodium. Lithium is freely filtered, and more than 80% is reabsorbed by the proximal tubule. There is also a small amount reabsorbed in the loop of Henle and distal tubule.<sup>39,81,136,222</sup> Lithium excretion is therefore dependent on factors that affect the glomerular filtration rate (GFR) or decrease serum sodium concentration. Any condition that makes the kidney sodium avid, such as volume depletion or salt restriction, increases lithium reabsorption in the proximal tubule.<sup>98,222</sup> Thus, risk factors for accumulation of lithium and subsequent development of toxicity include advanced age (decrease in GFR); use of thiazide diuretics, nonsteroidal antiinflammatory drugs (NSAIDs), or angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs); decreased sodium intake; and low-output heart failure.<sup>16,163,229</sup>

The therapeutic index of lithium is narrow. The generally accepted steady-state therapeutic range of serum lithium concentrations is 0.6 to 1.0 mmol/L, although much disagreement exists about whether this serum concentration truly reflects therapeutic efficacy.<sup>80,98,147</sup> A detailed review of 246 studies examining long-term treatment of mood disorders found that although the target concentration should be individualized, tighter control (0.6–0.8 mmol/L) was associated with the best efficacy with the most tolerated side effect profile.<sup>208</sup> Both in therapeutic and overdose situations, clinical signs and symptoms seem to be a more valuable indicator of brain lithium concentrations than serum measurements.<sup>18,169</sup>

## CLINICAL MANIFESTATIONS

Similar to other xenobiotics having prolonged redistributive phases and tissue burdens, lithium toxicity is characteristically divided into three main categories: acute, acute on chronic, and chronic. In acute lithium toxicity, the

patient has no body burden of lithium present at the time of ingestion. The toxicity that develops depends on the amount ingested, along with rates of absorption, distribution, and elimination. In chronic toxicity, the patient has a stable body burden of lithium as the serum concentration is maintained in the therapeutic range, and then some factor disturbs this balance, either by enhancing absorption, or more commonly, decreasing elimination. For chronic users of lithium, small perturbations in the equilibrium between intake and elimination often leads to toxicity. In acute-on-chronic toxicity, the patient ingests an increased amount of lithium (intentionally or unintentionally) in the setting of a stable body burden. With tissue saturation, any additional lithium leads to signs and symptoms of toxicity.

### Acute Toxicity

Acute ingestions of lithium salts produce clinical findings similar to that of ingestions of other metal salts, with predominant early GI effects. Nausea, vomiting, and diarrhea are prevalent. Significant volume losses may result, leading patients to complain of lightheadedness, dizziness, and orthostasis. Neurologic manifestations occur several hours after ingestion in acute toxicity because the lithium redistributes slowly into the CNS from the serum.

### Chronic Toxicity

Lithium is primarily a neurotoxin. The earliest case reports of lithium toxicity described predominantly neurologic symptoms.<sup>215,231</sup> Most important, neurotoxicity does not precisely correlate with serum concentrations.<sup>73,195</sup> The initial clinical condition of the patient and the duration of exposure to an elevated concentration are more closely predictive of outcome than the initial serum lithium concentration.<sup>1,8,104,106,206</sup>

Approximately 27% of patients using lithium develop tremor, making this one of the most common movement disorders encountered in clinical practice.<sup>165</sup> Tremor is positively correlated with age, male sex, and concomitant use of neuroleptics and other antidepressants.<sup>12,227</sup> It may also be the most common drug-induced tremor encountered clinically, although it is typically mild.<sup>170</sup> The tremor is classified as a postural tremor and subcategorized as an exaggerated physiologic tremor, with a frequency of 8 to 12 Hz most commonly seen in the hands.<sup>12</sup> Drug-induced Parkinsonism also rarely occurs.<sup>110</sup> The mechanism that leads to development of the tremor is unknown.

The tremor diminishes over time with continued therapy but increases with toxicity. Other findings of chronic toxicity include fasciculations, hyperreflexia, choreoathetoid movements, clonus, dysarthria, nystagmus, and ataxia.<sup>165,223</sup> The mental status is often altered and progresses from confusion to stupor, coma, and seizures.<sup>147,163</sup> Electroencephalographic (EEG) changes are most frequently reported as “slowing.”<sup>105,210</sup> The progression of these symptoms follows no order, and any patient undergoing chronic therapy can have one or any combination of these features. In rats, lithium overdose consistently induced encephalopathy with increasing severity as per the pattern of exposure. The occurrence of seizures and fatality paralleled the severity of the encephalopathy. The neurotoxic effects of lithium, as evidenced by EEG abnormalities and clinical signs and symptoms outlast the normalization of serum lithium concentrations.<sup>73,105</sup>

The syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) is a descriptive syndrome of the irreversible neurologic and neuropsychiatric sequelae of lithium toxicity.<sup>1,103,116,183</sup> The syndrome of irreversible lithium-effectuated neurotoxicity is defined as neurologic dysfunction that is caused by lithium in the absence of prior neurologic illness and persists for at least 2 months after cessation of the drug. Case reports support these findings and this definition. However, as is true in most case reports, confounders make wide applicability of the findings difficult. Because of the polypharmacy prevalent in psychiatry, long-term neurologic sequelae attributed to lithium are frequently described in patients using lithium in combination with other xenobiotics, such as haloperidol, chlorpromazine, carbamazepine, phenytoin, aspirin, VPA, amitriptyline,  $\beta$ -adrenergic antagonists, calcium channel blockers, angiotensin-converting enzyme inhibitors, diuretics, and NSAIDs.<sup>1,76,103,107,156,168</sup> However, there exist reports of patients using lithium

without coingestants and no comorbid illness who sustained lasting dysfunction as a result of lithium toxicity.<sup>2,8,127,175,206</sup> Cerebellar findings predominate in patients with SILENT.<sup>1-3,158,183</sup> One of the predictors of persistent neurologic dysfunction is the concomitant finding of hyperpyrexia, an ominous finding in patients with lithium toxicity.<sup>99,158</sup> The mechanism of the persistent dysfunction is unclear, but demyelination and cellular loss are proposed.<sup>1,158,203</sup>

### Acute-on-Chronic Toxicity

Patients undergoing chronic therapy who acutely ingest an additional amount of lithium (either intentionally or unintentionally) are at risk for signs and symptoms of both acute and chronic toxicity. These patients display prominent GI and neurologic effects, which adds some confusion to diagnosis and management. Serum lithium concentrations in cases of acute or chronic toxicity are often difficult to interpret.

### Other Systemic Manifestations of Chronic Lithium Therapy

The most common adverse effect of chronic lithium therapy is nephrogenic diabetes insipidus (NDI), which can develop within weeks of the initiation of therapy and affects up to 40% of patients (Chap. 12).<sup>100,174</sup>

Lithium inhibits the transport of sodium through the amiloride-sensitive epithelial sodium channel (ENaC), which is also the main route of entry for lithium. Lithium has a twofold higher affinity than sodium for entry through this channel, without a corresponding means of extrusion and thus becomes concentrated intracellularly.<sup>100,174</sup> Lithium inhibits magnesium-dependent G proteins that activate vasopressin-sensitive adenylate cyclase, leading to decreased generation of cAMP in the cell membranes of distal tubular cells.<sup>38,56,221,230</sup> Decreased cAMP leads to reduced expression and translocation of the vasopressin-regulated water channel aquaporin-2 (AQP2), making the distal tubules resistant to the action of vasopressin, and thus unable to concentrate urine.<sup>5,38,146,232</sup> There is a potential mechanistic overlap with GSK-3 $\beta$ . With GSK-3 $\beta$  inhibition by lithium, the tonic inhibition of cyclooxygenase-2 (COX-2) is removed, and increased COX-2 activity leads to increased prostaglandin expression in the renal medulla. Increased prostaglandin expression is important in NDI through regulation of glomerular blood flow,<sup>188,189</sup> as well as increasing the degradation of AQP2, further decreasing the ability to form a concentrated urine.<sup>128,129,188,189</sup>

Chronic lithium therapy is associated with chronic tubulointerstitial nephropathy, as manifested by the development of acute kidney injury (AKI) and chronic kidney disease (CKD) with little or no proteinuria and biopsy findings of tubular cysts. This association was demonstrated in a biopsy-based study of 24 chronically treated patients, although the overall prevalence of this condition is low.<sup>100</sup> Long-term treatment (> 10 years) is associated with the development of CKD, including a small percentage of chronic kidney failure.<sup>6,125</sup>

Lithium causes a number of endocrine disorders. The most prevalent endocrine manifestation of chronic lithium therapy is hypothyroidism, which has a multifactorial etiology.<sup>44</sup> Lithium is selectively concentrated in the thyroid gland and competes for iodide transport, synthesis of triiodothyronine (T<sub>3</sub>), responsiveness of the gland to thyroid-stimulating hormone (TSH), release of T<sub>3</sub> and tetraiodothyronine (T<sub>4</sub>), and peripheral conversion of T<sub>4</sub> to T<sub>3</sub>.<sup>44,85</sup> Lithium decreases the responsiveness of peripheral tissues to T<sub>3</sub> and increases antithyroglobulin antibodies if already present, although it does not induce development de novo (Fig. 53-1).<sup>13,134,173</sup> Although hypothyroidism is most common, hyperthyroidism and thyrotoxicosis are also reported.<sup>33,41,110,200,220</sup> Hyperthyroidism, by altering proximal tubule function, leads to decreased lithium excretion.<sup>21</sup> Thus, hyperthyroidism leads to chronic lithium toxicity through impaired elimination, and the elevated lithium concentrations often can mask the manifestations of hyperthyroidism.<sup>19,173</sup> Interestingly, because lithium inhibits the release of thyroid hormone, it has been used as an adjunctive therapy for hyperthyroidism.<sup>101,134</sup>

The combination of hyperparathyroidism and hypercalcemia is frequently reported in patients receiving chronic lithium therapy, most commonly in older women. The mechanism is thought to be modification of

calcium feedback on parathyroid hormone release through alteration of a calcium-sensing receptor that prevents suppression of parathyroid hormone release in response to elevated calcium,<sup>191</sup> although stimulation of parathyroid hormone release, parathyroid gland hyperplasia, and adenomas are alternative suggested mechanisms.<sup>10,140,160,218</sup>

Lithium is associated with a number of electrocardiographic (ECG) abnormalities, although the evidence for significant toxicity is lacking. Most reports are uncontrolled case reports without corroborating experimental data or biologic plausibility. The most commonly reported manifestation is T-wave flattening or inversion, primarily in the precordial leads,<sup>177</sup> although prolongation of the QT interval is also noted.<sup>131,226</sup> One study associated elevated serum lithium concentrations with QT interval prolongation above 440 ms, although the number of patients studied was small.<sup>115</sup> Associations exist between lithium and sinoatrial dysfunction, with resultant bradycardia.<sup>9,91,176,211,219</sup> However, many of these cases had either electrolyte disturbances or multiple other cardioactive xenobiotics involved that would be more likely causative.<sup>50,155,171,211,219,233</sup> Numerous case reports link lithium with an ECG pattern that is consistent with a myocardial infarction, without biochemical markers of injury.<sup>123,124,184</sup> Additional case reports link lithium to ventricular dysrhythmias.<sup>42</sup> Lithium blocks cardiac sodium channels in a transfected Chinese hamster ovary cell, which is the putative link between lithium therapy and the unmasking of a Brugada pattern and cardiomyopathy.<sup>50,62,89,211,219,233</sup> For the most part, lithium has few consequential effects on cardiac function, even in overdose, and malignant dysrhythmias or significant dysfunction are very uncommon.

Developmentally, in utero exposure to lithium increases the incidence of congenital heart defects (approximately 1 additional case per 100 live births), specifically right ventricular outflow obstructions (including Ebstein abnormality), in a dose-dependent fashion.<sup>68,179,237</sup> Additionally, many effects similar to those that occur in patients undergoing chronic therapy are found in infants exposed in utero, including thyroid disease and neurotoxicity.<sup>88</sup>

Lithium causes a leukocytosis and an increase in neutrophils. It was proposed as an adjunct to chemotherapy-induced neutropenia, other marrow suppressive therapies, and acquired immunodeficiency syndrome (AIDS).<sup>63</sup> Although lithium increases the total neutrophil count, no improved clinical outcomes are documented, and its use is now superseded by recombinant colony-stimulating factors.<sup>77,182,193</sup>

## DIAGNOSTIC TESTING

Because of the prevalence of lithium use, therapeutic drug monitoring is readily available in most settings, and serum concentrations are usually readily obtainable.<sup>236</sup> A lithium concentration should be determined upon patient presentation and serial measurements obtained in most instances in which overdose or toxicity is likely, especially after ingestion of sustained-release preparations. Emphasis should be placed on the lithium concentration as a marker of exposure and response to therapy but not necessarily as a determinant of toxicity or treatment. The history, symptoms, and clinical signs, rather than the absolute lithium concentration, should guide therapy. The sample must be sent in an appropriate lithium-free tube because use of lithium-heparin tubes will lead to false-positive results, up to an additional 4 mEq/L.<sup>137</sup> Serum electrolyte concentrations and kidney function should be assessed because kidney function is important in determining the need for more aggressive therapy, such as hemodialysis. If the patient is hypernatremic, NDI should be suspected, and determinations of serum and urine osmolarity and electrolytes help confirm the diagnosis (Chap. 12). If thyroid disease is suspected, thyroid function tests should be obtained. If a deliberate ingestion has occurred, a serum acetaminophen concentration should be obtained. An ECG is also indicated. The complete blood count may indicate a leukocytosis as a stress response or caused by the hematologic effects of lithium.

## MANAGEMENT

The initial management and stabilization should begin with assessment and, if necessary, support of airway, breathing, and circulation. Lithium rarely, if ever, affects the patient's airway or breathing, although coingestants may.

Emesis, which occurs with significant frequency after acute exposure, may lead to aspiration and respiratory compromise. After the patient is stable, the characteristics of the exposure should be determined while the physical examination and laboratory assessment commence. The formulation and nature of the product should be ascertained and, most important, identified as immediate- or sustained-release. Whether or not lithium is part of the patient's medication regimen is helpful to determine whether the ingestion is acute, acute on chronic, or chronic.

## Gastrointestinal Decontamination

For patients who present after an acute overdose or an acute-on-chronic overdose, a risk benefit analysis of GI decontamination must be undertaken. Two factors should be considered. With an acute overdose and predominance of early GI symptoms, including emesis, self-decontamination may already have occurred. Second, immediate-release preparations are often rapidly absorbed and may not lend themselves to GI evacuation.

Gastrointestinal decontamination options are limited. Lithium salts are monovalent do not bind readily to activated charcoal.<sup>149</sup> Because of the danger of a depressed level of consciousness, potential loss of protective airway reflexes, and emesis, no beneficial effect from activated charcoal is expected unless indicated for treatment of a coingestant. Orogastric lavage has a limited role in the acute management of a patient with a lithium overdose but remains of reasonable benefit early in the clinical course after a substantial ingestion. Immediate-release preparations of lithium are rapidly absorbed and typically produce emesis, obviating the role of lavage, and sustained-release formulations of lithium (ie, controlled-release tablets) are compounded in a slowly dissolving film-coated formulation, often making the tablet too large to fit through even the largest lavage tube.

Sodium polystyrene sulfonate (SPS) is a cationic exchange resin often used for the treatment of severe hyperkalemia. It binds potassium in exchange for sodium, allowing elimination of excess potassium in the feces. Because of the ionic similarity between potassium and lithium, use of SPS has been proposed for decontamination of patients being treated for lithium toxicity. A number of models have examined the effectiveness of this technique.<sup>149-151</sup> Use of SPS has many theoretical benefits, including demonstrated effectiveness of lithium binding in vitro compared with activated charcoal and the ability of orally administered SPS to reduce serum concentrations of intravenously administered lithium in mice.<sup>149</sup> Unfortunately, the finding that doses used to increase lithium elimination also lead to significant hypokalemia in human participants limits the application of this technique.<sup>201</sup> In a murine model, potassium supplementation with SPS was found to mitigate this process but only at the expense of elevating lithium concentrations.<sup>151</sup> Two reports in the literature demonstrate increased lithium elimination with SPS, one in a healthy volunteer and another in a patient with an acute overdose. However, the serum potassium concentration was not reported in either case.<sup>87</sup> In a retrospective cohort review of 12 chronically poisoned patients, it was suggested that SPS reduced the elimination half-life of lithium by 50%. However, many of the patients had altered kidney function that was corrected at the same time as the intervention (which was not standardized), and no clinical outcomes were reported.<sup>90</sup> We therefore recommend against the routine use of SPS in the management of the lithium-poisoned patients.

Whole-bowel irrigation (WBI) is the only GI decontamination that has some demonstrated efficacy in eliminating lithium from volunteers. In one of the few clinical trials of WBI, the serum lithium concentrations of 10 normal volunteers who ingested sustained-release lithium carbonate were plotted against time over a 72-hour period. In the second phase of the trial, when the volunteers received 2 L/h of polyethylene glycol solution 1 hour after the ingestion, there was a significant reduction (67%) in the serum concentration, even as early as 1 hour after the therapeutic intervention.<sup>214</sup> Whole-bowel irrigation is recommended for patients manifesting significant toxicity (ie, neurologic dysfunction) and who have ingested sustained-release lithium preparations and have no contraindications (eg, protected airway, no obstruction or ileus) (Antidotes in Depth: A2).

## Fluid and Electrolytes

The critical initial management of the lithium-poisoned patient should focus on restoration of intravascular volume, both in those with acute poisonings with GI losses and in chronic poisonings with toxic effects that are often the result of disturbances of kidney function and lithium elimination. Many patients with lithium toxicity have volume-responsive decreases in kidney function,<sup>190</sup> which we recommend to manage with infusion of 0.9% sodium chloride solution at 1.5 to 2 times the maintenance rate.<sup>40,138</sup> This therapy increases renal perfusion, and GFR, which will increase lithium elimination. When the kidney is sodium avid (as in volume depletion) it will retain lithium. Increased intravascular volume will reduce this retention and increase the elimination of lithium. Urine output must be closely monitored and any electrolyte abnormalities corrected. Caution must be used in patients with prerenal AKI, CKD, and congestive heart failure. Monitoring for the development of hypernatremia in patients suspected of having NDI is critical because this occurs in approximately 55% of patients on long-term therapy.<sup>146,199,222</sup>

Lithium-induced NDI is sometimes reversed by discontinuation of the drug and repletion of electrolytes and water, although it may be permanent.<sup>128,222</sup> Use of amiloride, as well as acetazolamide, to mitigate lithium-induced polyuria is described, although the potential for volume contraction and stimulation of lithium reabsorption prevents recommendation of this drug as a routine adjunct to acute care.<sup>33,75,93,128,190</sup> A novel proposed therapeutic, the direct renin inhibitor aliskiren, improved the urinary concentrating defect in lithium-treated mice. Aliskiren upregulated AQP2 protein expression in inner medullary collecting duct principal cells and prevented lithium-induced NDI.<sup>148</sup>

We recommend against any attempt to enhance elimination of lithium by forced diuresis using loop diuretics (furosemide), osmotic agents (mannitol), carbonic anhydrase inhibitors (acetazolamide), or phosphodiesterase inhibitors (aminophylline). An initial small increase in elimination may be achieved, but typically salt and water depletion subsequently developed followed by increased lithium retention.<sup>39</sup> We also recommend against sodium bicarbonate administration for urinary alkalinization because it does not significantly increase elimination over volume expansion with sodium chloride and may lead to hypokalemia, alkalemia, and fluid overload.

## Extracorporeal Drug Removal

Lithium has pharmacokinetic properties that make it amenable to extracorporeal removal,<sup>22,74,114,118,136</sup> and with these characteristics, it would seem to be an ideal candidate for hemodialysis. In fact, hemodialysis is often recommended for treatment of acute, acute-on-chronic, and chronic lithium toxicity.<sup>14,74,117,180,223</sup> The original criteria for hemodialysis originated from a case series of 23 patients and a review of 100 other patients published in 1978, which was before the introduction of sustained-release products.<sup>106</sup> Those recommendations were never prospectively evaluated or subsequently reevaluated.<sup>15,74,84</sup>

Some characteristics of lithium make impactful extracorporeal elimination difficult. Lithium is predominantly localized intracellularly and diffuses slowly across cell membranes.<sup>74</sup> When traditional intermittent hemodialysis is used for patients with chronic exposures, clearance of the blood compartment is often followed by a rebound phenomenon of redistribution from tissue stores, leading to recurrent increased serum concentrations. The clinical significance of this rebound is uncertain, but without additional elimination, this can redistribute back into target tissues.<sup>43</sup> There have only been three cases reported of clinical deterioration after rebound from an extracorporeal elimination method, likely as a result of failed decontamination in an extended-release ingestion and ongoing absorption.<sup>41,45,83</sup> An additional complicating factor is that the brain, the "target organ" of toxicity, is not directly amenable to a rapid artificial elimination process. Attempts have been made to correlate the serum concentration with the lithium concentration in the CSF and brain. But in the few studies in which CSF concentrations were obtained, although serum and CSF lithium concentrations correlated, brain concentrations and clinical effects did not.<sup>111,119</sup> Magnetic resonance spectroscopy studies of bipolar patients with steady-state lithium concentrations demonstrated a significant

variability between brain and serum concentrations, especially within the therapeutic range.<sup>78,192</sup> In addition, because of the toxicokinetic profile of lithium, serum concentrations do not correlate well with toxicity.<sup>73,97,119,223</sup>

Consensus exists regarding when to perform an extracorporeal elimination technique (extracorporeal treatment {ECTR}). The Extracorporeal Treatments in Poisoning Workgroup (ExTRIP) performed an extensive analysis of the data available regarding lithium. Their consensus provides the following analysis: "ECTR is recommended in severe lithium poisoning," graded (I, D). The "I" indicates that more than 85% of the members strongly recommend, and the D that there is a very low level of evidence (no observational studies or randomized controlled trials).<sup>66</sup> In the statement, there is a movement away from absolute values and serum concentrations with simple thresholds combined with clinical symptoms as guidelines for intervention.

Extracorporeal treatment is recommended if kidney function is impaired and the lithium concentration is greater than 4.0 mEq/L or in the presence of a decreased level of consciousness, seizures, or life-threatening dysrhythmias regardless of the lithium concentration<sup>66</sup> (Table 70–1).

Extracorporeal treatment is suggested if the concentration is greater than 5.0 mEq/L, if confusion is present or if the expected time to obtain a concentration less than 1.0 mEq/L with optimal management is more than 36 hours.<sup>66</sup>

Whether hemodialysis diminishes or enhances the risk of permanent neurologic sequelae is the subject of ongoing debate.<sup>216,217</sup> Although no controlled studies have analyzed this important management question, a preponderance of evidence suggests a reduced risk.<sup>1,8,14,74,114,119,167,180,183,205,223</sup> A Cochrane systematic review was methodologically flawed because there have been no randomized controlled trials of hemodialysis for lithium poisoning, and thus was inconclusive regarding the benefits of hemodialysis in lithium poisoning.<sup>133</sup>

The choice of ECTR should be guided by the availability of the equipment and the clinical status of the patient. The recommended methodology is intermittent hemodialysis (IHD), although continuous methods are acceptable if IHD is not available. After the technique is complete, serial measurements should be obtained over 12 hours to determine if the ECTR should be repeated. After the initial treatment, both continuous and intermittent methods are equally acceptable.<sup>66</sup>

Continuous venovenous hemodialysis and continuous venovenous hemodiafiltration are two continuous renal replacement therapies (CRRTs) commonly used in the treatment of patients with AKI or volume overload and for elimination of xenobiotics.<sup>14,32,225</sup> Both techniques are effective in patients who are hemodynamically unstable because they are not dependent on arterial blood pressure.<sup>84,164,225</sup> Traditional IHD offers clearance rates that vary between 50 and 170 mL/min with blood flows of 250 mL/min or more.<sup>74,126,153,180,225</sup> Although CRRT techniques offer lower clearance per hour than does IHD, their overall daily clearances are similar.<sup>74</sup> With continued improvements in techniques, use of high volumes, and high dialysate flow rates, clearances are improving, approaching more than half the clearance per hour achieved by IHD in some studies.<sup>84</sup> One case of a rebound concentration was reported in a patient treated with continuous arteriovenous hemodiafiltration,<sup>35</sup> and one case with use of combined renal replacement therapies, including veno-venous techniques, showed no rebound.<sup>14</sup>

**TABLE 70–1** Consensus Recommendations for Hemodialysis<sup>a</sup>

Strength of Recommendation	Concentration	OR Clinical Features
Recommended	>4.0 mEq/L with ↓GFR	Decreased level of consciousness, seizures, or life-threatening dysrhythmias
Reasonable	>5.0 mEq/L	Confusion or [Li <sup>+</sup> ] not expected to fall to <1.0 mEq/L with optimal management in 36 h

<sup>a</sup> ↓ GFR = glomerular filtration rate <60 mL/min.

Data from Decker BS, Goldfarb DS, Dargan PI, et al. Extracorporeal Treatment for Lithium Poisoning: Systematic Review and Recommendations from the ExTRIP Workgroup. *Clin J Am Soc Nephrol*. 2015 May 7;10(5):875-887.

These techniques are most likely to be after IHD to prevent redistribution of lithium and rebound of serum concentrations (Chap. 6).

After an initial session of an ECTR such as IHD, a second session or more are recommended until serum lithium concentrations fall consistently below 1.0 mEq/L; clinical improvement is apparent; or as per the ExTrip consensus, after a minimum of 6 hours of therapy when a concentration is not readily available.<sup>66</sup>

Peritoneal dialysis offers no increased efficacy of clearance of lithium over the natural clearance of normal kidneys.<sup>14,74</sup> Although recommended in the past, given its lack of efficacy coupled with its infrequent use and potential for serious complications such as bowel perforation, peritoneal dialysis has no role in the management of lithium-poisoned patients.

## SUMMARY

- Lithium is a simple ion with extensive current usage and extremely varied and complex clinical and pathophysiological effects.
- Lithium is available in multiple formulations, both immediate release and sustained release, and has an essential role in clinical psychiatry.
- Because of the complexity of the pharmacokinetic profile of lithium, toxicity develops in a wide range of conditions and is precipitated by both intentional overdose and therapeutic misadventure.
- The care of lithium-poisoned patients should be predicated on rapid clinical evaluation of the condition of the patient coupled with identification of the type of poisoning.
- Management includes the use of volume resuscitation and WBI and/or another extracorporeal treatment, when indicated, to prevent or treat severe neurologic morbidity and to prevent death.
- Syndrome of irreversible lithium-effectuated neurotoxicity is a persistent neuropsychiatric consequence of lithium toxicity with predominant cerebellar findings that continue at least 2 months after cessation of lithium.

# MONOAMINE OXIDASE INHIBITORS

Alex F. Manini

## HISTORY AND EPIDEMIOLOGY

Monoamine oxidase inhibitors (MAOIs) have a unique history, pharmacology, and toxic syndrome. Although toxicity from MAOI ingestion is becoming less common because of more limited clinical usage of the traditional nonselective MAOIs, an understanding of MAOI toxicity is fundamental to any clinician who cares for patients with acute poisoning.

Monoamine oxidase (MAO) was discovered in 1928 and named by Zeller when the enzyme was recognized to metabolize primary, secondary, and tertiary amines such as tyramine and norepinephrine.<sup>132</sup> Subsequently, the “monoamine hypothesis” postulated depression as a condition of monoamine deficiency, and MAOIs targeted monoamine metabolism for therapeutic benefit. In the early 1950s, iproniazid, a drug previously used to treat tuberculosis, was found to produce favorable behavioral effects. By the mid-1950s, it was demonstrated that iproniazid inhibited MAO, and it then became the first antidepressant used clinically.<sup>22</sup>

In the late 1960s, two MAO isoforms were identified, each with substrate and inhibitor specificity. This determination led to the development of selective MAOIs in attempts to minimize the many food and drug interactions that occur with the traditional nonselective MAOIs. Nonselective MAOIs proved to be potent and efficient antidepressants and became the first-line therapy for depression. In the 1970s, alternative therapies for depression, such as the tricyclic antidepressants, were developed and achieved clinical success without as many food and drug interactions.

Intentional MAOI overdose is relatively uncommon and accounts for a dwindling number of annual exposures reported to the American Association of Poison Control Centers. From 2011 to 2015, there was a decreasing trend in the number of exposures with fewer than 100 exposures reported in 2015 (Chap. 130), representing less than 1% of all antidepressant exposures. Of the reported exposures in 2010, there were only five cases of “major toxic effect” (defined as life-threatening signs or symptoms), and no deaths were reported. Over the past 2 decades, annual reported MAOI exposures have decreased 34% since 1985 (Chap. 130). Global MAOI exposure rates declined in proportion with the United States, with the possible exception of exposures to moclobemide, a drug not approved by the US Food and Drug Administration (FDA).<sup>33</sup>

Many authors recommend the prescription of nonselective MAOIs only for resistant or atypical depression with prominent neurovegetative symptoms.<sup>30</sup> However, selective and reversible MAOIs are the subject of renewed clinical applicability and basic science research interest. Monoamine oxidase-B selective xenobiotics, such as selegiline, are widely used for the treatment of Parkinson disease. Reversible inhibitors of MAO, such as moclobemide, are used in Europe for depression, phobias, anxiety, and other select indications.<sup>130</sup> Current applicability of a new generation of experimental MAOIs is being investigated as neuroprotective xenobiotics for a variety of neurodegenerative diseases.<sup>132</sup>

## PHARMACOLOGY

### Chemistry

Monoamines, also known as biogenic amines, include the catecholamines (epinephrine, norepinephrine, dopamine, tyrosine), indolamines (serotonin, melatonin), and some naturally occurring amines (eg, tyramine, benzylamine). They share the presence of a single amine group and the ability to be metabolized by MAO, a flavin-containing enzyme present on the outer mitochondrial membrane of central nervous system (CNS) neurons, hepatocytes, and platelets. In a two-step reaction, MAO catalyzes the oxidative deamination of its various substrates. The reaction liberates  $H_2O_2$ , a reactive oxygen

species. Deamination by MAO is one of two major routes of elimination of monoamines, the other being extracellular degradation by catechol-*O*-methyltransferase (COMT). Serotonin and tyramine, which are not metabolized by COMT, are the exceptions to this rule.

### Monoamine Neurotransmitter Stores

Monoamine neurotransmitter synthesis, vesicle transport, vesicle storage, uptake, and degradation are described in detail in Chap. 13. In the neuron, MAO functions as a “safety valve” to metabolize and inactivate excess monoamine neurotransmitter molecules. After monoamines reenter the cytoplasm from the synaptic cleft, they can either reenter vesicles for further storage and release or can be rapidly enzymatically degraded by MAO.

### Monoamine Oxidase Isoforms

There are two MAO isoforms, each with its own substrate and inhibitor specificity (Table 71-1). Whereas MAO-A preferentially metabolizes norepinephrine and serotonin, MAO-B preferentially metabolizes phenylethylamine. Both isoforms metabolize tyramine and dopamine with comparable efficiency, but they are localized to different anatomic regions. Monoamine oxidase-A is concentrated in the intestine and liver, and MAO-B is concentrated in the basal ganglia of the brain.<sup>20</sup>

### Mechanism of Action

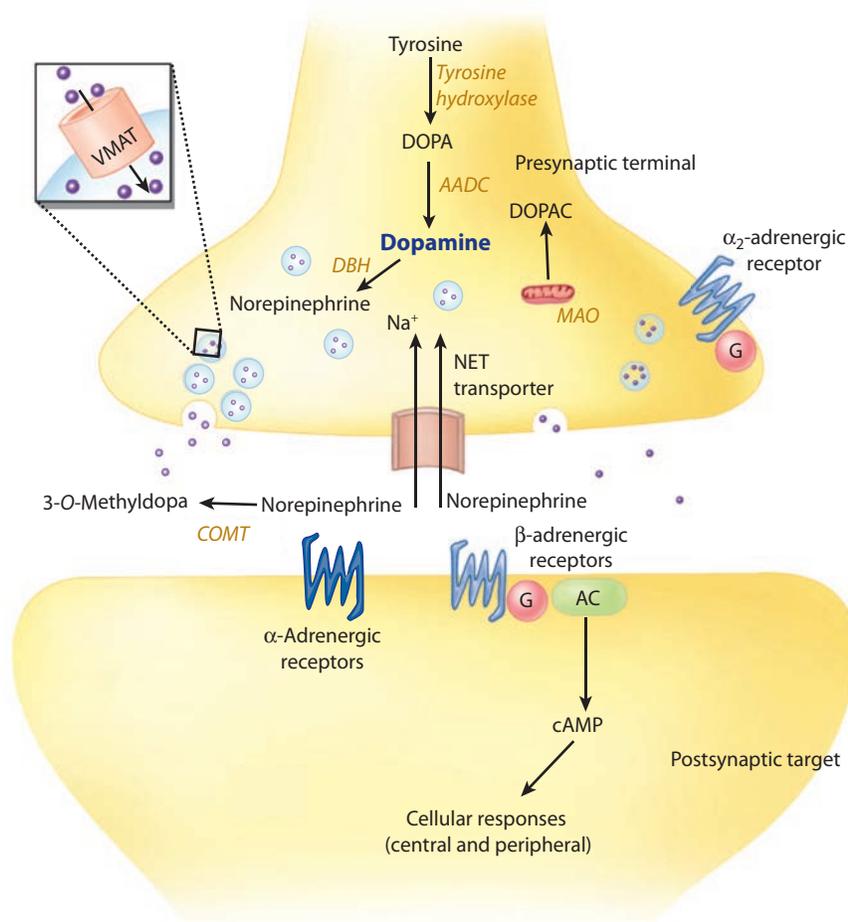

Monoamine oxidase inhibitors are transported into the neuron by the  $Na^+$ -dependent membrane norepinephrine-reuptake transporter.<sup>72</sup> Inhibition of MAO prevents presynaptic degradation of monoamines, thus increasing the concentration of monoamine neurotransmitters available for synaptic storage and subsequent release (Fig. 71-1). Inhibition of MAO also results in indirect release of norepinephrine into the synapse via displacement from presynaptic vesicles in a manner similar to amphetamines (Chap. 73).<sup>116</sup>

Elevated synaptic concentrations of serotonin are best correlated with the antidepressant therapeutic effects of MAOIs. The enzymatic inhibition produced by MAOIs precedes the clinical effects by as long as 2 weeks. This finding, which is similar to other antidepressants, most likely relates to the relatively slow downregulation of postsynaptic CNS serotonin receptors.<sup>93</sup>

In overdose, MAOIs also impair norepinephrine synthesis caused by dopamine- $\beta$ -hydroxylase inhibition. Impaired norepinephrine synthesis

TABLE 71-1 Monoamine Oxidase (MAO) Isoforms: Substrate Affinities and Localization

	MAO Isoforms	
	MAO-A	MAO-B
<b>Substrate Affinity</b>		
Dopamine	Moderate	Moderate
Epinephrine	Moderate	Moderate
Norepinephrine	High	Low
Serotonin	High	Low
Tyramine	Moderate	Moderate
<b>Localization</b>		
Brain	Low	High
Intestine	Moderate	Low
Liver	Moderate	Moderate
Placenta	High	Absent
Platelets	Absent	High

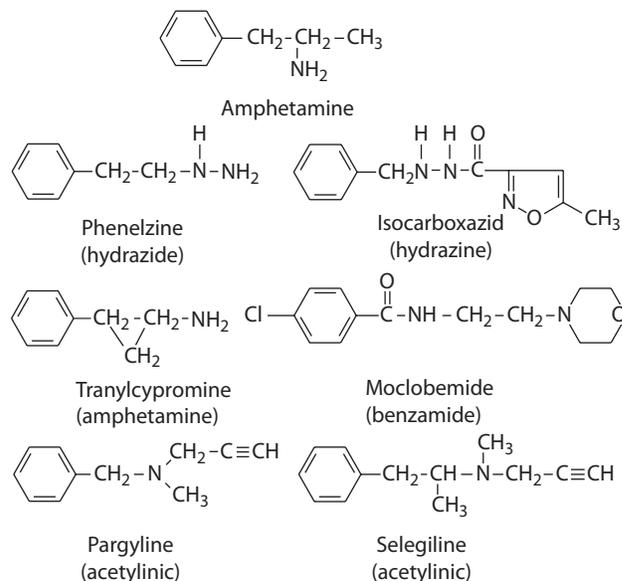

**FIGURE 71-1.** Sympathetic nerve terminal. Dopamine is synthesized in the sympathetic nerve cell and transported into vesicles, where it is converted to norepinephrine (NE) and stored in vesicles (●). An action potential causes the vesicles to migrate to and fuse with the presynaptic membrane. Norepinephrine diffuses across the synaptic cleft and binds with and activates postsynaptic  $\alpha$ - and  $\beta$ -adrenergic receptors. Neuronal NE reuptake occurs via the monoamine transporter. Norepinephrine is transported back into vesicles by the vesicular monoamine transporter (VMAT; inset) or metabolized to 3,4 dihydroxyphenyl acetic acid (DOPAC) by mitochondrial monoamine oxidase (MAO). Norepinephrine that diffuses away from the synaptic cleft is inactivated by catechol-*O*-methyl transferase (COMT). AADC = aromatic L-amino acid decarboxylase; cAMP = cyclic adenosine monophosphate; DBH = dopamine  $\beta$ -hydroxylase; NET = Membrane NE reuptake transporter.

leads to eventual depletion of norepinephrine stores. Additionally, indirect dopamine agonism occurs via elevated synaptic concentrations of dopamine. Dopamine agonism results in  $\beta$ -adrenergic stimulation, peripheral vasodilation, and direct  $\alpha$ -adrenergic stimulation at high doses.

The hydrazide MAOIs (eg, phenelzine, isocarboxazid) are thought to be cleaved to liberate pharmacologically active products (eg, hydrazides), which are metabolized by acetylation in the liver.

### First-Generation Monoamine Oxidase Inhibitors: Nonselective and Irreversible

Monoamine oxidase inhibitors are a chemically heterogeneous group of xenobiotics (Fig. 71-2). First-generation MAOIs (ie, irreversible and nonselective) in clinical use worldwide include the reactive hydrazide derivatives (phenelzine, isocarboxazid) and an amphetamine derivative (tranylcypromine).<sup>45</sup> First-generation MAOIs bind covalently to MAO and irreversibly inhibit the function of the enzyme. Thus, patients taking these MAOIs are depleted of the enzyme until new MAO is synthesized, a process that typically takes up to 3 weeks, resulting in short half-lives but long durations of effect. Patients taking first-generation MAOIs remain at risk for food and xenobiotic interactions during much of this period. Because nonselective MAOIs inhibit both isoforms of MAO (ie, MAO-A and MAO-B), inhibition of intestinal and hepatic degradation of biogenic amines occurs.

**FIGURE 71-2.** Structural similarities between amphetamine and the monoamine oxidase inhibitors (MAOIs). The words in parentheses are the chemical classes of the MAOI.

As a result, patients who receive these MAOIs must be placed on a restrictive diet to prevent adverse events resulting from the absorption of undigested tyramine from the gut.

Phenelzine, isocarboxazid, and tranylcypromine are currently FDA approved for treatment of refractory depression.<sup>57,76</sup> Other enzyme systems inhibited by first-generation MAOIs include amine oxidases such as diamine oxidase and semicarbazide-sensitive oxidases, arylamine *N*-acetyltransferase (by tranylcypromine), ceruloplasmin, alcohol dehydrogenase (by tranylcypromine), dopa decarboxylase, L-glutamic acid decarboxylase,  $\gamma$ -aminobutyric acid (GABA) decarboxylase and GABA transaminase (by hydrazide MAOIs), alanine aminotransferase (by phenelzine), and other pyridoxine ( $B_6$ )-containing enzyme systems.<sup>48</sup> The clinical implications of inhibiting these diverse enzyme systems, other than alcohol dehydrogenase and cytochrome P450 enzymes,<sup>104</sup> are poorly understood.

### Second-Generation Monoamine Oxidase Inhibitors: Selective and Irreversible

Selective MAOIs preferentially inhibit one of the two MAO isoforms, although isoform selectivity is dose dependent.

#### MAO-A Inhibitors

Clorgyline is an MAO-A inhibitor structurally related to pargyline. Once thought to be useful for treatment of depression, it has not found widespread use in psychiatry because of disappointing results from clinical trials.

#### MAO-B Inhibitors

Selegiline is a selective MAO-B inhibitor that is FDA approved for the treatment of Parkinson disease.<sup>57,67</sup> Monoamine oxidase-B selectivity may be lost in large overdoses. Selegiline transdermal system is FDA approved for treatment of major depressive disorder in adults as an alternative to the traditional oral delivery system.<sup>1,2,57</sup> Rasagiline is another MAO-B selective MAOI that is FDA approved to treat Parkinson disease.<sup>19</sup>

### Third-Generation Monoamine Oxidase Inhibitors: Selective and Reversible

Reversible inhibitors of monoamine oxidase-A (RIMAs) are a class of drugs that selectively and reversibly inhibit MAO-A.<sup>57</sup> These xenobiotics were developed in an effort to compensate for the limitations of first- and second-generation MAOIs (see Clinical Manifestations). Reversible inhibitors of monoamine oxidase-A can be displaced by tyramine from the active site of the enzyme MAO-B, thereby enabling peripheral metabolism of the amine. Because tyramine is not present in high concentrations in the brain, MAO-A continues to be inhibited, and the antidepressant effects are achieved.<sup>57</sup> Moclobemide is the most widely studied RIMA and is approved as an antidepressant in Europe and other parts of the world but not the United States.<sup>33</sup>

### Naturally Occurring Monoamine Oxidase Inhibitors

The extract of the plant St. John's wort (*Hypericum perforatum*) is licensed in Germany for use as an antidepressant. Although the major constituents, hypericin and hyperforin, have weak MAOI activity, it is uncertain whether this activity is responsible for its antidepressant effect. However, MAOI activity explains sporadic reports of hypertensive crises, cardiovascular collapse during anesthesia, and the development of serotonin toxicity associated with use of St. John's wort.<sup>51,84</sup>

Ayahuasca, a hallucinogenic beverage used by South American natives, is an ethnobotanical mixture of dimethyltryptamine and harmala alkaloids that circumvents gastrointestinal (GI) MAO. Dimethyltryptamine, which is a potent hallucinogen, is derived from several local plant species<sup>26</sup> but is not normally orally bioavailable because of its first-pass metabolism by MAO.<sup>75</sup> When *Banisteriopsis caapi*, a plant containing the MAO-inhibiting harmala alkaloids, is mixed with dimethyltryptamine-containing plants, the bioavailability of this hallucinogenic amine is increased.<sup>73,74</sup> Cortical activation occurs in the anterior and posterior cingulate cortex, parietal and occipital cortex, and other areas. 5-HT<sub>2A</sub> mediated reductions in  $\alpha$  oscillations in

the parietal and occipital cortex correlate with visual imagery intensity.<sup>23</sup> Ayahuasca has been evaluated in preclinical studies for its potential antidepressant, anxiolytic, and antiaddictive properties, with limited success. Ayahuasca is currently being used as an alternative medicine approach to drug detoxification at many centers in North and Central America, although data on efficacy are lacking. Toxicity includes visual hallucinations, perceptual modifications, blurred vision, euphoria, intense "emotional modification," panic, cerebellar signs (incoordination, ataxia), anxiety, listlessness, CNS depression, seizures, tachycardia, hypertension, tachypnea, nausea, vomiting, and in some instances prolonged psychotic disorders. Similarly, Syrian rue (*Peganum harmala*) contains harmine and harmaline alkaloids, short-acting inhibitors of MAO<sub>A</sub>. It has been used alone or in combination with *Acacia confusa*, which contains dimethyltryptamine (DMT) for similar hallucinogenic intent.

Monoamine oxidase-B activity in tobacco plants has prompted studies to find a link between the lower platelet MAO-B activity of smokers and their lower rate of Parkinson disease.<sup>15</sup> This finding has led to interest in studying other MAO-B inhibitors for potential applications as neuroprotective xenobiotics.<sup>132</sup>

### Miscellaneous and Experimental Monoamine Oxidase Inhibitors

Other xenobiotics with nonselective MAO inhibitory properties are used for purposes unrelated to MAO inhibition. Furazolidone is an antimicrobial used to treat protozoan-related diarrhea and bacterial enteritis. Procarbazine is a hydrazide derivative indicated as a chemotherapeutic for stage III and IV Hodgkin disease as part of the MOPP (nitrogen mustard, vincristine, procarbazine, prednisone) regimen. Linezolid is an antibiotic that produces weak, nonselective MAO inhibition in Parkinson disease.<sup>29,113,120</sup> Azure B, a metabolite of methylene blue, is a high-potency reversible inhibitor of MAO.<sup>85</sup>

Research is active for novel MAO combination xenobiotics that target multiple mechanistic approaches for the treatment of dementia and parkinsonism.<sup>27</sup> Ladostigil combines the cholinergic effects of a carbamate with the aminergic effects of MAO-B inhibition.<sup>103</sup> M30 is an actively researched xenobiotic that combines iron chelation and radical scavenger effects with irreversible, nonselective MAO inhibition.<sup>35</sup> Neither xenobiotic has been approved by the FDA.

## PHARMACOKINETICS AND TOXICOKINETICS

Monoamine oxidase inhibitors are absorbed readily when given by mouth, and peak plasma concentrations are reached within 2 to 3 hours. Similar to other antidepressants, these xenobiotics are lipophilic and readily cross the blood-brain barrier. Monoamine oxidase inhibitors are hepatically metabolized by both oxidation (various CYP enzymes, including CYP2D6 and CYP2C19) and acetylation (*N*-acetyltransferase), to metabolites that are excreted in the urine.<sup>4</sup>

Similar to the original MAOI, iproniazid, phenelzine and isocarboxazid are metabolized to hydrazides. The rate of metabolism of the hydrazide MAOIs is dependent on the *N*-acetyltransferase phenotype (ie, "acetylator status") of the patient (ie, fast or slow). About half of the US population, but as low as 10% of Native Americans, have a recessive single gene trait that affects the *N*-acetyltransferase enzyme to cause slow acetylator status in the liver, contributing to exaggerated clinical effects despite standard therapeutic dosing or even mild overdose.

The clinical effects of MAOI inhibition occur rapidly and are usually maximal within a few days. First-generation, irreversible MAOIs have durations of effect that far surpass their pharmacologic half-lives, as discussed earlier.<sup>117</sup> Thus, when switching from one MAOI to another serotonergic drug such as a selective serotonin reuptake inhibitor (SSRI) or cyclic antidepressant, a sufficient time period of 2 to 3 weeks must be allowed to prevent an adverse drug interaction. It should be noted that the reverse is not true (ie, switching from SSRI to MAOI), except in the case of fluoxetine, whose active metabolite, norfluoxetine, has a long half-life; therefore, a time period of 5 weeks is recommended when switching from fluoxetine to an MAOI.

## PATHOPHYSIOLOGY

As discussed earlier (see Mechanism of Action), MAOIs contribute to adrenergic stimulation via release of norepinephrine from sympathetic nerve terminals.<sup>63</sup> This leads to hyperadrenergic crises particularly in the presence of xenobiotics that serve as substrates for, or enhancers of, monoamine formation, such as tyramine.<sup>62</sup> In addition, norepinephrine release combined with MAO inhibition results in so-called “autopotential,” or synergistic sympathomimetic effects. Autopotential is responsible for paradoxical or hypertensive reactions sometimes observed after therapeutic doses of MAOIs.<sup>21,96</sup>

Hydrazide MAOIs such as phenelzine inactivate pyridoxal 5′ phosphate, the cofactor necessary for neuronal decarboxylation of glutamic acid to the inhibitory neurotransmitter GABA. In addition, hydrazides complex with pyridoxine, the precursor of pyridoxal 5′ phosphate, thus enhancing its urinary elimination and further inhibiting the formation of neuronal GABA.<sup>83</sup> Decreased availability of neuronal GABA leads to CNS excitation after overdose of hydrazide MAOIs (Chaps. 56 and 117).<sup>60</sup>

Impaired GABA<sub>A</sub> activity contributes to symptoms of CNS excitation such as seizures, which occur in MAOI overdose. In animal models, isocarboxazid and tranylcypromine directly inhibit GABA-mediated Cl<sup>-</sup> influx at GABA<sub>A</sub> receptors (Chap. 13).<sup>113</sup> The exact binding site of MAOIs on the GABA<sub>A</sub> receptor complex is unknown.  $\gamma$ -Aminobutyric acid effects appear to be most localized in the caudate putamen and nucleus accumbens areas in one animal model.<sup>83</sup> Elevated neuronal glutamate concentrations caused by MAOI effects also synergistically enhance CNS excitation.<sup>106</sup>

## ADVERSE EFFECTS

### Overdose

Monoamine oxidase inhibitor overdose results in severe and life-threatening clinical manifestations, especially if the MAOI is a first-generation drug such as phenelzine. Classically, the clinical course involves a biphasic response characterized by initial CNS excitation and peripheral sympathetic stimulation that terminates in coma and cardiovascular collapse.<sup>65</sup> This biphasic model is hypothesized to result from an initial adrenergic crisis followed by inhibition of norepinephrine release<sup>134</sup> and is supported by animal studies.<sup>37,41</sup> Additionally, depletion of norepinephrine stores is responsible for delayed hypotension observed over the course of an MAOI overdose. Toxic dose–response relationships in humans are unclear, but an overdose of 5 mg/kg of a first-generation MAOI is potentially life threatening.<sup>8,65</sup> Clinical manifestations of MAOI overdose are summarized in Table 71–2.

Patients with MAOI overdose are initially asymptomatic for several hours. Delays in clinical toxicity are well described.<sup>69,71,95</sup> Hypotheses that might explain this phenomenon include all of the following: initial reversible binding to MAO, cumulative effects, time-dependent alterations to MAO

substrate stores, individual acetylator status, and hydrolysis of the hydrazide MAOIs. Although clinical toxicity should generally be apparent within the first several hours (initially with neuromuscular and sympathetic effects),<sup>65</sup> maximal toxicity is reportedly delayed up to 24 hours after overdose.<sup>65,71,95</sup>

Neurologic effects can be considered neuropsychiatric, neuromuscular, mental status alteration, seizures, and chronic effects. Neuropsychiatric effects include agitation, akathisia, and hallucinations. Neuromuscular effects include flailing and tremor of the extremities, nystagmus, opsoclonus, fasciculation, myoclonus, hypertonia, hyperreflexia, muscular irritability, and muscular rigidity, the latter of which leads to secondary effects such as hyperthermia and rhabdomyolysis. Effects on mental status include a variable spectrum from confusion to coma, the latter of which is a typically end-stage finding.

Severe hyperthermia (>106°F) caused by MAOI toxicity has a multifactorial etiology and is an ominous sign.<sup>107</sup> Temperature dysregulation is caused by adrenergic crisis, muscular hypertonia, or CNS effects. Secondary effects from severe hyperthermia include disseminated intravascular coagulation and metabolic acidosis.<sup>71</sup>

Cardiovascular effects follow the previously described initial hyperadrenergic crisis followed by cardiovascular collapse. Thus, initially, hypertension, tachycardia, palpitations, and tachydysrhythmias are to be expected.<sup>54</sup> In severe poisoning, late toxicity includes development of hypotension, reflex tachycardia or bradycardia, bradydysrhythmias, and sudden death.<sup>69,97</sup> Alterations in myocardial supply–demand dynamics lead to myocardial injury with possible elevations of serum cardiac biomarkers (eg, troponin I). Myonecrosis<sup>87</sup> and myocarditis<sup>126</sup> are also attributed to MAOI overdose.

Abnormalities on electrocardiography (ECG) include ischemic changes on ECG (contiguous lead findings of T-wave inversion or ST-segment depression or elevation). Peaked T waves, in the presence<sup>65</sup> or absence<sup>90</sup> of hyperkalemia, are also noted. Myocardial manifestations associated with catastrophic CNS processes (eg, intracranial hemorrhage) can also lead to T-wave inversions.

In addition to the effects mentioned above and listed in Table 71–2, reported complications of MAOI overdose include acute kidney injury,<sup>65,69,87,97</sup> fetal demise,<sup>97</sup> and hemolysis.<sup>65,71</sup>

### Selegiline Overdose

Selegiline is metabolized to L-methamphetamine, which results in hypertension and tachycardia, even at therapeutic doses.<sup>5,3,101</sup> Postmarketing surveillance safety data on the selegiline transdermal system demonstrated that only 13 (<1%) of 1,516 patients studied reported a hypertensive event, none of which were objectively confirmed.<sup>80</sup> Selegiline overdose produces hallucinations and convulsions and is associated with elevated urinary concentrations of L-methamphetamine and L-amphetamine.<sup>32,56</sup>

**TABLE 71–2** Comparison of the Clinical Manifestations of Monoamine Oxidase Inhibitor (MAOI) Toxicity

Clinical Category	Hyperadrenergic Crisis	Serotonin Toxicity	MAOI Overdose
Onset	Minutes to hours	Minutes to hours	≤24 h
Duration	Hours	Hours	Days
Temperature	Normal	Elevated	Elevated
Neurologic	Headache, hemorrhagic stroke Neuromuscular excitation	Akathisia, hyperreflexia, shivering, tremor, seizures, autonomic instability, coma Myoclonus, “wet dog shakes,” muscular rigidity	Neuropsychiatric effects, neuromuscular effects, headache, seizures Myoclonus, muscular rigidity
Cardiovascular	Hypertension, dysrhythmias, myocardial injury	Hypertension, hypotension, tachycardia, palpitations, dysrhythmias	Hypertension (early), hypotension (late), tachycardia, palpitations, dysrhythmias, myocardial injury
Gastrointestinal	Nausea	Hyperactive bowel sounds	Nausea, vomiting, diarrhea
Dermatologic	Flushing, diaphoresis	Diaphoresis	Flushing, piloerection, diaphoresis
Ophthalmologic	Mydriasis	Mydriasis	Mydriasis, ocular clonus

**Moclobemide Overdose**

Moclobemide overdose typically produces mild to moderate CNS depression (drowsiness, disorientation), GI effects (nausea), and cardiovascular effects (tachycardia and mild hypertension).<sup>33,75</sup> Serotonin toxicity caused by the ingestion of moclobemide, alone<sup>49</sup> and in combination with other serotonergics,<sup>77,86,124,129</sup> is well described. In massive overdose, fatalities attributed solely to the toxic effects of moclobemide are reported.<sup>14,34,40</sup>

**Hyperadrenergic Crisis**

Hyperadrenergic crisis occurs in patients with MAO-A inhibition in the setting of exposure to other sympathomimetic drugs such as cocaine, epinephrine, or amphetamines or when tyramine-containing foods such as aged cheeses and fermented drinks are eaten (Table 71–3).<sup>132</sup> Tyramine is an indirect-acting sympathomimetic amine with an amphetaminelike mechanism of action.<sup>134</sup> The MAO-A present in the intestinal wall and liver extensively metabolizes dietary amines preventing them from entering the circulation, but in the presence of irreversible MAO-A inhibition, this protective mechanism is lost, allowing tyramine and other dietary monoamines to enter the circulation.<sup>9</sup> This enzymatic failure results in an amphetaminelike release of norepinephrine from peripheral adrenergic neurons and provocation of hyperadrenergic crisis. A meal that contains 6 to 8 mg of tyramine per serving can potentially precipitate this reaction, and ingestion of a total of 25 to 50 mg can produce a severe and possibly life-threatening reaction.<sup>28,118,125</sup> A European study of biogenic amines contained in retail meat products (eg, sausage, cold cuts) found that such products contained up to 50 mg/kg of tyramine, which would pose a high risk for individuals receiving first-generation MAOI therapy.<sup>82</sup> Additionally, despite compliance with diet, chronically elevated cytoplasmic and synaptic concentrations of norepinephrine caused by therapeutic MAOI administration leads to adrenergic crises in some patients. Dietary restrictions and recommendations for patients prescribed first-generation MAOIs are summarized in Table 71–3.<sup>28,118,125</sup> As detailed earlier, a period of 3 weeks is sufficient to allow a normal diet to be resumed.<sup>119</sup>

The clinical syndrome of tyramine-related hyperadrenergic crisis is characterized by hypertension, headache, flushing, diaphoresis, mydriasis, neuromuscular excitation, and potential cardiac dysrhythmias.<sup>121</sup> This reaction is subjectively reported in up to 10% of patients taking MAOIs chronically.<sup>91</sup> Monoamine oxidase inhibitors specific for the MAO-B isoform are less likely to predispose to food or drug interactions by maintaining significant hepatic MAO-A activity; however, isoform specificity is lost as dose is increased.

**Serotonin Toxicity**

Any xenobiotic with serotonin-potentiating activity can interact with the MAOIs to produce serotonin toxicity<sup>10</sup> (Chap. 69). Combinations of xenobiotics commonly implicated in this reaction are involved with serotonin synthesis (eg, L-tryptophan), release (eg, amphetamines), agonism (eg, triptans

metabolized by MAO), neuromodulation (eg, lithium), or reuptake inhibition (eg, selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, meperidine, tramadol, dextromethorphan). Animal studies demonstrate that both meperidine<sup>108</sup> and dextromethorphan<sup>109</sup> administration can lead to fatal serotonin toxicity. Serotonin toxicity most commonly occurs in patients receiving combination therapy with two or more serotonergic xenobiotics; however, it rarely occurs with just one serotonergic xenobiotic such as venlafaxine.<sup>81</sup>

Clinically, serotonin toxicity runs a spectrum of severity<sup>10</sup> and is described in detail in Chap. 69. Minor findings can include akathisia, myoclonus, hyperreflexia, diaphoresis, penile erection, shivering, hyperactive bowel sounds, and tremor. Tremor and hyperreflexia are typically greater in the lower extremities. Shivering is classically described as similar to “wet dog shakes”<sup>43</sup> and can occur at a range of body temperatures.<sup>79</sup> Severe signs and symptoms include life-threatening autonomic instability, muscular rigidity, and hyperthermia.

Several diagnostic schemes for serotonin toxicity exist.<sup>10,24,46,92,114</sup> However, the key diagnostic criterion is exposure to a serotonergic. Because no diagnostic test is yet available, the diagnosis of serotonin toxicity must be established on clinical grounds. The onset of clinical symptoms typically occurs within minutes after a change in medication or self-poisoning.<sup>68</sup> Most patients with serotonin toxicity develop symptoms within 6 hours. Key clinical features of MAOI-induced serotonin toxicity are summarized in Table 71–2.

**Other Adverse Drug Reactions**

Clinically significant drug interactions with MAOIs can be caused by serotonergic effects (see Serotonin Toxicity) and alterations to drug metabolism. Chronic use of phenelzine is also associated with an isoniazidlike peripheral neuropathy,<sup>42</sup> possibly explained by pyridoxine deficiency.<sup>115</sup> Administration of opioids with serotonergic properties (eg, meperidine, dextromethorphan) is absolutely contraindicated because of the risk of precipitating the serotonin toxicity.<sup>10,39,100,108,109</sup> Adverse drug reactions are expected with other coadministered drugs that are metabolized by cytochrome P450 enzymes because first-generation MAOIs have an extensive inhibitory effect on CYP2C9, CYP2C19, and CYP2D6.<sup>4,104</sup> Thus, prolonged sedation and respiratory depression is reported when barbiturates (eg, phenobarbital) and benzodiazepines (eg, diazepam, lorazepam), which are both metabolized by hepatic cytochrome P450 enzymes, are coadministered. Table 71–4 summarizes analgesic safety in combination with MAOI drugs.<sup>39</sup>

**TABLE 71–3 Dietary Restrictions for Patients Taking Monoamine Oxidase Inhibitors<sup>a</sup>**

Low Tyramine Content (0–4 mg/serving)	Moderate Tyramine Content (4–8 mg/serving)	High Tyramine Content (> 8 mg/serving)
Chocolate	Avocado or guacamole	Aged, mature cheeses
Cottage cheese, cream cheese, yogurt, sour cream	Banana peels or stewed whole bananas	Broad beans or fava beans
Distilled alcohol	Meat extracts	Fermented sausage
Non-overripe fruit	Overripe fruit or figs	Liver
Soy sauce	Pasteurized light and pale beers	Red wines, selected beers
		Smoked, pickled, aged, putrefying meats or fish, caviar
		Yeast and meat extracts

<sup>a</sup>Recommendation: Foods with high tyramine content should be avoided, those with moderate content should be consumed in restricted moderation, and those with low content can be cautiously consumed.

**TABLE 71–4 Analgesics/Anesthetics/Sedatives Safety When Combined with Monoamine Oxidase Inhibitors (MAOIs)**

Analgesic Class	Monitor Closely or Use Alternative if Medically Appropriate		
	Safe		Avoid Combination (Contraindicated)
Nonprescription	Acetaminophen Aspirin Nonsteroidal antiinflammatory drugs		Dextromethorphan
Opioids	Buprenorphine Codeine Morphine Oxycodone	Propoxyphene	Meperidine Pentazocine Tramadol Tapentadol
Nonopioids	Inhalational anesthetics Nitroglycerin	Barbiturates <sup>a</sup> Benzodiazepines <sup>a</sup> Ketamine	
Local anesthetics	Lidocaine		Cocaine

<sup>a</sup>Drugs metabolized by hepatic cytochrome P450 may produce prolonged sedation and respiratory depression when combined with MAOIs.

## Drug Discontinuation Syndrome

Monoamine oxidase inhibitor drug discontinuation syndrome typically begins 24 to 72 hours after discontinuation. Classically, sudden discontinuation of MAOI produces symptoms that are the worst after high therapeutic doses of tranylcypromine and isocarboxazid.<sup>5</sup> Symptoms range from nausea, vomiting, and malaise to CNS symptoms such as agitation, psychosis, and convulsions. Treatment is generally supportive and typically involves a benzodiazepine such as diazepam or lorazepam and restarting the medication if clinically indicated.

## DIAGNOSTIC TESTING

The clinical utility of therapeutic drug monitoring in the routine use of MAOIs is limited. Evaluation of MAO activity is not routinely available, requires a fresh specimen (preferably jejunal biopsy),<sup>64</sup> and is therefore not recommended. Experimental evidence suggests that inhibition of human platelet MAO-B activity by at least 85% is associated with a favorable clinical antidepressant response to phenelzine.<sup>31,36</sup>

Evaluation of MAOI toxicity remains a clinical diagnosis. Serum concentrations of MAOIs that correlate meaningfully with clinical effects are not well established. In addition, serum concentrations of any antidepressant, in general, can be misleading when obtained postmortem for forensic purposes.<sup>89,99</sup> Hyperglycemia and leukocytosis are reported but likely are nonspecific findings. Elevations in serum lactate concentrations and metabolic acidosis result from seizures, muscular hypertonia, or hyperthermia.

Measurement of blood and urinary concentrations of MAO substrates provides indirect evidence of MAOI effects. Monoamine oxidase inhibitors increase serum serotonin, increase or decrease serum norepinephrine, increase urinary epinephrine and norepinephrine, and decrease urinary serotonin metabolites. Because of the indirect nature of this testing and the fact that its interpretation is fraught with confounding factors (eg, if the patient is receiving vasopressors), the routine measurement of serum and urinary MAO substrates is not recommended in the assessment of MAOI toxicity. Of note, patients taking selegiline<sup>105</sup> and tranylcypromine<sup>132</sup> occasionally test positive for amphetamines on drug screens because of their metabolites.

## MANAGEMENT

### Out of Hospital

Decisions regarding referral to the emergency department (ED) must take into account factors such as patient age, intent of exposure, and symptoms, as well as timing of exposure. All patients with MAOI exposures who display suicidal intent should be referred to an ED for evaluation. Children with exposure to even one adult formulation MAOI tablet or selegiline patch should be referred to the ED because of the potential for late-onset significant toxicity.<sup>3</sup> Patients who exhibit more than mild headache or minimal diaphoresis after an acute therapeutic error involving MAOI ingestion should be referred to an ED. Observation at home is warranted in patients who are asymptomatic and more than 24 hours have elapsed since the time of ingestion. Because of the paucity of data at this time, patients with selegiline patch ingestion should be referred to the ED for observation, even if suicidal intent is absent.

### Prehospital

Activated charcoal is reasonable to be administered to asymptomatic patients who have ingested overdoses of MAOI if no contraindications are present.<sup>17</sup> Transportation to the hospital should not be delayed to administer activated charcoal. Use of intravenous (IV) benzodiazepines for seizures and external cooling measures for severe hyperthermia ( $>106^{\circ}\text{F}$  [ $>41.1^{\circ}\text{C}$ ])<sup>107</sup> is recommended in consultation or authorization with medical direction from emergency medical services, by a written treatment protocol or policy, or with direct medical oversight.

### Initial Approach in the Emergency Department

As with any serious ingestion, initial stabilization must include rapid assessment of the airway, breathing, and circulation as well as establishment of

IV access, supplemental oxygen, and continuous cardiac monitoring. Hyperthermia or hemodynamic instability after MAOI ingestion is a manifestation of significant toxicity. Intravenous volume repletion should begin while focusing on stabilization of hyperthermia, seizures, and muscular rigidity. In any patient with altered mental status who will likely deteriorate, early endotracheal intubation not only protects the airway but also facilitates safe gastric decontamination measures.

### Gastrointestinal Decontamination

Patients who overdose with MAOIs are more likely to benefit from GI decontamination than most other overdose patients because of their high potential for morbidity and mortality.<sup>58,88</sup> Orogastric lavage with a large bore orogastric tube (36–40 Fr) is recommended if a life-threatening ingestion is suspected to have occurred within several hours before presentation.<sup>39,58,88</sup> Single-dose activated charcoal is recommended orally (or via nasogastric tube) for patients who present within several hours of ingestion unless contraindications are present. Whole-bowel irrigation with oral polyethylene glycol electrolyte solution likely has limited utility unless there are coingestions with other sustained-release preparation medications and therefore not routinely recommended. The lack of early clinical findings of poisoning should not dissuade the use of GI decontamination given the potential for delayed clinical deterioration.

### Cooling Measures

Severe hyperthermia must be treated with aggressive cooling. Ice baths (first choice for life-threatening hyperthermia),<sup>110</sup> cold water, and fans are the mainstays of treatment (Chap. 29). There is no available evidence to support use of invasive cooling devices either catheter based or noninvasive devices such as cooling blankets. Indications for ice bath immersion to treat MAOI toxicity include a rectal temperature greater than  $106^{\circ}\text{F}$  ( $41.1^{\circ}\text{C}$ ),<sup>107</sup> rigidity, and altered mental status. Benzodiazepines help to control muscular rigidity, seizures, and agitation and to contribute to amelioration of hyperthermia and tachycardia. Patients with refractory hyperthermia despite the above measures require neuromuscular blockade, using nondepolarizing paralytics, in conjunction with endotracheal intubation and ventilation. The depolarizing paralytic succinylcholine should be avoided in severe MAOI toxicity because of the risk of precipitating lethal dysrhythmia caused by hyperkalemia in the setting of rhabdomyolysis. Neuromuscular blockade eliminates hyperthermia that results from muscular rigidity and is recommended if first-line treatments are unsuccessful. Antipyretics such as acetaminophen and nonsteroidal antiinflammatory drugs should not be administered because the hyperthermia is not caused by alterations in the hypothalamic temperature set point (Chap. 29).<sup>105</sup>

### Blood Pressure Control

Because there is characteristic fluctuation in vital signs associated with MAOI overdose, hemodynamic monitoring should be instituted even for patients who initially are stable. When supporting the patient's blood pressure, preference should be given to titratable drugs with a rapid onset and termination of action because of the potential for rapid hemodynamic changes. Use of  $\beta$ -adrenergic antagonists is contraindicated for control of hypertension in MAOI-related toxicity because the action of monoamines (eg, norepinephrine) at the neuronal synapse in the autonomic nervous system could result in refractory hypertension caused by unopposed  $\alpha$ -adrenergic agonism.<sup>94</sup>

Patients who are normotensive at baseline and who experience MAOI-related severe hypertension can be preferably treated with phentolamine for effective control (2–5 mg IV).<sup>9</sup> Alternatively, nicardipine, nitroprusside, and nitroglycerin all allow for titratable blood pressure control.<sup>19</sup> Tyramine-related mild hypertensive crises can theoretically be controlled with the dihydropyridine calcium channel blockers such as nifedipine and possibly the oral  $\alpha$ -adrenergic antagonists such as terazosin but should be used with caution.<sup>18,47</sup> Particular caution must be exercised in patients with baseline hypertension because overly aggressive blood pressure lowering will reduce cerebral perfusion pressure, potentially causing cerebral ischemia.

Patients who are hypotensive require aggressive support with IV fluid resuscitation and vasopressors. The direct-acting sympathetic vasopressors epinephrine and norepinephrine can be used safely in patients taking MAOIs.<sup>11</sup> Rather than causing release of a stored pool of norepinephrine, they bind directly with postsynaptic  $\alpha$ - and  $\beta$ -adrenergic receptors, unlike dopamine.

Dopamine is contraindicated in hypotensive patients who have overdosed on MAOIs for several reasons. The indirect action of dopamine administration may produce a synergistic effect with MAOI, resulting in excessive adrenergic activity and exaggerated rises in blood pressure. In addition, most of the  $\alpha$ -adrenergic receptor mediated vasoconstriction of dopamine is secondary to norepinephrine release; in the presence of MAOIs, norepinephrine synthesis is likely impaired from concomitant dopamine- $\beta$ -hydroxylase inhibition, and dopamine will not reliably raise blood pressure if cytoplasmic and vesicular neuronal stores have been depleted. Finally, in the presence of impaired norepinephrine release or  $\alpha$ -adrenergic blockade by any cause, unopposed dopamine-induced vasodilation from action on peripheral dopamine and  $\beta$  adrenoceptors may paradoxically lower blood pressure further.

### Dysrhythmias

Because of the unique pharmacologic and toxicokinetic considerations of MAOI toxicity, Advanced Cardiac Life Support protocols should be slightly tailored to the patient.<sup>122</sup> Removal of the offending xenobiotic as well as correction of hypoxia, hypokalemia, and hypomagnesemia, if present, is the recommended initial step.

Patients with immediately life-threatening dysrhythmias require rapid cardioversion. In the presence of the nonperfusing dysrhythmias such as ventricular fibrillation, pulseless ventricular tachycardia, and torsade de pointes, unsynchronized electrical defibrillation is the treatment of choice.

In patients with stable ventricular tachycardia, a trial of an antidysrhythmic such as procainamide or amiodarone is recommended. High-quality studies evaluating the use of these xenobiotics in the setting of MAOI overdose are not available.

Hemodynamically significant supraventricular tachycardia from MAOI toxicity should be corrected to prevent myocardial ischemia or infarction, ventricular dysrhythmia, and high-output heart failure. Benzodiazepines are safe and effective to treat sinus tachycardia as long as respiratory status remains monitored. Adenosine and synchronized cardioversion are unlikely to be useful in the setting of ongoing presence of the MAOI, but are reasonable in rare cases that are unresponsive to benzodiazepines. In patients with borderline hypotension, nondihydropyridine calcium channel antagonists such as diltiazem and verapamil are relatively contraindicated because they may further lower blood pressure due to bradycardia and heart block.

Hemodynamically significant bradycardia from MAOI toxicity includes management of IV fluid and atropine as first-line therapy to temporize the patient with bradycardia and hypotension. Epinephrine and isoproterenol are recommended second choices while a pacemaker (transcutaneous or transvenous) is prepared.

### Management of Central Nervous System Manifestations

In any patient with acute altered mental status, hypoglycemia should be rapidly excluded.<sup>12,102</sup> For patients with mild to moderate CNS excitation with small incremental doses of parenteral diazepam or midazolam are recommended. Patients with seizures should be treated with benzodiazepines in standard incremental doses. Empiric administration of pyridoxine (vitamin B<sub>6</sub>), intravenously at 70 mg/kg, up to 5 g in adults, is reasonable in patients with status epilepticus, particularly after massive ingestions of hydrazide-derived MAOIs such as phenelzine because of its ability to deplete endogenous pyridoxine stores (Antidotes in Depth: A15).<sup>115</sup> Phenytoin should not be used for treatment of MAOI-induced seizures because there is no distinct seizure focus but rather generalized neuronal dysfunction in the presence of MAOI (and metabolites) in the CNS.

### Cyproheptadine

Cyproheptadine is a nonselective serotonin antagonist (with additional anticholinergic, histaminic, and some serotonin agonism) that is recommended

as third-line therapy (after benzodiazepine administration and cooling measures) for serotonin toxicity.<sup>10</sup> Cyproheptadine prevents lethality in animal models of serotonin toxicity<sup>78</sup> and reportedly is beneficial in humans, although its efficacy has not been rigorously established.<sup>38,44</sup> It is suggested when the diagnosis of serotonin toxicity is likely, especially if incomplete response has been achieved with aggressive cooling and benzodiazepine therapy.<sup>61</sup> In addition, its use to treat neuromuscular rigidity and hyperthermia associated with MAOI overdose is reported.<sup>7,25</sup>

The recommended initial dose in adults is 12 mg orally followed by 2 mg every 2 hours while symptoms continue.<sup>10</sup> A dose of 12 to 32 mg will bind 85% to 95% of serotonin receptors.<sup>55</sup> The dose of cyproheptadine used to treat the serotonin toxicity may cause sedation, but this effect is a goal of therapy and should not deter clinicians from using the drug. Relative contraindications to its use include acute asthma exacerbation, GI obstruction, and age younger than 2 years (because of a lack of safety information for this age group).

### Dantrolene

Use of dantrolene in patients with serotonin toxicity is not recommended (Antidotes in Depth: A24). Case reports citing its utility with off-label usage probably involved misdiagnosis.<sup>10,52</sup> Malignant hyperthermia, for which dantrolene is indicated, is a disease that is completely unrelated to serotonin toxicity. In animal models of serotonin toxicity, dantrolene administration has no effect on survival.<sup>50,78</sup> In addition, dantrolene is implicated in the fatality of one case of serotonin toxicity.<sup>55</sup>

### Extracorporeal Elimination

The utility of extracorporeal measures, such as hemodialysis, to treat MAOI toxicity remains to be demonstrated. There is limited rationale to perform hemodialysis because toxicity persists long after the xenobiotic is gone. Additionally, the data regarding protein binding and volumes of distribution of the first-generation MAOI drugs such as isocarboxazid are not well characterized. Use of peritoneal dialysis<sup>66</sup> and hemodialysis<sup>72</sup> to treat MAOI overdose has been reported in the literature. However, time to resolution of symptoms for all cases did not differ (~24 hours) from those in which hemodialysis was not used. Therefore, extracorporeal elimination is not recommended in the management of MAOI overdose unless other indications are present such as severe acidemia or life-threatening hyperkalemia or the need to eliminate dialyzable toxic coingestions.

### Disposition

Recommendations for the ideal time frame for observation of patients with suspected MAOI overdose are limited by a paucity of relevant studies in the clinical toxicology literature. For patients with presumed MAOI (selective or nonselective) overdose, it is reasonable to observe them with telemetry monitoring, preferably in an intensive care unit, for at least 24 hours regardless of the initial clinical findings. This recommendation takes into account the potential for delayed-onset of clinical toxicity as well as the potential for severe morbidity and mortality.<sup>69,71,95</sup> However, patients with MAOI–food or MAOI–xenobiotic interactions often do not require hospital admission if the interaction is mild and resolution of symptoms is complete.

### SUMMARY

- Toxicity from MAOI exposures is becoming less common because of more limited clinical usage of the traditional nonselective MAOIs; however, clinical and research use of selective MAOIs and RIMAs is increasing.
- Inhibition of MAO has effects on myriad neuronal neurotransmitters, which are responsible for the majority of the therapeutic and toxic effects of MAOIs.
- The clinical effects of MAOI overdose include neurotoxicity and cardiovascular collapse; this overdose is potentially life threatening and should be managed aggressively.
- Aside from overdose, other consequential manifestations of MAOI toxicity include hyperadrenergic crisis and the serotonin toxicity.

# SEDATIVE–HYPNOTICS

Payal Sud and David C. Lee

## HISTORY AND EPIDEMIOLOGY

*Sedative–hypnotics* are xenobiotics that limit excitability (sedation) and/or induce drowsiness and sleep (hypnosis). *Anxiolytics* (formerly known as *minor tranquilizers*) are medications prescribed for their sedative–hypnotic properties. Mythology of ancient cultures is replete with stories of xenobiotics that cause sleep or unconsciousness (Chap. 1). Sedative–hypnotic overdoses were described in the medical literature soon after the commercial introduction of bromide preparations in 1853. Other commercial xenobiotics that subsequently were developed include chloral hydrate, paraldehyde, sulfonamide, and urethane.

Barbiturates were introduced in 1903 and quickly supplanted older xenobiotics. Barbiturates dominated the sedative–hypnotic market for the first half of the 20th century. Because of their narrow therapeutic index and substantial potential for abuse, they quickly became a major health problem. By the 1950s, barbiturates were frequently implicated in overdoses and were responsible for the majority of drug-related suicides. As fatalities from barbiturates increased, attention shifted toward preventing their abuse and finding less toxic alternatives.<sup>19</sup> After their introduction in the early 1960s, benzodiazepines quickly became the most commonly used sedatives in the United States.

Intentional and unintentional overdoses with sedative–hypnotics occur frequently. According to the American Association of Poison Control Centers, sedative–hypnotics is consistently one of the top five classes of xenobiotics associated with overdose fatalities (Chap. 130). With the ubiquitous worldwide use of sedative–hypnotics, they may be associated with a substantially higher number of overdoses and deaths than are officially reported. Compared with barbiturate overdoses, overdoses of benzodiazepines alone account for relatively few deaths.<sup>29,36,43</sup> Most deaths associated with benzodiazepines result from mixed overdoses with other respiratory depressants.<sup>36,112</sup>

Chlordiazepoxide, the first commercially available benzodiazepine, was initially marketed in 1960. Since then, more than 50 benzodiazepines have been marketed, and more are being developed. Although the benzodiazepines remain the most popular prescribed anxiolytics, several benzodiazepine-receptor agonists were developed in 1989 in an attempt to circumvent some of the side effects of benzodiazepines. These drugs include zolpidem, as zaleplon, zopiclone, and eszopiclone.<sup>6,107</sup> Newer formulations of zolpidem tartrate such as *Intermezzo* are now available, which is a low-dose sublingual tablet form (1.75 mg and 3.5 mg compared with 5 mg and 10 mg). Ramelteon and tasimelteon are newer sleep aids that function as melatonin receptor (MT<sub>1</sub> and MT<sub>2</sub>) agonists rather than benzodiazepine-receptor agonists.<sup>112,134</sup> Dexmedetomidine, a central  $\alpha_2$ -adrenergic agonist, is now increasingly used in the hospital setting for short-term sedation.<sup>143</sup> An additional medication is suvorexant, a dual orexin receptor antagonist that inhibits the action of orexin, a neuropeptide that promotes wakefulness.<sup>30</sup>

This chapter focuses primarily on pharmaceuticals prescribed for their sedative–hypnotic effects, many of which interact with the  $\gamma$ -aminobutyric acid-A (GABA<sub>A</sub>) receptor (Table 72–1). Specific sedative–hypnotics such as ethanol and  $\gamma$ -hydroxybutyric acid (GHB) are discussed in more depth in their respective chapters (Chaps. 76 and 80).

## PHARMACODYNAMICS AND TOXICODYNAMICS

All sedative–hypnotics induce central nervous system (CNS) depression. Most clinically effective sedative–hypnotics produce their physiologic effects by enhancing the function of GABA-mediated chloride channels via agonism at the GABA<sub>A</sub> receptor. These receptors are the primary mediators of inhibitory neurotransmission in the brain (Chap. 13). The GABA<sub>A</sub> receptor is a

pentameric structure composed of varying polypeptide subunits associated with a chloride on the postsynaptic membrane. These subunits are classified into families (eg,  $\alpha$ ,  $\beta$ ,  $\gamma$ ). Variations in the five subunits of the GABA receptor confer drug selectivity and clinical effects such as sedation, anxiolysis, hypnosis, amnesia, and muscle relaxation.<sup>133</sup> The most common GABA<sub>A</sub> receptor in the brain is composed of  $\alpha_1\beta_2\gamma_2$  subunits. Almost all sedative–hypnotics bind to GABA<sub>A</sub> receptors containing the  $\alpha_1$  subunit. One exception may be etomidate, which produces sedation at the  $\beta_2$  unit and anesthesia at the  $\beta_3$  subunit.<sup>24,94</sup> Benzodiazepines are effective only at GABA<sub>A</sub> receptors with the  $\gamma_2$  subunit. Even within classes of sedative–hypnotics, there are varying affinities and actions for differing subunits of the GABA receptor.<sup>33,78</sup> The  $\alpha_1$  subunit is responsible for sedation and amnesia, the  $\alpha_2$  subunit is responsible for anxiolysis, and the  $\alpha_4$  and  $\alpha_6$  subunits are completely insensitive to benzodiazepines. Nonbenzodiazepine sedative–hypnotics such as zolpidem, zaleplon, and zopiclone selectively bind the  $\alpha_1$  subunit and thus cause primarily sedation and not anxiolysis at therapeutic doses.

The role of GABA receptors in the peripheral nervous system has been increasingly recognized, especially in the gastrointestinal (GI) tract.  $\gamma$ -Aminobutyric acid agonism is involved in modulation of GI visceral pain processing.<sup>7</sup> Furthermore, GABA<sub>B</sub> agonism by baclofen was found to reduce duodenal ulcer formation.<sup>64</sup>

Many sedative–hypnotics also act at receptors other than the GABA<sub>A</sub> receptor. Trichloroethanol and propofol also inhibit glutamate-mediated *N*-methyl-D-aspartate (NMDA) receptors, thereby inhibiting excitatory neurotransmission.<sup>26,102,121</sup> Certain benzodiazepines inhibit adenosine metabolism and reuptake, thereby potentiating both A<sub>1</sub>-adenosine (negative dromotropy) and A<sub>2</sub>-adenosine (coronary vasodilation) receptor-mediated effects.<sup>90,131</sup> Benzodiazepines can also interact with serotonergic pathways. The anxiolytic effects of clonazepam can be partially explained by upregulation of serotonergic receptors, specifically 5-HT<sub>1</sub> and 5-HT<sub>2</sub>.<sup>9</sup> Sleep aids such as melatonin, ramelteon, and tasimelteon are agonists at melatonin receptor subtypes MT<sub>1</sub> and MT<sub>2</sub> in the suprachiasmatic nucleus of the brain.<sup>116,134,140,146</sup> Dexmedetomidine is a central  $\alpha_2$ -adrenergic agonist similar to clonidine.<sup>143</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

Most orally administered sedative–hypnotics are rapidly absorbed via the GI tract, with the rate-limiting step consisting of dissolution and dispersion of the xenobiotic. Barbiturates and benzodiazepines are primarily absorbed in the small intestine. Clinical effects are determined by their relative ability to penetrate the blood–brain barrier. Xenobiotics that are highly lipophilic penetrate most rapidly. The ultrashort-acting barbiturates are clinically active in the most vascular parts of the brain (gray matter first), with sleep occurring within 30 seconds of administration. Table 72–1 lists individual sedative–hypnotics and some of their pharmacokinetic properties.

After initial distribution, many of the sedative–hypnotics undergo a redistribution phase as they are dispersed to other body tissues, specifically adipose tissue. Xenobiotics that are extensively redistributed, such as the lipophilic (ultrashort-acting) barbiturates, have a brief clinical effect as the early peak concentrations in the brain rapidly decline.

Many of the sedative–hypnotics are metabolized to pharmacologically active intermediates. This is particularly true for chloral hydrate and some of the benzodiazepines. The benzodiazepines can be demethylated, hydroxylated, or conjugated with glucuronide in the liver. Glucuronidation results in the production of inactive metabolites. Benzodiazepines such as diazepam and chlordiazepoxide are demethylated, which produces active intermediates with a more prolonged half-lives than the parent compound

**TABLE 72-1** Sedative-Hypnotics: Duration of Action and Active Metabolites

	Duration of Action <sup>a</sup>	Active Metabolite Important
<b>Benzodiazepines</b>

<sup>a</sup>The duration of action usually approximates the half-life (t<sub>1/2</sub>); some lipophilic xenobiotics have a short duration of action with a single dose because of redistribution from the central nervous system but with multiple doses become longer acting.

I = intermediate acting t<sub>1/2</sub> = 6–24 h; L = long acting t<sub>1/2</sub> >24 h (a long-acting metabolite may contribute to a long duration of action); S = short acting t<sub>1/2</sub> <6 h; US = ultrashort acting t<sub>1/2</sub> <1 h.

(Table 72-1). Because of the individual pharmacokinetics of sedative-hypnotics and the production of active metabolites, there is often little correlation between the duration of effect and biologic half-lives.

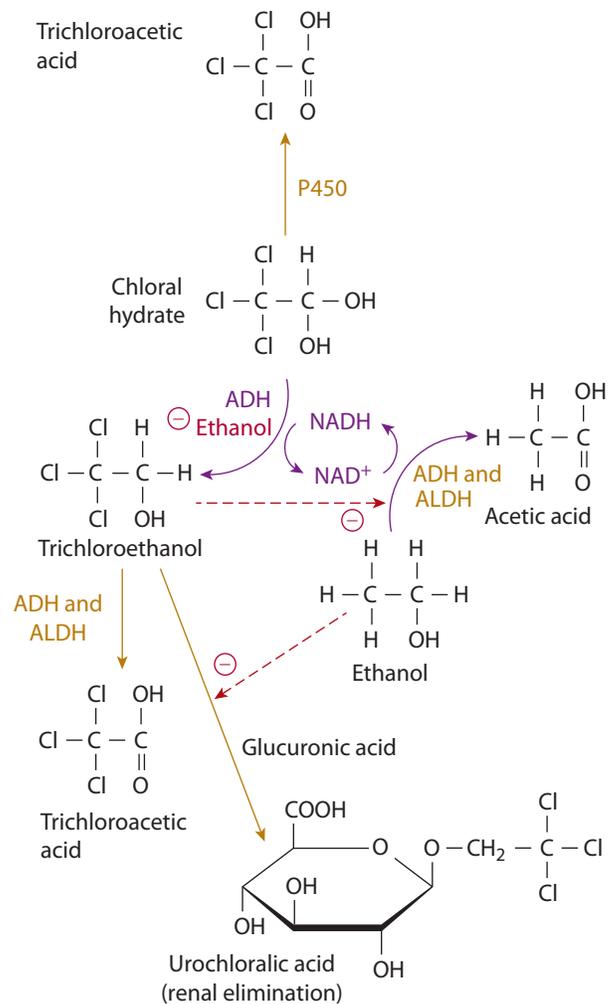

Most sedative-hypnotics, such as the highly lipid-soluble barbiturates and the benzodiazepines, are highly protein bound. These drugs are poorly filtered by the kidneys. Elimination occurs principally by hepatic metabolism. Chloral hydrate and meprobamate are notable exceptions. Xenobiotics with a low lipophilicity and limited protein binding are more subject to renal excretion.

Overdoses as well concomitant therapeutic usage of combinations of sedative-hypnotics enhance toxicity through additive and synergistic effects. For example, both barbiturates and benzodiazepines act on the GABA<sub>A</sub> receptor, but barbiturates prolong the opening of the chloride ionophore,

and benzodiazepines increase the frequency of ionophore opening.<sup>135</sup> Various sedative-hypnotics increase the affinity of another xenobiotic at its respective binding site. For example, pentobarbital increases the affinity of  $\gamma$ -hydroxybutyric acid (GHB) for its non-GABA binding site.<sup>137</sup> Propofol potentiates the effect of pentobarbital on chloride influx at the GABA<sub>A</sub> receptor.<sup>111</sup> Propofol also increases the affinity and decreases the rate of dissociation of benzodiazepines from their site on the GABA<sub>A</sub> receptor.<sup>18,150</sup> These actions increase the clinical effect of each xenobiotic and lead to deeper CNS and respiratory depression when they are used concomitantly.

Another mechanism of synergistic toxicity occurs via alteration of metabolism. The combination of ethanol and chloral hydrate, historically known as a “Mickey Finn,” has synergistic CNS depressant effects. Chloral hydrate competes for alcohol and aldehyde dehydrogenases, thereby prolonging the half-life of ethanol. The metabolism of ethanol generates the reduced form of nicotinamide adenine dinucleotide (NADH), which is a cofactor for the metabolism of chloral hydrate to trichloroethanol, an active metabolite. Finally, ethanol inhibits the conjugation of trichloroethanol, which in turn inhibits the oxidation of ethanol (Fig. 72-1).<sup>1,80,128,129</sup> The end result of these synergistic pharmacokinetic interactions is enhanced CNS depression.

Multiple drug-drug interactions prolong the half-life of sedative-hypnotics and significantly increase their potency or duration of action (Chap. 9). The half-life of midazolam, which undergoes hepatic metabolism via cytochrome CYP3A4, can change dramatically in the presence of

**FIGURE 72-1.** Metabolism of chloral hydrate and ethanol demonstrating the interactions between chloral hydrate and ethanol metabolism. Note the inhibitory effects (dotted lines) of ethanol on trichloroethanol metabolism and the converse. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; NAD<sup>+</sup> = Nicotinamide adenine dinucleotide; NADH = nicotinamide adenine dinucleotide.

certain xenobiotics that compete for its metabolism or that induce or inhibit CYP3A4 (Table 11–2).<sup>96,153</sup> For example, the half-life of midazolam rises 400-fold when coadministered with itraconazole.<sup>8,136</sup>

## TOLERANCE AND WITHDRAWAL

Ingestions of typical doses of sedative–hypnotics have less predictable effects in patients who chronically use them. This is due to *tolerance*, defined as the progressive diminution of effect of a particular drug with repeated administrations that results in a need for greater doses to achieve the same effect. Tolerance occurs when adaptive neural and receptor changes (plasticity) occur after repeated exposures. These changes include a decrease in the number of receptors (downregulation), reduction of firing of receptors (receptor desensitization), structural changes in receptors (receptor shift), or reduction of coupling of sedative–hypnotics and their respective GABA<sub>A</sub>-related receptor site (Chap. 14). Tolerance can also be secondary to pharmacokinetic factors, such as increased metabolism after repetitive doses. However, in most cases, tolerance to sedative–hypnotics is caused by pharmacodynamic changes such as receptor downregulation.<sup>136</sup>

Cross-tolerance readily exists among the sedative–hypnotics. For example, chronic use of benzodiazepines not only decreases the activity of the benzodiazepine site on the GABA receptor but also decreases the binding affinity of the barbiturate sites.<sup>2,54</sup> Many sedative–hypnotics are also associated with drug dependence after chronic exposure. Some of these—classically, the barbiturates, benzodiazepines, and ethanol—are also associated with life-threatening withdrawal syndromes.

## CLINICAL MANIFESTATIONS

Patients with sedative–hypnotic overdoses exhibit slurred speech, ataxia, and incoordination. Larger doses result in stupor or coma. In most instances, respiratory depression parallels CNS depression. However, not all sedative–hypnotics cause significant hypoventilation. Although oral overdoses of benzodiazepines alone produce sedation and hypnosis, they rarely produce life-threatening hypoventilation. Typically, the patient appears comatose but with normal vital signs. In contrast, large intravenous (IV) doses of benzodiazepines occasionally lead to potentially life-threatening respiratory depression. Single overdoses of zolpidem and its congeners do not typically cause life-threatening respiratory depression in adults.<sup>127,162</sup>

Although the physical examination is rarely specific for a particular sedative–hypnotic, it can sometimes offer clues of exposure based on certain physical and clinical findings (Table 72–2). Hypothermia is described with most of the sedative–hypnotics but is more pronounced with barbiturates.<sup>55,119</sup>

**TABLE 72–2 Clinical Findings of Sedative–Hypnotic Overdose**

Clinical Signs	Sedative–Hypnotics
Acneiform rash	Bromides
Cardiotoxicity	
Hypotension from myocardial depression	Meprobamate
Dysrhythmias	Chloral hydrate
Coma (fluctuating)	Glutethimide, meprobamate
GI hemorrhage	Chloral hydrate
Hypothermia	Barbiturates, bromides, ethchlorvynol
Muscular twitching	γ-Hydroxybutyric acid, γ-butyrolactone, 1,4-butanediol, γ-valerolactone, propofol, etomidate
Odors (Unique)	Chloral hydrate (pear), ethchlorvynol (new vinyl shower curtain)
Urine (discolored)	Propofol (green/pink)

GI = gastrointestinal.

Fixed drug eruptions that are often bullous can appear over pressure-point areas. Although classically referred to as “barbiturate blisters,” this phenomenon is not specific to barbiturates because other CNS xenobiotics, including carbon monoxide, methadone, imipramine, benzodiazepines, and several others, can lead to the same finding.

Large single doses or prolonged duration of IV dosing of sedative–hypnotics can also cause toxicities due to their diluents. Propylene glycol accumulates with prolonged infusions of certain medications such as lorazepam. Rapid infusions of propylene glycol induce hypotension. Accumulated amounts of propylene glycol lead to metabolic acidosis and a hyperosmolar state with elevated lactate concentrations.<sup>101,110,152,154</sup> In one study, two-thirds of critical care patients given high doses of lorazepam (0.16 mg/kg/h) for more than 48 hours had significant accumulations of propylene glycol as manifested by hyperosmolarity and an anion gap metabolic acidosis<sup>5</sup> (Chap. 46).

## DIAGNOSTIC TESTING

When overdose is a primary concern in an undifferentiated comatose patient without a clear history, laboratory testing is useful to exclude metabolic abnormalities. This includes electrolytes, liver function tests, thyroid function tests, blood urea nitrogen, creatinine, glucose, venous blood gas analysis, and cerebrospinal fluid analysis as clinically indicated. With any suspected intentional overdose, a serum acetaminophen concentration should be obtained. Diagnostic imaging studies, such as neuroimaging of the head, are warranted on a case-by-case basis.

Routine laboratory screening for “drugs of abuse” generally is not helpful in the management of undifferentiated comatose adult patients. However, screening may be useful for epidemiologic purposes in a particular community or in psychiatric patients. These tests vary in type, sensitivity, and specificity. Furthermore, many sedative–hypnotics are not included on standard screening tests for drugs of abuse. For example, a typical benzodiazepine urine screen identifies metabolites of 1,4-benzodiazepines, such as oxazepam or nordiazepam (desmethyldiazepam). Many benzodiazepines, including the commonly used lorazepam and clonazepam, are metabolized to alternative compounds and remain undetected, thus exhibiting a false-negative result on the benzodiazepine-screening assay. Alprazolam and triazolam are not detected because they undergo minimal metabolism.<sup>34</sup>

Specific concentrations of xenobiotics such as ethanol or phenobarbital, although readily available at most hospitals, are rarely crucial in clinical decision making. Concentrations of most other sedative–hypnotics are not routinely performed in hospital laboratories. Because of its radiopacity, large ingestions of chloral hydrate are evident on abdominal radiography (Chap. 8). Although immediate identification of a particular sedative–hypnotic may be helpful in predicting the length of toxicity, it rarely affects the acute management of the patient. One exception is phenobarbital, for which urinary alkalization and multiple-dose activated charcoal (MDAC) enhance elimination.<sup>38,73,106,117</sup> The EXtracorporeal TReatments in Poisoning (EXTRIP) workgroup recommends intermittent hemodialysis for severe barbiturate poisoning, and hemoperfusion and continuous renal replacement therapy are viable alternatives.<sup>74</sup>

## MANAGEMENT

Death secondary to sedative–hypnotic overdose usually results from cardiorespiratory collapse. Careful attention should focus on monitoring and maintaining adequate airway, oxygenation, and hemodynamic support. Supplemental oxygen, respiratory support, and prevention of aspiration are the cornerstones of treatment. Hemodynamic instability should be treated initially with volume expansion. With proper supportive care and adequate airway and respiratory support as needed, patients with sedative–hypnotic overdoses should eventually recover. Patients with meprobamate and chloral hydrate overdoses occasionally present with both respiratory depression and cardiac toxicity. In 40% of cases, meprobamate toxicity was found to be associated with myocardial depression and significant hypotension, often resistant to IV fluid resuscitation.<sup>21</sup> The cardiotoxic effects of chloral hydrate include lethal ventricular

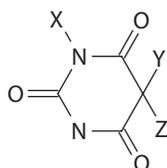

dysrhythmias resulting from its active halogenated metabolite trichloroethanol causing myocardial sensitization to catecholamines. In the setting of cardiac dysrhythmias from chloral hydrate, use of  $\beta$ -adrenergic antagonists such as propranolol is reported to cause resolution of the dysrhythmia.<sup>15,17,166,175</sup> We recommend administering IV  $\beta$ -adrenergic antagonists in patients with chloral hydrate–induced dysrhythmias resistant to standard therapy.

The use of GI decontamination should be decided on a case-by-case basis. The benefits of activated charcoal (AC) must be balanced with the risks of its aspiration and subsequent potential for pulmonary toxicity. The use of AC should be determined based on the current mental status of the patient, the potential for further deterioration, the xenobiotic(s) ingested, and the expected clinical course. Phenobarbital overdose is one particular scenario in which MDAC increases elimination by 50% to 80%.<sup>10,11,14</sup> In a prospective study of 10 comatose patients after phenobarbital overdose, the serum half-life of phenobarbital was significantly decreased after multiple dose activated charcoal (MDAC) administration ( $36 \pm 13$  hours) compared with the group treated with single dose activated charcoal (SDAC) ( $93 \pm 52$  hours) (Antidotes in Depth: A1).<sup>105</sup>

Although the efficacy of orogastric lavage is controversial, orogastric lavage is reasonable in overdoses with xenobiotics that slow GI motility or that are known to develop concretions, specifically phenobarbital and meprobamate.<sup>21,59,125</sup> Orogastric lavage in the setting of oral benzodiazepine overdoses alone is not recommended because the benefits of lavage are minimal compared with the significant risks of aspiration (Chap. 5). No antidote counteracts all sedative–hypnotic overdoses. Flumazenil, a competitive benzodiazepine antagonist, rapidly reverses the sedative effects of benzodiazepines as well as zolpidem and its congeners.<sup>71,123,165,172</sup> However, flumazenil can precipitate life-threatening benzodiazepine withdrawal in benzodiazepine-dependent patients. Flumazenil use is also associated with seizures, especially in patients who have overdosed on tricyclic antidepressants (Antidotes in Depth: A25).<sup>56,139</sup> Because the lethality of sedative–hypnotics is associated with their ability to cause respiratory depression, asymptomatic patients can be downgraded to a lower level of care after a period of observation when there are no signs of respiratory depression. The exact length of the observation period will vary based on the patient's clinical presentation, age, and the type and amount of xenobiotic(s) ingested. Patients with symptomatic overdoses of long-acting sedative–hypnotics, such as meprobamate and clonazepam, or drugs that have significant enterohepatic circulation may require 24 hours of observation in the intensive care unit. Patients with mixed overdoses of various sedative–hypnotics and CNS depressants also warrant closer observation for respiratory depression because of synergistic respiratory depressant effects.

## SPECIFIC SEDATIVE–HYPNOTICS

### Barbiturates

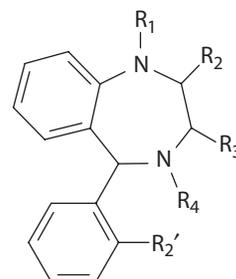

The general structure of barbiturates is shown above. Barbitol became the first commercially available barbiturate in 1903. Although many other barbiturates were subsequently developed, their popularity has greatly waned since the introduction of benzodiazepines. Barbiturates are derivatives of barbituric acid (2,4,6-trioxo-hexa-hydropyrimidine), which itself has no CNS depressant properties. The addition of various side chains influences the pharmacologic properties. Barbiturates with long side chains tend to have increased lipophilicity and potency and slower rates of elimination. However, the observed clinical effects also depend on absorption, redistribution, and the presence of active metabolites. For this reason, the duration of action of barbiturates (like those of benzodiazepines) does not correlate well with their biologic half-lives.

Oral barbiturates are preferentially absorbed in the small intestine and are eliminated by both hepatic and renal mechanisms. Shorter acting barbiturates tend to be more lipid soluble, more protein bound, have a higher  $pK_a$ , and are metabolized almost completely by the liver. Longer acting barbiturates such as phenobarbital accumulate less extensively in tissues and are excreted renally as the parent drug. An example of this is phenobarbital, with a relatively low  $pK_a$  (7.24). Alkalinizing the urine with sodium bicarbonate to a urinary pH of 7.5 to 8.0 can increase the elimination of phenobarbital by 5- to 10-fold. This procedure is not effective for the short-acting barbiturates because they have higher  $pK_a$  values, are more protein bound, and are primarily metabolized by the liver with very little unchanged drug excreted by the kidneys (Antidotes in Depth: A5 and Chap. 6). Urinary alkalization is utilized to decrease the serum half-life of phenobarbital. The clinical benefits are supported in a prospective controlled trial and few case reports.<sup>117</sup> Given the pharmacokinetic properties of barbiturates, the EXTRIP Workgroup recommends dialysis for cases of severe long-acting barbiturate poisoning presenting with prolonged coma, respiratory depression requiring mechanical ventilation, shock, persistent toxicity or persistently elevated or rising serum concentrations despite MDAC. Intermittent hemodialysis and continuation of MDAC during dialysis is recommended.<sup>74</sup>

Barbiturates (especially the shorter acting barbiturates) can accelerate their own hepatic metabolism by cytochrome P450 enzyme autoinduction. Phenobarbital is a nonselective inducer of hepatic cytochromes, the greatest effects being on CYP2B1, CYP2B2, and CYP2B10, although CYP3A4 is also affected.<sup>120,151</sup> Not surprisingly, a variety of interactions are reported after the use of barbiturates. Clinically significant interactions as a result of enzyme induction lead to increased metabolism of  $\beta$ -adrenergic antagonists, corticosteroids, doxycycline, estrogens, phenothiazines, quinidine, theophylline, and many other xenobiotics.

Early deaths caused by barbiturate ingestions result from respiratory arrest and cardiovascular collapse. Delayed deaths result from acute kidney failure, pneumonia, acute respiratory distress syndrome, cerebral edema, and multiorgan system failure as a result of prolonged cardiorespiratory depression.<sup>3,42</sup>

### Benzodiazepines

The general structure of benzodiazepines is shown above. The commercial use of benzodiazepines began with the introduction of chlordiazepoxide for anxiety in 1961 and diazepam for seizures in 1963. Benzodiazepines are used principally as sedatives and anxiolytics. Clonazepam is the only benzodiazepine approved for use as a chronic anticonvulsant. Benzodiazepines rarely cause paradoxical psychological effects, including nightmares, delirium, psychosis, and transient global amnesia.<sup>83,86,176</sup> The incidence and intensity of CNS adverse events increase with age.<sup>81</sup>

Similar to barbiturates, variations of the benzodiazepine side chains influence potency, duration of action, metabolites, and rate of elimination. Most benzodiazepines are highly protein bound and lipophilic. They passively diffuse into the CNS, their main site of action. Because of their lipophilicity, benzodiazepines are extensively metabolized via oxidation and conjugation in the liver before their renal elimination.

Benzodiazepines bind nonselectively to “central” benzodiazepine sites located throughout the brain. These sites contain the GABA<sub>A</sub>  $\alpha$  and  $\gamma$  subunits.<sup>33,161</sup> The binding of the benzodiazepine to its particular site changes the GABA receptor to “lock” into a position that promotes GABA binding to

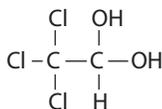

the GABA receptor. Whereas benzodiazepines that are active at the  $\alpha_1$  subunit affect anxiety, sleep, and amnesia, those that are active in the  $\alpha_2$  and  $\alpha_3$  subunits tend to have greater anxiolytic properties. “Peripheral” benzodiazepine sites are found throughout the body, with the greatest concentrations in steroid-producing cells in the adrenal gland, anterior pituitary gland, and reproductive organs. These sites are not affiliated with the GABA receptor (Antidotes in Depth: A26).

One unique property of the benzodiazepines is their relative safety even after substantial ingestion, which probably results from their GABA receptor properties.<sup>33,97</sup> Unlike many other sedative-hypnotics, benzodiazepines do not open GABA channels independently at high concentrations. Benzodiazepines do not cause any specific systemic injury, and their long-term use is not associated with specific organ toxicity. Most often deaths are secondary to a combination of alcohol or other sedative-hypnotics.<sup>130,168,170</sup> Supportive care is the mainstay of treatment.

Flumazenil is a competitive benzodiazepine receptor antagonist that is ideal for either benzodiazepine-naïve patients with a sole benzodiazepine overdose or benzodiazepine-naïve patients who develop respiratory depression after IV administration of benzodiazepines (Antidotes in Depth: A25). Caution should be exercised if flumazenil is administered to patients with an unknown overdose because seizures and dysrhythmias are reported to occur from the effects of the coingestant after the effect of the benzodiazepine has been reversed. Similarly, chronic benzodiazepine users are at risk of developing withdrawal symptoms, including seizures, after receiving flumazenil. The duration of effect of flumazenil is shorter than that of most benzodiazepines, and re sedation can occur.<sup>118</sup>

Tolerance to the sedative effects of benzodiazepines occurs more rapidly than does tolerance to the antianxiety effects.<sup>73,115</sup> Abrupt discontinuation after long-term use of benzodiazepines precipitates benzodiazepine withdrawal, characterized by autonomic instability, changes in perception, paresthesias, headaches, tremors, and seizures.<sup>13</sup> Withdrawal from benzodiazepines is common, manifested by almost one-third of chronic users.<sup>66</sup> Alprazolam and lorazepam are associated with more severe withdrawal syndromes compared with chlordiazepoxide and diazepam.<sup>66,67</sup> This is likely because both chlordiazepoxide and diazepam have active metabolites, accumulation of which prolongs the clinical effect of the drug and results in a gradual tapering effect. This leads to delayed presentation of withdrawal from benzodiazepines with active metabolites. Withdrawal may also occur when a chronic user of a particular benzodiazepine is switched to another benzodiazepine with a greater affinity for different receptor subunits.<sup>76</sup>

## Chloral Hydrate

First introduced in 1832, chloral hydrate belongs to one of the oldest classes of pharmaceutical hypnotics, the chloral derivatives. Although still used sporadically in children, its use has substantially decreased.<sup>1,75,93,103</sup> Chloral hydrate is well absorbed but is irritating to the GI tract. It has extensive tissue distribution, rapid onset of action, and rapid hepatic metabolism by alcohol and aldehyde dehydrogenases. Trichloroethanol is a lipid-soluble, active metabolite that is responsible for the hypnotic effects of chloral hydrate. It has a serum half-life of 4 to 12 hours and is metabolized to inactive trichloroacetic acid by alcohol dehydrogenases. It is also conjugated with glucuronide and excreted by the kidney as urochloric acid. Less than 10% of trichloroethanol is excreted unchanged.

Metabolic rates in children vary widely because of variable development and function of hepatic enzymes, in particular those achieving glucuronidation.<sup>16,80</sup> The elimination half-life of chloral hydrate and trichloroethanol is markedly increased in children younger than 2 years. This is especially concern in neonates and in infants exposed to repetitive doses.

Acute chloral hydrate poisoning is unique compared with that of other sedative-hypnotics because of the production of toxic metabolites. Cardiac dysrhythmias are the major cause of death.<sup>41</sup> Chloral hydrate and its metabolites reduce myocardial contractility, shorten the refractory period, and increase myocardial sensitivity to catecholamines. Persistent cardiac dysrhythmias (ventricular fibrillation, ventricular tachycardia, torsade de pointes) are common terminal events.<sup>79</sup>  $\beta$ -Adrenergic antagonists such as propranolol mitigate this myocardial sensitivity and are recommended in patients with chloral hydrate-induced dysrhythmias resistant to standard therapy.<sup>15,17,166,175</sup>

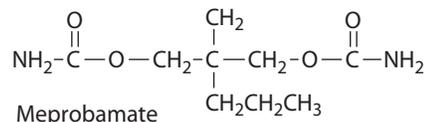

In addition to cardiotoxicity, chloral hydrate toxicity causes vomiting, hemorrhagic gastritis, and rarely gastric and intestinal necrosis, leading to perforation and esophagitis with stricture formation.<sup>69,157</sup> Although large ingestions of chloral hydrate are evident on abdominal radiographs because of its radiopacity, a normal radiograph should not be used to exclude chloral hydrate ingestion. Few hospital-based laboratories have the ability to rapidly detect chloral hydrate or its metabolites.

## Bromides

Bromides were used in the past as “nerve tonics,” headache remedies, and anticonvulsants. Although medicinal bromides have largely disappeared from the US pharmaceutical market, bromide toxicity still occurs through the availability of bromide salts of common drugs, such as dextromethorphan hydrobromide, in large overdoses.<sup>91</sup> There is also documentation of bromism from excessive consumption of cola with brominated vegetable oils.<sup>52</sup> Poisoning may also occur in immigrants and travelers from other countries where bromides are still therapeutically used.<sup>37</sup> An epidemic of more than 400 cases of mass bromide poisoning occurred in the Cacucaco municipality of Luanda Province, Angola, in 2007. According to a World Health Organization report, the etiology of the bromide exposure in these cases was believed to be table salt contaminated with sodium bromide. Although the majority of persons affected were children, no actual deaths were attributed to bromide poisoning in this epidemic.<sup>167</sup>

Bromides tend to have long half-lives, and toxicity typically occurs overtime as concentrations accumulate in tissue. Bromide and chloride ions have a similar distribution pattern in the extracellular fluid. It is postulated that because the bromide ion moves across membranes slightly more rapidly than the chloride ion, it is more quickly reabsorbed in the tubules from the glomerular filtrate than the chloride ion. Although osmolar equilibrium persists, CNS function is progressively impaired by a poorly understood mechanism, with resulting inappropriateness of behavior, headache, apathy, irritability, confusion, muscle weakness, anorexia, weight loss, thickened speech, psychotic behavior, tremulousness, ataxia, and eventually, coma. Delusions and hallucinations occur. Bromides lead to hypertension, increased intracranial pressure, and papilledema.<sup>20,37,149</sup> Chronic use of bromides also produces dermatologic changes called bromoderma, with the hallmark characteristic of a facial acneiform rash.<sup>49,149</sup> Toxicity with bromides during pregnancy causes accumulation of bromide in the fetus and resultant CNS depression.<sup>104</sup> A spurious laboratory result of hyperchloremia with decreased or negative anion gap results from the interference of bromide with the chloride assay on some analyzers<sup>109,171</sup> (Chap. 12). Thus, an isolated elevated serum chloride concentration with neurologic symptoms should raise suspicion of possible bromide poisoning.

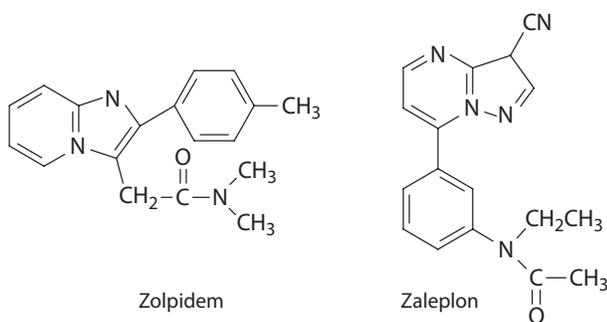

## Carisoprodol and Meprobamate

Meprobamate was introduced in 1950 and was used for its muscle-relaxant and anxiolytic characteristics. Carisoprodol, which was introduced in 1955, is metabolized to meprobamate. Both drugs have pharmacologic effects on the GABA<sub>A</sub> receptor similar to those of the barbiturates. Similar to the

barbiturates, meprobamate can directly open the GABA-mediated chloride channel and inhibits NMDA receptor currents.<sup>113</sup> Both are rapidly absorbed from the GI tract. Meprobamate is metabolized in the liver to inactive hydroxyl and glucuronide metabolites that are excreted almost exclusively by the kidney. Of all the nonbarbiturate tranquilizers, meprobamate is most likely to produce euphoria; the exact mechanism of this is unknown.<sup>57,58</sup> Unlike most sedative–hypnotics, meprobamate causes profound hypotension from direct myocardial depression.<sup>21</sup> Adherent masses or bezoars of pills are reported in the stomach at autopsy after large meprobamate ingestions.<sup>125</sup> Orogastric lavage with a large-bore tube and MDAC is reasonable for patients with a significant meprobamate ingestion while keeping in mind the risk of aspiration. Whole-bowel irrigation is also reasonable if multiple pills or small concretions are suspected. Patients can experience recurrent toxic manifestations as a result of concretion formation with delayed drug release and absorption. Careful monitoring of the clinical course is essential even after the patient shows initial improvement because recurrent and cyclical CNS depression can occur.<sup>125</sup>

### Zolpidem, Zaleplon, Zopiclone, and Eszopiclone

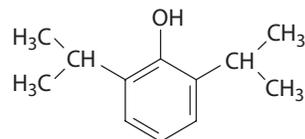

These oral hypnotics have supplanted benzodiazepines as the most commonly prescribed sleep aid medications.<sup>35</sup> Although they are structurally unrelated to the benzodiazepines, they bind preferentially to the benzodiazepine site subtype in the brain that contains the GABA<sub>A</sub>  $\alpha_1$  subunit.<sup>33</sup> They have a lower affinity for benzodiazepine sites that contain the other  $\alpha$  isoforms; therefore, they have potent hypnotic effects with less potential for dependence and antiepileptic properties.<sup>48</sup> Each of these xenobiotics has a relatively short half-life (6 hours or less), with zaleplon exhibiting the shortest half-life (1 hour). Unlike benzodiazepines that prolong the first two stages of sleep and shorten stages 3 and 4 of rapid eye movement sleep, zolpidem and its congeners all decrease sleep latency with little effect on sleep architecture. Because of their receptor selectivity, they appear to have minimal effect at other sites on the GABA<sub>A</sub> receptor that mediate anxiolytic, antiepileptic, or muscle-relaxant effects.<sup>68,158</sup> A low-dose sublingual tablet of zolpidem tartrate (Intermezzo) was recently approved for middle of the night awakenings. An unusual side effect of these drugs, even during therapeutic dosing, is somnambulism, transient anterograde global amnesia, with the majority of these reports involving zolpidem.<sup>45</sup>

They are hepatically metabolized by various CYP450 enzymes. Zolpidem is mainly metabolized by CYP3A4. Zaleplon is primarily metabolized by aldehyde oxidase, but CYP3A4 is also involved in parent compound oxidation. Whereas zopiclone is primarily metabolized by CYP3A4 and CYP2C8, eszopiclone is metabolized mainly by CYP3A4 and CYP2E1. Various pharmacokinetic interactions with inhibitors or inducers of CYP450 enzymes and these medications are reported.<sup>47</sup>

In isolated overdoses, drowsiness and CNS depression are common. However, prolonged coma with respiratory depression is exceptionally rare. Isolated overdoses usually manifest with depressed level of consciousness without respiratory depression. For example, even at 40 times the therapeutic dose of zolpidem, no biologic or electrocardiographic abnormalities were reported.<sup>40</sup> Zopiclone overdoses are rarely associated with methemoglobinemia.<sup>39</sup> Tolerance to zolpidem and its congeners occurs, and as expected, withdrawal follows abrupt discontinuation of chronic use.

The withdrawal syndrome is typically mild.<sup>46,164</sup> Flumazenil reverses the hypnotic and cognitive effects of these xenobiotics, and given the lack of antiepileptic effects of these xenobiotics, flumazenil reversal may be safer here than in the case of benzodiazepines (Antidotes in Depth: A25).<sup>71,172</sup> Because of increasing prevalence of these xenobiotics, they have been associated with increasing hospitalizations especially when ingested with other sedative–hypnotics.<sup>179</sup> Deaths result when zolpidem is taken in large amounts with other CNS depressants.<sup>40</sup>

### Propofol

Propofol is a rapidly acting IV sedative–hypnotic that is both a postsynaptic GABA<sub>A</sub> agonist and induces presynaptic release of GABA.<sup>95,150</sup> Propofol is also an antagonist at NMDA receptors.<sup>63,138,177</sup> In addition, propofol interacts with dopamine, promotes nigral dopamine release possibly via GABA<sub>B</sub> receptors,<sup>98,126</sup> and has partial agonist properties at dopamine (D<sub>2</sub>) receptors.<sup>124</sup> Propofol is used for procedural sedation and either induction or maintenance of general anesthesia, as well as an antiepileptic to manage status epilepticus. It is highly lipid soluble, so it crosses the blood–brain barrier rapidly. The onset of anesthesia usually occurs in less than 1 minute. The duration of action after short-term dosing is usually less than 8 minutes because of its rapid redistribution from the CNS.

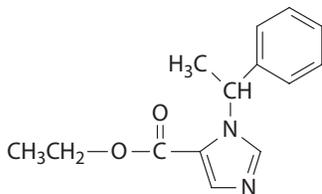

Propofol use is associated with various adverse events. Acutely, propofol causes dose-related respiratory depression. Propofol decreases systemic arterial pressure and causes myocardial depression. Although short-term use of propofol does not typically cause dysrhythmias or myocardial ischemia, atropine-sensitive bradycardias are noted, specifically sinus bradycardia and Mobitz type 1 atrioventricular block.<sup>148,163,174</sup> Short-term use of propofol in the perioperative setting is associated with a myoclonic syndrome manifesting as opisthotonus, myoclonus, and sometimes myoclonic seizure-like activity.<sup>84,92</sup>

Prolonged propofol infusions, typically more than 48 hours at rates of 4 to 5 mg/kg/h or greater, are associated with a life-threatening propofol-infusion syndrome involving metabolic acidosis, cardiac dysrhythmias, and skeletal muscle injury.<sup>60,61</sup> The clinical signs of propofol infusion syndrome often begin with the development of a new right bundle branch block and ST-segment convex elevations in the electrocardiogram precordial leads.<sup>60</sup> Predisposing factors to the development include young age, severe brain injury (especially in the setting of trauma), respiratory compromise, concurrent exogenous administration of catecholamines or glucocorticoids, inadequate carbohydrate intake, and undiagnosed mitochondrial myopathy. Some authors propose a “priming” and “triggering” mechanism for propofol infusion syndrome with endogenous glucocorticoids, catecholamines, and possibly cytokines as “priming” agents and exogenous catecholamines and glucocorticoids in the setting of high-dose propofol infusion as “triggering” stimuli.<sup>155</sup> Propofol disrupts mitochondrial free fatty acid utilization and metabolism, causing a syndrome of energy imbalance and myonecrosis similar to mitochondrial myopathies.<sup>22,132,156</sup> Most case reports associate propofol with metabolic acidosis, elevated lactate concentration, and fatal myocardial failure in both children and young adults. However, this syndrome is also reported in older adults.<sup>100</sup> Some cases of metabolic acidosis are associated with an inborn disorder of acylcarnitine metabolism.<sup>169</sup> Prolonged propofol infusions unmask previously undiagnosed myopathy that would cause them to be at increased risk for propofol infusion syndrome, especially in children.

The unique nature of the carrier base of propofol, a milky soybean emulsion formulation, is associated with multiple adverse drug events such as impairment of macrophage function,<sup>22</sup> hypertriglyceridemia,<sup>65,72,156</sup> histamine-mediated anaphylactoid reactions,<sup>33,62,156</sup> and impairment of platelet and coagulation function.<sup>331</sup> Additionally, the carrier base is a fertile medium

for many organisms, such as enterococcal, pseudomonal, staphylococcal, streptococcal, and candidal species. In 1990, the US Centers for Disease Control and Prevention first reported an outbreak of *Staphylococcus aureus* associated with contaminated propofol.<sup>87</sup> Since then, 20 propofol-related outbreaks have been reported, which have affected 144 patients and caused 10 deaths.<sup>178</sup>

## Etomidate

Etomidate is an IV nonbarbiturate, hypnotic primarily used for an anesthesia induction. It is active at the GABA<sub>A</sub> receptor, specifically the  $\beta_2$  and  $\beta_3$  subunits.<sup>24,94</sup> Only the IV formulation is available in the United States. The onset of action is less than 1 minute, and its duration of action is less than 5 minutes.

Etomidate is commercially available as a 2-mg/mL solution in a 35% propylene glycol solution. Propylene glycol toxicity from prolonged etomidate infusions is implicated in the development of hyperosmolar metabolic acidosis (Chap. 46).<sup>70,152,154</sup> Etomidate has minimal effect on cardiac function, but rare cases of hypotension are reported because of adrenal suppression.<sup>142</sup> Etomidate has both proconvulsant and antiepileptic properties.<sup>25,108</sup> Involuntary muscle movements are common during induction and are caused by etomidate interaction with glycine receptors at the spinal cord level.<sup>28,88,89</sup>

Etomidate depresses adrenal production of cortisol and aldosterone; therefore, it is associated with adrenocortical suppression, usually after prolonged infusions.<sup>122,159,160</sup> Etomidate is associated with increased morbidity and mortality in critically ill and trauma patients.<sup>27,50</sup> However, the clinical significance of adrenal suppression from etomidate administration is disputed.<sup>51,144,145</sup> In the appropriate setting, etomidate does not appear to have any greater risk of significant adverse events compared with its counterparts.

## Dexmedetomidine

Dexmedetomidine is a central  $\alpha_2$ -adrenergic agonist that decreases central presynaptic catecholamine release, primarily in the locus ceruleus. When dexmedetomidine is used to help wean patients from ventilators, sedation is achieved with less associated delirium compared with other agents.<sup>99,143</sup> It is also used for procedural sedation in certain settings such as interventional radiology procedures and awake fiberoptic intubations. Compared with propofol, dexmedetomidine sedation lessens opioid requirements in postoperative patients.

Dexmedetomidine has minimal effect at the GABA<sub>A</sub> receptor. Unlike other sedative-hypnotics, it is not associated with significant respiratory depression. Although mechanistically similar to clonidine, dexmedetomidine does not appear to cause as much respiratory depression as clonidine. Dexmedetomidine is said to induce a state of “cooperative sedation” in which a patient is sedated but yet able to interact with health care providers. Dexmedetomidine also has analgesic effects.<sup>23</sup>

Dexmedetomidine is currently only approved for use for less than 24 hours. Extensive safety trials have not yet explored its use beyond 24 hours. Unlike clonidine, rebound hypertension and tachycardia have not been described upon cessation. Because dexmedetomidine decreases central sympathetic outflow, its use should probably be avoided in patients whose clinical stability is dependent on high resting sympathetic tone. The most common adverse effects from its use are nausea, dry mouth, bradycardia, and varying effects on blood pressure (usually hypertension followed by hypotension). Slowing of the continuous infusion may help to prevent or lessen the hypotensive effects.<sup>23</sup> In one case, a 60-fold overdose in a child was associated with hypoglycemia.<sup>12</sup>

## Melatonin, Ramelteon, and Tasimelteon

Melatonin (*N*-acetyl-5-methoxytryptamine) and melatonin-containing products are sold as dietary supplements. Melatonin is naturally synthesized from tryptophan by the enzyme 5-hydroxyindole-O-methyltransferase, primarily within the pineal gland in humans. Ramelteon is a synthetic melatonin-analog that is FDA approved for the treatment of chronic insomnia. Ramelteon is thought to decrease both latency to sleep induction and length of persistent sleep.<sup>134</sup> Tasimelteon, the newest melatonin receptor agonist, is the only FDA-approved drug used to treat non-24-hour sleep-wake disorder that occurs in blind individuals in whom light cues do not reach the suprachiasmatic nucleus of the brain to allow for a normal sleep-wake cycle.<sup>53</sup> Melatonin, ramelteon, and tasimelteon act as agonists at MT<sub>1</sub> and MT<sub>2</sub> receptors, which are G protein-coupled receptors mainly located in the suprachiasmatic nucleus of the brain.<sup>127</sup> Whereas MT<sub>1</sub> receptors are involved in sleep induction, MT<sub>2</sub> receptors are involved in regulation of the circadian sleep-wake cycle in humans.<sup>140</sup>

Ramelteon administered orally is rapidly absorbed but undergoes significant first-pass metabolism primarily by CYP1A2.

Adverse effects of ramelteon are mild and usually include drowsiness, dizziness, fatigue, and headache. The endocrine effects of long-term exposure to ramelteon seem to be limited to subclinical increases in serum prolactin concentration in women and do not appear to affect adrenal or thyroid function.<sup>114</sup> In addition, ramelteon appears to have a low abuse potential and does not appear to be associated with a withdrawal syndrome or rebound insomnia.<sup>44,77,85</sup> A retrospective review of 222 poison control center calls of ramelteon overdose reported no significant clinical effect in 88.3% of cases. Isolated cases of bradycardia, hypotension, and seizures did occur.<sup>147</sup> There are no published reports of tasimelteon toxicity from overdose.

## Suvorexant

Suvorexant is a newly approved dual orexin receptor antagonist. Orexin (also known as hypocretin) promotes wakefulness; as an orexin antagonist, suvorexant induces and maintains sleep. This is the first drug in this class of sedative-hypnotics.<sup>141,173</sup> Preliminary studies have shown that patients taking this drug have a shorter sleep latency and stayed asleep longer than the control group taking placebo. There are no reports of physical dependence on this drug or withdrawal upon its cessation. There are no trials comparing suvorexant with other drugs for noninferiority or efficacy. The most commonly reported side effect with overdose is somnolence after awakening.<sup>82</sup>

## SUMMARY

- Sedative-hypnotics encompass a wide range of xenobiotics that predominantly interact with the GABA<sub>A</sub> receptor but can also have varying mechanisms of action.
- Patients with sedative-hypnotic overdoses often present with the primary manifestation of CNS depression; however, death typically results from respiratory depression and subsequent cardiovascular collapse in the setting of concurrent coingestion of other CNS depressants.
- Treatment is largely supportive, including careful monitoring, airway protection, and proper supportive care, with a rare need for GI decontamination in select severe cases.
- Specific antidotes such as flumazenil and hemodialysis are rarely indicated.

## FLUMAZENIL

Mary Ann Howland

Synthetic derivatives of this molecule led to the creation of benzodiazepines with potent anxiolytic and anticonvulsant activity and diminished sedative and muscle-relaxing properties. Testing revealed these derivatives had high in vitro binding affinities but lacked in vivo agonist activity. An inability to enter the central nervous system (CNS) was considered an explanation for the discordance. During an experiment that attempted to demonstrate CNS penetration of these derivatives, diazepam given to incapacitate the animals had a surprisingly weak effect. This lack of efficacy of diazepam led to the discovery of a benzodiazepine antagonist. Further modifications led to the synthesis of flumazenil.<sup>23,68</sup>

**PHARMACOLOGY****Mechanism of Action**

The benzodiazepine receptor modulates the effect of GABA on the GABA<sub>A</sub> receptor by increasing the frequency of Cl<sup>-</sup> channel opening, leading to hyperpolarization. Agonists such as diazepam stimulate the benzodiazepine receptor to produce anxiolytic, anticonvulsant, sedative-hypnotic, amnestic, and muscle relaxant effects.<sup>38</sup> Flumazenil is a water-soluble benzodiazepine analog with a molecular weight of 303 Da. It acts as a competitive antagonist at the  $\alpha_1$  subtype of GABA<sub>A</sub> benzodiazepine receptors with very weak partial agonist properties at the  $\alpha_2$ ,  $\alpha_3$ , and  $\alpha_5$  subtypes of the GABA<sub>A</sub> benzodiazepine receptors in animal models and possibly in humans.<sup>21,52</sup> Inverse agonists bind the benzodiazepine receptor and result in the opposite effects of anxiety, agitation, and seizures. Antagonists, such as flumazenil, competitively occupy the benzodiazepine receptor without causing any functional change and without allowing an agonist or inverse agonist access to the receptor. The zero setpoint of intrinsic activity may be influenced by the activity of the GABA system or by chronic treatment with benzodiazepines.<sup>27</sup> Positron emission tomography investigations in adult humans revealed that 1.5 mg of flumazenil led to an initial receptor occupancy of 55%, but 15 mg caused almost total blockade of benzodiazepine receptor sites.<sup>72</sup>

**PHARMACOKINETICS AND PHARMACODYNAMICS**

Table A25-1 summarizes the physicochemical and pharmacologic properties of flumazenil.<sup>24,42</sup> Volunteer studies demonstrate that the ability of flumazenil to reverse the effects of sedating doses of IV benzodiazepines (eg, 30 mg diazepam, 3 mg lorazepam, 10 mg midazolam) is dose dependent and begins within minutes.<sup>21</sup> Peak effects occur within 6 to 10 minutes.<sup>24</sup> Most individuals achieve complete reversal of benzodiazepine effect with a total IV dose of 1 mg, titrated in 0.2-mg aliquots.<sup>5,14</sup> A 3-mg IV dose produces similar effects that last approximately twice as long as the 1-mg dose. A study in monkeys reports the pharmacodynamic half-life of flumazenil as similar to the pharmacokinetic half-life.<sup>91</sup>

**ROLE IN CONSCIOUS SEDATION**

A number of studies evaluated patients who received midazolam or diazepam (average doses of 10 and 30 mg, respectively) as conscious sedation for endoscopy or cardioversion.<sup>6,13,14,18,45,47</sup> When a benzodiazepine is given for conscious sedation during a procedure, flumazenil appears safe and effective for reversal of prolonged sedation and partial reversal of amnesia and cognitive impairment.<sup>30,40,46</sup> The practitioner performing conscious sedation is able to obtain a more reliable history of whether contraindications to flumazenil exist. Most patients respond to total doses of 0.4 to 1 mg.<sup>24</sup>

**INTRODUCTION**

Flumazenil is a competitive benzodiazepine receptor antagonist. Its role in patients with an unknown overdose is limited because seizures and dysrhythmias may develop when the effects of a benzodiazepine are reversed if the patient has taken a mixed overdose of a benzodiazepine and a proconvulsant. Flumazenil also has the potential to induce benzodiazepine withdrawal symptoms, including seizures in patients who are benzodiazepine dependent. Flumazenil does not reliably reverse the respiratory depression induced by intravenous (IV) benzodiazepines.<sup>24</sup> Flumazenil is the ideal antidote for the relatively few patients who are both naïve to benzodiazepines and who overdose solely on a benzodiazepine as well as benzodiazepine-naïve patients whose benzodiazepines must be reversed during or after procedural sedation. Because the duration of effect of flumazenil is shorter than that of most benzodiazepines, repeat doses may be necessary and vigilance is warranted. Flumazenil has no role in the management of ethanol intoxication. In patients with hepatic encephalopathy, further study is necessary before it can be recommended.<sup>4</sup> Case reports raise the possibility of a role for flumazenil in patients with paradoxical reactions to therapeutic doses of benzodiazepines.<sup>78,86</sup> Flumazenil is neither rational nor effective in patients who overdose with baclofen.<sup>15</sup> Flumazenil is effective for overdoses of zolpidem and zaleplon, nonbenzodiazepines that interact with  $\omega_1$  receptors, a subclass of central benzodiazepine receptors.<sup>50,62,65,79</sup>

**HISTORY**

The initial work of Haefely and Hunkeler<sup>42,82</sup> on chlordiazepoxide synthesis led to an attempt to develop benzodiazepine derivatives that would act as antagonists.<sup>37</sup> This endeavor was initially unsuccessful but led to the promising  $\gamma$ -aminobutyric acid (GABA) hypothesis as the benzodiazepine mechanism of action. Radioligand binding identified specific high-affinity benzodiazepine binding sites and others isolated a product produced by a *Streptomyces* species that had the basic 1,4-benzodiazepine structure.

**TABLE A25–1** Physicochemical and Pharmacologic Properties of Flumazenil

pK <sub>a</sub>	Weak base
LogD	1.15 (octanol/aqueous PO <sub>4</sub> buffer)
Volume of distribution (SS)	1.06 L/kg
Distribution half-life (min)	4–11
Metabolism	Hepatic: three inactive metabolites Clearance dependent on hepatic blood flow
Elimination	First order
Protein binding (%)	54–64
Elimination half-life (min)	54
Onset of action (min)	1–2
Duration of action	Dependent on dose and elimination of benzodiazepine, time interval, dose of flumazenil, and hepatic function

Administering flumazenil slowly at a rate of 0.1 mg/min minimizes the disconcerting symptoms associated with rapid arousal, such as confusion, agitation, and emotional lability. Persistent or recurrent sedation becomes evident within 20 to 120 minutes, depending on the dose and pharmacokinetics of the specific chosen benzodiazepine and the dose of flumazenil.<sup>30</sup> One study evaluated 887 patients who received 5 mg of midazolam for endoscopy followed by a median reversal dose of 0.2 mg of flumazenil. Most procedures lasted 30 minutes, and flumazenil was administered 5 minutes after arrival in the recovery room. Patients left for home 65 minutes after the last dose of midazolam with only 83% of the patients fully alert. Of concern is that 3 patients fainted, fell or had a near fall, although without harm demonstrating the risks of incomplete or transient reversal.<sup>57</sup> Flumazenil does not alter the clinical course of most patients who receive it and provides a false sense of effectiveness to the clinician. Therefore, patients must be carefully monitored and subsequent doses of flumazenil titrated to clinical response. Because the amnestic effect of benzodiazepines and the cognitive and psychomotor effects are not fully reversed, posttreatment instructions should be reinforced in writing and given to a responsible caregiver accompanying the patient.<sup>21,30</sup>

Two patients undergoing endoscopy who developed seizures after benzodiazepine reversal are reported.<sup>77</sup> One patient had a history of seizures, and the other had no obvious etiology. Both patients recovered uneventfully.

## ROLE IN PARADOXICAL REACTIONS

Paradoxical reactions to benzodiazepines are unpredictable and documented in as many as 10% of adults and in 3.4% of children.<sup>16,34,55,56,78</sup> Common features include worsening restlessness, agitation, disorientation, irrational talking, flailing and excessive movements, hostile behavior, and dysphoria.<sup>29,32,63,78,86</sup> The mechanism is unclear and is attributed to disinhibition.<sup>26</sup> These reactions are reported to occur from several minutes to 210 minutes after initiation of sedation.<sup>32,86</sup> One study of 98 pediatric patients found that administering a flumazenil dose of 0.1 mg/kg as a 0.1% solution at 0.2 mL/s compared with 1 mL/s significantly reduced the occurrence of paradoxical reactions.<sup>58</sup> Management strategies include administering higher doses of the benzodiazepines, adding other drugs such as opioids or droperidol, stopping the procedure, and using flumazenil.<sup>20,26,29,43,56,63,86</sup> Intravenous flumazenil was administered to six adults with paradoxical reactions to midazolam in 0.1-mg aliquots. Doses of 0.2 to 0.5 mg were effective in all the patients with a response occurring within 30 seconds.<sup>86</sup> Attention to other causes of unexpected behavior such as hypoxia or hypoglycemia must be addressed and corrected.

## ROLE IN THE OVERDOSE SETTING

Although the flumazenil package insert prescribing information carries an indication for the management of benzodiazepine overdose, the role of flumazenil in the overdose setting is controversial.<sup>24,48,83</sup> The first argument against flumazenil use is the rare morbidity and mortality associated with benzodiazepine use. An analysis of 702 patients who had taken benzodiazepines alone or in combination with ethanol or other xenobiotics and were subsequently admitted to a medical intensive care unit over a 14-year period revealed a 0.7% fatality rate (five deaths) and 9.8% complication rate (69 patients).<sup>41</sup> In comparison, the fatality rate for patients with nonbenzodiazepine-related overdoses was 1.6% (55 of 3,430 patients). In the benzodiazepine group, two patients died, and 18 (12.5%) of 144 patients had complications, mostly aspiration pneumonitis and decubitus ulcers. Proponents of flumazenil therapy suggest that some of the 29 diagnostic procedures used in the patients were unnecessary, and some of the complications could have been prevented by the use of flumazenil. We and others suggest that many of the cases of aspiration pneumonitis occurred before hospital admission and that the patients also suffered from trauma and infectious diseases, making most diagnostic procedures necessary.

In an effort to develop indications for safe and effective use of flumazenil, overdosed comatose patients were retrospectively assigned to either a low-risk or non-low-risk group.<sup>35</sup> Low-risk patients had CNS depression with normal vital signs, no other neurologic findings, no evidence of ingestion of a tricyclic antidepressant by history or electrocardiography, no seizure history, and absence of an available history of chronic benzodiazepine use. All other patients fell into the non-low-risk category. Of 35 consecutive comatose patients, 4 were assigned to the low-risk group. Flumazenil resulted in complete awakening in three patients and partial awakening in the fourth patient in the low-risk group, with no adverse events. In the non-low-risk group of 31 patients, flumazenil caused complete awakening in 4 patients and partial awakening in 5 patients. Seizures occurred in 5 patients, of whom only 1 had a history of seizures, 5 were long-term benzodiazepine users, 4 had abnormal vital signs before reversal, and 3 had evidence of hyperreflexia or myoclonus. Therefore, although flumazenil use probably was safe and effective in the low-risk group, few patients could be considered low risk. The risk of seizures appears substantial in non-low-risk patients.

A systematic review with an analysis of randomized controlled trials of the use of flumazenil compared to placebo in emergency department patients with coma and a suspicion of benzodiazepine overdose included a total of 994 patients divided equally between flumazenil and placebo.<sup>66</sup> More serious adverse events (supraventricular dysrhythmias and seizures) and more adverse events in general (eg, aggressive behavior, nausea, vomiting, and abdominal cramps, sweating, shivering, and anxiety) occurred in the flumazenil group than placebo.<sup>75</sup>

The risks of flumazenil usually outweigh the benefits in patients with overdoses.<sup>66,67,73,75</sup> When non-benzodiazepine-dependent patients solely ingest benzodiazepines in overdose, as rarely occurs in adults but might be expected in children, the risks associated with flumazenil are limited.<sup>49,88</sup> Table A25–2 summarizes the indications for flumazenil use in the overdose setting.

## ROLE IN NONBENZODIAZEPINE TOXICITY

### Hepatic Encephalopathy

Hepatic encephalopathy is considered a reversible metabolic encephalopathy characterized by a spectrum of CNS effects. Symptoms may progress

**TABLE A25–2** Indications for Flumazenil Use in the Overdose Setting

- Pure benzodiazepine overdose in a nontolerant individual who has
- CNS depression
- Normal vital signs, including SaO<sub>2</sub>
- Normal ECG findings
- Otherwise normal neurologic examination

CNS = central nervous system; ECG = electrocardiogram.

from confusion and somnolence to coma. One current hypothesis implicates an increase in GABAergic tone in the development of encephalopathy.<sup>7,76</sup>

Animal studies of hepatic encephalopathy secondary to galactosamine or thioacetamide (hepatotoxins) demonstrate an increase in GABA effect, which is antagonized by flumazenil, bicuculline (a GABA receptor antagonist), and isopropylbicyclopentylphosphate chloride (a calcium channel blocker).<sup>7</sup> Cerebrospinal fluid (CSF) from these animals contained a benzodiazepine receptor ligand with agonist activity. Rat studies involving hepatic encephalopathy resulting from acute liver ischemia showed only a slight response to flumazenil but significant improvement after administration of a partial inverse agonist.<sup>12,84</sup>

Human studies have detected benzodiazepine binding activity in the CSF and serum of patients with hepatic encephalopathy. One group identified four to 19 peaks representing benzodiazepine binding ligands from the frontal cortex of 11 patients who died of hepatic encephalopathy.<sup>10</sup> Two of the peaks were further characterized as diazepam and *N*-desmethyldiazepam. Brain concentrations of these substances were 2 to 10 times higher than normal in 6 of the patients and were normal in 5 patients. Patients with idiopathic recurring stupor have measurable “endozepines” (endogenous benzodiazepine ligands) in serum and CSF.<sup>69,81</sup>

Flumazenil improves the clinical and electrophysiologic responses of patients with hepatic encephalopathy and idiopathic recurring stupor.<sup>4,8,22,69,81</sup> Some patients with encephalopathy have improved from stage IV to stage II encephalopathy after IV flumazenil. Maximal improvement after flumazenil lasts approximately 1 to 2 hours and gradually dissipates within 6 hours. The response rate in a meta-analysis averaged approximately 30%.<sup>33</sup> The proposed explanations for the unresponsiveness include cerebral edema, hypoxia, other systemic diseases or complications, and irreversible CNS damage.

Animal and human data convincingly support the concept that increased GABAergic tone is responsible for hepatic encephalopathy. Evidence for endogenous benzodiazepine ligands that enhance GABA action also are demonstrated but controversial.<sup>1,3</sup> The source of these benzodiazepine receptor agonists is unclear, but diet or production by gut bacteria (or both) is postulated.<sup>7</sup> Some authorities believe endogenous de novo synthesis is unlikely and propose prior benzodiazepine exposure and persistence of clinical effects as an explanation. Hyperammonemia, neurosteroids, and hemoglobin metabolites are also implicated in the pathophysiology of hepatic encephalopathy.<sup>3,11,19,71</sup>

Flumazenil can lead to short-term improvement of the clinical condition of a subgroup of patients with hepatic encephalopathy and may prove useful as an addition to conventional therapy.<sup>2,4,9</sup> Existing guidelines recommend that use be reserved for patients with acute hepatic encephalopathy and a history of benzodiazepine use.<sup>11,25</sup> Additional research is necessary to prospectively identify responders, provide dosing considerations, and evaluate adverse events. There is no known survival benefit, and we do not currently recommend flumazenil utilization.<sup>31</sup>

### Ethanol Intoxication

Animal studies indicate that many of the actions of ethanol are mediated through GABA neurotransmission.<sup>80</sup> Acute ethanol administration appears to enhance GABA transmission and inhibit *N*-methyl-D-aspartate excitation. Chronic ethanol administration leads to downregulation of the GABA system. Ethanol enhances GABA<sub>A</sub>-induced chloride influx in a dose-dependent fashion without a direct effect on chloride. Flumazenil does not influence this action of GABA. Chronic ethanol use selectively increases the sensitivity to inverse benzodiazepine agonists, invoking a change in coupling or conformation of the receptor. These changes may explain the development of tolerance as well as the kindling effect and production of seizures that occur during ethanol withdrawal.

A randomized, double-blind, crossover study was conducted in eight male volunteers given IV ethanol to achieve a constant serum ethanol concentration of 160 mg/dL.<sup>17</sup> After being stabilized, the volunteers were given either placebo or 5 mg of flumazenil. Subjective and objective psychomotor tests were conducted, with no differences noted between groups. Thus, the probability of ethanol reversal at the doses achieved appears unlikely.

Based on this information, flumazenil likely does not have a significant effect on ethanol intoxication, and low doses (< 1 mg) of flumazenil have no effect.<sup>51,54</sup> The 5-mg doses reportedly produce favorable changes in sensorium, but these findings may be the result of confounding factors. Flumazenil should not be administered in this dose range in the overdose setting. Therefore, to avoid the increased risk of adverse effects, flumazenil cannot be recommended for reversal of ethanol intoxication.

### ADVERSE EFFECTS AND SAFETY ISSUES

More than 3,500 patients worldwide received flumazenil, including healthy volunteers and overdosed patients, or patients who had undergone conscious sedation. The safety of flumazenil in healthy volunteers is well established without discernible objective or subjective effects. However, seizures in benzodiazepine-dependent patients, dysrhythmias in patients who coingest a benzodiazepine and a pro-dysrhythmic xenobiotic, and resedation within 20 to 120 minutes in patients receiving benzodiazepines for conscious sedation are recognized adverse events associated with flumazenil administration.

The ability of flumazenil to precipitate acute benzodiazepine withdrawal seizures in a more controlled environment than the overdose setting was demonstrated by reversal of long-term benzodiazepine sedation in the intensive care unit. A study of 1,700 patients revealed that 14 patients developed adverse drug reactions; probably half of these reactions were related to abrupt arousal.<sup>6</sup> Two patients with a history of epilepsy developed tonic-clonic seizures, and one patient developed myoclonic seizures.<sup>6</sup> Dose-dependent induction of withdrawal reactions is therefore suggested. Small total doses (< 1 mg) of titrated flumazenil are suggested to allow sufficient occupation of the benzodiazepine receptor sites by benzodiazepines to limit the occurrence of withdrawal seizures.

In a study of 12 patients receiving midazolam sedation for 4 ± 3 days, 0.5 mg of flumazenil was administered as a rapid bolus. Serum norepinephrine and epinephrine concentrations rose within 10 minutes, returned to baseline within 30 minutes, and correlated with increased heart rate, blood pressure, and myocardial oxygen consumption.<sup>44</sup> Flumazenil causes a significant overshoot in cerebral blood flow and risks causing a large increase in intracranial pressure in patients who have received midazolam for severe head injury.<sup>90</sup>

Thirty published case series involving 758 patients with benzodiazepine overdoses were reviewed.<sup>28</sup> In total, 387 patients participated in double-blind study protocols and 371 patients in open-label studies.<sup>28</sup> Fifty percent of cases were associated with mixed benzodiazepine overdoses. The doses of flumazenil ranged from 0.2 to 5 mg. Five cases of seizures were temporally related to flumazenil administration, all followed large bolus doses. In three of the five patients, high concentrations of TCAs were present in the blood. The seizures resolved either without treatment or after administration of a small dose of a benzodiazepine. Dysrhythmias developed in two patients given small doses of flumazenil, both presumably associated with the presence of a TCA. Of 497 patients enrolled in two clinical US studies sponsored by the manufacturer,<sup>28</sup> 6 patients developed seizures (5 had coingested TCAs), and 1 patient who had taken a TCA and carbamazepine had a junctional tachycardia, which normalized after several minutes. Thus, in reviewing 1,255 patients, 11 patients had seizures, and 3 developed dysrhythmias, for an incidence of approximately 0.9%. We agree with the consensus report, which stated that (1) flumazenil is not a substitute for primary emergency care; (2) hypoxia and hypotension should be corrected before flumazenil is used; (3) when used, small titrated doses of flumazenil should be given; (4) flumazenil should not be used in patients with a history of seizures, evidence of seizures or jerking movements, or evidence of a TCA overdose; and (5) flumazenil should not be used by inexperienced clinicians.

An analysis was published of all seizures associated with flumazenil gathered from previously published cases or reports to the manufacturer.<sup>77</sup> Forty-three patients had seizures, and six patients died, but the author believed that none of the deaths were attributable to flumazenil.<sup>77</sup> Four patients developed status epilepticus; two were presumed to be caused by concomitant TCA exposure, and the other two patients had received benzodiazepines

**TABLE A25-3** Contraindications to Flumazenil Use

History	Clinical
Seizure history or current treatment of seizures	Potential ECG evidence of cyclic antidepressant use: terminal rightward 40-ms axis, QRS or QT interval prolongation
Ingestion of a xenobiotic capable of provoking seizures or cardiac dysrhythmias	Hypoxia or hypoventilation <sup>a</sup> Hypotension Head trauma
Long-term use of benzodiazepines	

<sup>a</sup>Do not rely on flumazenil to reverse benzodiazepine-induced respiratory depression. ECG = electrocardiogram.

to treat status epilepticus before flumazenil therapy. In six of 43 seizure episodes, the relationship to flumazenil use was believed to be inadequately defined. The remaining 37 patients were stratified into five categories. In category 1, seven patients were given flumazenil after they had received a benzodiazepine for treatment of a seizure disorder. Six of these seven patients received greater than 1 mg flumazenil. In category 2, 20 patients received flumazenil for reversal of a benzodiazepine in a mixed drug overdose. Many of these patients had coingested TCAs. Thirteen of these patients received more than 1 mg of flumazenil. Two of the patients in this group developed status epilepticus and died, possibly secondary to a severe TCA overdose. Category 3 included five patients who received benzodiazepines for suppression of non-drug-induced seizures. Two of these five patients received more than 1 mg of flumazenil. Category 4 included three patients with acute benzodiazepine overdoses in the presence of chronic benzodiazepine dependence. Category 5 included two patients who received a benzodiazepine for conscious sedation. Therefore, flumazenil use places the patient at risk for seizures by unmasking a toxic effect in mixed overdose, by removing the protective anticonvulsant effect in a patient with non-drug-induced seizures, or by precipitating acute benzodiazepine withdrawal. **Table A25-3** summarizes the contraindications and precautions essential to evaluate before flumazenil use.

Flumazenil does not consistently reverse benzodiazepine-induced respiratory depression and is not suggested as the initial intervention if respiratory depression occurs.<sup>24,33,59,74</sup> Interestingly, in one preliminary observational study of 13 patients being mechanically ventilated for more than 4 days who were receiving midazolam, the administration of flumazenil increased diaphragm electrical activity.<sup>70</sup> It is likely that after oral overdose, benzodiazepine-induced respiratory insufficiency is related to smooth muscle relaxation, resulting in a mechanical effect with an increase in upper airway resistance and obstructive apnea rather than a central effect.<sup>36</sup> Although flumazenil might improve the clinical situation,<sup>36,64</sup> other standard procedures such as airway repositioning, supplemental oxygen, bag-valve-mask ventilation, and endotracheal intubation, if indicated, should be used either before or during reversal.

## PREGNANCY AND LACTATION

Flumazenil is US Food and Drug Administration (FDA) Pregnancy Category C. There are no adequate studies done in pregnant women.<sup>24</sup> It is not known whether flumazenil is excreted in breast milk.<sup>24</sup>

## DOSING AND ADMINISTRATION

Slow IV titration (0.1 mg/min) and waiting 1 minute between doses, to a total dose no higher than 1 mg, seems most reasonable in adults. In pediatric patients, for the reversal of conscious sedation, the package insert recommends an initial dose of 0.01 mg/kg (up to 0.2 mg). We think it is prudent to administer the flumazenil slowly as described for adults. Administration into a large freely running vein minimizes the potential for pain at the injection site. Resedation should be anticipated to occur between 20 and 120 minutes, and readministration of flumazenil may be necessary. Flumazenil

is compatible with 5% dextrose in water, lactated Ringer's solution, and normal saline.<sup>24</sup> Although not approved by the FDA, continuous IV infusion of flumazenil 0.1 to 1.0 mg/h in 0.9% sodium chloride solution or 5% dextrose in water is used by some authors after the loading dose, although we do not consider this approach of well-defined value or appropriate.<sup>50,87,89</sup>

## FORMULATION

Flumazenil is available by many manufacturers in a concentration of 0.1 mg/mL with parabens in 5- and 10-mL vials.

## SUMMARY

- The risks of flumazenil greatly outweigh the potential benefits of reversal when benzodiazepines are used chronically or acutely to treat a seizure disorder.
- We believe that flumazenil can be safely administered to patients naïve to benzodiazepines for the reversal of CNS sedation.
- We recommend that flumazenil be avoided in the overdose setting when evidence indicates coingestion of a drug capable of causing seizures or dysrhythmias.
- Flumazenil should not be used when involvement of a TCA is strongly suggested based on history, clinical findings, or findings on electrocardiography (prolonged QRS complex).<sup>39,52,60,85</sup>
- We recommend that flumazenil be avoided in any patients where theophylline, carbamazepine, chloral hydrate, chloroquine, and/or chlorinated hydrocarbons are a part of the overdose history.<sup>85</sup>
- We believe that in the event of a seizure induced by a therapeutic dose of flumazenil, a benzodiazepine such as diazepam or lorazepam should be effective; however, because of the competitive nature of flumazenil, higher doses are necessary to reverse higher doses of flumazenil.

## AMPHETAMINES

Meghan B. Spyles and David H. Jang

Methylenedioxyamphetamine

Methamphetamine

Epinephrine

## HISTORY AND EPIDEMIOLOGY

Amphetamine was first synthesized in 1887 but was essentially lost until the 1920s, when concerns arose regarding the supply of ephedrine for asthma therapy.<sup>67</sup> The attempt to synthesize ephedrine led to the rediscovery of dextroamphetamine in the United States and methamphetamine (*d*-phenylisopropylmethylamine hydrochloride) in Japan. Amphetamine was first marketed by Smith, Kline, and French in 1932 as the nasal decongestant Benzedrine. Both amphetamine and methamphetamine were supplied as stimulants for soldiers and prisoners of war during World War II. Amphetamine tablets were later available in 1935 for the treatment of narcolepsy and were advocated as anorexiant in 1938.<sup>17</sup>

The stimulant and euphoric effects of amphetamine were immediately recognized, with abuse reported as early as 1940.<sup>74</sup> As a result, Benzedrine inhalers were banned by the US Food and Drug Administration (FDA) in 1959. From 1950 to the 1970s, there were sporadic periods of widespread amphetamine use and abuse in the United States. In the 1960s and early 1970s, various amphetamines such as methylenedioxyamphetamine (MDA), *para*-methoxyamphetamine (PMA), and *para*-methoxymethylamphetamine (PMMA) were popularized as hallucinogens.<sup>97,127</sup> The Controlled Substance Act of 1970 placed amphetamines in Schedule II to prevent the diversion of pharmaceutical amphetamines for nonmedicinal uses. Abuse of amphetamines subsequently declined.<sup>136</sup>

In the 1980s, use of methylenedioxy derivatives of amphetamine and methamphetamine surfaced and circumvented existing regulations. The best known of these derivatives were 3,4-methylenedioxyamphetamine (MDMA) and 3,4-methylenedioxyethamphetamine (MDEA).<sup>6</sup> Since the late 1980s, a dramatic resurgence of methamphetamine abuse has spread throughout much of the United States. A high-purity preparation of methamphetamine hydrochloride was illegally marketed in a large crystalline form termed “ice” by abusers.<sup>46</sup> Methamphetamine-related deaths in the United States increased through the 1990s, initially at several hundred per year. From 2010 to 2014, deaths involving methamphetamine doubled from 1,388 to 3,728 per year.<sup>171</sup> Men who have sex with men in New York City (and perhaps elsewhere) remain a specific population at risk, with a persistently high prevalence of methamphetamine use.<sup>72</sup> The ease and low cost of methamphetamine synthesis encourage establishment of illegal clandestine laboratories in the United States.<sup>72</sup> Since the

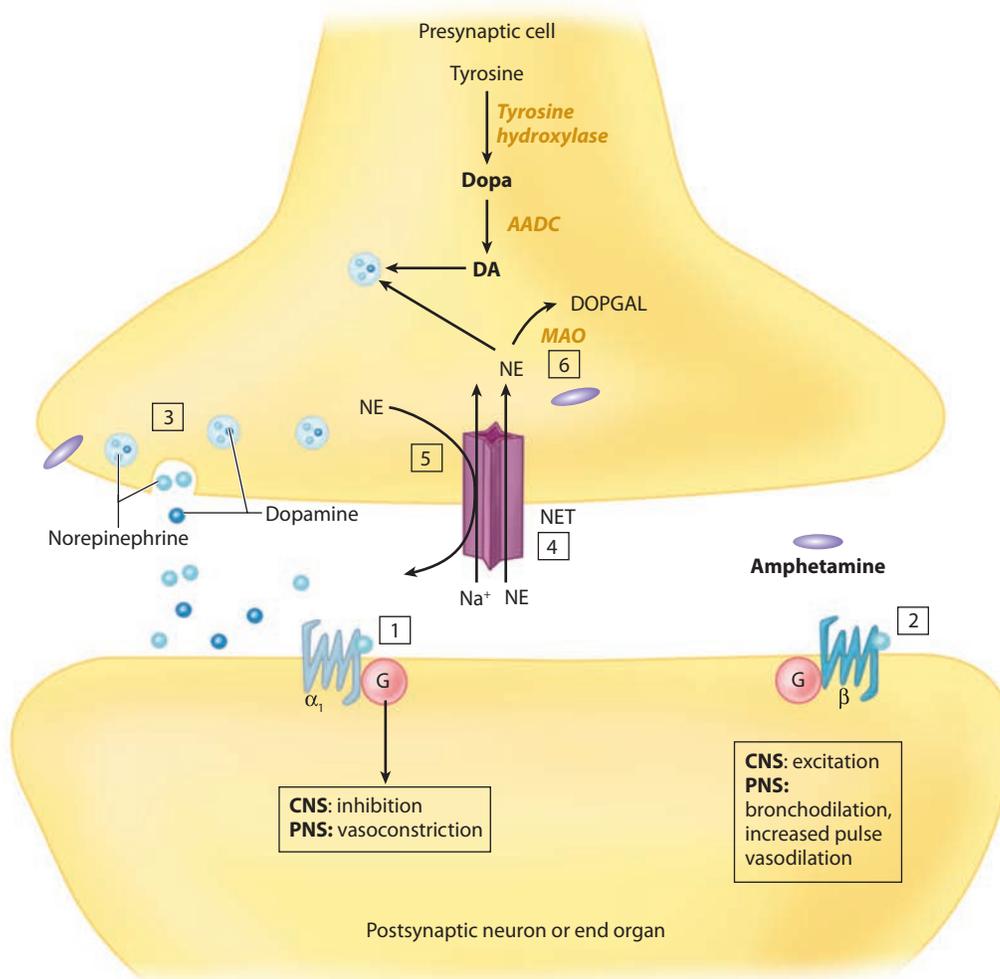

mid-1990s, MDMA has been widely used by college students and teenagers in large gatherings, known as “rave” or “techno” parties, in Europe and the United States.<sup>134</sup> Methcathinone (a khat-derived substance) and 4-bromo-2,5-methoxyphenylethylamine (2CB) were popular in dance clubs in the Midwestern United States in the 1990s, but use was not widespread.<sup>59,62</sup> Synthetic cathinones are currently sold as “bath salts” or “legal highs” to circumvent existing laws, resulting in serious toxicity and deaths.<sup>31</sup> Recently, older amphetamines such as PMA and PMMA made a resurgence, with new reports of toxicity and deaths.<sup>102</sup>

## PHARMACOLOGY

*Amphetamine* is the acronym for racemic  $\beta$ -phenylisopropylamine. Amphetamine is representative of a broader group of compounds with a shared phenylethylamine structure, which is a more accurate term. Numerous substitutions on the phenylethylamine backbone are possible, resulting in a variety of xenobiotics, some with unique properties. For the purposes of this chapter, all phenylethylamines, even those that are not actually amphetamines, will be called *amphetamines* for simplicity, and the name *amphetamine* specifically refers to  $\beta$ -phenylisopropylamine.

The pharmacologic effects of amphetamines are complex, but their primary mechanism of action is the release of biogenic amines. Release of catecholamines from the presynaptic terminals, particularly dopamine and norepinephrine, leads to a hyperadrenergic condition, but release of serotonin favors a serotonergic condition. Although there are conflicting mechanistic models of amphetamine induction of catecholamine release, these variable results are directly correlated with the different concentrations of amphetamine used in experimental models. Our understanding of the mechanism of action of amphetamines is based on dopaminergic neurons; similar mechanisms occur with norepinephrine and serotonin. Two storage pools exist for dopamine in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of dopamine and other biogenic amines is maintained by the acidic environment within the vesicles and the persistence of a stabilizing electrical gradient within the cytoplasm. This environment is maintained by an adenosine triphosphate-dependent active proton transport system.<sup>115,145</sup>

Amphetamines enter the nerve cell either by passive diffusion or by exchange diffusion through a reuptake transporter that is partially dose dependent. At low concentrations, amphetamines enter the cell by exchange diffusion at the dopamine reuptake transporter and cause the release of dopamine from the cytoplasmic pool. At moderate concentrations, amphetamines passively diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter on the vesicular membrane to cause exchange release of dopamine into the cytoplasm. Dopamine is subsequently released into the synapse by reverse transport at the dopamine reuptake site.<sup>145,170</sup> At high concentrations, an additional mechanism is invoked as amphetamines diffuse through the cellular and vesicular membranes. Because amphetamines are bases, they alkalize the vesicles, reducing the pH gradient necessary for vesicle integrity, resulting in dopamine release from the vesicles and delivery into the synapse by reverse transport (Chap. 13 and Fig. 73–1).<sup>161,162</sup> Amphetamines also block the reuptake of biogenic amines by competitive inhibition.<sup>68,181</sup> However, the contribution of this to the ultimate clinical effects are likely minor. Amphetamine’s structural

**FIGURE 73-1.** Noradrenergic nerve ending. The postsynaptic membrane represents an end organ or another neuron in the central nervous system (CNS). The primary mechanism of action of amphetamines is the release of catecholamines, particularly dopamine (DA) and norepinephrine (NE), from the presynaptic terminals. Two storage pools exist for DA in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of DA and other biogenic amines is maintained by the acidic environment within the vesicles and the persistence of a stabilizing electrical gradient with respect to the cytoplasm. (1, 2) Activating or antagonizing postsynaptic  $\alpha$ - and  $\beta$ -adrenoceptors. (3) Amphetamines release DA or NE from the cytoplasmic pool by exchange diffusion at the DA uptake transporter site in the membrane. (4) Amphetamines diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter on the vesicular membrane to cause exchange release of DA or NE into the cytoplasm. DA is subsequently released into the synapse by reverse transport at the DA uptake site. (5) Amphetamines diffuse through the cellular and vesicular membranes, alkalizing the vesicles, and permitting dopamine release from the vesicles and delivery into the synapse by reverse transport. (6) Inhibiting monoamine oxidase (MAO) to prevent NE degradation; or inhibiting catechol-O-methyltransferase (COMT) to prevent NE degradation. AADC = aromatic L-amino acid decarboxylase; DOPGAL = 3,4-dihydroxyphenylglycoaldehyde; G = G protein; NET = membrane norepinephrine uptake transporter; NME = normetanephrine; PNS = peripheral nervous system.

similarity to amphetamine derived monoamine oxidase inhibitors (MAOIs) such as tranylcypromine explains their weak MAOI effect, the clinical significance of which is unclear.<sup>131</sup>

Binding selectivity to the neurotransmitter transporters largely determines the range of pharmacologic effects for a particular amphetamine. The affinity of MDMA for serotonin transporters, for example, is 10 times greater than that for dopamine and norepinephrine transporters. With this high affinity for serotonin transporters, MDMA produces primarily serotonergic effects.<sup>64</sup> Other predominantly serotonergic amphetamines include *para*-methoxyamphetamine and bromo-dragonFLY (Table 73-1).

The most identifiable effects of amphetamines are those caused by excessive biogenic amine release and the resultant stimulation of various receptors including  $\alpha$ -adrenergic,  $\beta$ -adrenergic, dopamine, and serotonin receptors. The majority of serotonergic neurons in the central nervous system (CNS) are located in the raphe nuclei, which connects the brainstem to the rest of the CNS via serotonergic projections. Within the CNS,

serotonin regulates a wide variety of functions, including, but not limited to, mood, memory, temperature regulation, sleep, and pain.<sup>67</sup> Serotonin is also involved in the release of antidiuretic hormone, the excessive release of which leads to hyponatremia. This is particularly associated with amphetamines with potent serotonergic effects such as MDMA.<sup>73</sup> Additional effects of serotonin include regulation of fluid secretion and peristalsis, as well as regulation of many vascular beds, predominantly via vasoconstriction. Peripherally, serotonergic actions of amphetamines can result in carcinoidlike effects.<sup>103,144</sup>

Norepinephrine is another important neurotransmitter central to the action of amphetamines. Norepinephrine is found in the CNS and is also released peripherally from postganglionic sympathetic fibers. The main noradrenergic nucleus in the CNS is the locus ceruleus. Amphetamine induced excessive release of norepinephrine within the CNS results in decreased fatigue and increased attentiveness. Peripherally, norepinephrine acts on the adrenergic receptors ( $\alpha$  and  $\beta$ ), which mediate

TABLE 73-1 Examples of Amphetamines

Xenobiotic	Clinical Manifestations	Structure
4-Bromo-2,5-dimethoxyamphetamine (DOB)	Marked psychoactive effect, potency > mescaline Fantasy, mood altering Agitation, sympathetic excess Sold as impregnated paper, like LSD	
4-Bromo-2,5-methoxyphenylethylamine (2CB, MFT)	Relaxation Sensory distortion Agitation Hallucination Potency > mescaline	
Methcathinone (cat, Jeff, khat, ephedrone)	Hallucinations Sympathetic excess	
4-Methyl-2,5-dimethoxyamphetamine (DOM/STP) (serenity, tranquility, peace)	Narrow therapeutic index Euphoria, perceptual distortion Hallucinations, sympathetic excess	
3,4-Methylenedioxyamphetamine (MDA, love drug)	Empathy, euphoria Agitation, delirium, hallucinations, death associated with sympathetic excess	
3,4-Methylenedioxyethamphetamine (MDEA, Eve)	Comparable to MDMA Sympathetic excess	
3,4-Methylenedioxymethamphetamine (MDMA, Adam, molly, ecstasy, XTC)	Psychotherapy "facilitator" Euphoria, empathy nausea, anorexia, anxiety, insomnia Sympathetic excess	
para-Methoxyamphetamine (PMA)	Potent hallucinogen Sympathetic excess	
2,4,5-Trimethoxyamphetamine	Similar to mescaline	

LSD = lysergic acid diethylamide.

vasoconstriction and increased cardiac activity, resulting in hypertension and tachycardia.

The increase in CNS dopamine, particularly in the neostriatum, mediates stereotypical behavior and other locomotor activities as well as reward pathways.<sup>36</sup> The activity of dopamine in the neostriatum appears to be linked to glutamate release and inhibition of  $\gamma$ -aminobutyric acid (GABA) efferent neurons.<sup>86</sup> Stimulation of the glutamatergic system contributes significantly to the stereotypical behavior, locomotor activity, and neurotoxicity of amphetamines.<sup>86,152,153</sup> The effects of serotonin and dopamine

on the mesolimbic system alter perception, cause psychotic behavior and anorexia.<sup>76,160</sup>

### Structure Modification

Phenylethylamines are chemical structures with an ethyl group backbone that has an aromatic group and a terminal amine. Specific substitutions made to the phenylethylamine backbone have led to the wide variety of novel drugs, described later. Substitutions at different positions of the phenylethylamine molecule alter the general pharmacology and clinical effects of

amphetamines, as demonstrated by both animal and human observations. Large-group substitution at the  $\alpha$  carbon reduces the stimulant and cardiovascular effects of the amphetamine but allows retention of the anorectic properties (such as phentermine). Substitution at the *para* position of the phenyl ring enhances the hallucinogenic or serotonergic effects of amphetamines (such as in *para*-chloroamphetamine and MDMA).<sup>60</sup> Although these generalizations enable an understanding of the effects of amphetamines, there are many exceptions, and such generalizations do not necessarily apply after exposure to large doses of a particular molecule. There is a broad spectrum of clinical effects that derive from the various amphetamines: methamphetamine results in the most potent cardiovascular effects, and 2,5-dimethoxy-4-bromoamphetamine (DOB) results in the most consequential hallucinogenic and serotonergic effects.<sup>60,117</sup> Table 73-2 further describes the pharmacology of specific substitutions.

Other specific substitutions are worth noting. The addition of an extra methyl group to the terminal amine in amphetamine produces methamphetamine, greatly increasing CNS activity. This extra methyl group also makes methamphetamine more lipid soluble, allowing faster penetration across the blood-brain barrier and more resistance to degradation by monoamine oxidase. The addition of an  $\alpha$ -methyl group results in strong stimulant, cardiovascular, and anorectic properties.<sup>60,117</sup> This is largely due to resistance to metabolism by monoamine oxidase conferred by the addition of this group. These characteristics permit better oral bioavailability and longer duration of effect. The  $\alpha$ -methyl group in the amphetamine structure also introduces chirality to the molecule. With few notable exceptions including MDMA, the *d*-enantiomer is typically 4 to 10 times more potent than the *l* form of amphetamine. Addition of a methoxy group to either the 2 or 5 position of the aromatic ring on the amphetamine or methamphetamine compound increases serotonergic activity. Another important substitution to the phenylethylamine backbone is the addition of a halogen group (eg, iodine or bromine), which increases the potency and neurotoxicity of the compound compared to nonhalogenated compounds. Neurotoxicity is thought to be due to significant serotonin depletion, leading to irreversible neuron damage.<sup>76</sup> The ability of amphetamines to directly interact with neurotransmitter transporters enable minor modifications of the molecule to significantly alter its pharmacologic profile.<sup>80</sup> The addition of a ketone group at the  $\beta$  position results in a group of compounds

known as the synthetic cathinones. Specifically, the addition of this group to amphetamine results in cathinone. The  $\beta$ -ketone group is responsible for increased polarity, which decreases penetration of the blood-brain barrier.

## PHARMACOKINETICS AND TOXICOKINETICS

### Absorption

Amphetamines can be absorbed by intravenous, oral, intranasal, and inhalational routes. Amphetamines are rapidly absorbed, with bioavailability that ranges between 60% and 90% depending on the route of administration. Peak serum concentrations are variable and are substance and route dependent. Methamphetamine has peak serum concentrations in less than 15 minutes when used via an intravenous (IV) or intranasal route and up to 180 minutes when taken orally.

### Distribution

After absorption, amphetamines are distributed to most compartments of the body. Most amphetamines are also relatively lipophilic and readily cross the blood-brain barrier. Amphetamines have large volumes of distribution, varying from 3 to 5 L/kg for amphetamine, 3 to 4 L/kg for methamphetamine and phentermine, and to 11 to 33 L/kg for methylphenidate. Some amphetamines such as pemoline have a small volume of distribution (0.2–0.6 L/kg).

### Metabolism

Amphetamines are eliminated via multiple pathways, including diverse routes of hepatic transformation and renal elimination. For MDMA and its analogs, *N*-dealkylation, hydroxylation, and demethylation are the dominant hepatic pathways. Depending on the particular amphetamines, active metabolites of amphetamines and ephedrine derivatives are formed. *N*-demethylation of methamphetamine and MDMA result in the formation of amphetamine and MDA, respectively.<sup>108</sup> Dealkylation and demethylation are mainly performed by CYP1A2, CYP2D6, and CYP3A4, as well as flavin monooxygenase. Polymorphism of CYP2D6 in humans was recognized because of the diversity of rates of *p*-hydroxylation of amphetamines. Since its discovery, CYP2D6 polymorphism has been implicated in drug toxicity, substance use and abuse, and lack of drug efficacy in selected individuals.<sup>146</sup> Increased toxicity of amphetamines is a potential concern in patients with decreased CYP2D6 activity. Although animals with CYP2D6 deficiency are more susceptible to MDMA toxicity, limited studies in humans do not demonstrate an association between mortality and CYP2D6 polymorphism.<sup>121</sup> In general, because multiple enzymes and elimination pathways (including renal) are involved in amphetamine metabolism, it is less likely that CYP2D6 polymorphism or drug interactions with CYP3A4 alone will significantly increase toxicity. However, it is unclear if toxicity is enhanced when multiple mechanisms for altering drug metabolism and kidney dysfunction are present simultaneously.

### Elimination

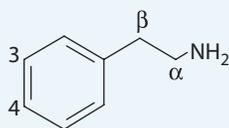

Renal elimination of the parent compound is substantial for amphetamine (30%), methamphetamine (40%–50%), MDMA (65%), and phentermine (80%). Amphetamines are bases with a typical  $pK_a$  range of 9 to 10, and renal elimination varies depending on the urine pH, with elimination increasing as pH decreases.<sup>14</sup> The half-life of amphetamines varies significantly: amphetamine, 8 to 30 hours; methamphetamine, 12 to 34 hours; MDMA, 5 to 10 hours; methylphenidate, 2.5 to 4 hours; and phentermine, 19 to 24 hours. Repetitive administration, which occurs typically during binge use, leads to drug accumulation and prolongation of the apparent half-life and duration of effect.<sup>13,108</sup>

## PATHOPHYSIOLOGY

Most complications associated with amphetamines are a result of an uncontrolled hyperadrenergic condition similar to that which occurs with other sympathomimetics such as cocaine, except the duration of effect is typically longer (Table 73-3). Most patients with acute amphetamine toxicity manifest effects in the CNS and cardiovascular system. The majority of the specific

TABLE 73-2 Specific Substitutions on Phenylethylamine

Substitution	Pharmacological Effect
$\alpha$ -Carbon	Indirect acting; resists oxidation by monoamine oxidase
$\beta$ -Carbon	Decreases central nervous system penetration Whereas hydroxyl (–OH): increases adrenergic activity
Amino group	No substitution: $\alpha$ -adrenergic > $\beta$ -adrenergic effects Larger group: $\beta$ -adrenergic > $\alpha$ -adrenergic effects <i>t</i> -Butyl group: $\beta_2$ -adrenergic selective Methyl (–CH <sub>3</sub> ) group: maximum $\alpha$ - and $\beta$ -adrenergic effects
3-, 4- of aromatic ring	Hydroxylation at 3- and 4-: increased $\alpha$ - and $\beta$ -adrenergic effects Absence of hydroxylation (at one or both positions) prevents degradation by catechol- <i>O</i> -methyltransferase.
Halogenation	Enhances potency of neurotoxic properties of amphetamines by selective action on the serotonin system

 Cardiomyopathy  
 Dopaminergic and serotonergic neuron damage  
 Pulmonary hypertension  
 Vasculitis

effects are from excessive catecholamine release as opposed to direct effects from the amphetamines themselves. Additional organ-specific pathophysiologic effects are described later.

**Central Nervous System**

Anxiety, agitation, and hallucinations are typical CNS findings that result from adrenergic stimulation. Choreoathetoid movements, often described as irregular jerking or twisting movements, are related to increased dopaminergic stimulation in the striatal area.<sup>88,101,107</sup> Seizures are the direct result of amphetamine or occur secondarily to hyponatremia as reported with MDMA and certain synthetic cathinones.<sup>19</sup> Psychosis, often a finding with acute use, is likely to recur with subsequent use, even after periods of prolonged

abstinence. This phenomenon of recurrent psychosis on reexposure is likely related to a kindling phenomenon.<sup>112</sup>

**Cardiac**

Cardiomyopathy is reported in chronic amphetamine users. Excessive catecholamine exposure is likely responsible for their associated cardiomyopathies, similar to that occurring in patients with pheochromocytomas or chronic cocaine use.<sup>85,177</sup> Some postulate that polymorphisms in CYP2D6 activity influences the risk of developing cardiomyopathy; however, a clear association is not demonstrated.<sup>164</sup> Valvular heart disease and pulmonary hypertension are associated with amphetamines taken for diet suppression. The mechanism of toxicity is incompletely understood but is likely do to serotonergic activity occurs in carcinoid pathology. Specifically, alterations in serotonin reuptake transporter (SERT) activity is thought to play a significant role in the pathophysiology of both diseases, and drug effect at the 5HT<sub>2B</sub> receptor is implicated in the development of valvular heart disease.<sup>103,144</sup>

**Vascular**

Necrotizing vasculitis of small- and medium-sized arteries occurs in association with amphetamine use and affects multiple organ systems as described later. The etiology of the arteritis remains unclear. Although various contaminants associated with injection drug use are postulated as potential etiologies, in animal models, oral and IV amphetamine administration is also associated with vasculitis, suggesting that this is a direct amphetamine effect.<sup>18,32,165</sup>

**Chronic Central Nervous System Toxicity**

Chronic administration of certain amphetamines to animals alters dopamine and serotonin transporter functions, depletes dopamine and serotonin in the neuronal synapses, and produces irreversible destruction of those neurons.<sup>16,56,139,140,145,180</sup> The cause of neuronal toxicity is related to the generation of oxygen free radicals, resulting in the generation of toxic dopamine and serotonin metabolites as well as neuronal destruction. Based on animal models, dose, frequency and duration of exposure, and ambient temperature affect toxicity. Intact dopamine or serotonin transporters are necessary to produce neurologic injury. Xenobiotics that inhibit transporter function appear to prevent neurologic injuries in animals.<sup>64</sup> Although not as well studied as MDMA, studies of former methamphetamine users demonstrate impaired memory and psychomotor functions, as well as corresponding dopamine transporter dysfunction and abnormal glucose metabolism on positron emission tomography scans. However, species-specific susceptibility to neurologic injuries, the duration of effects in primates and humans, and functional consequences of neurotoxicity in humans remain unclear and require further study.

**CLINICAL MANIFESTATIONS**

Acute and chronic toxicity of amphetamines are described next. Refer to the section Individual Amphetamines for effects specific to each individual molecule.

**Acute Toxicity**

Central nervous system effects from acute amphetamine use include anxiety, agitation, hallucinations, seizures, mydriasis, diaphoresis, and hyperthermia.<sup>47,48,143</sup> The pathophysiology of amphetamine-induced hyperthermia is multifactorial and includes increased catecholamine release, increased metabolic and psychomotor activity, and vasoconstriction-mediated impaired heat dissipation.<sup>106</sup> Psychosis appears to be a more prominent feature after amphetamine than after cocaine use.<sup>2</sup> Intracerebral hemorrhage and cerebral infarction are also reported with amphetamine use.<sup>49,84,110,129</sup>

Cardiovascular toxicity from acute amphetamine use involves hypertension, tachycardia, and dysrhythmias. Reported dysrhythmias range from premature ventricular complexes to ventricular tachycardia and ventricular fibrillation.<sup>78</sup> Other vascular complications reported with acute use include myocardial ischemia or infarction,<sup>113,173</sup> aortic dissection,<sup>176</sup> acute respiratory distress syndrome,<sup>166,175</sup> obstetric complications, fetal death,<sup>63,99</sup>

and ischemic colitis.<sup>77,82</sup> Additional acute complications include metabolic acidosis, rhabdomyolysis,<sup>50</sup> acute kidney injury (AKI); acute tubular necrosis), and coagulopathy, often from uncontrolled agitation and hyperthermia.<sup>39,70,170</sup> Unless these systemic signs and symptoms are rapidly reversed, multiorgan failure and death ensue.

### Chronic Toxicity

Amphetamine users seeking intense “highs” go on “speed runs” for days to weeks. Because of the development of tolerance, they use increasing amounts of amphetamine during these periods, usually without much nutritional sustenance or sleep, while attempting to achieve their desired euphoria.<sup>150</sup> Acute psychosis resembling paranoid schizophrenia occurs during these binges and has contributed to both amphetamine-related suicides and homicides.<sup>51</sup> A normal sensorium usually returns within a few days after discontinuation of the drug. Typically, after such binges, patients sleep for prolonged periods of time, feel hungry and depressed when awake, and often have amphetamine cravings.<sup>89,93</sup>

Compulsive repetitive behavior patterns from the use of amphetamines are reported in humans and animals. Individuals pick at their skin, grind their teeth (bruxism), or perform repetitive tasks, such as constantly cleaning the house or car. 3,4-Methylenedioxymethamphetamine users often carry pacifiers to relieve bruxism and prevent tooth damage. Choreoathetoid movements, although uncommon, are reported with acute and chronic amphetamine use.<sup>88,101,107</sup>

Necrotizing vasculitis is associated with amphetamine abuse. Angiography typically demonstrates beading and narrowing of the small- and medium-sized arteries (Fig. 8–29). Progressive necrotizing arteritis involves multiple organ systems, including the brain, heart, gut, and kidney.<sup>18,32,92,165</sup> Complications include cerebral infarction and hemorrhage, coronary artery disease, pancreatitis, and AKI. Cardiomyopathy is also reported with acute and chronic amphetamine abuse.<sup>156,182</sup> Valvular disease and pulmonary hypertension are reported when amphetamines such as fenfluramine, dexfenfluramine, and phentermine are used for dieting.<sup>144,163</sup>

Finally, complications can result from IV drug use and from the associated contaminants. Contamination with microbes leads to human immunodeficiency virus infection, hepatitis, and malaria. Bacterial and foreign body contamination results in endocarditis, tetanus, wound botulism, osteomyelitis, and pulmonary and soft tissue abscesses.<sup>100</sup>

### DIAGNOSTIC TESTING

The choice and extent of diagnostic tests should be guided by the history and physical examination. In all patients with altered mental status, blood specimens should be sent for glucose, blood urea nitrogen, and electrolyte assays. An electrocardiogram should be obtained in all patients to screen for tachydysrhythmias and coingestants, and continuous cardiac monitoring should be initiated. A complete blood count, urinalysis, coagulation profile, creatine phosphokinase, chest radiograph, computed tomography scan of the head, echocardiogram of the heart, and lumbar puncture will be necessary, depending on the clinical presentation.

Qualitative urine immunoassays are available for amphetamines, but several considerations limit their utility in the management of acutely poisoned patients. Although point-of-care urine tests are available, these tests rarely contribute to management in the acute setting. A major limitation is the high rate of false-positive and false-negative results common to the amphetamine immunoassay. For example, many cold preparations contain pseudoephedrine, which is structurally similar and cross-reacts with the immunoassay.<sup>33,53</sup> Likewise, selegiline, a selective monoamine oxidase type B inhibitor used for the treatment of parkinsonism, is metabolized to amphetamine and methamphetamine. Other common drugs that produce false-positive results include bupropion, trazodone, amantadine, and certain antihistamines.<sup>21,119,123</sup> Even a true-positive result only means that the patient has used certain amphetamines within the past several days and does not distinguish remote from acute use. False-negative results may occur with certain amphetamines such as MDMA and cathinones, which are not recognized on standard

urinary drug testing.<sup>33,155</sup> Utilization of such tests is often misleading and rarely directly contributes to the acute management of patients. The gold standard for drug testing, gas chromatography–mass spectrometry analysis, can misidentify isomeric substances such as *l*-methamphetamine, which is present in nasal inhalers, with *d*-methamphetamine, if performed by inexperienced personnel.<sup>10</sup> In summary, the use of urine immunoassays should not guide clinical management of patients who present with suspected toxicity from amphetamines.

### MANAGEMENT

The initial medical assessment of the agitated patient must include vital signs, a rapid glucose determination, and a complete physical examination. Determination of core body temperature is essential to diagnose the presence and degree of hyperthermia, which is a frequent and rapidly fatal manifestation in patients with drug-induced delirium. Significant hyperthermia necessitates immediate interventions to achieve rapid cooling<sup>24,58</sup> (Chap. 29). Some patients require temporary physical restraint to gain pharmacologic control and prevent personal harm to themselves or others. Physical restraints should be discontinued as soon as possible; prolonged restraints result in rhabdomyolysis and continued heat generation. IV access should be obtained so that IV sedation can be initiated. If IV access cannot be obtained, it is necessary to attempt to administer intramuscular benzodiazepines such as midazolam until definitive access is accomplished.

The most appropriate choice of chemical sedation is a benzodiazepine because of the characteristic high therapeutic index, good antiepileptic activity, and predictable pharmacokinetic properties. Benzodiazepines are effective not only for the treatment of delirium induced by acute overdose of cocaine, amphetamines, and other xenobiotics but also the delirium associated with ethanol and sedative–hypnotic withdrawal (Antidotes in Depth: A26).<sup>44,61,122</sup> Sedation should be titrated rapidly until the patient is calm. In our clinical experience, cumulative benzodiazepine doses required in the initial 30 minutes to achieve adequate sedation will periodically exceed 100 mg of diazepam or its equivalent (Table 73–4).

Antipsychotics, particularly potent dopamine antagonists such as haloperidol and droperidol, are frequently recommended as adjuncts for amphetamine-induced delirium. Potent blockade of dopamine receptors functions

**TABLE 73–4 Management of Patients with Amphetamine Toxicity**

#### Agitation

Benzodiazepines (usually adequate for the cardiovascular manifestations)  
Diazepam 10 mg (or equivalent) intravenously; repeat rapidly until the patient is calm (cumulative dose periodically be as high as 100 mg of diazepam). An equivalent dose of IM midazolam is recommended if IV access is not available.

#### Seizures

Benzodiazepines  
Barbiturates  
Propofol for status epilepticus (typically will require endotracheal intubation)

#### Hyperthermia

External cooling  
Control agitation rapidly

#### Gastric Decontamination and Elimination

Activated charcoal for recent ingestions

#### Hypertension

Control agitation first  
 $\alpha$ -Adrenergic antagonist (phentolamine)<sup>a</sup>  
Vasodilators (nitroglycerin, or nicardipine)

#### Delirium or Hallucinations with Abnormal Vital Signs

If agitated: benzodiazepines

<sup>a</sup>Avoid  $\beta$ -adrenergic antagonists, especially with suspected cocaine toxicity.

IM = intramuscular; IV = intravenous.

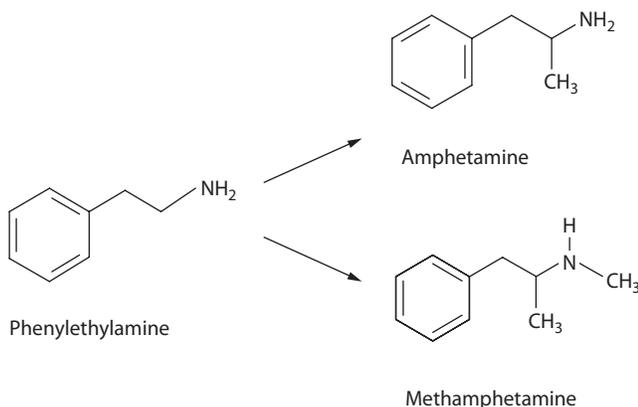

to antagonize the psychiatric and psychomotor effects of amphetamines. In experimental models, antipsychotics are not always as effective as benzodiazepines in treatment of amphetamine toxicity; however, results are mixed regarding their safety and efficacy.<sup>40,45,61</sup> Very little clinical data are available evaluating antipsychotics in the management of amphetamine toxicity, but at least one study in children demonstrates safety when antipsychotics are used adjunctively with benzodiazepines.<sup>40,142</sup> In our clinical experience, antipsychotics are very effective for benzodiazepine-resistant methamphetamine toxicity in children, particularly for symptoms of psychomotor agitation. However, antipsychotics have several negative effects that must be taken into consideration. Antipsychotics lower the seizure threshold, alter temperature regulation, cause acute dystonia, and precipitate cardiac dysrhythmias. Hyperthermia and seizures are potential life-threatening complications of amphetamine toxicity, and the use of antipsychotics could worsen these outcomes. Additionally, they do not interact with the benzodiazepine–GABA–chloride channel receptor complex, which could aggravate the clinical outcomes related to occult or concomitant cocaine toxicity and ethanol withdrawal.<sup>61,65,122</sup> Based on these concerns, benzodiazepines are recommended as first-line treatments in the management of acute toxicity from amphetamines. In a patient without hyperthermia or seizure activity, in whom psychomotor or psychiatric agitation is a predominant feature, adjunctive use of antipsychotics after benzodiazepine administration is reasonable, particularly in children.

Rhabdomyolysis from amphetamines usually results from psychomotor agitation and hyperthermia.<sup>141</sup> Sedation, typically with benzodiazepines, prevents further muscle contraction and heat production. External cooling should be instituted for hyperthermia.<sup>95</sup> Although some promote dantrolene as potential treatment option for amphetamine-induced hyperthermia, evidence is limited to case reports, predominantly involving MDMA.<sup>69</sup> Strong evidence to support the use of dantrolene is limited to cases of malignant hyperthermia, and side effects, including significant respiratory muscle weakness, are reported.<sup>90</sup> Given the potential harms of dantrolene and limited supportive evidence, in contrast to known efficacy of supportive measures, we do not currently recommend its use for amphetamine-induced hyperthermia. Adequate IV hydration and cardiovascular support should maintain urine output of at least 1 to 2 mL/kg/h. Although urinary acidification can significantly increase amphetamine elimination and decrease the half-lives of amphetamine and methamphetamine,<sup>13,14</sup> urinary pH manipulation does not decrease toxicity and instead increases the risk of AKI from rhabdomyolysis by precipitating ferrihemate in the renal tubules.<sup>37</sup> Some patients with AKI, acidemia, and hyperkalemia require urgent hemodialysis.

Amphetamine body packers, although uncommon, should be treated similarly to those who transport cocaine (Special Considerations: SC5). Any sympathomimetic symptom suggesting leakage of the packets requires surgical intervention.<sup>172</sup> Intravenous fluids, benzodiazepines, intubation, and external cooling are often necessary to stabilize these patients.

## INDIVIDUAL AMPHETAMINES

### Methamphetamine

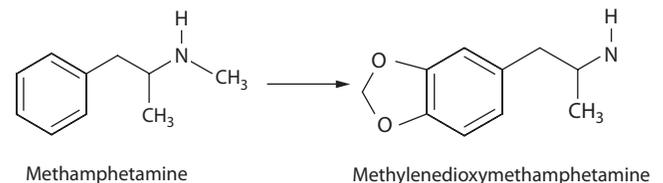

Methamphetamine is known by many names, including, but not limited to, “yaba,” “speed,” “go,” “crack,” “uppers,” and “dexies.” The terms “crystal,” “shard,” and “ice” refer to the crystalline form of methamphetamine. Methamphetamine was first synthesized from ephedrine in Japan in 1893, soon after the synthesis of amphetamine in 1887. Crystallized methamphetamine was synthesized in 1919 through the reduction of ephedrine using red phosphorus. From the 1950s to the 1970s, there were multiple epidemics of methamphetamine abuse in the United States.<sup>135</sup> Methamphetamine is approved by the FDA for the short-term treatment of attention deficit hyperactivity disorder and obesity, and it is sold under the trade name Desoxyn as a Schedule II drug. It is also prescribed for off-label use for refractory depression and narcolepsy.

The production of methamphetamine is relatively simple, requiring minimal equipment and chemicals. There are many methods of methamphetamine production that initially use pseudoephedrine, ephedrine, or phenyl-2-propanone (P2P). The primary ingredient of methamphetamine synthesis is ephedrine, which can be hydrogenated into methamphetamine. The ephedrine method, using pharmaceutical grade L-ephedrine, produces a product with few contaminants that is stereochemically pure.<sup>46,132</sup> Phenyl-2-propanone, as an alternative ingredient, can be methylated into ephedrine and then transformed into methamphetamine.<sup>23</sup> Because of the strict control of ephedrine and P2P, illicit chemists use phenylacetic acid to synthesize P2P.<sup>23,38</sup> Lead acetate, which is used as a substrate for the reaction, resulted in an epidemic of lead poisoning associated with methamphetamine abuse in Oregon.<sup>3,120</sup> Mercury contamination was also documented, although clinical mercury toxicity has not been reported.<sup>23</sup> Methamphetamine laboratories use many potentially toxic xenobiotics, including phosphine gas, methylamine gas, chloroform, and hydrochloric acid.<sup>479</sup> These laboratories therefore pose a significant health risk to law enforcement officers and the general public, causing respiratory and ophthalmic irritation, headaches, and burns.<sup>29,154</sup> Currently, the sale of other potential amphetamine synthetic ingredients, such as hydrochloric acid, hydrogen chloride, anhydrous ammonia, red phosphorus, and iodine, is also monitored and restricted in the United States.<sup>23,30</sup>

Methamphetamine exists as a chiral molecule with two isomers that include levomethamphetamine and dextromethamphetamine. Although the levorotatory form is devoid of CNS stimulatory properties, it retains its vasoactive effects and is used in nonprescription nasal decongestant inhalers. In the racemic mixture, the dextrorotatory form is solely responsible for the stimulant effects observed with methamphetamines. Methamphetamine undergoes metabolism in the liver mainly to amphetamine and 4-hydroxymethamphetamine and has prolonged half-life of 19 to 34 hours, although the duration of its acute effects can be greater than 24 hours.<sup>46</sup>

### 3,4-Methylenedioxyamphetamine

3,4-Methylenedioxyamphetamine, also known as MDMA, was first synthesized in 1912 and was rediscovered in 1965 by Shulgin. 3,4-Methylenedioxyamphetamine is known as “ecstasy,” “E,” “Adam,” “XTC,” “Molly,” and “MDM,” and it is commonly abused.<sup>128,174,178</sup> Other amphetamines similar to MDMA include MDEA (“Eve”) and MDA (“love drug”). With similar clinical effects, these xenobiotics are also used or distributed as MDMA in areas of MDMA popularity. Amphetamines sold as MDMA include 2CB, 2,4-dimethoxy-4-(*n*-propylthiophenylethylamine (2C-T7), and *N*-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB).<sup>28,59</sup> Typically, MDMA is available in 50- to 200-mg colorful and branded tablets.

3,4-Methylenedioxyamphetamine and similar analogs are so-called *entactogens* (meaning “touching within”), capable of producing euphoria, inner

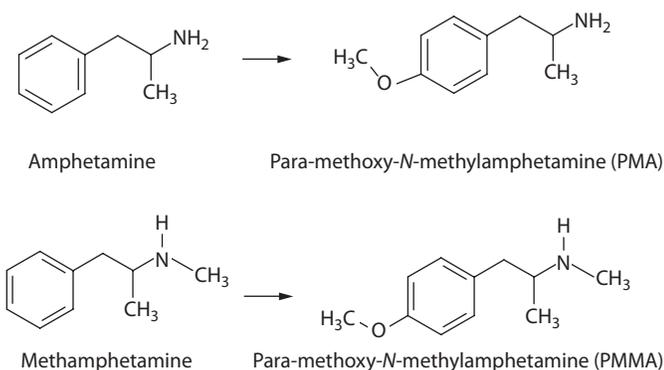

peace, and a desire to socialize.<sup>151</sup> In addition, some psychologists used MDMA to enhance psychotherapy until the Controlled Substances Act of 1986 placed MDMA in Schedule I, thereby eliminating its medical use.<sup>127</sup> People who use MDMA report that it enhances pleasure, heightens sexuality, and expands consciousness without the loss of control.<sup>66</sup> Negative effects reported with acute use included ataxia, restlessness, confusion, poor concentration, and impaired memory.<sup>151</sup> 3,4-Methylenedioxyamphetamine has about one-tenth the CNS stimulant effect of amphetamine. Unlike amphetamine and methamphetamine, MDMA is a potent stimulus for the release of serotonin.<sup>25,41,68</sup> The concentration of MDMA required to stimulate the release of serotonin is 10 times less than that required for the release of dopamine or norepinephrine. In animal models, the stereotypic and discriminatory effects of MDMA, and its congeners can be distinguished from those of other amphetamines.<sup>25</sup>

The sympathetic effects of MDMA are mild in low doses. However, when a large amount of MDMA is taken, the clinical presentation is similar to that of other amphetamines. Dysrhythmias, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation (DIC), and deaths are reported.<sup>57,87,137</sup> Significant hyponatremia is also reported with MDMA use.<sup>1,22,73</sup> 3,4-Methylenedioxyamphetamine and its metabolites increase the release of vasopressin (antidiuretic hormone), and this is thought to be related to the serotonergic effects.<sup>52</sup> Furthermore, substantial free water intake combined with sodium loss from physical exertion in dance clubs increases the risk of the development of hyponatremia.

Molly is a purified or crystallized form of MDMA that is typically sold as a powder rather than a pill and is taken orally. It gained popularity because of what was perceived as a more rapid onset of symptoms and a subtler offset or “come-down” period. Molly is also commonly viewed as a safer form of MDMA because it is erroneously believed by users to contain no adulterants. The use of Molly is associated with typical amphetamine adverse effects.<sup>83</sup> Although Molly is often sold on the street as pure MDMA, Molly may contain various compounds including members of the 2C series, amphetamines that have two methoxy groups and a halogen such as iodine (2C-I) or bromide (2C-B).

A major concern with MDMA is its long-term effects on the brain. In numerous animal models, acute administration of MDMA leads to the decrease in SERT function and number. Recovery of SERT function takes several weeks. Repetitive administration of MDMA ultimately results in permanent damage to serotonergic neurons, typically causing injury to the axons and the terminals while sparing the cell bodies.<sup>109,139</sup> Some regeneration of synaptic terminals occurs even with neuronal damage, but functional recovery is incomplete. Intact SERT function is necessary for MDMA-induced neurotoxicity. Xenobiotics that inhibit the reuptake of serotonin prevent MDMA-induced neurotoxicity in animals. Animal data suggest that MDMA induces hydroxyl free radical generation and decreases antioxidants in serotonergic neurons.<sup>147</sup> 3,4-Methylenedioxyamphetamine itself is not the ultimate neurotoxin; rather, its metabolites 3-methyldopamine and *N*-methyl- $\alpha$ -methyldopamine appear to be responsible in animals.<sup>114</sup> When antioxidants are depleted, neuronal damage occurs.

### Para-methoxyamphetamine and Para-methoxymethamphetamine-Monomethoxy Derivatives

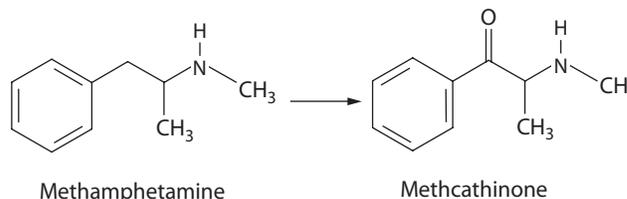

*Para*-methoxyamphetamine (PMA) is the 4-methoxylated analog of amphetamine, and *para*-methoxy-*N*-methylamphetamine (PMMA; methyl-MA) is the 4-methoxy analog of methamphetamine. *Para*-methoxyamphetamine was first produced in 1973 and sold as a hallucinogen for a short period of time and then reemerged in the 1990s. *Para*-methoxy-*N*-methylamphetamine soon appeared after PMA, with multiple reports of death also emerging during that time.<sup>12,81,91</sup> *Para*-methoxyamphetamine and PMMA are commonly found as tablets or capsules sold as MDMA or “ecstasy.” Although the effects of PMA and PMMA mimic some aspects of MDMA and methamphetamine, unique properties of PMA and PMMA make them considerably more lethal, earning the street name “death.” More than 100 fatalities and severe poisonings attributed to PMMA and PMA are reported in North America, Australia, and Europe.<sup>94,98,102,105</sup>

Methoxy ring substitution of amphetamine or methamphetamine at the 3 or 4 positions (*para* substitution is the most common) yields PMA and PMMA derivatives that have significantly less sympathomimetic activity than amphetamine but very potent serotonergic activity.<sup>35,158</sup> Both PMA and PMMA inhibit reuptake of serotonin and inhibit monoamine oxidase A found centrally and peripherally. The methoxy ring substitution is also responsible for poor penetration of the blood–brain barrier.<sup>8,54</sup>

*Para*-methoxyamphetamine and PMMA poisoning results in autonomic hyperactivity similar to that observed with other amphetamines, namely, hypertension, tachycardia, and agitation. Poor blood–brain barrier penetration results in a delayed onset of CNS effects and overall a comparatively weak euphoric effect. These properties often lead users to repeat doses, resulting in severe toxicity and the seemingly high mortality rate.

### Cathinones (Methcathinone, Methylenedioxypropylvalerone, and Mephedrone)—“Bath Salts”

Cathinone (2-amino-1-phenyl-1-propanone) is a naturally occurring substance found in the leaves of the *Catha edulis* (khat) plant. Also known as *guat* and *gat*, the fresh leaves and stems are commonly used as a stimulant in Africa and the Middle East. The plant form contains numerous amphetamines in minute quantities, but the primary active ingredient is cathinone. As the leaves age, cathinone is degraded to cathine, which has about one-tenth the stimulant effect of *D*-amphetamine. Imported fresh khat must be consumed within a week, or much of its potency is lost. The primary effects of khat are increased alertness, insomnia, euphoria, anxiety, and hyperactivity. Khat chewing is linked to cardiac and gastrointestinal (GI) disease.<sup>124,125</sup>

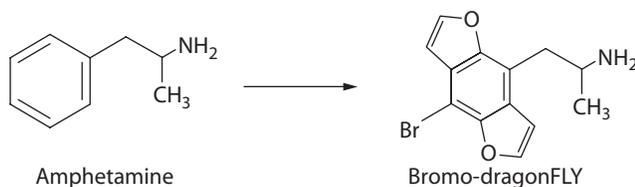

The syntheses of cathinone derivatives were reported in the early 1920s, with the production of methcathinone in 1928 and mephedrone in 1929. Methcathinone, the methyl derivative of cathinone, was used in Russia as an antidepressant in the 1930s and 1940s. Also known as “Cat” and “Jeff,” cathinone was used recreationally, historically most often in countries formerly part of the Soviet Union. Various synthetic cathinones, including mephedrone and methylenedioxypropylvalerone (MDPV), have gained popularity in both the United States and Europe in recent years.<sup>7</sup> Increased popularity of synthetic cathinones is likely due to a combination of media attention and widespread Internet availability.<sup>133,149</sup> Many other synthetic cathinones produced include methylone, mephedrone, butylone, MDPV, dimethylcathinone, ethcathinone, ethylone, 3-,4-fluoromethcathinone, and  $\alpha$ -pyrrolidinovalerophenone.  $\alpha$ -Pyrrolidinovalerophenone (1-phenyl-2-(pyrrolidin-1-yl)pentan-1-one), sold on the street as “flakka,” in particular is a popular drug of abuse.<sup>168</sup> Bupropion, a popular pharmaceutical licensed for treatment of depression and smoking cessation, is the only medicinally

used cathinone.<sup>111</sup> Sustained-release bupropion overdoses are associated with delayed toxicity. Serious toxicity in overdose, including seizures and refractory dysrhythmias requiring extracorporeal membrane oxygenation as well as fatalities, are reported.<sup>75,157</sup>

The synthetic cathinones differ structurally from other amphetamines by the addition of a ketone at the  $\beta$  position. The  $\beta$ -ketone group is responsible for increased polarity, which decreases penetration of the blood–brain barrier. Cathinones possess amphetamine-like properties and have sympathomimetic effects, although as a group, they are considered less potent. Both the US Poison Control Centers and the Toxicology Investigator’s Consortium Registry (Toxic) data report common adverse effects to include agitation, tachycardia, hallucinations, and a general sympathomimetic toxidrome.<sup>55,155</sup> Some synthetic cathinones cause hyponatremia, although the mechanism is not clear and may differ from that of MDMA.<sup>11,26,27,104,130</sup> Reported complications include compartment syndrome, DIC, AKI, cardiomyopathy, myocardial infarction, seizures, and sudden cardiac death.<sup>55,96,116,138,148,183</sup> An irreversible Parkinson syndrome was also described in chronic users of IV methcathinone that was manufactured with the use of potassium permanganate as an oxidizing agent. In one case series, T1-weighted magnetic resonance imaging showed symmetric hyperintensity in the globus pallidus, substantia nigra, and innominata in all active methcathinone users, characteristic of manganese poisoning. These cases were also confirmed with elevated whole-blood manganese concentrations.<sup>159</sup>

Synthetic cathinones are often sold as “bath salts” or “plant food” and labeled as “not for human consumption” to circumvent controlled substances legislation. The legal status differs among countries and changes over time. In the United States, the synthetic cathinones were initially unscheduled but were made illegal for human consumption under the Federal Analogue Act of 1986. In 2011, the Drug Enforcement Administration used its emergency scheduling authority to enact temporary control, making possession or sale of methylenedioxypropylamphetamine, methylenedioxymethamphetamine, and mephedrone illegal. This was later written into permanent law. In 2014, an additional 10 synthetic cathinones were given temporary Schedule I status.

### Bromo-dragonFLY

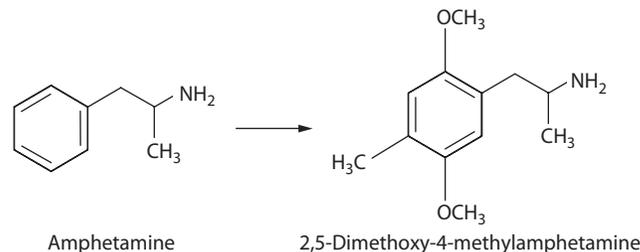

1-(8-Bromobenzo[1,2-b:4,5-b']difuran-4-yl)-2-aminopropane, also known as Bromo-dragonFLY (BDF), was first synthesized in 1998. Bromo-dragonFLY was named after its superficial structural resemblance to a dragonfly, similar to its less potent predecessor, the dihydrofuran series nicknamed FLY. Bromo-dragonFLY is a member of a new class of benzodifurans, which were used as potent tools for investigation of the serotonin receptor family. Benzodifurans were also briefly investigated as potential antidepressants.<sup>179</sup>

Structurally, BDF is closely related to other phenylethylamines such as DOB and 2C-B but contains two furan rings on either side of the benzene ring, creating a fully aromatic tricyclic structure. There are several similar compounds to BDF, differing by substitution of the bromine atom with other entities. Bromo-dragonFLY exists as R- and S-enantiomers, which are both biologically active. The R-enantiomer is considered more potent, with a significant hallucinogenic effect mediated primarily through the 5-HT<sub>2A</sub> serotonin receptor (also with affinity for the 5-HT<sub>2B</sub> and 5-HT<sub>2C</sub> serotonin receptors).<sup>126</sup>

Bromo-dragonFLY use is associated with deaths in Europe and the United States. Reports demonstrate delayed complications owing to severe peripheral vasoconstriction and limb ischemia. Such complications likely result from BDF’s potent serotonergic properties.<sup>5,34,41,167,179</sup>

### 2,5-Dimethoxy-4-Methylamphetamine and 2,5-Dimethoxy-4-Iodoamphetamine

2,5-Dimethoxy-4-methylamphetamine (DOM), also known as STP, which stands for “serenity, tranquility, and peace,” emerged in the 1960s as a hallucinogen. It was noted for its delayed onset of action and duration of effect, which resulted in a short-lived appearance. 2,5-Dimethoxy-4-iodoamphetamine (DOI) is another potent hallucinogen, previously sold as a substitute for lysergic acid diethylamide, or LSD.

Dimethoxy amphetamine derivatives are structurally characterized by methoxy ring substitution at the 2 and 5 positions on the aromatic ring, with varying substitution of hydrophobic moieties at the 4 position. 2,5-Dimethoxy-4-methylamphetamine and DOI are both serotonin receptor agonists with selectivity at the 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, and 5-HT<sub>2C</sub> receptor subtypes. Because of this selectivity, DOM and DOI are often used in scientific research involving study of the 5-HT<sub>2</sub> receptor subfamily. 2,5-Dimethoxy-4-methylamphetamine exists as a chiral molecule, with the R(-)-enantiomer considered the more potent.<sup>15</sup>

Potent hallucinogenic effects and dysphoria characterize the use of DOB and DOI, with minimal sympathomimetic effects. These symptoms can often be delayed with a prolonged duration of effect, sometimes refractory to the use of benzodiazepines. Reversible vasospasm with the use of dimethoxy amphetamine derivatives is reported.<sup>9,20</sup>

### The 2C-Series and N-2-methoxybenzylphenylethylamines

The 2C-series and its derivatives are similar in structure and function DOM and DOI as all are dimethoxy phenylethylamine derivatives with potent hallucinogenic properties. The 2C series differs in that they lack an  $\alpha$ -carbon methyl group and are thus not true amphetamines in structure.

The first of this series 2C-B was initially intended for psychotherapy, however, it fell out of favor because of GI side effects and limited entactogenic effects. Multiple other 2C compounds have been developed by altering substitutions at positions 2,4 and 5 on the phenyl ring. The compound 2C-I is an iodo-substituted dimethoxy phenylethylamine popularized in recent years as “smiles.” Reported clinical effects of this series include sympathomimetic effects, delirium, hallucinations, and psychosis.<sup>42</sup>

2-(4-Iodo-2,5-dimethoxyphenyl)-N-[(2-methoxyphenyl)methyl]ethanamine (2C-I-NBOMe, N-Bomb) was discovered in 2003, along with other similar NBOMe compounds. It possesses strong 5-HT<sub>2A</sub> agonism and was initially used as a pharmacologic tool to study 5-HT<sub>2A</sub> receptors. 2C-I-NBOMe is synthesized by N-benzyl substitution of 2C-I and is currently used recreationally as an LSD alternative. The high potency of NBOMe compounds compared with 2C-I allow efficacy in microgram doses, with subsequent potential for accidental overdose. NBOMes are used by all routes, but poor oral bioavailability limits oral use.<sup>71,118</sup> Reported clinical effects include euphoria, hallucinations, and sympathomimetic effects. Deaths are reported.<sup>118,169</sup>

### SUMMARY

- Novel amphetamines, often created to evade designer drug laws, continue to increase dramatically throughout the United States.
- The extensive knowledge of the modifications to the existing phenylethylamine backbone allows clinicians to predict the effects of the amphetamines. These effects are attributed to variable degrees of selectivity affecting dopamine, norepinephrine, and serotonin.

- Many complications associated with amphetamines are similar to those of cocaine, such as agitation, hyperthermia, rhabdomyolysis, myocardial ischemia, and cerebral infarction.
- The management of patients with acute toxicity of any of the amphetamines includes supportive care, with the judicious use of benzodiazepines and anticipation of complications of adrenergic and serotonergic toxicity such as hyperthermia and rhabdomyolysis.

## CANNABINOIDS

Jeff M. Lapoint

### HISTORY AND EPIDEMIOLOGY

Cannabis has been used for more than 4,000 years. The earliest documentation of the therapeutic use of marijuana is the fourth century B.C. in China.<sup>172</sup> Cannabis use spread from China to India to North Africa, reaching Europe around A.D. 500.<sup>138</sup> In colonial North America, cannabis was cultivated as a source of fiber. Similar to cocaine and morphine, cannabis was the focus of research efforts in the 19th century. Although the active chemical constituents of the former were isolated during this time, that of cannabis remained elusive.<sup>97</sup> This was because the active compounds of opium poppy and coca leaf are both alkaloids and were possible to extract with the technological means of the time, whereas the methods to isolate the active terpenes in cannabis were not available to researchers until several decades later.

The first pure phytocannabinoid to be isolated was cannabitol, in 1898. Synthesis of its structural isomers yielded the first synthetic cannabinoid (SC) years later— $\Delta^9$ -tetrahydrocannabinol (THC). Cannabitol was previously shown to lack psychoactive effects, but this new compound demonstrated similar effects to cannabis in a model of ataxia in dogs. Pure  $\Delta^9$ -THC was subsequently isolated from hashish extract in 1964, and the structure was elucidated in 1967.<sup>98</sup>

Cannabis was used in the United States as a substance of abuse from the 1850s until the 1930s when the US Federal Bureau of Narcotics began to portray marijuana as a powerful, addictive substance. Despite this, marijuana was listed in the US Pharmacopoeia from 1850 to 1942. In 1970, the Controlled Substances Act classified marijuana as a Schedule I drug.

In all populations, cannabis use by men exceeds use by women. Currently, marijuana is the most commonly used illicit xenobiotic in the United States; however, it is legal for recreational use in an increasing number of states, including at the time of this writing Colorado, Washington, California, Oregon, and Alaska. In 2015 in the United States, 8.2% (22 million persons) 12 years of age or older used marijuana in the month before the survey; this prevalence is increased from 6% in previous years. The prevalence of past-month users aged 12 to 17 years was 7% (increased from 6.8% in 2006). The number of first-time users was estimated to be 2.1 million, with 63.3% younger than 18 years of age.<sup>128</sup>

Interest in SCs as potential therapeutics increased after the progress of the late 1960s, and several SCs similar in structure to THC were created. These semisynthetic compounds were based on the dibenzopyran ring structure of THC and had varying cannabinoid receptor binding affinities relative to THC. The search for a nonopioid analgesic sparked research and development efforts by pharmaceutical companies, most notably Pfizer, from the 1960s to 1980s.<sup>67</sup> Despite its efforts, no medications came to market; new analgesics retained unwanted psychoactive side effects. During this period, an extensive understanding of structure activity relationships for cannabinoids developed.<sup>66</sup>

Subsequent synthetic compounds were developed as cannabinoid research tools and were important in the discovery of central and peripheral cannabinoid receptors (CB<sub>1</sub> and CB<sub>2</sub>) in the 1980s.<sup>34</sup> Many of these did not retain structural similarity to THC but remained potent and efficacious agonists at CB<sub>1</sub> and CB<sub>2</sub>.<sup>66</sup> In the 1990s, the endogenous cannabinoids were discovered and were subsequently synthesized.<sup>84</sup> These free fatty acids are quickly hydrolyzed in vivo, a fact that previously limited potential for pharmaceutical development. Researchers have since synthesized stable versions of endocannabinoids (Fig. 74-1).

In 2004, SC-laced herbal incense blends became available over the Internet and through smoke shops in Western Europe.<sup>88</sup> Popular use and subsequent publicity increased, resulting in several users presenting to

emergency departments in Germany. As the result of efforts by the German government and THC Pharma, JWH-018 was isolated as the psychoactive ingredient present in these early incense blends. The discovery led to legislative action and subsequent ban of herbal incense containing JWH-018 in Germany, but almost as soon as the ban took effect, manufacturers substituted a different SC—JWH-073. Since that time, many Western European countries have legislated further control of SCs.

The incidence of SC exposure in the United States increased, and in November 2010, the Drug Enforcement Administration (DEA) began the process of listing selected SCs as Schedule I drugs on a temporary basis. By March 2011, the DEA listed several nonclassical SCs as Schedule I, but as was the case in Germany, manufacturers of herbal incense blends in the United States switched to other unscheduled SCs. Second- and third-generation SCs, such as AM-2201, XLR-11, and the indazole derivatives, have since emerged and further complicate the clinical, regulatory, and public health efforts.

Toxicologists face a new era in the field of cannabinoids: Research continues to advance understanding of the cannabinoid system, a myriad of new and discrete SCs emerge ever year, and even the familiar marijuana is found with higher potency and changing phytocannabinoid ratios that may affect patients in unanticipated ways.

### MEDICAL USES

Cannabis has been used medicinally for thousands of years to treat a seemingly endless array of conditions. However, modern medicine is supported by an evidence-based system rather than the belief-based medicine of the past. Therefore, potential medicinals must be proven through rigorous investigation to be not only safe but effective in the treatment of a targeted malady. Although smoked marijuana and THC preparations have not typically proven acutely dangerous, efficacy is questionable. Several issues must be considered when examining the body of evidence both for and against the medical use of cannabinoids. Marijuana is not the same entity as, nor is interchangeable with,  $\Delta^9$ -THC. Although the latter is the chief psychoactive constituent of marijuana, the multiple additional cannabinoids present in marijuana are biologically active and must be considered. Second, significant study design flaws limit the conclusions that can be drawn from existing studies. Finally, poor overall understanding of cannabinoid physiology may hamper future study design. Proposed uses for medical cannabis and the available evidence supporting that use are reviewed next.

#### Pain

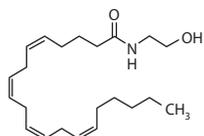

##### Acute Pain

Studies examining the efficacy of cannabis in the setting of induced acute pain showed no improvement. These studies were limited by the lack of a positive control and examined only extremes of induced pain.<sup>30</sup> Smoked marijuana failed to attenuate thermal pain in volunteers, and an oral THC analog had no effect on postsurgical pain.<sup>73</sup>

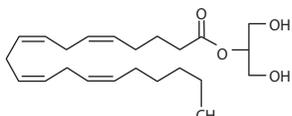

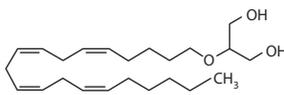

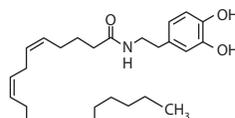

##### Chronic Pain

When used for the treatment of chronic and neuropathic pain, cannabinoids have had some favorable outcomes, although design flaws severely limit the quality of medical evidence.<sup>118</sup> Initial trials of combined cannabinoid and opioid therapy are encouraging, and the principle may have mechanistic merit based on the knowledge that opioid and cannabinoid receptors can form heterodimers,<sup>131</sup> but lack of proper controls and the presence of confounders limit the clinical applicability of cannabinoids as analgesics at this time.

## Endocannabinoids

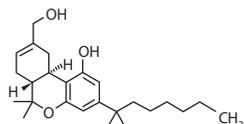

Anandamide

## Nausea and Vomiting

Trials of cannabinoids for treatment of chemotherapy-induced nausea and vomiting demonstrate superiority over placebo but compared with serotonin and dopamine antagonists, this difference is not statistically significant.<sup>17,38,90,100,169</sup> Dronabinol is currently FDA approved for this indication.

## Glaucoma

Trials investigating the efficacy of cannabinoids for the treatment of glaucoma demonstrate the inferiority to longer acting traditional therapeutics, which have more significant effects on intraocular pressure (IOP) and longer durations of effect. One small trial found no difference between the effect of cannabinoids and placebo on IOP.<sup>162</sup>

## Summary of Medical Use

In 2003, the Institute of Medicine undertook an extensive review of the evidence supporting the medical use of marijuana. It concluded that in some circumstances, cannabinoids show promise for use as therapeutics, but the quality of current studies necessitated further research specifically for the treatment of chronic pain. In addition, smoking marijuana provides a crude and unpredictable delivery mechanism, and safer, more precise methods of administration are needed.<sup>167</sup>

Similarly, a meta-analysis in 2015 composed of randomized clinical trials (RCTs) showed only moderate evidence to support the efficacy of cannabinoids in treating chronic pain and spasticity related to multiple sclerosis.<sup>169</sup> A Cochrane review of 23 RCTs found that pharmaceutical cannabinoids for use in the management of many clinical conditions but are only currently FDA approved for the control of chemotherapy-related nausea and vomiting that are resistant to conventional antiemetics, for breakthrough postoperative nausea and vomiting, and for appetite stimulation in patients with human immunodeficiency virus (HIV) patients with anorexia-cachexia syndrome.<sup>59</sup> The claims of benefit in the other medical conditions are not clearly supported by evidence.<sup>6,170</sup>

## PHARMACOLOGY AND PATHOPHYSIOLOGY

The term *cannabinoid* refers to compounds that bind to the cannabinoid receptors regardless of whether they are derived from plants (phytocannabinoids), synthetic processes (SCs), or endogenous sources (endocannabinoids). At one time, the term may have been used to delineate a structural similarity to  $\Delta^9$ -THC, but this naming convention was largely abandoned during the past 30 years of cannabinoid research as new compounds were discovered and synthesized. The structural diversity of cannabinoid receptor ligands and the absence of a true pharmacophore make nomenclature based purely on structure cumbersome and inconsistent. It is preferable then to use the term *cannabinoid* to denote receptor binding and subclassify cannabinoids further based on origin and structure (Fig. 74–1). The terms *cannabinoid*, *cannabinomelic*, and *cannabinoid receptor agonist* are interchangeable.

*Cannabis* is a collective term referring to the bioactive substances from the cannabis plant. The *Cannabis* genus (species *sativa* and *indica*) produces more than 60 chemicals (C21 group) called cannabinoids. The major cannabinoids are cannabitol, cannabidiol (CBD), and tetrahydrocannabinol. The principal psychoactive cannabinoid is THC, also known as  $\Delta^9$ -tetrahydrocannabinol. *Marijuana* is the common name for a mixture of dried leaves and flowers of the *C. sativa* plant. Hashish and hashish oil are the pressed resin and the oil expressed from the pressed resin, respectively. The concentration of THC varies from 1% in low-potency marijuana up to 50% in hash oil.  $\Delta^9$ -Tetrahydrocannabinol extracted from marijuana using butane (butane hash oil or BHO) approaches THC concentrations of 100%. Pure THC and several pharmaceutical SCs are available by prescription with the generic names of dronabinol and nabilone, respectively. Nabiximol is the generic name for an oral mucosal spray containing THC and cannabidiol, which is approved for medical use in Canada, the United Kingdom, and parts of Europe. Unregulated SCs originally designed as research chemicals have emerged as designer drugs of abuse over the past several years.

Cannabinoid receptors are G protein-linked neuromodulators that inhibit adenylyl cyclase in a dose-dependent and stereospecific manner. Although historically the cannabinoid receptor system is described as having a central  $CB_1$  and a peripheral  $CB_2$  receptor, the available evidence points to the central nervous system (CNS) presence of  $CB_2$  receptors.<sup>147</sup> The two currently identified cannabinoid receptors are labeled  $CB_1$  and  $CB_2$  and are distinguished largely by their anatomic distribution and mechanisms of cellular messaging (Fig. 74–2).

## $CB_1$ Receptors and the Psychogenic Effects of Cannabis

The  $CB_1$  receptors are structurally composed of seven transmembrane protein units coupled to pertussis-sensitive (decrease adenylyl cyclase) G proteins. They exhibit genetic variation via splice variants and are found as heterodimers with a multitude of other receptor types.<sup>67</sup>

Isolated agonism of  $CB_2$  receptors was the target for novel pharmaceutical candidates as antiinflammatory agents with minimal success as the psychoactive effects of  $CB_1$  agonism persisted.

The  $CB_1$  receptors are the most numerous G protein-coupled receptors in the mammalian brain, accounting for the multiple and varied effects of cannabinoids on behavior, learning, and mood as well as suggesting the enormous complexity of the endocannabinoid system.<sup>58</sup> The highest concentration of  $CB_1$  receptors is located in areas of the brain associated with movement and higher functions of cognition and emotions. A relative lack of  $CB_1$  receptors in the brainstem also explains lack of coma and respiratory depression that occurs with *Cannabis* use.

## Mechanism of Cellular Signaling

Cannabinoid receptors both in the CNS and in the periphery exist on the presynaptic terminus of various neurons. Depolarization in the postsynaptic portion of the neuron and subsequent increase in intracellular  $Ca^{2+}$  leads to on-demand synthesis and release of endocannabinoids.<sup>117</sup> These free fatty acid-based messengers diffuse into the synapse and bind to the presynaptic cannabinoid receptor. Ligand binding causes conformational change in the G protein subunits and inhibition of adenylyl cyclase, resulting in decreased intracellular cyclic adenosine monophosphate (cAMP) concentrations, decreased activity of voltage-gated  $Ca^{2+}$  channels, and ultimately decreased neurotransmitter release (Fig. 74–2). Exogenous cannabinoids act similarly to endogenous cannabinoids upon receptor binding, except that binding affinity will vary among exogenous ligands and endogenous cannabinoids, which are rapidly metabolized by fatty acid amide hydrolases.<sup>84</sup> Interestingly, some online chemical suppliers offer fatty acid amide hydrolase inhibitors for sale, along with various SCs, perhaps providing a glimpse into future products more closely related to endocannabinoids coming to market.

Both receptors inhibit adenylyl cyclase and stimulate  $K^+$  channel conductance.<sup>121</sup>  $CB_1$  receptors are located either presynaptically or postsynaptically, and their activation can inhibit or enhance the release of acetylcholine, L-glutamate,  $\gamma$ -aminobutyric acid, noradrenaline, dopamine, and 5-hydroxytryptamine.<sup>71,77,140</sup>

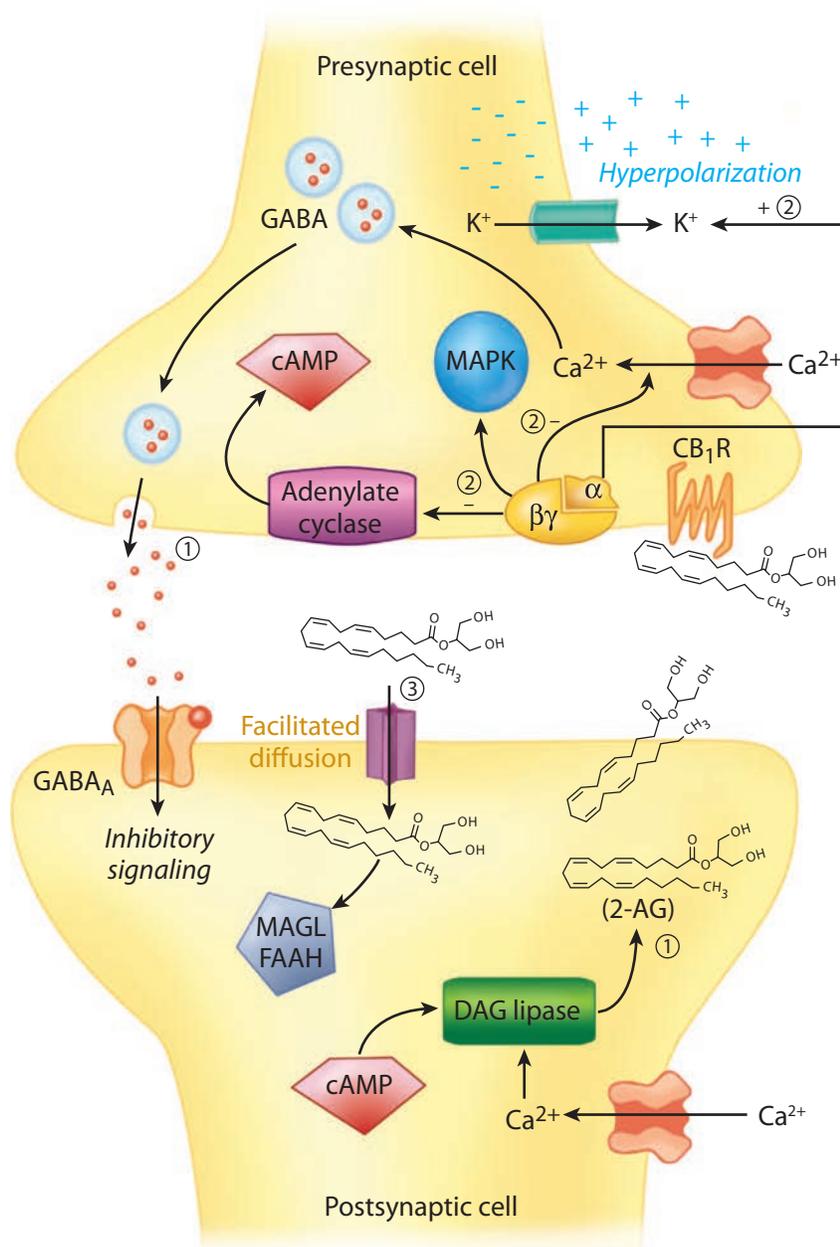

The neuropharmacologic mechanisms by which cannabinoids produce their psychoactive effects are not fully elucidated.<sup>60,71,121</sup> Nevertheless, activity at the  $CB_1$  receptors is believed to be responsible for the clinical effects of cannabinoids,<sup>12,40,71,153</sup> including the regulation of cognition, memory, motor activities, nociception, nausea, and vomiting. Chronic administration of a cannabinoid agonist reduces  $CB_1$  receptor density in several regions of the rat brain.<sup>13</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

### Absorption

The pharmacokinetics of phytocannabinoids was extensively reviewed.<sup>50</sup> The rate and completeness of absorption of cannabinoids depend on the route of administration and the type of cannabis product.

Inhalation of smoke containing THC results in the onset of psychoactive effects within minutes typically reaching peak serum concentration before

**FIGURE 74-2.** Endocannabinoids act as allosteric cellular messengers. ① In response to presynaptic  $\gamma$ -aminobutyric acid (GABA) release and postsynaptic binding resulting in increased cyclic adenosine monophosphate (cAMP), endocannabinoids are synthesized on demand and bind to presynaptic cannabinoid receptors. ② Activation of these G protein receptors results in decreased presynaptic adenylate cyclase, decreased cAMP, decreased calcium ion influx, and increased potassium efflux. The net results are hyperpolarization of the presynaptic cell and decreased neurotransmitter release. ③ After binding, endocannabinoids diffuse back to the postsynaptic area, where they undergo degradation by monoacylglycerol lipase (MAGL) and fatty acid amide hydrolase (FAAH). CB<sub>1</sub>R = cannabinoid type 1 receptor; DAG lipase = diacylglycerol lipase; MAPK = mitogen-activated protein kinase. 2-AG=2-arachidonoylglycerol. (Adapted with permission from Seely KA, Prather PL, James LP, et al. *Marijuana-based drugs: innovative therapeutics or designer drugs of abuse?* *Mol Interv.* 2011 Feb;11(1):36-51.)

finishing the cigarette. From 10% to 35% of available THC is absorbed during smoking, and peak serum concentrations depend on the dose. A marijuana cigarette containing 1.75% THC produces a peak serum THC concentration of approximately 85 ng/mL.<sup>63</sup>

Ingestion of cannabis results in an unpredictable onset of psychoactive effects in 1 to 3 hours. Only 5% to 20% of available THC reaches the systemic circulation after ingestion. Peak serum THC concentrations usually occur 2 to 4 hours after ingestion, but delays up to 6 hours are described.<sup>66</sup> Dronabinol has an oral bioavailability of approximately 10% with high interindividual variability.<sup>47,111</sup> Nabilone has an oral bioavailability estimated to be greater than 90% and reaches peak serum concentrations 2 hours after ingestion.<sup>137</sup>

### Distribution

$\Delta^9$ -Tetrahydrocannabinol has a steady-state volume of distribution of approximately 2.5 to 3.5 L/kg.<sup>47</sup> Cannabinoids are lipid soluble and accumulate in fatty tissue in a biphasic pattern. Initially, THC is distributed to highly vascularized tissues such as the liver, kidneys, heart, and muscle. After smoking or intravenous (IV) administration, the distribution half-life is less than 10 minutes.<sup>64</sup> After the initial distribution phase, THC accumulates more slowly in less vascularized tissues and body fat. Repeated administration of  $\Delta^8$ -THC (an isomer of  $\Delta^9$ -THC) to rats over 2 weeks resulted in steadily increasing concentrations of  $\Delta^8$ -THC in body fat and liver but not in brain tissue. After administration of  $\Delta^8$ -THC stopped,

the cannabinoids are slowly released from fat stores during adipose tissue turnover.<sup>116</sup>

$\Delta^9$ -Tetrahydrocannabinol crosses the placenta and enters the breast milk. Concentrations in fetal serum are 10% to 30% of maternal concentrations. Daily cannabis smoking by a nursing mother resulted in concentrations of THC in breast milk eightfold higher than concomitant maternal serum concentrations; THC metabolites do not accumulate in breast milk.<sup>123</sup>

### Metabolism

$\Delta^9$ -Tetrahydrocannabinol is nearly completely metabolized by hepatic microsomal hydroxylation and oxidation (primarily CYP2C9 and CYP3A4).<sup>50</sup> The primary metabolite (11-hydroxy- $\Delta^9$ -THC or 11-OH-THC) is active and is subsequently oxidized to the inactive 11-nor- $\Delta^9$ -THC carboxylic acid metabolite (THC-COOH) and many other inactive metabolites.<sup>1,4,127</sup>

In six volunteers, peak serum THC concentrations occurred at 8 minutes (range, 6–10 minutes) after the onset of smoking, peak 11-OH-THC at 13 minutes (range, 9–23 minutes), and peak THC-COOH at 120 minutes (range, 48–240 minutes) (Fig. 74–3).<sup>63</sup> Approximately 1 hour after beginning to smoke a marijuana cigarette, the THC to 11-OH-THC ratio is 3:1, and the THC to THC-COOH ratio is 1:2; at approximately 2 hours, the ratios are 2.5:1 and 1:8, respectively; and at 3 hours, the ratios are 2:1 and 1:16, respectively.<sup>63</sup> Ingestion of cannabis results in much more variable concentrations and time courses of THC and metabolites (Fig. 74–3). Nonetheless, at 2 to 3 hours after ingestion, the ratios are similar to those after smoking: THC to 11-OH-THC is 2:1, and THC to THC-COOH ranges from 1:7 to 1:14.<sup>165</sup>  $\Delta^9$ -Tetrahydrocannabinol is detectable in serum 1.5 to 4.5 hours after ingestion of dronabinol.<sup>46</sup>

Of the many aminoalkylindole (AAI) SCs isolated in “Spice” incense blends, human metabolic analyses are only published for JWH-018, JWH-073, and AM 2201.<sup>14,15</sup> In contrast to THC, these cannabinoids are metabolized largely through hydroxylation and oxidation by CYP2C9 and CYP1A2 (with minor contributions of CYP2D6) to active metabolites that retain affinity for and in most are agonists at both CB<sub>1</sub> and CB<sub>2</sub> receptors.<sup>27,28</sup> These metabolites undergo glucuronic acid conjugation in phase II metabolism.

### Excretion

Reported elimination half-lives of THC and its major metabolites vary considerably. After IV doses of THC, the mean elimination half-life ranges from 1.6 to 57 hours.<sup>50</sup> Elimination half-lives are expected to be similar after inhalation.<sup>50,63</sup> The elimination half-life of 11-OH-THC is 12 to 36 hours, and that of THC-COOH ranges from 1 to 6 days.<sup>79,165</sup>

$\Delta^9$ -Tetrahydrocannabinol and its metabolites are excreted in the urine and the feces. In the 72 hours after ingestion, approximately 15% of a THC dose is excreted in the urine, and roughly 50% is excreted in the feces.<sup>1,21,168</sup> After IV administration, approximately 15% of a THC dose is excreted in the

urine, and only 25% to 35% is excreted in the feces.<sup>165</sup> Inhalation is expected to produce results similar to IV administration.<sup>50,63</sup> Within 5 days, 80% to 90% of a THC dose is excreted from the body.<sup>55,68</sup>

Cannabinoids were measured in the urine after smoking a marijuana cigarette containing 27 mg of THC (Fig. 74–3).<sup>94</sup> After smoking THC, urine concentrations peaked at 2 hours (mean, 21.5 ng/mL; range, 3.2–53.3 ng/mL) and were undetectable (<1.5 ng/mL) in five of the eight participants by 6 hours. Urine concentrations of 11-OH-THC peaked at 3 hours (77.3 ± 29.7 ng/mL). The primary urinary metabolite is the glucuronide conjugate of THC-COOH.<sup>170</sup> The urine concentration of THC-COOH peaks at 4 hours (179.4 ± 146.9 ng/mL),<sup>95</sup> and it has an average urinary excretion half-life of 2 to 3 days (range, 0.9–9.8 days).<sup>50</sup> Both 11-OH-THC and THC-COOH remained detectable in the urine of all eight participants for the 8 hours of the study.<sup>94</sup>

After discontinuation of use, metabolites are often detected in the urine of chronic users for several weeks.<sup>39,74</sup> Factors such as age, weight, and frequency of use only partially explained the long excretion period.<sup>39</sup> Primary urinary metabolites of nonclassical SCs are summarized in Fig. 74–4.

### CLINICAL MANIFESTATIONS

The clinical effects of THC use, including time of onset and duration of effect, vary with the dose, the route of administration (ingestion is slower in onset than inhalation), the experience of the user, the vulnerability of the user to psychoactive effects, and the setting in which the THC is used. The concomitant use of CNS depressants such as ethanol or stimulants such as cocaine alters the psychological and physiological effects of marijuana. The therapeutic serum THC concentration for the treatment of nausea and vomiting is greater than 10 ng/mL.<sup>23</sup>

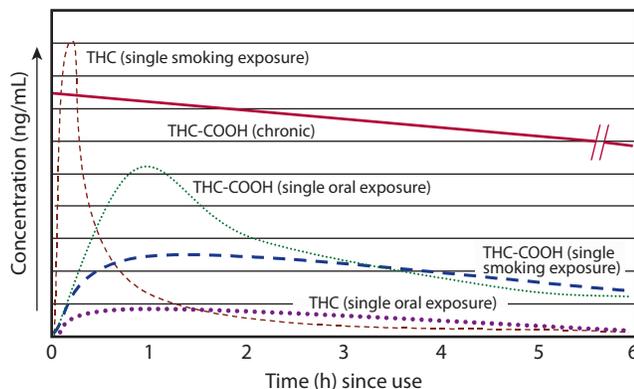

### Psychological Effects

Use of marijuana produces variable psychological effects.<sup>40</sup> The variation, which occurs both between and within users, is likely the result of drug tolerance, phase of clinical effects, strain of cannabis, physical and social settings, or user expectations or cognitive capacity. The most commonly self-reported effect is relaxation. Other commonly reported effects are perceptual alterations (heightened sensory awareness, slowing of time), a feeling of well-being (including giddiness or laughter), and increased appetite.<sup>49</sup>

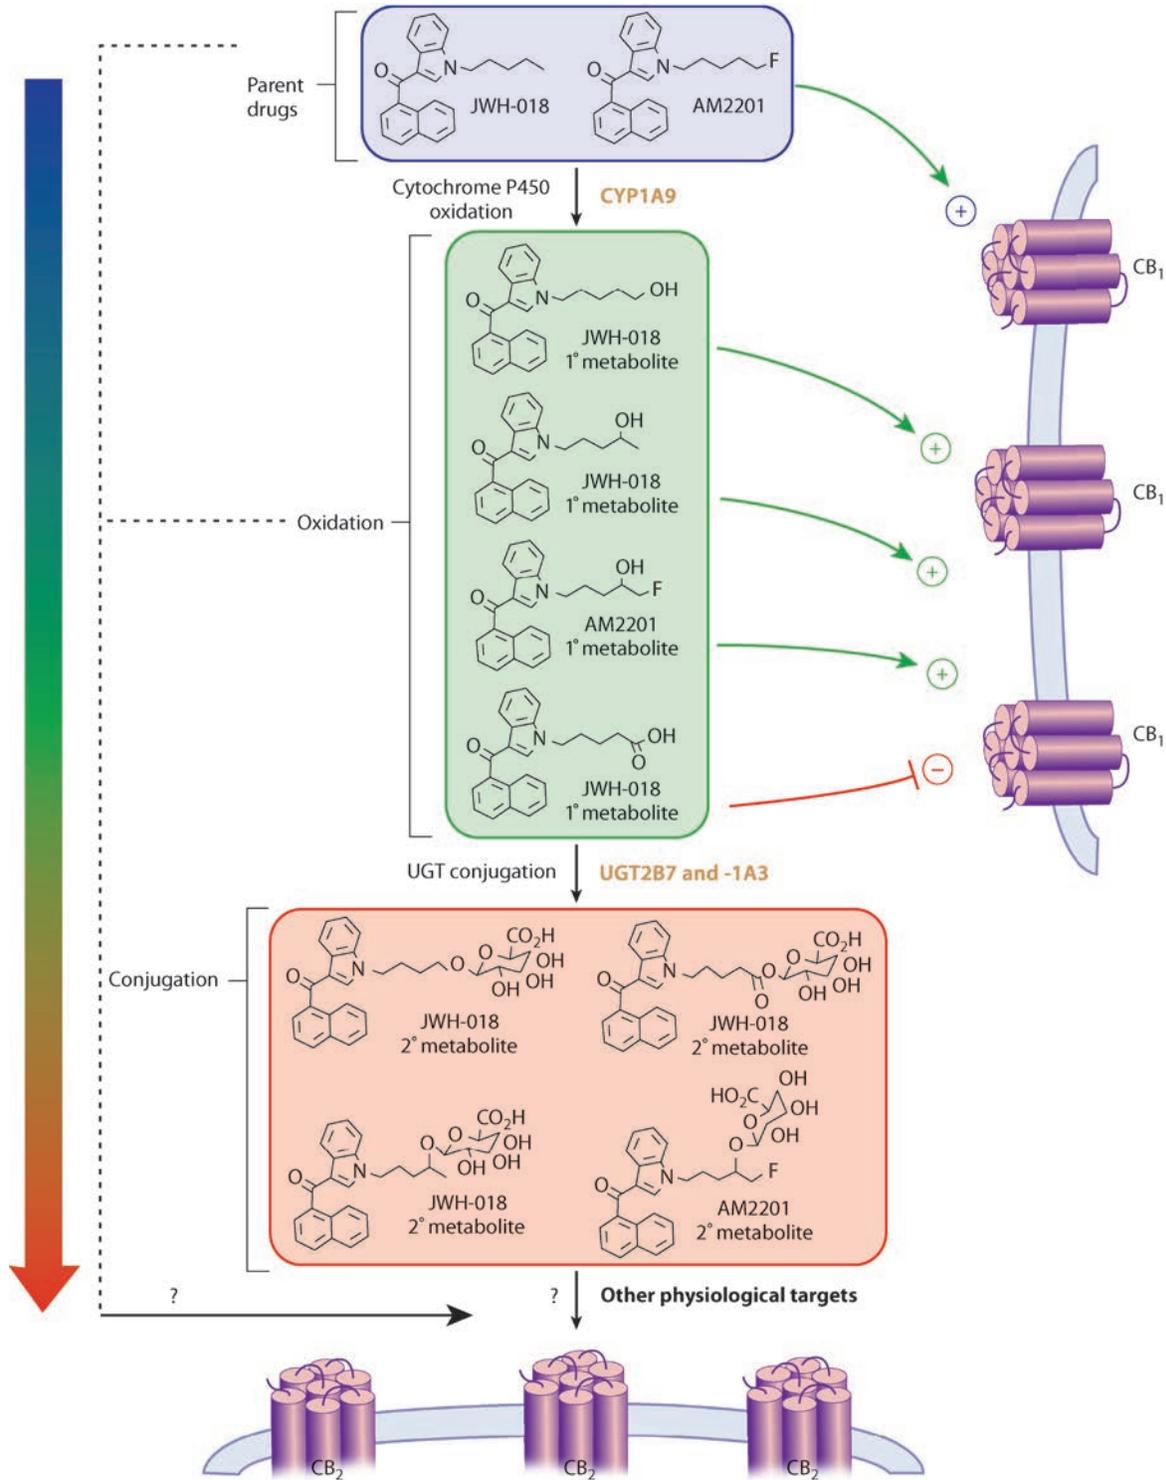

### Physiological Effects

Use of cannabis is associated with physiologic effects on cerebral blood flow, the heart, the lungs, and the eyes. In a controlled, double-blind positron emission tomography study,<sup>95</sup> Intravenous THC increased cerebral blood flow, particularly in the frontal cortex, insula, cingulate gyrus, and subcortical regions. These increases in cerebral blood flow occurred 30 to 60 minutes after use and were still elevated at 120 minutes.<sup>96</sup> Similar blood flow changes result from smoking marijuana.<sup>120</sup>

Common acute cardiovascular effects of cannabis use include increases in heart rate and decreases in vascular resistance.<sup>75,148</sup> Cannabis produces dose-dependent increases in heart rate within 15 minutes of using a marijuana cigarette (from a baseline mean of 66 beats/min to a mean of 89 beats/min) that reach a maximum (mean, 92 beats/min) 10 to 15 minutes after peak serum THC concentrations. These changes last for 2 to 3 hours.<sup>8</sup> Increases in blood pressure occur with cannabis use. In a study of six participants, an increase in blood pressure from a baseline mean of 119/74 mm Hg to a mean of 129/81 mm Hg occurred but was not statistically significant.<sup>8</sup> In a double-blind, controlled study of men being investigated for angina pectoris, smoking a marijuana cigarette resulted in statistically significant changes in blood pressure from a baseline mean of 123/79 mm Hg to a peak mean of 132/84 mm Hg.<sup>129</sup> In contrast, in one study, repeated THC use resulted in significant slowing of heart rate (from a mean of 68 beats/min to a low of 62 beats/min) and lowering of blood pressure (from a mean of 116/62 mm Hg to a low of 108/53 mm Hg).<sup>10</sup> Decreased vascular tone causes postural hypotension accompanied by dizziness and syncope.

**FIGURE 74–3.** Estimated relative time course of  $\Delta^9$  tetrahydrocannabinol (THC) and its major metabolite in the urine based on the route of exposure. THC-COOH =  $\Delta^9$  THC carboxylic acid.

**FIGURE 74-4.** JWH-018 and AM-2201 metabolism. Aminoalkylindole synthetic cannabinoid JWH-018 and its omega fluorinated analog AM-2201 undergo oxidation by CYP2C9 and CYP1A9 to primary metabolites that retain affinity and ability to bind with cannabinoid receptors. One JWH-018 primary metabolite acts as an antagonist at cannabinoid type 1 receptor (CB<sub>1</sub>). Secondary metabolites are formed by conjugation. These metabolites may retain ability to bind to cannabinoid receptors, but at this time it is unclear which do so and in what capacity (agonist, antagonist, or inverse agonist). (Adapted with permission from Chimalakonda KC, Seely KA, Bratton SM, et al. Cytochrome P450-mediated oxidative metabolism of abused synthetic cannabinoids found in K2/Spice: identification of novel cannabinoid receptor ligands. *Drug Metab Dispos.* 2012 Nov;40(11):2174-2184.)

Inhalation or ingestion of THC produces a dose-related short-term decrease in airway resistance and an increase in airway conductance in both normal individuals and individuals with asthma.<sup>156</sup> Smoking marijuana results in an immediate increase in airway conductance, which peaks at 15 minutes and lasts 60 minutes. Ingestion of cannabis produces a significant

increase in airway conductance at 30 minutes, which peaks at 3 hours and lasts 4 to 6 hours.<sup>157,158,161</sup> The mechanism for this effect is unclear.

The principal ocular effects of cannabis are conjunctival injection and a transient decrease in IOP. Cannabinoids, applied topically to a rabbit eye, resulted in hyperemia of the conjunctival blood vessels for 2 hours after

application.<sup>103</sup> Regardless of route of administration, cannabis causes a fall in IOP in 60% of users<sup>48</sup> by acting on CB<sub>1</sub> receptors in the ciliary body.<sup>126</sup> The mean reduction in IOP is 25% and lasts 3 to 4 hours.

Physiological effects of novel SCs are not yet studied in any controlled settings.

## ACUTE TOXICITY

In addition to the physiological and psychological effects described, acute toxicity includes decreases in coordination, muscle strength, and hand steadiness. Lethargy, sedation, postural hypotension, inability to concentrate, decreased psychomotor activity, slurred speech, and slow reaction time also occur.<sup>115,168</sup>

In young children, the acute ingestion of cannabis is potentially consequential.<sup>93</sup> Ingestion of estimated amounts of 250 to 1,000 mg of hashish resulted in obtundation in 30 to 75 minutes. Tachycardia (>150 beats/min) was found in one-third of the children. Less commonly reported findings include apnea, cyanosis, bradycardia, hypotonia, and opisthotonus.

The acute toxicity profile of nonclassical SCs stands in stark contrast to the relatively mild effects of smoked or ingested phytocannabinoid products. Given the general similarity in receptor binding, both users and clinicians initially expected the effects to be largely identical to marijuana and hashish. The significant differences are likely a result of AAI cannabinoids found in “incense blends” being more potent and efficacious at cannabinoid receptors as well as having active metabolites. Moreover, these products are unregulated, and the presence of additional xenobiotics, such as cathinones, methylxanthines, and long-acting  $\beta$ -adrenergic agonists such as clenbuterol must be considered.

The recent published reports of presumed SC toxicity are challenging to interpret because many lack laboratory confirmation of exposure. In addition, in cases involving “spice” blends, adverse effects may result from the plant matter or adulterants. Finally, the concentration of SCs varies by incense package, even of the same brand and lot, making dose estimation difficult if not impossible.

Agitation<sup>142</sup> and seizures are reported.<sup>85,141</sup> In one report with laboratory confirmation, a patient experienced multiple seizures within 30 minutes after ingesting JWH-018 in powder form.<sup>85</sup> The sample was confirmed as pure JWH-018.

Psychosis (new onset, acute exacerbation of existing psychiatric disorders, and increased risk of psychosis relapse) and anxiety have resulted after a single dose.<sup>57,69,124</sup>

Tachycardia was a common finding detailed in one series, and tachydyarrhythmias requiring cardioversion are reported.<sup>85</sup> Chest pain and increased troponin concentrations were observed in three patients who claimed to have smoked spice several days before presenting to the hospital, but laboratory confirmation of SC exposure was not performed.<sup>104</sup>

Diffuse pulmonary infiltrates and dyspnea requiring intubation and mechanical ventilation were reported in a habitual spice user. Laboratory confirmation revealed three parent SCs (AM-2201, JWH-122, and JWH-210).<sup>2</sup>

Accounts of acute kidney injury are described in a case series of 16 previously healthy participants. All patients reported smoking spice incense blends before presentation. The patients had flank pain, nausea, and vomiting with elevated serum creatinine concentrations. Laboratory confirmation was achieved in eight of the patients, and a previously unreported SC was isolated (XLR-11). Several of the patients required hemodialysis, but all eventually recovered.<sup>1</sup>

Cerebral ischemia was reported in a patient using a product confirmed to contain XLR-11. The patient presented after smoking SC with right-sided weakness and later had CT of the brain confirming a left insular stroke. Forensic testing of the product revealed XLR-11, but neither the parent or metabolites could not be identified in the patient’s urine, suggesting rapid metabolism.<sup>155</sup>

The fourth-generation indazole derivative SCs were likely responsible for several recent outbreaks of somnolence and bradycardia in suspected users.

This stands in contrast to earlier generations of SCs users who presented with sympathomimetic-like symptoms. Patients using nonclassical SCs respond to supportive care.<sup>106</sup>

## ADVERSE REACTIONS

### Acute Use

Cannabis users occasionally experience distrust, dysphoria, fear, panic reactions, or transient psychoses. Commonly reported adverse reactions at the prescribed dose of dronabinol or nabilone include postural hypotension, dizziness, sedation, xerostomia, abdominal discomfort, nausea, and vomiting. Acute pancreatitis (serum amylase concentration up to 3,200 IU/mL) after a period of heavy cannabis use is reported, but the causal relationship is unclear.<sup>47</sup>

Life-threatening ventricular tachycardia is reported.<sup>132</sup> In six individuals with acute cardiovascular deaths, postmortem whole-blood THC concentrations ranged from 2 to 22 ng/mL (mean, 7.2 ng/mL; median, 5 ng/mL).<sup>5</sup> Although the temporal association is clear, causality is less clear because three of the six people had significant preexisting cardiac pathology. The risk of myocardial infarction is increased five times over baseline in the 60 minutes after marijuana use, but subsequently declines rapidly to baseline risk levels.<sup>105</sup> Atrial fibrillation with palpitations, nausea, and dizziness was temporally associated with smoking marijuana in four patients.<sup>41,83,151</sup>

### Chronic Use

Long-term use of cannabis is associated with a number of adverse effects.

#### Immune System

Cannabinoids affect host resistance to infection by modulating the secondary immune response (macrophages, T and B lymphocytes, acute phase and immune cytokines). However, an immune-mediated health risk from using cannabis was not documented.<sup>81</sup>

#### Respiratory System

Chronic use of smoked marijuana is associated with clinical findings compatible with obstructive lung disease.<sup>161</sup> Smoking marijuana delivers more particulates to the lower respiratory tract than does smoking tobacco,<sup>171</sup> and marijuana smoke contains carcinogens similar to tobacco smoke. Case reports and a hospital-based case control study suggest that cancers of the respiratory tract (mouth, larynx, sinuses, lung) are associated with daily or near daily smoking of marijuana, although exposure to tobacco smoke and ethanol may be confounding factors.<sup>22,156,159</sup> By contrast a systematic review and a cohort study with 8 years of follow-up demonstrated no association between marijuana smoking and smoking-related cancers,<sup>53,99</sup> and a population-based case-control study found that marijuana use was not associated with an increased risk of developing oral squamous cell carcinoma.<sup>136</sup>

#### Cardiovascular System

Marijuana use is a risk for individuals with coronary artery disease. An exploratory prospective study of self-reported marijuana use among patients admitted for myocardial infarction found that patients who used marijuana were at significantly increased risk for cardiovascular and noncardiovascular mortality compared with nonusers.<sup>105,111</sup>

#### Reproductive System

Reduced fertility in chronic users is a result of oligospermia, abnormal menstruation, and decreased ovulation.<sup>18</sup> Cannabis is probably the most common illicit drug of abuse during the reproductive age. No definitive patterns of malformations are recognized.<sup>16</sup> Statistically significant reductions in birth weight (mean, 79 g less than nonusers) and length (mean, 0.5 cm shorter than nonusers) are reported in women who had urine assays positive for cannabis during pregnancy.<sup>163</sup> The results of three other studies are difficult to interpret because marijuana use in pregnancy was poorly documented.<sup>54,173</sup> Epidemiologic studies based on self-reporting of cannabis use

do not support an association between the use of cannabis during pregnancy and teratogenesis.<sup>82,89,173</sup>

The effect of maternal use of cannabis during pregnancy on neurobehavioral development in the offspring was studied. No detrimental effects were reported in children born to women who smoked marijuana daily (more than 21 cigarettes per week) in rural Jamaica.<sup>36</sup> Tremors and increased startle were reported in infants younger than 1 week of age whose mothers used cannabis during pregnancy.<sup>43</sup> These findings, which persisted beyond 3 days, were not associated with other signs of a withdrawal syndrome. There were no abnormalities in the children of parents who used more than five marijuana cigarettes per week in Ottawa, Canada, at 12, 24, and 36 months of age, but lower scores in verbal and memory domains at 48 months of age are reported.<sup>42,44,55</sup> The results of studies evaluating the effect of in utero exposure to cannabis on postnatal neurobehavioral development are equivocal because of methodologic concerns regarding exposure assessment and control of covariates,<sup>33</sup> including the continued parental use of cannabis during the postnatal and early childhood periods. The role of secondhand exposure to cannabis on postnatal and early childhood development of neurobehavioral problems remains unstudied.

### Endocrine System

In experimental animals, cannabis exposure is associated with suppression of gonadal steroids, growth hormone, prolactin, and thyroid hormone. In addition, cannabis alters the activity of the hypothalamic-pituitary-adrenal axis.<sup>18</sup> In human studies, the results are inconsistent, long term effects are not demonstrated, and clinical consequences are undefined.<sup>18</sup>

### Neurobehavioral Effects

There is a concern that chronic cannabis use results in deficits in cognition and learning that last well after cannabis use has stopped. Neuropsychological tests were administered to 27 adolescents: 10 cannabis abusers, 8 infrequent cannabis abusers, and 9 who used no psychoactive substances showed significant differences that persisted for the duration of the study (6 weeks of abstinence) between the cannabis group and the other groups in a visual retention test and a memory test.<sup>145</sup> In a study of three experienced marijuana smokers, arithmetic and recall tasks were impaired for up to 24 hours after smoking.<sup>36</sup> Adults who used cannabis more than seven times per week had impairments in math skills, verbal expression, and memory retrieval processes; people who used cannabis one to six times per week showed no impairments.<sup>11</sup> After 1 day of abstinence, 65 heavy marijuana users (median, use on 29 of past 30 days) showed greater impairment on neuropsychological tests of attention and executive functions than light marijuana users (median, use on 1 day of past 30 days).<sup>125</sup> The authors were uncertain whether this difference was caused by residual THC in the brain, a withdrawal effect from the drug, or a direct neurotoxic effect of cannabis.

There is little evidence that adverse cognitive effects persist after stopping the use of cannabis<sup>72</sup> or that cannabis use causes psychosocial harm to the user.<sup>92</sup> Patients using cannabinoids at younger ages, those using potent cannabinoids such as SCs, and those who have underlying psychiatric disorders are more likely to exhibit psychotic features after cannabinoid exposure.<sup>9,130</sup> An “amotivational syndrome” is attributed to cannabis use. The syndrome is a poorly defined complex of characteristics such as apathy, underachievement, and lack of energy.<sup>26,144</sup> The association of the syndrome with cannabis use is based primarily on anecdotal, uncontrolled observations.<sup>60</sup> Anthropologic field studies, evaluations of US college students, and controlled laboratory experiments have failed to identify a causal relationship between cannabis use and the amotivational syndrome.<sup>60</sup> A study evaluating the role of depression in the amotivational syndrome found significantly lower scores on “need for achievement” scales in heavy users (median, daily use for 6 years) with depressive symptoms compared with heavy users without depressive symptoms and light users (median, several times per month for 4.5 years) with or without depressive symptoms.<sup>113</sup> These data suggest that symptoms attributed to an amotivational syndrome are caused by depression, not cannabis.

Another study found that behavior that could be interpreted as amotivation was inversely related to the perceived size of the reward.<sup>26</sup>

### Abuse, Dependence, and Withdrawal

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, defines marijuana abuse as repeated instances of use under hazardous conditions; repeated, clinically meaningful impairment in social, occupational, or educational functioning; or legal problems related to marijuana use. The amount, frequency, and duration of cannabis use required to develop dependence are not well established.<sup>25,154</sup> Much of the support for cannabis dependence is based on the existence of a withdrawal syndrome. In animals repeatedly given cannabis, the administration of a CB<sub>1</sub> receptor antagonist produced signs of withdrawal.<sup>87,152</sup> In humans, chronic users experience unpleasant effects when abstaining from cannabis.<sup>19</sup> The time of onset of withdrawal symptoms is not well characterized.<sup>18</sup> The most reliably reported effects are irritability, restlessness, and nervousness as well as appetite and sleep disturbances.<sup>152</sup> Other reported acute withdrawal manifestations include tremor, diaphoresis, fever, and nausea. These symptoms and signs are reversed by the oral administration of THC.<sup>9,51</sup> The duration of withdrawal manifestations, without treatment, is not clearly established.<sup>20,152</sup> There are reports of a withdrawal syndrome observed after heavy and prolonged non-classical SC use.<sup>32, 91,114,139</sup>

### Cannabinoid Hyperemesis Syndrome

Chronic, heavy marijuana use is associated with a clinical syndrome (CHS) composed of abdominal discomfort, nausea, and hyperemesis. Symptoms are often refractory to opioids and antiemetics.<sup>166</sup> Patients typically have multiple visits to the emergency department and are subjected to a host of diagnostic and therapeutic modalities ranging from CT scans and endoscopy to cholecystectomy. The hallmark of the syndrome is almost immediate relief of symptoms with bathing or showering in hot water, and a major diagnostic feature is compulsive bathing. The pathophysiology of this syndrome is unclear. In animal models, excessive cannabinoid administration results in downregulation of CB<sub>1</sub> receptors. Endogenous cannabinoids, such as anandamide, demonstrate increased binding affinity for other G protein receptors such as transient receptor potential cation channel subfamily V member 1 (TPRV1).

Relief with hot water may indicate dysfunction of pain perception, excess substance P release, and involvement of TRPV1 which these factors may assist in elucidating the mechanism for this syndrome as well as providing new treatment modalities.<sup>133</sup> This hypothesis is supported by reports of successful treatment of CHS with topical capsaicin. Ultimately, resolution of this syndrome depends on cessation of marijuana use.<sup>3,24,35,45,149,150,166</sup>

Reports also exist of successful CHS treatment with benzodiazepines, dopamine antagonists, and substance P inhibitors. Opioids are not shown to be effective and are not indicated. Upon discharge, patients should be educated that the syndrome will likely return if the individual continues to use exogenous cannabinoids, and full resolution of symptoms should take place in 10 to 14 days.

### CANNABIS AND DRIVING

The perceptual alterations caused by cannabis suggest that its recent use could be associated with automobile crashes. Experimental and epidemiologic studies have provided limited evidence with regard to the effects of cannabis use on driving ability. The published analytical studies of the relationship between cannabis and driving behavior and motor vehicle crashes were reviewed elsewhere.<sup>7</sup> In experimental driving studies, cannabis impairs driving ability, but cannabis using drivers recognize their impairment and compensate for it by driving at slower speeds and increasing following distance. However, the slower reaction time caused by cannabis results in impaired emergency response behavior.

The epidemiologic studies evaluating the association of cannabis use and traffic crashes provide no evidence that cannabis alone increases the

risk of causing fatal crashes or serious injuries.<sup>7,119</sup> Regardless, cannabis use decreases reaction times and results in significant driving impairment.<sup>52</sup> One study comparing past driving records of subjects entering a drug treatment center with control participants found that a self-reported history of cannabis use was associated with a statistically significant increase in adjusted relative risk for all crashes (relative risk, 1.49; 95% confidence interval {CI}, 1.17–1.89) and for “at fault” crashes (relative risk, 1.68; 95%CI, 1.21–2.34).<sup>29</sup>

## DIAGNOSTIC TESTING

Cannabinoids can be detected in plasma or urine. Immunoassays are routinely available; gas chromatography–mass spectrometry (GC-MS) is the most specific assay and is considered the reference method.

Enzyme-multiplied immunoassay technique (EMIT) is a qualitative urine test that is often used for screening purposes. Enzyme-multiplied immunoassay technique identifies the metabolites of THC. In these tests, the concentrations of all metabolites present are additive. For the EMIT II Cannabinoid Assay, the cutoff concentration for distinguishing positive from negative samples is 20 ng/mL. A positive test result means that the total concentration of all the assayed metabolites present in the urine is at least 20 ng/mL. A positive urine test result for cannabis only indicates the presence of cannabinoids, and it does not identify which metabolites are present or at what concentrations. Qualitative urine test results do not indicate or measure toxicity or degree of exposure. The National Institute on Drug Abuse guidelines for urine testing specify test cutoff concentrations of 50 ng/mL for screening and 15 ng/mL for confirmation.

Variables affecting the duration of detection of urinary metabolites include dose, duration of use, acute versus chronic use, route of exposure, and sensitivity of the method. In addition, factors affecting the quantitative values of urine THC and metabolites include urine volume, concentration, and pH. Using GC/MS, metabolites are typically detected in the urine up to 7 days after the use of single marijuana cigarette.<sup>64,65</sup>

The length of time between stopping cannabis use and a negative EMIT urine test result (<20 ng/mL) depends on the extent of use. Release of THC from adipose tissue is important in drug test interpretation because many chronic users release cannabinoids in quantities sufficient to result in positive urine test results for several weeks. In addition, vigorous exercise stimulates the release of cannabinoids from fat depots. In light users being tested daily under observed abstinence, the mean time to the first negative urine test result is 8.5 days (range, 3–18 days), and the mean time to the last positive urine is 18.2 days (range, 7–34 days).<sup>39</sup> In heavy users (mean, 9 years of using at least once a day) being tested under the same conditions, the mean time to the first negative urine test result (EMIT assay less than 20 ng/mL) was 19.1 days (range, 3–46 days), and the mean time to the last positive urine sample was 31.5 days (range, 4–77 days).<sup>39</sup>

Standard laboratory analyses identify THC and its metabolites but cannot identify the source of the THC (eg, marijuana, hashish, dronabinol). Immunoassays for THC will not identify nabilone because it is not THC; however, nabilone can be specifically identified using high-performance liquid chromatography–tandem mass spectrometry.<sup>146</sup>

Immunoassays give false-negative and false-positive test results (Table 74–1). To help identify evidence tampering, negative urine immunoassays should be accompanied by examining the urine for clarity and measuring urinary specific gravity, pH, temperature, and creatinine<sup>146,163</sup> (Chap. 7).

Immunoassays for THC will not detect nonclassical SCs or their metabolites. Commercial urine immunoassays are available but need to be directed toward a specific nonclassical SCs. High-performance liquid chromatography–tandem mass spectrometry or gas chromatography mass spectrometry are currently the gold standard for laboratory confirmation for SCs, but their clinical utility is limited retrospective confirmation. Further challenges are presented by the multitude of known nonclassical SCs and the rate at which new illicit SCs are introduced to the illegal high market.<sup>49,70,76,78,107,108,135,160,164</sup>

**TABLE 74–1** Xenobiotics or Conditions Reported to Produce Inaccurate Screening Test Results for Tetrahydrocannabinol

False Negative <sup>a</sup>	False Positive
Bleach (NaOCl)	Dronabinol
Citric acid	Efavirenz
Detergent additives	Ethacrynic acid
Dettol	Hemp seed oil
Dilution	Nonsteroidal antiinflammatory drugs
Glutaraldehyde	Promethazine
Lemon juice	Riboflavin
Niacin	
Potassium nitrite (KNO <sub>2</sub> )	
Table salt (NaCl)	
Tetrahydrozoline	
Vinegar (acetic acid)	
Water	

<sup>a</sup>Xenobiotics “possibly” producing false-negative urine test results are usually added to a urine sample, not ingested.

## Passive Inhalation

Studies of passive exposure to marijuana smoke and the urinary excretion of cannabinoids have used enclosed spaces with nonsmokers present during and after active smoking by others.<sup>31,86,110,119,122</sup> In an unventilated room (12,225.8 L of air), five adult volunteers were exposed to the side stream smoke of 4 or 16 marijuana cigarettes (THC, 25 mg/cigarette) smoked simultaneously over 1 hour on each of 6 consecutive days.<sup>33</sup> After being exposed to four marijuana cigarettes, four of the volunteers had at least one positive urine by EMIT assay (cutoff, 20 ng/mL) at some unspecified time during the six study days; exposure to 16 marijuana cigarettes resulted in positive EMIT assays only after the second day of exposure.

In a car (1,650 L of air), three adult volunteers were exposed to the smoke from 12 marijuana cigarettes smoked by two people over 30 minutes.<sup>110</sup> Enzyme-multiplied immunoassay technique analyses of urine samples from one passive inhaler were positive at time 0 to 4 hours and on days 2 and 3; a second passive inhaler had one positive urine test result at time 4 to 24 hours after exposure.

Three adult volunteers in an unventilated room (21,600 L of air) were exposed to the side stream smoke of four marijuana cigarettes (THC, 27 mg/cigarette) smoked simultaneously over 1 hour.<sup>112</sup> The concentrations of cannabinoids in urine samples taken 20 to 24 hours after exposure were less than 6 ng/mL when analyzed using radioimmunoassay (RIA) methodology. Another study used an unventilated room (total volume of 27,950 L) containing three desks and a filing cabinet.<sup>86</sup> Over 10 to 34 minutes, each of six volunteers smoked a marijuana cigarette (THC, 17.1 mg/cigarette) and left the room. Four nonsmoking men were in the study room for 3 hours from the start of smoking. The door was opened and closed 18 times during the study. The maximum urine cannabinoid concentration (measured by RIA) in the nonsmokers was 6.8 ng/mL at 6 hours after the start of smoking.

Another study used a closed room (15,500 L of air) with each of four participants smoking two marijuana cigarettes containing 2.5% THC on one occasion and 2.8% THC on a second occasion.<sup>122</sup> On each occasion, two nonsmoking participants were in the room for 1 hour from the onset of smoking. None of the nonsmokers’ urine samples (0–24 hours) from either exposure period tested positive on an EMIT assay with a cutoff of 20 ng/mL. An identical experiment in a closed car (~3,500 L of air) resulted in 1 of 23 urine specimens testing positive at 6 hours.

Therefore, passive inhalation of marijuana smoke is unlikely to result in positive urine test results unless the exposure is substantial.

## Saliva

Saliva samples are used to establish the presence of cannabinoids and time of cannabis consumption. Cannabinoids (THC, THC-COOH, 11-OH-THC) in saliva are derived from either the smoke of the marijuana or hashish or from a preliminary metabolism in the mouth.<sup>143</sup> Saliva THC concentrations above 10 ng/mL are consistent with recent use and correlate with subjective toxicity and heart rate changes.<sup>101</sup>

## Hair

Hair sample analysis is not useful in identifying THC or its metabolites. Only small quantities of non-nitrogen-containing substances, such as cannabinoids, are found in hair pigments.<sup>37,80,102</sup>

## Sweat

Perspiration deposits drug metabolites on the skin, and these are renewed even after the skin is washed. Detection threshold is reported to be 10 ng/mL, but forensic confirmation by alternative means is required.<sup>80</sup>

## Estimating Time of Exposure

A measurable serum concentration of THC is consistent with recent exposure and toxicity, but there is poor correlation between serum THC concentrations and actual clinical effects.<sup>61</sup> The ratio of THC to THC-COOH is used to estimate time of smoking marijuana. Similar concentrations of each indicate cannabis use within 20 to 40 minutes and imply toxicity. In naïve users, a concentration of THC-COOH that is greater than THC indicates that use probably occurred more than 30 minutes ago. The high background concentrations of THC-COOH in habitual users make estimations of time of exposure unreliable in this population.

Serum concentrations of THC and THC-COOH were used in a logarithmic equation to predict the time since smoking a marijuana cigarette.<sup>94</sup> The ratio provided acceptable results up to 3 hours after smoking (predicted time of exposure averaged 27 minutes longer than actual exposure time), but more than 3 hours after smoking, the predicted exposure time was overestimated by 3 hours. Mean overestimations of predicted exposure time of 2.5 to 4.2 hours for smoking and of 1.6 hours for ingestions are reported when serum samples are taken more than 4 hours after exposure.<sup>63</sup>

Chronic use or oral administration of cannabis increases the concentration of 11-OH-THC relative to the concentrations of THC or THC-COOH. In these cases, estimating time of exposure based on relative concentrations is problematic.<sup>62</sup> In four participants, ingestion of cannabis produced total serum metabolite concentrations less than 20 times the serum THC concentration for 3 hours after ingestion, suggesting that a ratio of this magnitude is consistent with recent oral consumption.<sup>86</sup>

## MANAGEMENT

Gastrointestinal (GI) decontamination is not recommended for patients who ingest cannabis products, nabilone, dronabinol, or nonclassical SCs because clinical toxicity is rarely serious and responds to supportive care. In addition, a patient with a significantly altered mental status, such as somnolence, agitation, or anxiety, has risks associated with GI decontamination that outweigh the potential benefits of the intervention.

We recommend that agitation, anxiety seizures or transient psychotic episodes be treated with quiet reassurance and benzodiazepines (midazolam 1–2 mg intramuscularly or diazepam 5–10 mg intravenously) as needed. The management of patients exposed to SCs should not be expected to mirror that of THC or prescription THC-based cannabinoids. Symptomatic and supportive care is often necessary.

Laboratory evaluation should be initiated for signs of electrolyte disturbances and direct toxicity of the CNS, cardiovascular, renal, and musculoskeletal systems. Appropriate crystalloid fluid resuscitation should be given for rhabdomyolysis and acute kidney injury.

Antipsychotics are not recommended at this time during any phase of undifferentiated agitated delirium. If psychotic features persist after the resolution of sympathomimetic features, a quiet space with close observation

is indicated, and antipsychotic medications are reasonable if resolution is prolonged. Patients should be observed until asymptomatic.

If available, drug samples in addition to the patient's blood and urine, although not clinically useful, may aid in unknown designer SC identification and understanding of clinical effects.

There are no specific antidotes for cannabis or SC toxicity. Coingestants, such as cocaine, ethanol, designer amphetamines, methylxanthines, and long-acting  $\beta$ -adrenergic agonists, should be identified and their effects anticipated and treated as indicated.

## SUMMARY

- Phytocannabinoids were used for centuries both as medicinal substances and as intoxicants.
- Despite the collective human history with cannabinoids, we are only beginning to understand the endocannabinoid system and the consequences of alterations to that system.
- Medical use of THC and smoked marijuana have long existed, and although the safety profile of these xenobiotics is established, evidence of the efficacy of medical marijuana over the gamut of currently prescribed maladies is sparse. Still, the cannabinoid system provides an attractive target for treatment of chronic pain and appetite modulation, but more rigorous and properly designed investigations are needed.
- The toxicity profile of traditional cannabinoids and designer SCs used as drugs of abuse and research chemicals are as different as their chemical structures. Clinicians, users, and public health policy makers alike would do well to separate these groups of cannabinoids in both thought and practice.

## COCAINE

Craig G. Smollin and Robert S. Hoffman

### HISTORY AND EPIDEMIOLOGY

Cocaine is contained in the leaves of *Erythroxylum coca* (coca plant), a shrub that grows abundantly in Colombia, Peru, Bolivia, the West Indies, and Indonesia. As early as the sixth century, the inhabitants of Peru chewed or sucked on the leaves for social and religious reasons. In the 1100s, the Incas used cocaine-filled saliva as local anesthesia for ritual trepanations of the skull.<sup>78</sup>

In 1859, Albert Niemann isolated cocaine as the active ingredient of the plant. By 1879, Vassili von Anrep demonstrated that cocaine could numb the tongue.<sup>118</sup> However, Europeans knew little about cocaine until 1884, when the Austrian ophthalmologist Karl Koller introduced cocaine as an effective local anesthetic for eye surgery and Koller's colleague, Sigmund Freud, wrote extensively on the psychoactive properties of cocaine.<sup>63</sup> Following these revelations, Merck, the main cocaine producer in Europe, increased production from less than 0.75 pounds in 1883 to more than 150,000 pounds in 1886.<sup>114</sup>

Simultaneously, reports of complications from the therapeutic use of cocaine began to appear. In 1886, a 25-year-old man had a "pulseless" syncope after cocaine was applied to his eye to remove a foreign body.<sup>229</sup> By 1887, more than 30 cases of severe toxicity were reported,<sup>198</sup> and by 1895, at least eight fatalities resulting from a variety of doses and routes of administration were summarized in one article.<sup>66</sup> Recreational cocaine use was legal in the United States until the passage of the Harrison Narcotics Act of 1914, when cocaine was restricted to medicinal use. Not until 1982, however, was the first cocaine-associated myocardial infarction (MI) reported in the United States.<sup>36</sup>

Currently, cocaine is an approved pharmaceutical. It is used primarily for topical anesthesia of cutaneous lacerations or during otolaryngology procedures as a vasoconstrictor and topical anesthetic. Although multiple factors fostered a decline in the medicinal use of cocaine,<sup>24,73,142</sup> the recreational use of cocaine remains a significant problem.

The United Nations office on Drugs and Crime estimates that there are 19 million cocaine users worldwide.<sup>233</sup> In the United States, it was estimated that in 2015, there were 1.9 million cocaine users,<sup>51</sup> and in 2011, cocaine was the most common illicit xenobiotic resulting in emergency department (ED) visits.<sup>52</sup> The dramatic evolution of the cannabinoid and opioid epidemics will probably change the profile of the ED patients using illicit xenobiotics (Chaps. 36 and 74).

### PHARMACOLOGY

The alkaloid form of cocaine, benzoylecgonine, is a weak base that is relatively insoluble in water. It is extracted from the leaf by mechanical degradation in the presence of a hydrocarbon. The resulting product is converted into a hydrochloride salt to yield a white powder, cocaine hydrochloride, which is very water soluble. Cocaine hydrochloride is used by insufflation, application topically to mucous membranes, injection after dissolution in water, or ingestion; however, it degrades rapidly when pyrolyzed. Smokable cocaine (crack) is formed by dissolving cocaine hydrochloride in water and adding a strong base. A hydrocarbon solvent is added, the cocaine base is extracted into the organic phase, and then evaporated. The term "free-base" refers to the use of cocaine base in solution.

Cocaine is rapidly absorbed after all routes of exposure; however, when applied to mucous membranes or ingested, its vasoconstrictive properties slow the rate of absorption and delay the peak effect. Bioavailability when smoking cocaine exceeds 90% and is approximately 80% after nasal application.<sup>110</sup> Data for ingested cocaine and application to other mucous membranes such as the urethra, vagina, or rectum are inadequately documented. **Table 75-1** lists the typical onsets and durations of action for various routes of cocaine use.

After absorption, cocaine is approximately 90% bound to plasma proteins, primarily  $\alpha_1$ -acid glycoprotein.<sup>178</sup> Based on human volunteer studies with small doses of cocaine, the volume of distribution is reported to range from 1.6 to 2.7 L/kg,<sup>11,32,110</sup> but it is unclear if the volume of distribution changes with overdose.

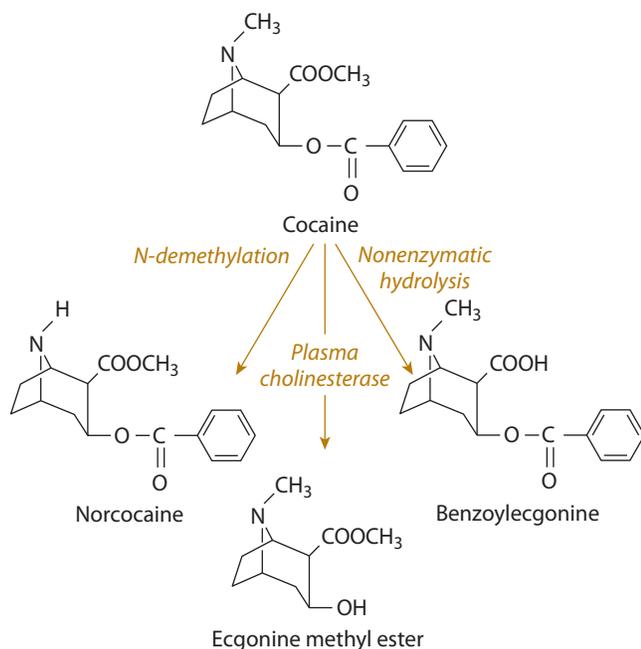

The metabolism of cocaine is complex and dependent on both genetic and acquired factors. Three major pathways of cocaine metabolism are well described (**Fig. 75-1**). Cocaine undergoes *N*-demethylation in the liver to form norcocaine, a minor metabolite that rarely accounts for more than 5% of drug.<sup>106,223</sup> However, norcocaine readily crosses the blood-brain barrier and produces clinical effects in animals that are quite similar to cocaine.<sup>17,113,210</sup> Nearly half of a dose of cocaine is both nonenzymatically<sup>222</sup> and enzymatically hydrolyzed<sup>48</sup> to form benzoylecgonine (BE). When BE is injected into animals, some reports suggest that it is virtually inactive,<sup>115,218</sup> but other studies demonstrate cerebral vasoconstriction<sup>41</sup> and seizures.<sup>122,160</sup> When either injected directly into the cerebral ventricles<sup>161,210</sup> or applied to the surface of cerebral arteries,<sup>145</sup> BE is a potent vasoconstrictor. Although BE traverses the blood-brain barrier poorly,<sup>162</sup> the potential effects are of concern as some BE is probably formed from cocaine that has already entered the central nervous system (CNS). In vitro, BE has little or no effect on cardiac sodium or potassium channels.<sup>41,58</sup> Finally, plasma cholinesterase (PChE) and other esterases metabolize cocaine to ecgonine methyl ester (EME). In normal individuals, between 32% and 49% of cocaine is metabolized to EME.<sup>4,106</sup> Similar to BE, EME crosses the blood-brain barrier poorly.<sup>161</sup> Although many authors state that EME has little or no pharmacologic activity,<sup>160,161,207</sup> diverse animal models demonstrate contradictory results, concluding that EME is a vasodilator,<sup>145,176,208</sup> sedative, anticonvulsant,<sup>210</sup> and protective metabolite against lethal doses of cocaine.<sup>90</sup>

Genetic or acquired alterations in PChE activity modulate the effects of cocaine. Early in vitro studies showed that cocaine was poorly metabolized in serum from patients with succinylcholine sensitivity (low PChE activity). In subsequent studies and case series, patients with low PChE activity

**TABLE 75-1** Pharmacology of Cocaine by Various Routes of Administration

Route of Exposure	Onset of Action (min)	Peak Action (min)	Duration of Action (min)	Relative Peak Concentrations (ng/mL)
Intravenous	<1	3-5	30-60	180 ± 56
Nasal insufflation	1-5	20-30	60-120	220 ± 39
Smoking	<1	3-5	30-60	203 ± 88
Gastrointestinal	30-60	60-90	30-140	210 ± 58

Data from Jeffcoat AR, Perez-Reyes M, Hill JM, et al. Cocaine disposition in humans after intravenous injection, nasal insufflation (snorting), or smoking. *Drug Metab Dispos.* 1989 Mar-Apr;17(2):153-159 and Van Dyke C, Jatlow P, Ungerer J, et al. Oral cocaine: plasma concentrations and central effects. *Science.* 1978 Apr 14;200(4338):211-213.

**FIGURE 75-1.** Metabolism of cocaine. The three principal metabolic pathways of cocaine are depicted.

demonstrate increased sensitivity to cocaine,<sup>89,174</sup> findings that are corroborated in multiple animal models.<sup>26,90,143</sup>

Multiple other metabolites of cocaine are well characterized.<sup>39</sup> Several have clinical or diagnostic importance. In 1990, a unique metabolite was identified in patients who smoke cocaine, now known either as anhydroecgonine methyl ester (AEME) or methylecgonide.<sup>108</sup> The presence of this compound and its metabolite, ecgonidine, are useful to help determine the route of administration in cocaine users.<sup>206</sup> Additionally, AEME has demonstrable agonism and antagonism at various muscarinic receptor subtypes, which has important clinical implications.<sup>65,250</sup> Animal models also suggest that AEME has greater neurotoxic potential compared with cocaine.<sup>65</sup>

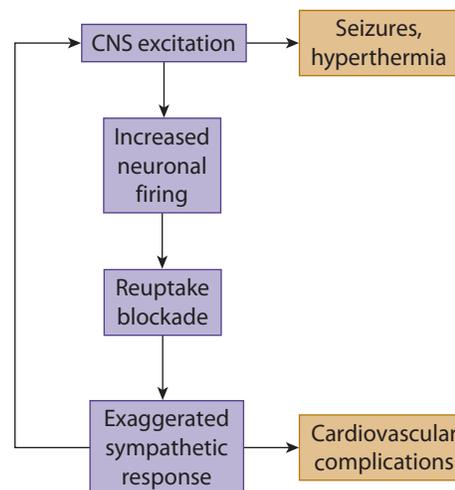

Ethanol has a unique pharmacologic interaction with cocaine. A transesterification reaction between the two drugs produces ethylbenzoylecgonine, which is also called “ethyl cocaine” or “cocaethylene” (CE).<sup>17</sup> In human volunteers given cocaine and ethanol, CE accounted for approximately 17% of the metabolites, producing a decrease in the amount of BE and an increase in the amount of EME formed.<sup>82,83</sup> Cocaethylene has a longer duration of action than cocaine and similar neurotoxic and cardiotoxic effects.

## PATHOPHYSIOLOGY

### Neurotransmitter Effects

Cocaine blocks the reuptake of biogenic amines. Specifically, these effects are described on serotonin and the catecholamines dopamine, norepinephrine, and epinephrine. Several animal investigations elucidated the particular roles of each neurotransmitter. Mice lacking the dopamine transporter are relatively insensitive to the locomotor effects of cocaine.<sup>68</sup> Whereas tachycardia emanates from adrenally derived epinephrine, hypertension results from neuronally derived norepinephrine.<sup>227,228</sup> Serotonin is an important modulator of dopamine and has a role in cocaine addiction, reward, and seizures.<sup>80,133,153</sup>

Although much emphasis is placed on the reuptake blockade of these biogenic amines, it is clear that this effect is insufficient to account for the clinical manifestations of cocaine toxicity. Other xenobiotics that block the reuptake of biogenic amines, such as cyclic antidepressants, produce quite distinct clinical manifestations<sup>230</sup> (Chap. 68). Xenobiotics that block the effects of dopamine, epinephrine, and norepinephrine not only fail to protect against cocaine toxicity but actually exacerbate toxicity.<sup>29,75,142,201</sup> Although this results in part from an unopposed  $\alpha$ -adrenergic effect, hypertension and vasospasm fail to explain the increase in psychomotor agitation, seizures, and

**FIGURE 75-2.** Cocaine-induced central nervous (CNS) system effects modulate peripheral events.

hyperthermia that result.<sup>29,75</sup> These effects most likely result from an interaction between cocaine and excitatory amino acids. Cocaine increases excitatory amino acid concentrations in the brain,<sup>217</sup> and excitatory amino acid antagonists prevent both seizures and death in experimental animals.<sup>18,192</sup> Finally, because experimental evidence in animals<sup>28,75,211</sup> and clinical experience in humans demonstrate that sedation treats both the central effects of cocaine and the peripheral effects of biogenic amines, a newer model was proposed (Fig. 75-2). This model emphasizes the necessity of diffuse CNS excitation as a prerequisite for cocaine toxicity, explains experimental and clinical observations, and provides insight into the treatment of acute toxicity.

### Cardiovascular Effects

Cocaine use is associated with myocardial ischemia and MI. The increased risk of MI results from several different mechanisms, including hypertension and tachycardia with resultant increase in myocardial oxygen demand, vasospasm resulting in decrease coronary artery blood flow, accelerated atherogenesis, and hypercoagulability. In addition, chronic exposure to high concentrations of catecholamines results in mitochondrial disruption and oxidative stress on a cellular level with direct myocardial injury.<sup>138</sup>

### Vasospasm

Although increased myocardial oxygen demand is sufficient to cause ischemia in some individuals, it is clear that cocaine also produces profound vasoconstriction. Evidence suggests that cocaine-induced vasoconstriction is mediated through both neuronal norepinephrine and BE.<sup>127,144</sup> Benzoylecgonine has a direct effect on vessels that is calcium mediated.<sup>144</sup> Additionally nicotine, which is simultaneously used by many substance users, has additive, if not synergistic, effects with cocaine.<sup>166</sup>

### Oxidative Stress

Chronic exposure to elevated concentrations of catecholamines in the context of repetitive cocaine use results in the formation of reactive oxygen species and oxidation products known as “aminochromes” that directly damage myocardial cells. Evidence suggests that this pathophysiologic pathway is important in the development of cocaine-induced cardiomyopathy.<sup>138</sup>

### Atherogenesis

Cocaine use accelerates atherosclerosis. Rabbits fed a normal diet supplemented with cholesterol do not develop atherosclerotic vascular disease. However, when that diet includes cocaine, rabbits develop classic atherosclerotic lesions.<sup>120,129,130</sup> Experiments with human endothelial cells demonstrate that cocaine directly increases the permeability to lipids by altering tight junctions.<sup>121</sup> This probably promotes the formation of subendothelial atherosclerotic plaques.

### Dysrhythmias

Like other local anesthetics (Chap. 64), cocaine blocks neuronal sodium channels, thereby preventing saltatory conduction. Because of homology between neuronal and cardiac sodium channels, cocaine also inhibits the rapid inward  $\text{Na}^+$  current responsible for phase 0 depolarization of the cardiac action potential (Chaps. 15 and 68). Experimental evidence suggests that cocaine enters the sodium channel and binds on the inner membrane.<sup>42,119,183</sup> Like many sodium channel blockers, binding is both pH and use dependent such that binding increases as pH falls or heart rate increase (Chap. 68).<sup>43,242</sup> Furthermore, although norcocaine has a greater affinity for inactivated sodium channels, it has a much more rapid offset of action than cocaine.<sup>42</sup> Consequently, cocaine can be characterized as a Vaughan-Williams class 1C antidysrhythmic<sup>249</sup> (Chap. 57). Cocaine-induced QRS complex prolongation is exacerbated by Vaughan-Williams class IA antidysrhythmics<sup>247</sup> and ameliorated by hypertonic sodium bicarbonate, hypertonic sodium chloride, and lidocaine.<sup>13,73,177</sup> Another effect of sodium channel blockade, the Brugada pattern, is also associated with cocaine use (Fig. 15–12).<sup>141,171</sup>

In addition to its sodium channel-blocking properties, cocaine also blocks cardiac potassium channels (Chap. 15). This results in QT interval prolongation<sup>181,226,242</sup> and increases the risk of torsade de pointes.<sup>209</sup> Cocaethylene also has dysrhythmogenic effects.<sup>172</sup> In vivo experiments demonstrated inhibition of the myocardial hERG potassium channels, which helps to explain this phenomenon.<sup>58</sup> In animal studies, CE is associated with increased incidence of dysrhythmias, prolonged myocardial depression, and increased lethality.<sup>115,246</sup>

### Hematologic Effects

Enhanced coagulation and impaired thrombolysis compound the effects of accelerated atherogenesis and vasospasm. Cocaine activates human platelets and causes  $\alpha$ -granule release, resulting in platelet aggregation.<sup>85,126</sup> Thus, even in the absence of endothelial injury, cocaine initiates a thrombotic cascade while simultaneously enhancing the activity of plasminogen activator inhibitor type 1 (PAI-1), thereby impairing clot lysis.<sup>165</sup>

### Pulmonary Effects

#### Bronchospasm

The association between cocaine use and asthma<sup>195</sup> was not recognized until smoked cocaine became prevalent.<sup>56</sup> Furthermore, experiments in human volunteers demonstrate that only smoked cocaine (not intravenous {IV} cocaine) produces bronchospasm.<sup>225</sup> Although it is possible that bronchospasm results from direct administration of cocaine to the airways, inhaled contaminants of cocaine, or thermal insult, and the unique pyrolytic metabolite of cocaine that acts as a muscarinic agonist (AEME) produces bronchospasm in experimental animals.<sup>31</sup>

## CLINICAL MANIFESTATIONS

Many clinical manifestations of toxicity develop immediately after cocaine use. These are typically associated with the sympathetic overactivity, and their duration of effect is predictable based on the pharmacokinetics of cocaine use. Other manifestations, such as those associated with tissue ischemia, often present in a delayed fashion, with a clinical latency of hours to even days after last cocaine use. The reasons for this delay are not clear but may relate to the presence of an altered sensorium associated with acute cocaine use and its anesthetic effects (see the later section Cessation of Use).

Vital sign abnormalities that develop during cocaine toxicity are characteristic of the sympathomimetic toxidrome. Thus, varying degrees of hypertension, tachycardia, tachypnea, and hyperthermia occur. Although any of these vital sign abnormalities can be life threatening, experimental and clinical evidence suggests that hyperthermia is the most critical.<sup>29,75,150</sup> Initially, with typically used doses, and at any time with a massive dose, apnea, hypotension, and bradycardia can result, all from direct suppression (anesthesia) of brainstem centers.<sup>127,142,158</sup> These effects are fleeting and rarely noted when patients present a health care facility when either the sympathetic overdrive rapidly ensues or sudden death results. Additional sympathomimetic findings include mydriasis, diaphoresis, and neuropsychiatric manifestations.

Cocaine produces end-organ toxicity in virtually every organ system in the body. These events result from vasospasm, hemorrhage secondary to increased vascular shear force ( $dp/dt$ ), or enhanced coagulation. Each organ system is discussed separately in the following sections.

### Central Nervous System

Seizures, coma, headache, focal neurologic signs or symptoms, or behavioral abnormalities that persist longer than the predicted duration of effect of cocaine should alert the clinician to a potential catastrophic CNS event. Hemorrhage occurs at any anatomic site in the CNS. Subarachnoid, intraventricular, and intraparenchymal bleeding are all well described in association with cocaine use.<sup>2,46,136,148,185,212</sup> Early discussions suggested an underlying predisposition due to the presence of arteriovenous malformations or congenital aneurysms,<sup>248</sup> but subsequent larger studies failed to support this analysis, suggesting that effects occur independently of preexisting disease.<sup>2,170,237</sup> Ruptured intracerebral aneurysms in cocaine users are almost exclusively in the carotid artery circulation.<sup>2,170,237</sup> Presumably, CNS bleeding is a manifestation of abnormal shear force. Spontaneous extraaxial bleeding is also associated with cocaine use.<sup>200</sup>

Both vasospastic infarction and transient ischemic attack are reported in association with cocaine use.<sup>46,47,136</sup> In one epidemiologic study, women younger than age 45 years who had strokes were seven times more likely to report cocaine use than control participants.<sup>182</sup> Patients can present with any of the classic physical findings associated with thrombotic or embolic stroke. Additionally, paralysis is reported after cocaine-associated vasospasm of an anterior spinal artery.<sup>46,164</sup>

Seizures are commonly provoked by cocaine use.<sup>92,167</sup> Typically, they are discrete and occur within minutes after exposure; however, in some cases, they occur after as long as 24 hours after last use.<sup>191</sup> Although cocaine use serves as a trigger in some patients with epilepsy, an underlying focus is not necessary for seizures to occur.<sup>123</sup>

Headache is also well described in cocaine users. Although the exact mechanism is unclear, hypertension or dysregulation of neurotransmitters are likely contributory. In addition to typical tension headache, classic migraine and cluster headaches are also reported.<sup>180,202</sup>

### Eyes, Nose, and Throat

Sympathetic excess produces mydriasis through stimulation of the dilator fibers of the iris with characteristic retention of the ability to respond to light. Like other mydriatics, cocaine produces acute narrow angle-closure glaucoma.<sup>81</sup> Vasospasm of the retinal vessels causes both unilateral and bilateral loss of vision.<sup>91,139</sup> Additionally, although cocaine produces excellent corneal anesthesia, it is highly toxic to the corneal epithelium. After application of cocaine to the eye, the superficial corneal layer is shed, resulting in pain and decreased acuity.<sup>186</sup> The loss of eyebrow and eyelash hair from thermal injury associated with smoking crack cocaine is called madarosis.<sup>224</sup>

Chronic intranasal insufflation of cocaine produces perforation of the nasal septum. This finding most likely results from repeated ischemic injury with resultant cartilage loss. This ischemia is usually asymptomatic, and necrotic tissue is sloughed. At least one reported case of wound botulism (Chap. 38) was associated with intranasal insufflation. Presumably, this resulted from accumulation of necrotic tissue in the nose, serving as a culture medium for *Clostridium botulinum*.<sup>125</sup>

Angioedema and oropharyngeal burns, located as far distally as the esophagus, are associated with smoking crack cocaine.<sup>27,33,117,159</sup> These effects are probably the result of inhalation or ingestion of superheated fumes and hot liquid (from the smoking apparatus) rather than direct toxicity from cocaine.

### Pulmonary

Pneumothorax, pneumomediastinum, and pneumopericardium are reported after both smoked and intranasal cocaine use.<sup>146,187,204,230,234</sup> These findings do not result directly from cocaine toxicity but rather are epiphenomena related to the mechanism of drug use. After insufflation or inhalation, the user commonly performs a Valsalva maneuver in an attempt to retain the drug. Bearing

down against a closed epiglottis increases intrathoracic pressure, and an alveolar bleb ruptures against the pleural, mediastinal, or pericardial surfaces.

Cocaine use exacerbates reversible airways disease, and it is common for patients to present with shortness of breath and wheezing.<sup>56,135,176,194</sup> Like so many manifestations of cocaine toxicity, it is unclear whether this is a direct effect of cocaine or related to inhalation of some contaminant of the drug. However, as discussed earlier, the muscarinic agonist effects of the pyrolysis metabolite AEME might be contributory.

“Crack lung” is the term given to an acute pulmonary syndrome that occurs after inhalational use of crack cocaine. The syndrome is a poorly defined constellation of symptoms, including fever, hemoptysis, hypoxia, acute respiratory distress syndrome, and respiratory failure. It is associated with diffuse alveolar and interstitial infiltrates on chest radiography.<sup>187</sup> Histopathology shows diffuse alveolar damage and hemorrhage with inflammatory cell infiltration and hemosiderin-laden macrophages. Eosinophilia was noted in several cases.<sup>62</sup> The syndrome is variously attributed to impurities mixed with the crack, carbonaceous material generated from pyrolysis, and direct cocaine toxicity.

Vasospasm and subsequent thrombosis of the pulmonary artery or its branches can produce pulmonary infarction.<sup>49</sup> Patients present with shortness of breath and pleuritic chest pain characteristic of a pulmonary embolus. Clinical signs and symptoms of ventilation-perfusion (V/Q) mismatch (Chap. 28), as well as abnormalities on arterial blood gas analysis, are noted.

### Cardiovascular

Chest pain or discomfort is a common ED complaint in cocaine users.<sup>21</sup> Cocaine use is associated with cardiac ischemia and infarction in young people and reportedly accounts for as much as 25% of MIs in patients younger than 45 years of age.<sup>184</sup> Although MI is of concern, only approximately 6% of patients with complaints referable to the heart manifest biochemical evidence of myocardial injury.<sup>96,243</sup> Many others have an ischemic cardiac event, but for the remainder, the differential diagnosis is broad.<sup>128</sup> Entities to consider include the pulmonary and esophageal etiologies described previously, referred abdominal symptoms (see Abdominal), chest wall injury,<sup>44,72,104,137,140</sup> aortic dissection, coronary artery dissection,<sup>203,221</sup> and dysrhythmias. No single sign or symptom or combination of signs and symptoms reliably identifies cardiovascular injury from among the discussed differential diagnosis.<sup>96</sup>

Catecholamine-induced direct myocardial toxicity contributes to both acute and chronic cardiac disease. Takotsubo cardiomyopathy is a reversible form of left ventricular apical ballooning associated with myocardial ischemia in the absence of atherosclerotic lesions. It is thought to result from catecholamine toxicity on the myocardium during high levels of stress and is also reported after cocaine use.<sup>7</sup> Chronic cocaine use is associated with a dilated cardiomyopathy,<sup>86,128</sup> the etiology of which is presumed to be the result of repeated subclinical ischemic events. Patients typically present with signs and symptoms of congestive heart failure or pulmonary edema. The pathologic finding of contraction band necrosis is indicative of some direct catecholamine-induced oxidative damage to cardiac myocytes because this finding only commonly occurs with cocaine and amphetamine use, pheochromocytoma, and in patients receiving high-dose vasopressors.<sup>60,239</sup>

### Abdominal

Abdominal pain or other gastrointestinal (GI) complaints suggest a broad differential diagnosis. Cocaine users have a disproportionate incidence of perforated ulcers.<sup>134,179,215</sup> The etiology is not elucidated but is hypothesized to be related to local ischemia of the GI tract or increased acid production associated with sympathetic activity. Vasospasm produces ischemic colitis that presents with abdominal pain or bloody stools.<sup>140,169</sup> More severe vasospasm, with or without thrombosis, leads to intestinal infarction<sup>64,87,101,175</sup> with associated hypotension and metabolic acidosis. Signs and symptoms of bowel obstruction, such as vomiting or distension, might suggest body packing (GI drug smuggling). Although less common, splenic<sup>171</sup> and renal infarctions<sup>53,163,199</sup> also occur, and splenic rupture with

associated hemoperitoneum and hemodynamic instability is reported.<sup>8,10,100</sup> Spontaneous hemoperitoneum without identifiable organ injury is also described, although occult trauma could not be definitively excluded.<sup>14</sup>

Animals frequently develop hepatotoxicity after cocaine administration. In human cocaine users, minor elevations of liver enzyme concentrations are common and rarely associated with symptoms.<sup>25,124</sup> When more severe liver injury occurs, it is usually associated with multisystem organ dysfunction from hyperthermia or another type of hepatic injury.<sup>9</sup> Isolated hepatic injury from cocaine is distinctly uncommon because of differences in metabolic pathways because animals are known to make a hepatotoxic metabolite of cocaine that is not described in humans.<sup>236</sup>

### Musculoskeletal

Rhabdomyolysis is common in all conditions that produce an agitated delirium and or hyperthermia; cocaine is no exception.<sup>40,103,196</sup> Unlike most other toxicologic disorders, however, psychomotor agitation is not a prerequisite for cocaine-associated rhabdomyolysis.<sup>251</sup> Muscle injury also results from either vasospasm or direct muscle toxicity; however, the exact mechanism remains unclear. Patients with cocaine toxicity present with a spectrum of illness that ranges from asymptomatic enzyme and electrolyte abnormalities characteristic of rhabdomyolysis, to localized or diffuse muscle pain, to frank compartment syndrome and acute kidney injury.<sup>54</sup>

Limb ischemia associated with cocaine use is reported.<sup>37,50,76,155,157</sup> Although vasospasm, accelerated atherogenesis, and increased thrombogenesis (see Pathophysiology) place users at increased risk, the majority of the cases reported above appear to result from vasospasm.

Traumatic injury is also fairly common in the setting of cocaine use.<sup>152</sup> Clinicians should be aware of the possibilities of occult fractures or other injuries that are masked by the anesthetic properties of cocaine or the patient's altered level of consciousness.<sup>142,151</sup>

### Neuropsychiatric

The neuropsychiatric effects of cocaine are most likely dose dependent. Low-dose administration produces alertness, exhilaration, hypersexual behavior, and other “desired” effects. These effects rarely bring users to health care facilities. As the cocaine dose increases, agitation, aggressive behavior, confusion, disorientation, and hallucinations develop.

Other possible manifestations include a variety of movement disorders that most likely result from dysregulation of dopamine. Some patients develop acute dystonias<sup>28,59,235</sup> or choreoathetoid movements that are referred to as “crack dancing.”<sup>45,77</sup>

### Obstetric

The majority of obstetric findings associated with cocaine use involve developmental problems in the fetus and neonate and are probably a result of a combination of chronic vascular insufficiency from cocaine-induced spasm of the uterine artery or distal vessels and other risk factors, such as poor maternal nutrition, cigarette smoking, and a lack of prenatal care (Chap. 30). These events are extensively reviewed elsewhere.<sup>30,57,214</sup> Acute cocaine use during pregnancy is associated with abruptio placentae, causing patients to present with abdominal pain and vaginal bleeding.<sup>1,61</sup> The remaining maternal and fetal complications comprise every possible complication described in nonpregnant patients.

### DIAGNOSTIC TESTING

Cocaine and BE, its principal metabolite, can be detected in blood, urine, saliva, hair, and meconium. Routine drug of abuse testing relies on urine testing using a variety of immunologic techniques (Chap. 7) Although cocaine is rapidly eliminated within just a few hours of use, BE is easily detected in the urine for 2 to 3 days after last use.<sup>4</sup> When more sophisticated testing methodology is applied to chronic users, cocaine metabolites are identified for several weeks after the last use.<sup>245</sup>

Urine testing, even using rapid point-of-care assays, offers little to clinicians managing patients with presumed cocaine toxicity because it cannot distinguish recent from remote cocaine use. In addition, false-negative

testing results when there is a large quantity of urine in the bladder with very recent cocaine use or when the urine is intentionally diluted by increased fluid intake,<sup>38</sup> leading to a urine cocaine concentration below the cutoff value and interpretation of the test result as negative. Under these circumstances, repeat testing is almost always positive. False-positive test results are extremely unlikely.

Although false-positive test results do occur, they are more common with hair testing than urine or blood because of the increased risk of external contamination.<sup>38,193</sup> Because of the very low rate of false-positive results, confirmation of a positive urine is unnecessary for medical indications (Chap. 7).

The greatest benefit for cocaine testing is in cases of unintentional poisoning or suspected child abuse and neglect. Here confirmation of a clinical suspicion is essential to support a legal argument. In addition, there is a role for urine testing of body packers, especially when the concealed xenobiotic is unknown.<sup>232</sup> Although many body packers have negative urine throughout their hospitalizations, a positive urine test result is suggestive of the concealed drug but obviously not confirmatory. More important, a conversion from a negative study on admission to a positive study not only confirms the substance ingested but also suggests packet leakage, which could be a harbinger of life-threatening toxicity (Special Considerations: SC5). Another indication for urine testing for cocaine occurs in young patients with chest pain syndromes in whom the history of drug use, specifically cocaine, is not forthcoming.<sup>93</sup> Routine diagnostic tests such as a bedside rapid reagent glucose, electrolytes, renal function tests, and markers of skeletal muscle and cardiac muscle injury are more likely to be useful than urine drug screening. Occasionally, the electrocardiogram (ECG) will show signs of ischemia or infarction, or dysrhythmias that require specific therapy. Unfortunately, in the setting of cocaine-associated chest pain, the ECG has neither the sensitivity nor the specificity necessary to permit exclusion or confirmation of cardiac injury.<sup>98</sup> Cardiac markers are therefore always required adjuncts when considering myocardial ischemia or MI. Because cocaine use is associated with diffuse muscle injury, assays for troponin are preferred over myoglobin or myocardial band enzymes of creatine phosphokinase (CPKMB).<sup>97</sup> Additionally, computed tomography (CT) angiography of the coronary arteries is reported by some to be a useful tool to exclude MI after cocaine use (CPKMB).<sup>241</sup> This test exposes the patient to high levels of radiation, and the relative risk versus benefit has not been studied, especially given the likelihood of repeated episodes of chest pain and inconsistent follow-up. For these reasons, we believe the data are insufficient to routinely recommend coronary CT at this time. Chest radiography is useful to exclude certain causes in patients with chest discomfort or to identify free air under the diaphragm when GI perforation is suspected. Supplemental diagnostic studies, such as CT scans of the head, chest, or abdomen and functional cardiac imaging, should be guided by the clinical condition of the patient.<sup>40,55,79</sup>

## CESSATION OF USE

A cocaine withdrawal syndrome is not reported. After binge use of cocaine, a “washed-out” syndrome occurs that is best described by dopamine depletion.<sup>220,231</sup> Patients complain of anhedonia and lethargy, and they have trouble initiating and sustaining movement. However, they are arousable with minimal stimulation and usually remain cognitively intact.

Symptoms typically associated with cocaine toxicity sometimes present in a delayed fashion after cessation of cocaine use. The reasons for this delay are multifactorial and not entirely apparent but are presumed to be related to prolonged elimination of metabolites such as CE; changes in receptor regulation;<sup>168</sup> or effects on platelets, coagulation, and thrombolysis that stimulate a slow cascade, leading to thrombosis.

## MANAGEMENT

### General Supportive Care

As in the case of all poisoned patients, the initial emphasis should be on stabilization and control of the patient's airway, breathing, and circulation. If

tracheal intubation is required, it is important to recognize that cocaine toxicity is a relative contraindication to the use of succinylcholine.<sup>154</sup> Specifically, in the setting of rhabdomyolysis, hyperkalemia will be exacerbated by succinylcholine administration, and life-threatening dysrhythmias may result (Chap. 66). Additionally, it is essential to recognize that PChE metabolizes both cocaine and succinylcholine.<sup>109</sup> Thus, their simultaneous use will either prolong cocaine toxicity, paralysis, or both. Human data are insufficient to predict which interaction is more likely to occur. If hypotension is present, the initial approach should be intravenous (IV) infusion of 0.9% sodium chloride solution because many patients are volume depleted as a result of poor oral intake and excessive fluid losses from uncontrolled agitation, diaphoresis, and hyperthermia. Administration of IV fluids is also important in patients with rhabdomyolysis secondary to cocaine-associated agitation and hyperthermia.

In the setting of cocaine toxicity, it is important to recognize that both animal<sup>29,75</sup> and human<sup>150</sup> experience suggests that elevated temperature represents the most critical vital sign abnormality. Determination of the core temperature is an essential element of the initial evaluation, even when patients are severely agitated. When hyperthermia is present, rapid cooling with ice water immersion is required to normalize core body temperature (Chap. 29).<sup>132</sup> Sedation or paralysis and intubation are often necessary to facilitate the rapid cooling process. We recommend not to use antipyretics, drugs that prevent shivering (chlorpromazine or meperidine), and dantrolene<sup>62</sup> because they are ineffective and have the potential for adverse drug interactions such as serotonin toxicity (meperidine) (Chap. 36) or seizures (chlorpromazine).

Sedation remains the mainstay of therapy in patients with cocaine-associated agitation. It is important to remember that cocaine use is associated with hypoglycemia caused by catecholamine discharge.<sup>19,163</sup> Clinical findings of hypoglycemia and increased catecholamines are similar; consequently, a rapid bedside glucose should be obtained, or hypertonic dextrose should be empirically administered if indicated before or while simultaneously achieving sedation.

Both animal models<sup>29,75</sup> and extensive clinical experience in humans support the central role of benzodiazepines. Antipsychotics have also been used in the treatment of acute cocaine toxicity. A meta-analysis evaluating benzodiazepines and antipsychotics in animal models of cocaine toxicity found that both reduced mortality rates. However, benzodiazepine treatment reduced the mortality rate by 52% compared with only 29% for antipsychotics.<sup>84</sup> Although the choice among individual benzodiazepines is not well studied, an understanding of the pharmacology of these drugs allows for rational decision making. The goal is to use parenteral therapy with a drug that has a rapid onset and a rapid peak of action, making titration easy. Using this rationale, we recommend midazolam and diazepam over lorazepam because significant delay to peak effect for lorazepam often results in oversedation when it is dosed rapidly or in prolonged agitation when the appropriate dosing interval is used. Drugs should be administered in initial doses that are consistent with routine practices and increased incrementally based on an appropriate understanding of their pharmacology. For example, if using diazepam, the starting dose should be 5 to 10 mg IV, which can be repeated every 3 to 5 minutes and increased if necessary. Large doses of benzodiazepines are often necessary (on the order of 1 mg/kg of diazepam). This may result from cocaine-induced alterations in benzodiazepine receptor function (Antidotes in Depth: A26).<sup>69,70,112</sup>

On the rare occasion when benzodiazepines fail to achieve an adequate level of sedation, it is reasonable to administer either a rapidly acting barbiturate or propofol. There is recent interest in the use of ketamine to control patients with acute agitation,<sup>35,99,173,190,205</sup> but there is insufficient evidence demonstrating safety and efficacy to support its use in patients with cocaine-associated behavioral disorders. Controlled animal studies clearly show that the use of phenothiazines or butyrophenones as monotherapy is contraindicated.<sup>29,75,139</sup> In animal models, these drugs enhance toxicity (seizures), lethality, or both. Additional concerns about these drugs include

interference with heat dissipation, exacerbation of tachycardia, prolongation of the QT interval, induction of torsade de pointes, and precipitation of dystonic reactions.

After sedation is accomplished, often no additional therapy is required. Specifically, patients with hypertension and tachycardia usually respond to sedation and volume resuscitation. In the uncommon event that hypertension or tachycardia persists, a direct-acting vasodilator such as nitroglycerin, nicardipine, or an  $\alpha$ -adrenergic antagonist (eg, phentolamine) is recommended. The use of a  $\beta$ -adrenergic antagonist or a mixed  $\alpha$ - and  $\beta$ -adrenergic antagonists in patients with acute cocaine toxicity is contraindicated. In both animal models and human reports, these drugs increase lethality and fail to treat the underlying CNS excitation<sup>16,29,75,201,231</sup> (see Specific Management later.) Severe and life-threatening hypertension or vasospasm will result from an unopposed  $\alpha$ -adrenergic effect.

## Decontamination

The majority of patients who present to the hospital after cocaine use do not require GI decontamination because the most popular methods of cocaine use are smoking and IV and intranasal administration. If the nares contain residual white powder presumed to be cocaine, gentle irrigation with 0.9% sodium chloride solution will help remove adherent material. Less commonly, patients ingest cocaine unintentionally or in an attempt to conceal evidence during an arrest (body stuffing)<sup>88,111,147,219</sup> or transport large quantities of drug across international borders (body packing).<sup>67,73</sup> These patients often require intensive decontamination and possibly surgical removal (Special Considerations: SC5).

## Specific Management

In patients with end-organ manifestations of vasospasm that do not resolve with sedation, cooling, and volume resuscitation we recommend treatment with vasodilators (eg, phentolamine). When possible, direct delivery via intra-arterial administration to the affected vascular bed is preferable. Because this approach is not always feasible, systemic therapy is typically indicated. Phentolamine is dosed IV in increments of 1 to 2.5 mg and repeated as necessary until symptoms resolve or systemic hypotension develops.

## Acute Coronary Syndrome

A significant amount of animal, *in vitro*, and *in vivo* human experimentation has been directed at defining the appropriate approach to patients with presumed cardiac ischemia or infarction. In some instances, an approach that is similar to the treatment of coronary artery disease (CAD) is indicated, although there are certain notable exceptions. An overall approach to care is available in the American Heart Association (AHA) guidelines and a number of reviews.<sup>3,5,6,93,127,156</sup>

In the setting of hypoxia, high-flow oxygen therapy is clearly indicated because it will help overcome some of the supply–demand mismatch that occurs with coronary insufficiency. Aspirin is likely safe in patients with cocaine-associated chest pain and is recommended for routine use.<sup>156</sup> In addition, administration of morphine is likely to be effective because it relieves cocaine-induced vasoconstriction.<sup>198</sup> Morphine also offers the same theoretical benefits of preload reduction and reduction of catecholamine release associated with pain.

Nitroglycerin is recommended because it reduces cocaine-associated coronary constriction of both normal and diseased vessels and relieves chest pain and associated symptoms.<sup>89</sup> Interestingly, in several clinical trials of cocaine-associated chest pain, benzodiazepines are at least as effective or superior to nitroglycerin.<sup>12,102</sup> Although the reasons for this are unclear, possible etiologies include blunting of central catecholamines or direct effects on cardiac benzodiazepine receptors. Either or both drugs are recommended in standard dosing (Antidotes in Depth: A26).

Although the benefits of  $\beta$ -adrenergic antagonism are demonstrated in patients with CAD, there is controversy surrounding their use in patients with cocaine-associated chest pain. In determining the risks and benefits of  $\beta$ -adrenergic antagonist administration, the established safety of their use

should be compared with the magnitude of the benefit achieved in relation to other available therapies.

Several studies in both animals and humans underscore the potential risks of  $\beta$ -adrenergic antagonism in the setting of acute cocaine toxicity.  $\beta$ -Adrenergic antagonism increases lethality in cocaine-poisoned animals<sup>29,75</sup> and in humans exacerbates cocaine-induced coronary vasoconstriction.<sup>127</sup> In one study, the administration of esmolol to patients with acute cocaine poisoning produced severe paradoxical hypertension.<sup>201</sup> Mixed  $\alpha$ - and  $\beta$ -adrenergic antagonists do not appear to offer any advantage in the treatment of patients with cocaine-associated coronary artery vasospasm. Labetalol was no better than placebo in this regard,<sup>16</sup> likely due in part to the relative ratios of receptor blockade. Intravenous labetalol has a relative  $\beta$ : $\alpha$  receptor blockage of 7:1.<sup>188</sup> Carvedilol has a ratio of 2.4:1.<sup>20</sup>

Despite these studies,  $\beta$ -adrenergic antagonists are frequently administered in the context of cocaine-associated chest pain for a variety of reasons, and several authors have argued in favor of their safety.<sup>189</sup> They often fail to distinguish acute toxicity from chronic or remote use, suggest that the aforementioned adverse events are extremely rare compared with the overall number of patients receiving  $\beta$ -adrenergic antagonists<sup>189</sup> and point to the absence of any documented cases of severe adverse events with the administration of combined  $\alpha$ - and  $\beta$ -adrenergic antagonists.<sup>189</sup>

Even if the frequency of severe adverse events is rare, no quality data currently support the efficacy of  $\beta$ -adrenergic antagonism in the context of acute cocaine use. Studies in this area produce variable and conflicting results and are based on case reports and retrospective reviews using inconsistent outcome measures.

Thus, in the setting of acute cocaine toxicity,  $\beta$ -adrenergic antagonism is contraindicated. The 2008 AHA guidelines for the treatment of cocaine-associated chest pain and MI state that use of  $\beta$ -adrenergic antagonists should be avoided in the acute setting.<sup>156</sup> The 2014 AHA guidelines on the management of non–ST-segment elevation MI list  $\beta$ -adrenergic antagonists as class III (harm) because of the risk of potentiating coronary artery vasospasm.<sup>5</sup> If, after the measures mentioned previously are initiated, hypertension or vasospasm is still present and treatment is indicated, phentolamine is recommended based on its demonstrable experimental and clinical results.<sup>95,127</sup> If tachycardia does not respond to these accepted therapies, then diltiazem administration is reasonable.<sup>15</sup> Before the administration of any negative inotrope, it is essential to confirm that the tachycardia is not compensatory for a low cardiac output resulting from global myocardial dysfunction. Noninvasive methods of assessment of cardiac function have been used successfully in patients with cocaine-associated acute coronary syndromes and are recommended.<sup>12</sup>

There are no data on the use of unfractionated heparin (UFH) or low-molecular-weight heparins (LMWHs), glycoprotein IIb/IIIa inhibitors, or clopidogrel. The recent AHA guidelines recommend the administration of UFH or LMWH in patients with cocaine-associated MI.<sup>156</sup> The decision to use any of these medications should be based on a risk-to-benefit analysis. The possibility of underlying atherosclerotic heart disease should be evaluated. When acute thrombosis is likely, thrombolytic therapy is reasonable. Mechanistically, cocaine inhibits endogenous thrombolysis through augmentation of the inhibitor of tissue plasminogen activator. Additionally, there is sufficient clinical evidence to support the safety of thrombolytic therapy in patients with cocaine-associated MI.<sup>89,94</sup> Even though the number of patients treated with thrombolytic therapy is insufficient to demonstrate efficacy in terms of mortality, evidence of revascularization is encouraging. If available, cardiac catheterization with revascularization is preferable to thrombolysis.<sup>213,216</sup> A high rate of stent thrombosis after MI is reported in cocaine users. Thrombolysis would not be expected to be useful in treating ischemia caused by vasospasm. Because of the high incidence of coexisting atherosclerotic disease and an increased hypercoagulable state in cocaine-associated MI, thrombolysis is an acceptable alternative when catheterization is unavailable. Standard contraindications such as persistent hypertension, aortic dissection, trauma, and altered mental status must be considered before thrombolysis.

### Dysrhythmias

Most patients present with sinus tachycardia that resolves after sedation, cooling, rehydration, and time to metabolize the drug. Other stable dysrhythmias should be treated similarly and often spontaneously revert because of the short duration of effect of cocaine. However, cocaine use is associated with atrial, supraventricular, and ventricular dysrhythmias, including torsade de pointes.<sup>107,128,209</sup> Most notably, wide complex tachycardias result from sodium channel blockade.

When approaching patients with cocaine-associated dysrhythmias, there are several important points to consider. The first is that  $\beta$ -adrenergic antagonism is contraindicated. Furthermore, class IA and IC antiarrhythmics are also contraindicated because of their ability to exacerbate cocaine-induced sodium and potassium channel blockade.<sup>128,247</sup> Additionally, although popular in many advanced cardiac life support dysrhythmia algorithms, the effects of amiodarone are largely unknown in the setting of cocaine toxicity. Because of the lack of data demonstrating a benefit for amiodarone and because of concerns about its  $\beta$ -adrenergic antagonist effects, the use of this drug is not recommended at this time. Finally, although adenosine and synchronized cardioversion transiently help convert narrow complex tachycardias, if a substantial amount of cocaine is unmetabolized, the patient will likely revert back to the original dysrhythmia as these therapeutic interventions have short durations of effect. Thus, for rapid atrial fibrillation and narrow complex reentrant tachycardias, a calcium channel blocker such as diltiazem is reasonable. For wide-complex dysrhythmias, a trial of hypertonic sodium bicarbonate is recommended and has demonstrable usefulness analogous to treating patients with cyclic antidepressant overdose (Antidotes in Depth: A5).<sup>116,126,177,198,242,247</sup> When the use of hypertonic sodium bicarbonate fails to treat the dysrhythmia, lidocaine is recommended. Although lidocaine blocks sodium channels, its fast-on, fast-off properties allow it to antagonize the effects of cocaine. The benefits and safety of lidocaine were demonstrated in multiple animal models<sup>74,79,85,90,247</sup> and in humans with cocaine-associated MI.<sup>115,234</sup>

### Ischemic Stroke

The safety of thrombolysis in cocaine-associated ischemic stroke is uncertain. Cocaine use can increase the risk of both ischemic stroke and intracerebral hemorrhage. One study found no increase in intracerebral hemorrhage after administration of tissue plasminogen activator in patients who had recently used cocaine, although acute cocaine intoxication was not specifically investigated.<sup>149</sup> Mechanical intervention with stent placement for ischemic stroke secondary to vasospasm was used, but data are insufficient to recommend routine use at this time.<sup>238</sup>

### Limb and Bowel Ischemia

Only limited case reports address the management of patients with limb and bowel ischemia. Imaging is essential because it is important to try to distinguish thrombosis or embolus from vasospasm. If a discrete lesion is found, either angioplasty<sup>50</sup> or thrombolysis is reasonable depending on institutional resources. Because embolectomy or bypass may be required, a consultation with either interventional radiology or vascular surgery should be obtained. Vasodilators such as phentolamine, nitroglycerin,<sup>76,157</sup> and nicardipine and anticoagulation are also reasonable in an attempt to improve the low flow state and prevent clot.<sup>37,155,157</sup> Interestingly, continuous infusion of iloprost (an analog of the vasodilatory prostacyclin PGI<sub>2</sub>) was reportedly beneficial in several cases.<sup>37,155,157</sup> If the patient is hemodynamically unstable, there is a theoretical role for direct intraarterial administration of vasodilators in an attempt to minimize the systemic effects.

### ADULTERANTS

A variety of adulterants, contaminants, and diluents, collectively called “cutting agents,” are present in cocaine. Adulterants are pharmacologically active substances intentionally added to enhance or mimic the effects of a drug. Diluents describe inert substances added to increase bulk, and contaminants describe unintentional byproducts present as a result of impure

manufacturing processes or drug storage. Historically, common cocaine adulterants included starches, sympathomimetics, and other local anesthetics.<sup>24</sup> Currently, the main adulterants of cocaine supplies include caffeine, diltiazem, hydroxyzine, levamisole, and phenacetin.<sup>22</sup>

The adulterant levamisole is worth special mention. First identified in cocaine in 2003, levamisole is an antihelminthic and immunomodulator. It was withdrawn from the US market in 2000 primarily because of agranulocytosis. By 2009, the US Drug Enforcement Administration estimated that 69% of cocaine contained levamisole.<sup>131</sup> Levamisole is metabolized to aminorex, a drug with potent amphetaminelike effects at dopamine and norepinephrine transporters. It is postulated that the addition of levamisole acts to both enhance and potentially lengthen the duration of effects of cocaine.<sup>23</sup> Two primary categories of levamisole toxicity are identified. The first is hematologic effects, including neutropenia and agranulocytosis. The second is dermatologic effects, including vasculitis and purpura. Reexposure to cocaine with levamisole is associated with recurrence of these symptoms. A multifocal inflammatory leukoencephalopathy characterized by cerebral demyelination and white matter lesions is also reported after use of cocaine adulterated with levamisole.<sup>71,240</sup>

### DISPOSITION

Patients who present to health care facilities with classic sympathomimetic signs and symptoms that resolve spontaneously in the absence of signs of end-organ damage can be safely discharged after short periods of observation. When hyperthermia, rhabdomyolysis, or other signs of end-organ damage are evident, hospital admission is usually required. Patients who use cocaine are at increased risk for sudden death likely related in part to dysrhythmias and myocardial ischemia. In one series, patients with cardiac arrest after smoking crack cocaine were younger, more likely to survive, and less likely to have neurologic sequelae than case controls.<sup>105</sup>

For patients with chest pain, a specific management algorithm was derived based on substantial clinical experience. Those patients with clearly diagnostic or evolving ECGs suggestive of ischemia or infarction, positive cardiac biomarkers, dysrhythmias other than sinus tachycardia, congestive heart failure, or persistent pain require admission. Patients who become pain free and whose ECGs are stable are candidates for discharge if a single cardiac marker obtained at least 8 hours after the onset of chest pain is normal.<sup>244</sup> Although the AHA guidelines recommend 9 to 12 hours of observation for low- and intermediate-risk patients with cocaine-associated chest pain,<sup>156</sup> it is unclear whether the few extra hours offers additional benefit.

For all patients, it is essential to provide a referral for detoxification. Repeated cocaine use is the greatest risk factor for future cardiovascular complications.<sup>96,197,245</sup> Additionally, cocaine use in patients treated for traumatic injury is a risk factor for subsequent death from unintentional injury.

### SUMMARY

- A sympathomimetic toxidrome is the typical clinical presentation.
- Hyperthermia is the most life-threatening vital sign abnormality and should be rapidly treated with ice water immersion.
- Treatment of agitation should focus on rapid sedation with a benzodiazepine and cooling if indicated.
- Myocardial infarction and dysrhythmias occur via diverse mechanisms.
- Both ischemic and hemorrhagic stroke also occur.

## BENZODIAZEPINES

Fiona Garlich Horner, Robert S. Hoffman, Lewis S. Nelson, and Mary Ann Howland

Benzodiazepines are a class of sedative–hypnotics that share similar chemical structures, receptor physiology, and clinical effects. Benzodiazepines are used broadly for a range of clinical indications, including xenobiotic-induced seizures, xenobiotic-induced psychomotor agitation, withdrawal from ethanol and other sedative–hypnotics, cocaine-associated myocardial ischemia, chloroquine overdose, and to induce muscle relaxation in serotonin toxicity, neuroleptic malignant syndrome, strychnine poisoning, and black widow spider envenomation. This Antidotes in Depth provides a summary of the clinical pharmacology of benzodiazepines and a review of their use in specific clinical scenarios, with an emphasis on specific drug selection and safe administration. A discussion of the manifestations and treatment of overdose of benzodiazepines and similar xenobiotics is found in Chap. 72.

## HISTORY

The first benzodiazepine, chlordiazepoxide, was discovered serendipitously in 1957 as part of a quest to develop safer and more marketable sedatives.<sup>70</sup> Before this, the most commonly prescribed sedative–hypnotics were the barbiturates, which by the 1920s had largely supplanted chloral hydrate, bromides, and opium as the sedatives of choice.<sup>71</sup> Although safer than their predecessors, barbiturates were associated with dependence, abuse, and numerous overdose deaths, limiting their therapeutic use. Meprobamate, marketed in the 1950s as the first anxiolytic, was soon withdrawn from the market because of similar problems. The introduction of chlordiazepoxide in 1960 represented a major breakthrough in the field of psychopharmacology and ushered in an era of rapid development and widespread use of numerous other benzodiazepines. The improved safety profile of benzodiazepines as a class allowed them to become, for a time, the most widely prescribed drugs in the world.<sup>70</sup>

## CHEMISTRY

All benzodiazepines share a common chemical structure, shown in Fig. A26–1. This structure links a benzene ring with a diazepine ring and gives rise to the name used to describe the drug class. The additional phenyl ring is present in all clinically important benzodiazepines and serves as a site of substitution that modulates certain pharmacologic characteristics. Modification of side chains of the ring structures leads to differences in lipophilicity, central nervous system (CNS) penetration, duration of action, potency, and rate of elimination. The majority of benzodiazepines are highly protein bound and lipophilic, entering the CNS via passive diffusion.<sup>48</sup> The nonbenzodiazepine hypnotics (zolpidem, zopiclone, and zaleplon) lack the typical benzodiazepine structure but have similar pharmacologic effects.<sup>40</sup> A discussion of the manifestations and treatment of overdose of benzodiazepines and other sedative–hypnotics is found in Chap. 72.

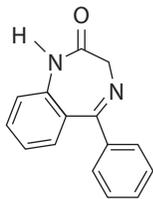

FIGURE A26–1. Generic structure of benzodiazepines.

 $\gamma$ -AMINOBTYRIC ACID TYPE A RECEPTORS

Benzodiazepines bind to a specific site on the postsynaptic  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor. The GABA<sub>A</sub> receptor is a ligand-gated chloride channel that, when bound by the inhibitory neurotransmitter GABA, opens to allow an inward flux of negatively charged chloride ions. This results in membrane hyperpolarization and subsequent inhibition of neuronal excitability. When benzodiazepines bind to the GABA<sub>A</sub> receptor, the frequency of channel opening is increased in the presence of GABA, resulting in increased chloride ion influx and enhanced neuronal inhibition.<sup>112</sup> In the absence of GABA, the benzodiazepines have no effect on chloride conductance.

The GABA<sub>A</sub> receptor is formed by five polypeptide subunits that span the cell membrane in a circular fashion to create the chloride channel. These subunits are coded as  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ ,  $\theta$ ,  $\lambda$ , or  $\rho$ , and at least 19 isoforms of these subunits (eg,  $\alpha_{1-5}$ ) are identified.<sup>106,114</sup> Numerous subunit configurations are possible, but the most common pentamer is composed of two  $\alpha$  subunits; two  $\beta$  subunits; and an additional subunit, most commonly  $\gamma_2$ .<sup>100,114</sup> Different GABA<sub>A</sub> receptor subunit isoforms predominate in different areas of the CNS and confer distinct functional effects and pharmacologic properties.<sup>100</sup> Benzodiazepines have no appreciable binding to GABA<sub>B</sub> receptors.

## BENZODIAZEPINE RECEPTORS

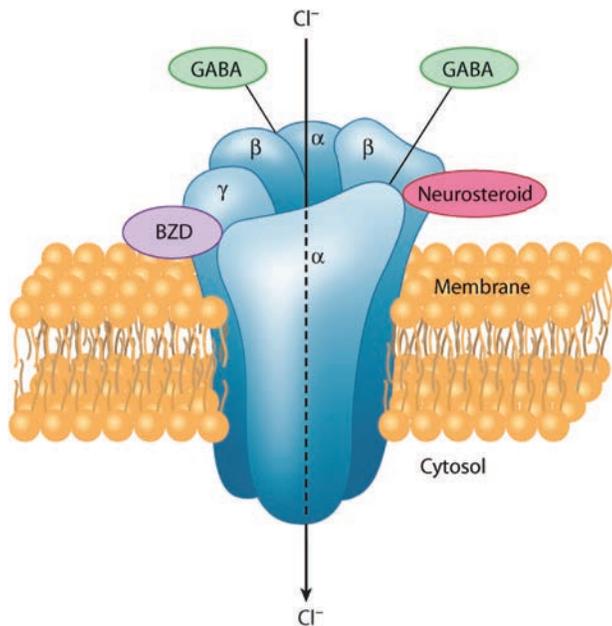

Rapidly evolving neuroscience has resulted in an exponential expansion in the understanding of benzodiazepine receptors. As a result, significant evolution in nomenclature has occurred. Older, imprecise terminology was replaced by more specific characterization of binding sites defined by molecular structure and function.<sup>100</sup>

## Central

The term “central benzodiazepine receptors” is used to refer to benzodiazepine binding sites on GABAergic neurons of the nervous system. The benzodiazepine binding site is located at the interface of an  $\alpha$  and a  $\gamma$  subunit; most commonly an  $\alpha_1$  and a  $\gamma_2$  subunit.<sup>106,114</sup> Anatomical variations in the  $\alpha$  isoforms of GABA<sub>A</sub> receptors confer distinct pharmacologic response to benzodiazepine binding.<sup>80</sup> The  $\alpha_1$  isoform, located in the sensory and motor areas of the brain, mediates sedative and hypnotic effects. The  $\alpha_2$ ,  $\alpha_3$ , and  $\alpha_5$  isoforms are dispersed throughout the subcortical and limbic areas of the brain and mediate anxiolytic and anticonvulsant effects.  $\gamma$ -aminobutyric acid type A receptors that contain  $\alpha_4$  and  $\alpha_6$  subunits are insensitive to benzodiazepines and are of low prevalence in the brain.<sup>100</sup>

In older nomenclature, GABA<sub>A</sub> receptors with primarily  $\alpha_1$  isoforms were termed benzodiazepine type 1 (BZ<sub>1</sub>) receptors or  $\omega_1$  receptors, and those with predominance of  $\alpha_2$ ,  $\alpha_3$ , and  $\alpha_5$  isoforms were called benzodiazepine type 2 (BZ<sub>2</sub>) receptors or  $\omega_2$  receptors.<sup>81</sup> Most typical benzodiazepines have substantial affinity for the  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_3$ , and  $\alpha_5$  isoforms, which explains their combined sedative–hypnotic, anxiolytic, and anticonvulsant effects. In contrast, the nonbenzodiazepine hypnotics (eg, zolpidem) have high affinity for  $\alpha_1$ , intermediate affinity for  $\alpha_2$  and  $\alpha_3$ , and low affinity for  $\alpha_5$  isoforms, which explains their lack of antiepileptic effects.<sup>40</sup>  $\gamma$ -Aminobutyric acid type A receptors are now more simply classified as having high-, low-, or intermediate-affinity benzodiazepine binding sites.<sup>100</sup>

Opposite the benzodiazepine binding site, situated at the  $\alpha$ – $\beta$  subunit interface, is the binding site for neurosteroids such as pregnenolone (Fig. A26–2).<sup>53</sup> These neurosteroids are potent modulators of GABA<sub>A</sub> receptor function and

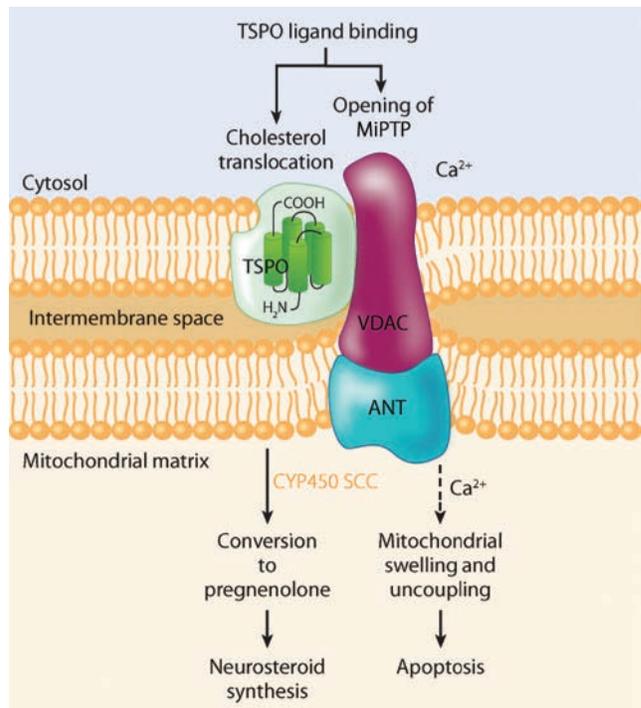

**FIGURE A26-2.** The  $\gamma$ -aminobutyric acid type A ( $\text{GABA}_A$ ) chloride ( $\text{Cl}^-$ ) channel. The figure demonstrates a typical configuration of the  $\text{GABA}_A$   $\text{Cl}^-$  channel, which consists of two  $\alpha$ , two  $\beta$ , and one  $\gamma$  subunit. The benzodiazepine (BZD) receptor is located between an  $\alpha$  and a  $\gamma$  subunit. Neurosteroid binding at the opposite side of the  $\alpha$  isoform is a positive allosteric modulator.

are important products of the tryptophan-rich sensory protein receptor (see below).

### Peripheral (Tryptophan-Rich Sensory Protein)

The term “peripheral benzodiazepine receptor” (PBR) was originally used in the 1970s to define any benzodiazepine binding sites outside of the nervous system.<sup>18</sup> They were also termed  $\text{BZ}_3$  or  $\omega_3$  receptors to distinguish them from the “central receptors” described earlier.<sup>63</sup> However, it was subsequently discovered that this receptor was also expressed in CNS tissues, that it was the binding site for numerous other nonbenzodiazepine ligands, and that its structure and function were immensely complex and vastly dissimilar from that expressed in  $\text{GABA}_A$  neurons.<sup>91</sup> The PBR was determined to be an 18-kDa translocator protein located primarily on the outer mitochondrial membrane, and a member of a family of proteins involved in transmembrane signaling as part of host defense, stress response, and regulatory mechanisms in many species.<sup>22,35,37,91</sup> This protein is termed tryptophan-rich sensory protein and abbreviated as TSPO. Although the term PBR remains attractive, for simplicity and consistency, the current term TSPO will be used in the remainder of this discussion.

The TSPO has a heterotrimer structure that is composed of an isoquinoline binding protein, which is the actual receptor (TSPO); a voltage-dependent anion channel (VDAC); and an adenine nucleotide transporter (ANT).<sup>91</sup> The TSPO protein and the VDAC span the outer mitochondrial membrane, and the ANT bridges the outer and inner membranes (Fig. A26-3). Sequencing of TSPOs demonstrates that they are of ancient evolutionary origin with DNA from bacteria and fungi having a nearly 50% homology of the isoquinoline binding domain with human DNA.<sup>35,38</sup> This finding suggests that the TSPO performs a “housekeeping function,” that is, they are involved in a process or processes that are essential for life. In higher life forms, TSPOs are found in the brain, adrenal glands, heart, and kidney and are especially concentrated in tissues in which steroids are synthesized.<sup>91</sup> Tryptophan-rich sensory proteins are implicated in cholesterol and protoporphyrin transport required for the synthesis of neurosteroids, heme, and bile salts; ischemia and reperfusion; regulation of calcium channels; mitochondrial respiration; apoptosis; microglial activation; and the immune response.<sup>38,91,113</sup> More recently, TSPO ligands were investigated as potential targets for a variety of disorders, including

**FIGURE A26-3.** The “peripheral benzodiazepine receptor” has three main components: the tryptophan-rich sensory protein (TSPO; 18-kDa translocator protein), a voltage-dependent anion channel (VDAC), and an adenine nucleotide transporter (ANT), which are shown on the mitochondrial membrane. Stimulation of the TSPO can trigger influx of  $\text{Ca}^{2+}$  or cholesterol across the mitochondrial membrane. MiPTP = mitochondrial permeability transition pore; SCC = side chain cleavage.

anxiety, cancer, ischemia, and others.<sup>24,30,57,59,86,92,107,122</sup> It is hypothesized that the TSPO has two major roles: opening of the mitochondrial permeability transition pore, leading to calcium influx and apoptosis,<sup>11,37,69</sup> and, as noted earlier, in synthesis of neurosteroids that modulate  $\text{GABA}_A$  function.<sup>90,101</sup>

### PHARMACOKINETICS AND PHARMACODYNAMICS

In the hospital setting, benzodiazepines are usually administered to treat seizures, psychomotor agitation, or sedative-hypnotic withdrawal. This Antidotes in Depth focuses on the most commonly used parenteral benzodiazepines: diazepam, lorazepam, and midazolam. Clinically important pharmacologic parameters of these three benzodiazepines are listed in Table A26-1. Of note, although they are often used interchangeably for a variety of indications, the onsets and peak effects of sedative and antiepileptic activity are distinctly different for each benzodiazepine. Thus, an understanding of pharmacology is crucial in selecting the optimal benzodiazepine, dose, route, and interval to ensure adequate response and limit adverse reactions.

The intravenous (IV) route is preferred in critically ill patients because it guarantees immediate and complete absorption with a relatively rapid onset of action. Intraosseous delivery of benzodiazepines is equivalent to IV administration and thus should be used in critically ill patients when IV access cannot be rapidly established.<sup>64</sup> When IV or intraosseous access is unavailable, intramuscular (IM) lorazepam or midazolam is recommended because they both have good absorptive profiles.<sup>43,54,105,118</sup> In contrast, the absorption after IM diazepam is best described as slow, incomplete, erratic, and dependent on the site of administration and the skill of the person administering it.<sup>33,54,61</sup> We therefore recommend not to use IM injection of diazepam unless no other alternatives exist.

Intranasal and rectal administration is occasionally used for benzodiazepine delivery when IV access is not available, especially in children with seizures. However, both routes are inferior to IV administration. When rectal diazepam was compared with IV diazepam in children with seizures, the

Formulations	5 mg/mL 5 mg/mL (Rectal gel)	1 mg/mL 5 mg/mL	2 mg/mL 4 mg/mL

<sup>a</sup>Avoid intraarterial administration because severe spasm may occur with resulting ischemia or gangrene. Also avoid extravasation. D<sub>5</sub>W = 5% dextrose in water; IV = intravenous; NS = 0.9% NaCl.

peak concentration was more variable, was delayed by about 20 minutes, and resulted in higher failure rates.<sup>88,96</sup> Similarly, although midazolam is more rapidly absorbed than diazepam after both nasal and rectal administration, the kinetic profile of nasal or rectal midazolam is still inferior to IV administration of either diazepam or midazolam (Table A26-2).<sup>50,75,96</sup>

After being absorbed, benzodiazepines distribute into the CNS to produce their sedative and antiepileptic effects. The differences among individual drugs are evaluated in terms of their pharmacokinetics, such as plasma or cerebral drug concentrations, or their onset and pharmacodynamics, such as changes in either consciousness or electroencephalographic (EEG) findings. In animal and human studies, whereas diazepam demonstrates the most rapid onset and time to peak clinical effects, lorazepam is associated with significant pharmacodynamic delays.<sup>10,44,45</sup> In a cat model, intravenously administered diazepam, midazolam, and lorazepam all appeared rapidly in the cerebrospinal fluid (CSF), but lorazepam exhibited a slower time to peak concentration, a slower onset of EEG effect, and a longer duration of EEG activity.<sup>10</sup>

In similar human studies, volunteers were given a 1-minute IV infusion of diazepam (0.15 mg/kg), midazolam (0.1 mg/kg), or lorazepam (low dose, 0.0225 mg/kg; high dose, 0.045 mg/kg).<sup>44,45</sup> Electroencephalographic analysis was used as a surrogate for the pharmacodynamic effects of sedation. Peak EEG effects were present immediately at the end of the diazepam infusion but were delayed for 5 to 10 minutes after midazolam administration<sup>45</sup> and 30 minutes after lorazepam administration (Table A26-3).<sup>44</sup> The delay to peak effect after lorazepam administration is due to its decreased lipophilicity compared with diazepam and midazolam, whose greater lipophilicity allows them to rapidly cross the blood–brain barrier.<sup>46</sup>

Benzodiazepines, like many centrally acting xenobiotics, undergo a two-phase elimination in which they redistribute from the central to the peripheral compartment (represented by the alpha half-life) and then are eliminated from the body via metabolism and excretion (represented by the β half-life).<sup>110</sup> Benzodiazepines are classically categorized as long acting (diazepam and chlordiazepoxide), intermediate acting (lorazepam, alprazolam, clonazepam), and short acting (midazolam) based on their terminal beta elimination half-lives.<sup>47</sup> However, this does not necessarily correlate accurately with their clinical duration of action, which is more dependent on α redistribution. For example, because of rapid peripheral redistribution,

**TABLE A26-3** Selected Pharmacokinetic and Pharmacodynamic Properties of Intravenous Benzodiazepines<sup>44,45</sup>

Parameter	Diazepam (0.15 mg/kg)	Midazolam (0.1 mg/kg)	Lorazepam (0.045 mg/kg)

Time to peak EEG effect (min)	1	5–10	30
Duration of EEG effect (h)	5–6	2	8
Elimination half-life (h)	33 ± 5	2.8 ± 0.5	12 ± 2

EEG = electroencephalographic; IV = intravenous.

a single dose of diazepam has a relatively short duration of action despite its long elimination half-life of 20 to 70 hours. Lorazepam has a much shorter elimination half-life of 10 to 20 hours, but the duration of action after a single dose is relatively long.<sup>47</sup> These characteristics change after repeated dosing.

The presence of pharmacologically active metabolites prolongs the duration of action of select benzodiazepines, especially when repeated doses are administered. All benzodiazepines undergo hepatic metabolism, either by oxidation (phase I) or by conjugation with glucuronide (phase II).<sup>93</sup> Drugs that undergo phase I oxidation, such as diazepam, midazolam, and chlordiazepoxide, produce active metabolites. Diazepam is metabolized to nordiazepam (desmethyldiazepam, half-life, 48–72 hours) and temazepam (half-life, 8–22 hours), which are both subsequently metabolized to oxazepam (half-life, 4–15 hours).<sup>47,121</sup> These long-acting active metabolites effectively prolong the clinical effect of diazepam, though because of redistribution out of the CNS, the duration of clinical effect is significantly less than the elimination half-life. Glucuronidation, as in the case of lorazepam, results in the production of pharmacologically inactive metabolites. Older adult patients and those with hepatic failure have decreased clearance of drugs that undergo phase I oxidative metabolism.<sup>93</sup> As such, administration of diazepam, midazolam, or chlordiazepoxide in these patients often results in excessive accumulation of parent drug, a prolonged half-life, and increased adverse effects. Lorazepam is often recommended in patients with cirrhosis for this reason. The relative pharmacodynamic properties of diazepam, lorazepam, and midazolam are shown in [Table A26-2](#).

## ROLE OF BENZODIAZEPINES IN SELECT CLINICAL SCENARIOS

Many chapters in this text discuss the use of benzodiazepines as GABA<sub>A</sub> agonists in the management of poisoned patients (Chaps. 13, 14, 69, 73, 75, 77, 79, and 83). A few commonly encountered clinical scenarios deserve brief discussion here: xenobiotic-induced seizures, sedative–hypnotic withdrawal, and psychomotor agitation. There is extensive pharmacologic and clinical evidence supporting the use of GABA<sub>A</sub> agonists in these settings, although the choice of agonist is based on many variables. In contrast, the use of benzodiazepines as modulators of TSPOs for the treatment of poisoned patients is a more speculative but evolving field. As such, focused discussions of two additional xenobiotics, chloroquine (Chap. 55) and cocaine (Chap. 75), are warranted.

### Xenobiotic-Induced Seizures

Benzodiazepines are well-established as the initial treatment of choice for xenobiotic-induced seizures.<sup>25,31,72,103,104,123,124</sup> Unlike in traumatic or epileptic seizure disorders which arise from a localized seizure focus, the initiation and propagation of xenobiotic-induced seizures result from a global decrease in seizure threshold, either from a decrease in GABAergic tone or an increase in excitatory amino acid neurotransmission.<sup>25</sup> Therefore, non-sedative–hypnotic antiepileptics such as phenytoin are likely to be ineffective in treating xenobiotic-induced seizures and should be avoided.<sup>5,103</sup> Furthermore, there is evidence that use of non-sedative–hypnotic antiepileptics result in increased toxicity, as occurs with the enhanced cardiotoxicity of phenytoin in tricyclic antidepressant poisoning.<sup>21,103</sup>

The selection of a specific benzodiazepine is informed by pharmacokinetic data and clinical studies of patients with epileptic seizures and status epilepticus. Current data and clinical guidelines indicate that IV lorazepam

or IM midazolam is preferred for rapid seizure cessation. Clinical trials demonstrate that despite its slower CNS penetration, IV lorazepam is more effective than other IV benzodiazepines in the cessation of status epilepticus, with a lower risk of seizure recurrence.<sup>2,8,68,94,111</sup> Intravenous midazolam may be as effective as IV lorazepam, but it is not as well studied.<sup>94</sup> A large multicenter, randomized, double-blind trial demonstrated that a large dose of IM midazolam (10 mg) was at least, if not more, effective than IV lorazepam (4 mg) for seizure cessation in the prehospital setting.<sup>105,117</sup> Another study suggests that IM or intranasal benzodiazepines are superior to the IV route if IV access is not already established.<sup>3</sup> Thus, IV lorazepam and IM midazolam are the recommended first-line antiepileptics for seizures or status epilepticus in the absence of withdrawal,<sup>20,117</sup>

If seizure control is not achieved promptly with rapidly escalating doses of benzodiazepines, second-line sedative–hypnotics such as phenobarbital or propofol are recommended along with appropriate management of airway, ventilation, and circulation.<sup>25</sup> If overdose of isoniazid or other hydrazine-containing compound is suspected, high-dose pyridoxine should be administered (Chaps. 56 and Antidotes in Depth: A15).<sup>115</sup> Benzodiazepines potentiate the effect of pyridoxine by acting synergistically<sup>28</sup> but are often ineffective as sole treatment for hydrazine-induced seizures because of their upstream blockade of GABA synthesis.

### Sedative–Hypnotic Withdrawal

Benzodiazepines were established almost 50 years ago as the first-line treatment of alcohol withdrawal in a landmark study in which patients treated with chlordiazepoxide had significantly lower incidence of seizures and delirium tremens.<sup>58</sup> Since then, the benzodiazepines have also been used as the primary management of withdrawal from benzodiazepines,<sup>89</sup>  $\gamma$ -hydroxybutyric acid (GHB)<sup>16,109</sup> and GHB precursors 1,4-butanediol and gamma-butyrolactone,<sup>102,120</sup> as well as important adjuncts in the treatment of withdrawal from baclofen,<sup>99,125</sup> gabapentin,<sup>14</sup> and the nonbenzodiazepine hypnotics (eg, zolpidem, zopiclone).<sup>9,26</sup>

Numerous trials have investigated various benzodiazepines, routes, doses, and treatment strategies. Diazepam has favorable properties that make it a desirable first-line treatment for moderate to severe sedative–hypnotic withdrawal, in which prolonged agitation is expected. It has the most rapid time to onset and peak clinical effect, which limits oversedation when repeated dosing is required. The presence of active diazepam metabolites also confers a longer duration of therapeutic effect and an autotapering effect at the end of therapy.<sup>121</sup> The delay of lorazepam to onset and peak clinical effect frequently results in oversedation when serial doses are administered in rapid succession (“dose stacking”). The relatively short duration of action of midazolam limits its utility in xenobiotic withdrawal. Oral chlordiazepoxide is commonly used in early uncomplicated alcohol withdrawal because of its long duration of action and active metabolites (Chap. 77).

### Psychomotor Agitation

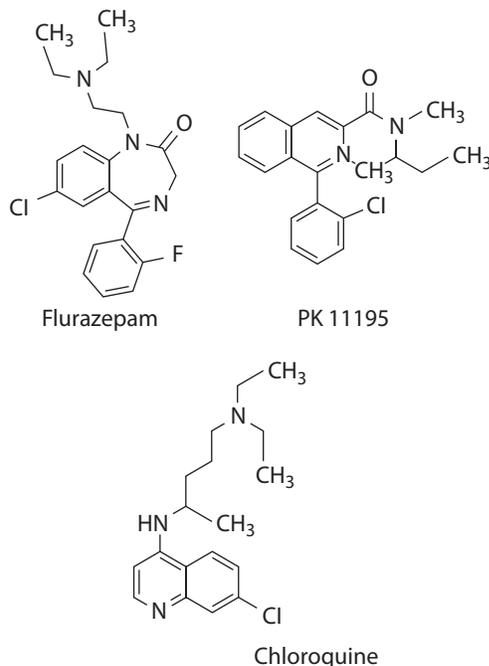

In patients with extreme psychomotor agitation caused by sympathomimetic or other xenobiotic toxicity, IV diazepam or midazolam is recommended because of their rapid onset and rapid peak effects. The relatively slow onset and delayed peak of lorazepam often leads to the administration of several doses before the full effect of the first dose is appreciated, with resultant oversedation. When a short duration of sedation is anticipated, such as

when treating a patient with toxicity after IV or inhaled use of cocaine, midazolam is recommended over diazepam or lorazepam in that the duration of the effects of midazolam better matches the duration of effects of cocaine, thereby limiting oversedation when cocaine is rapidly metabolized. In some patients with severe psychomotor agitation, obtaining IV access can be difficult or impractical and can place staff at undue risk. In such cases, we recommend IM midazolam for the treatment of undifferentiated agitation.<sup>56,60,77</sup> This should be followed, when conditions permit, by IV diazepam or midazolam if agitation persists (Chaps. 73 and 75).

### Chloroquine

Although chloroquine overdose is uncommon, case fatality rates are extremely high, and ingestion of 5 g or more was once considered universally fatal. However, in 1988, a case series of patients with chloroquine overdose who survived with the use of an aggressive new regimen was described.<sup>97</sup> The protocol, consisting of early endotracheal intubation, high-dose epinephrine infusion, and IV diazepam (2 mg/kg over 30 min), resulted in the survival of 10 of 11 patients who ingested at least 5 g of chloroquine. This treatment strategy was based on observations that patients with mixed chloroquine and diazepam overdoses experienced less cardiovascular toxicity.<sup>29</sup> Subsequent animal studies demonstrated that diazepam mitigated the convulsant effect<sup>4</sup> as well as the hemodynamic and electrocardiographic manifestations<sup>98</sup> of chloroquine poisoning.

The mechanism of the beneficial cardiovascular effect of diazepam in chloroquine toxicity is unclear, but peripheral TSPO agonism appears to play a role. In isolated perfused hearts, high-dose diazepam has positive inotropic effects that are suppressed by a TSPO antagonist.<sup>67</sup> Benzodiazepines, chloroquine, and experimental TSPO agonists share some structural elements, suggesting a receptor-based mechanism (Fig. A26–4). Functional similarity is also suggested by evidence that both flurazepam and PK 11195 (a TSPO agonist) have antimalarial activity.<sup>34</sup> Thus, despite the limitations in translating laboratory data to human poisoning, one could speculate that the beneficial effects of high-dose diazepam result from competitive inhibition between chloroquine and TSPOs. Although the ideal regimen has not been defined, for patients with severe chloroquine toxicity it is reasonable to administer high-dose diazepam at a dose of 2 mg/kg IV over 30 minutes followed by 1 to 2 mg/kg/d for 2 to 4 days. Seizures should be treated with diazepam or another IV benzodiazepine.

**FIGURE A26–4.** Comparative structures of flurazepam, PK 11195 (a PBR agonist), and chloroquine. Note the similarity and particularly the shared isoquinoline rings of chloroquine and PK 11195.

### Cocaine-Associated Chest Pain

Patients who use cocaine frequently present to emergency departments with chest pain or signs or symptoms that could represent myocardial ischemia or infarction.<sup>19</sup> Unlike most patients with acute cocaine toxicity, however, these patients often present hours after their last drug use and without the classic sympathomimetic findings of acute cocaine toxicity.<sup>51</sup> Although the pathophysiology of cocaine-induced myocardial ischemia is complex and multifactorial (Chap. 75), one component of delayed myocardial ischemia likely results from the vasoconstrictive actions of benzoylecgonine, the principal metabolite of cocaine.<sup>74</sup> Benzoylecgonine is distinct from cocaine in that it has a much longer half-life,<sup>6,7</sup> does not produce CNS stimulation,<sup>83,84</sup> and is a direct constrictor vasoconstricts or through modulation of calcium channels.<sup>73</sup>

Limited research suggests that chronic cocaine use is associated with an increased number of TSPOs on human platelets.<sup>27</sup> Also in humans, cocaine withdrawal is associated with a decrease in TSPOs on neutrophils. In the myocardium, TSPOs are either present on mitochondria or coupled to calcium channels.<sup>82</sup> Specifically, TSPO ligands have inhibitory effects on myocardial L-type calcium channels.<sup>23</sup> Also in experimental models of cardiac ischemia and reperfusion injury, TSPO agonists limit myocardial infarction size and improve cardiac function.<sup>65,122</sup> This effect most likely occurs through inhibition of the opening of the mitochondrial permeability transition pore,<sup>87</sup> the opening of which is a common final mechanism of cell death. Additionally, although the exact mechanism is unclear, TSPO agonists directly antagonize the vasoconstrictive effects of norepinephrine in rat aortic tissue.<sup>41</sup>

Benzodiazepines are commonly used to treat the agitation associated with sympathomimetic overdose (Chaps. 73 and 75). Although it is assumed that the normalization of vital signs results from a decrease in CNS stimulation and psychomotor agitation, it is reasonable to believe that the effects on TSPOs are contributory. In the same isolated perfused hearts described earlier, low-dose diazepam has a negative inotropic effect that results from an interaction with calcium currents.<sup>66</sup>

Two randomized controlled studies evaluated the use of benzodiazepines in patients with cocaine-associated chest pain.<sup>15,52</sup> In the first study, patients were randomized to receive nitroglycerin, diazepam, or combined therapy.<sup>15</sup> Diazepam was equivalent to nitroglycerin in improving chest pain, and combined therapy appeared to offer no additional benefit. The second study randomized patients to nitroglycerin or combined nitroglycerin with lorazepam therapy.<sup>52</sup> In this trial, combined therapy was better than nitroglycerin alone. Thus, it is reasonable to administer IV lorazepam or diazepam as an adjunct to nitroglycerin therapy in patients with chest pain in the setting of recent cocaine use.

### ADVERSE EFFECTS AND SAFETY ISSUES

The most common adverse effects of benzodiazepines are CNS and respiratory depression. Although this is unavoidable in some cases, it is limited by selecting the optimal drug and the proper dose and dosing interval. Extra caution is advised in older adult patients because they are more sensitive, particularly to the sedative and respiratory depressant effects of midazolam.<sup>1</sup> Additionally, patients with hepatic failure are at increased risk of adverse effects with diazepam or midazolam because of decreased drug clearance. For this reason, we recommend lorazepam in patients with cirrhosis. In contrast, paradoxical reactions rarely occur in which some patients become more agitated after benzodiazepine administration, particularly children.<sup>76,78,116</sup> These infrequent reactions probably result from disinhibition and typically respond to larger doses of benzodiazepines. Although paradoxical agitation also responds to flumazenil (Antidotes in Depth: A25), we recommend against reversal when benzodiazepines are used for most toxicologic indications.

Intravenous benzodiazepines produce a mild reduction in heart rate and both systolic and diastolic blood pressure. The effects of midazolam are reportedly greater than diazepam,<sup>95</sup> but this may merely be based on an inability to determine an equivalent dosing regimen. Although these reductions result in part from diminished sympathetic tone, direct myocardial effects are rarely severe and are often considered desirable in the overdose setting.

Whereas respiratory depression is generally not a concern with oral benzodiazepines, parenteral administration is documented to impair ventilation. Early investigations demonstrated that IM diazepam (10 mg) blunted the hypoxic ventilatory drive in normal subjects.<sup>62</sup> Intravenous diazepam impaired the ventilatory response to a rising PCO<sub>2</sub> in normal volunteers.<sup>12</sup> The impaired response to a rising PCO<sub>2</sub> was evident almost immediately and lasted for at least 25 minutes after injection of 0.4 mg/kg of diazepam in healthy volunteers.<sup>49</sup> Studies with midazolam demonstrate similar alterations in respiratory physiology<sup>36</sup> that are comparable in magnitude to those reported with diazepam.<sup>17</sup> Apnea is reported after IV midazolam and is dose and rate related, with doses greater than or equal to 0.15 mg/kg being of particular concern.<sup>65</sup> Individuals with preexisting pulmonary disorders, extremes of age, or exposure to other CNS or respiratory depressants are more susceptible. When IM midazolam is used for the treatment of agitation, some transient respiratory depression is noted, but the need for ventilatory support is uncommon.<sup>56,60,62</sup>

### Pregnancy and Lactation

Diazepam, lorazepam, and midazolam all cross the placenta and are labeled as US Food and Drug Administration Pregnancy Category D because of the risk of adverse effects with chronic use or at the time of delivery.<sup>55,79</sup> Administration of benzodiazepines late in pregnancy or during labor can result in neonatal flaccidity, respiratory difficulties, and hypothermia, termed the “floppy infant syndrome.” Chronic use late in pregnancy can result in neonatal withdrawal symptoms. Additionally, an association with congenital anomalies is suggested with use of prescription benzodiazepines in early pregnancy,<sup>32,79</sup> although the bulk of evidence suggests risk of teratogenicity is very low, if not nonexistent.<sup>39,55,119</sup> The risk to a fetus is likely negligible from short-term benzodiazepine administration in emergent situations, in which the risk of harm from untreated xenobiotic poisoning vastly outweighs any potential adverse medication effects. Thus, we recommend that benzodiazepines not be withheld in critically ill poisoned patients because of pregnancy status. If delivery is imminent, it is reasonable to select a short-acting benzodiazepine such as midazolam.

Benzodiazepines are excreted into breast milk in very small quantities.<sup>55,79</sup> Although single standard doses typically do not result in adverse effects, high doses, repeated administration, or prolonged use may result in accumulation in the serum of breastfed infants, with a resultant risk of sedation.<sup>108</sup> It is thus reasonable to forgo breastfeeding (by discarding pumped breast milk, ie, “pumping and dumping”) for several hours after a single IV dose or for 24 hours after repeated benzodiazepine dosing (Chaps. 30 and 31).<sup>85</sup>

### DOSING AND ADMINISTRATION

When selecting a benzodiazepine for a given clinical scenario, the pharmacokinetic and pharmacodynamic parameters presented in [Tables A26–1](#) and [A26–3](#) should be considered, along with existing clinical data. Onset of effect, peak effect, and duration of effect should be weighed in the context of the anticipated clinical course. It is worth noting that each of the three benzodiazepines discussed will likely have some efficacy in all clinical scenarios for which a benzodiazepine is indicated. Although selection of a specific benzodiazepine is often based on availability within the hospital and regional historic preferences, some general recommendations can be made.

Intravenous dosing is recommended for critically ill patients, although other routes such as IM, intranasal, or intraosseous are effective when IV access is unavailable or impractical. Benzodiazepines with rapid onset of action, such as diazepam or midazolam, are recommended when rapid symptom control is necessary. A long-acting benzodiazepine with active metabolites, such as diazepam, is recommended in cases of sedative–hypnotic withdrawal and ethanol withdrawal when prolonged symptoms are anticipated. Lorazepam is reasonable in patients with hepatic failure because of its relatively preserved clearance and lack of active metabolites. Intravenous lorazepam or IM midazolam is recommended for seizure cessation.

Common equivalent initial IV doses in adults are: lorazepam 1 mg, diazepam 5 mg, and midazolam 2 mg.<sup>13,42</sup> When repeated administration is

necessary, appropriate spacing between doses is crucial to avoid oversedation and respiratory depression. Intravenous diazepam and midazolam can be safely administered every 2 to 5 minutes, but we recommend delays prior to repeating lorazepam doses of at least 15 minutes to account for the slower time to peak effect. It is important to note that switching from one benzodiazepine to another is rarely indicated and increases the risk of an adverse drug event from unpredictable peak effects or improper therapeutic doses or dosing intervals (Chaps. 14, 73, 75, and 77).

### FORMULATION AND ACQUISITION

Parenteral benzodiazepines are available from multiple manufacturers in varying concentrations. It is essential to recognize that some formulations contain several significant and varied diluents, most notably propylene glycol ([Table A26–1](#)). Large doses or prolonged continuous infusions of benzodiazepines may result in toxicity from these excipients (Chap. 46).

### SUMMARY

- Although benzodiazepines are commonly used in a variety of medical settings, subtle differences exist in their pharmacokinetics and pharmacodynamics. Optimal use of these drugs requires a thorough understanding of these differences.
- When choosing among different benzodiazepines, the desired onset of action, peak effect, and duration of action aid in selecting the preferred therapy.
- In general, IV administration is preferred in an emergency because of rapid and reliable absorption.
- Because of rapid onset of action and short time to peak effect, expedient sedation is best achieved with midazolam when a short duration of action is desirable or diazepam for a longer duration of action.
- When IV access is not available, pharmacokinetic and pharmacodynamic parameters favor the use of IM midazolam for sedation.
- When used for control of the agitated patient, the delayed peak effect of lorazepam (regardless of route of administration) is undesirable.
- Intravenous lorazepam is highly effective for seizure cessation, with a longer duration of antiepileptic effect than IV diazepam or midazolam. Large doses of IM midazolam are effective for status epilepticus in the prehospital setting.
- Although the use of benzodiazepines as TSPO (peripheral benzodiazepine receptor) agonists may explain some unique therapeutic effects of these drugs, existing research is too limited to offer guidance with regard to choice of drug, dose, or dosing interval required to optimize peripheral benzodiazepine receptor response.

## ETHANOL

Luke Yip

### HISTORY AND EPIDEMIOLOGY

Ethanol, or ethyl alcohol, is commonly referred to as “alcohol.” This term is somewhat misleading because there are numerous other alcohols. However, ethanol is one of the most commonly used and abused xenobiotics in the world. Its use is pervasive among adolescents and adults of all ages and socioeconomic groups and represents a tremendous financial and social cost.<sup>3,228</sup> The ethanol content of alcoholic beverages is expressed by volume percent or by proof. Proof is a measure of the absolute ethanol content of distilled liquor, made by determining its specific gravity at an index temperature. In the United Kingdom, the Customs and Excise Act of 1952 declared proof spirits (100 proof) as those in which the weight of the spirits is 12/13 the weight of an equal volume of distilled water at 11°C (51°F). Thus, 100-proof spirits are 48.24% ethanol by weight or 57.06% by volume. Other spirits are designated over or under proof, with the percentage of variance noted. In the United States, a proof spirit (100 proof) is one containing 50% ethanol by volume.

The derivation of proof comes from the days when sailors in the British Navy suspected that the officers were diluting their rum (grog) ration and demanded “proof” that this was not the case. They achieved this by pouring a sample of grog on black granular gunpowder. If the gunpowder ignited by match or spark, the rum was up to standard, 100% proof that the liquor was at least 50% ethanol. This became shortened to 100 proof (Table 76–1).

In addition to beverages, ethanol is present in hundreds of medicinal preparations used as a diluent or solvent in concentrations ranging from 0.3% to 75%.<sup>36,52,61,169,173,227</sup> Mouthwashes have up to 75% ethanol (150 proof), and colognes typically contain 40% to 60% ethanol (80–120 proof).<sup>17,107,173,192</sup> These products occasionally cause inebriation, especially when unintentionally ingested by children.<sup>39,58,94,229</sup> Other sources in which significant amounts of ethanol are found include alcohol-based hand sanitizers and food extracts or flavorings for baking and cooking. Alcohol-based hand sanitizers are widely available as low-viscosity rinses, gels, or foams. They contain 60% to 95% ethanol, isopropanol, or both. Ingestion of these products for their ethanol content is reported in adults and children with an intention to be inebriated and results in serious consequences.<sup>56,100,183,195</sup> Vanilla extract is required by US Food and Drug Administration to have an ethanol content not less than 35% by volume, and inebriation after vanilla extract ingestion is reported.<sup>139</sup>

Veisalgia, “alcohol hangover,” comes from the Norwegian *kveis*, “uneasiness following debauchery” and the Greek *algia*, “pain.” The “hangover” syndrome is attributable to congeners that appear in alcoholic beverages in addition to ethanol and water.<sup>33,41,42</sup> Congeners contribute to the special characteristics of taste, flavor, aroma, and color of a beverage. The combinations and exact amounts of congeners vary with the type of beverage, ranging from 33 mg/L in vodka, to averages of 500 mg/L in some whiskies and as much as 29,000 mg/L in specially aged whiskies or brandies.<sup>33,41,42</sup> The conventional listing of congeners includes fusel oil (a mixture containing amyl, butyl, propyl, and methyl alcohol), aldehydes, furfural, esters, low-molecular-weight organic acids, phenols, and other carbonyl compounds, tannins, solids, and a relatively large number of additional organic and inorganic compounds, usually in trace amounts.<sup>33,42</sup>

Consumption of illicitly produced ethanol (“moonshine”) results in methanol, lead or arsenic poisoning, and botulism.<sup>21,54,74,104,125,131,149,170</sup> Incidental lead contamination is also reported in draught beers or wine contained in lead-capped bottles.<sup>202,203</sup> Of historic interest is that the addition of cobalt salts to beer to stabilize the “head” (foam) led to outbreaks of congestive cardiomyopathy among heavy beer drinkers in the United States, Canada, and

Belgium in the 1960s (Chap. 91). The clinical-pathological pattern of this disease is distinct from the classical alcoholic cardiomyopathy.<sup>142,144</sup>

Alcoholism is the leading cause of morbidity and mortality in the United States. The prevalence of ethanol dependence in the United States is relatively stable, at around 6% for men and 2% for women.<sup>29</sup> The overall estimated annual cost of excessive drinking in the United States for 2010 was \$249 billion with binge drinking representing 76.7% of the total costs.<sup>188</sup> More than 70% of this cost was attributed to lost productivity, most of which resulted from ethanol-related impaired productivity at work or death. Most of the remaining estimated costs were expenditures for health care services to treat ethanol-induced disorders (11.4%), criminal justice system costs of ethanol-related crime (10.0%), and ethanol-related motor vehicle crashes (5.4%). Excessive ethanol use is the fourth leading cause of preventable

**TABLE 76–1 Basic Information and Calculations**

Ethanol MW: 46 Da

$$\text{mmol} = \frac{\text{mg}}{\text{MW}} = \frac{\text{mg}}{46}$$

$$\text{mmol/L} = \frac{\text{mg/dL}}{4.6}$$

Specific gravity:<sup>a</sup> 0.7939 (–0.8) g/mL

Volume of distribution ( $V_d$ ): 0.6 L/kg

$$\text{Serum ethanol concentration (mg/dL)}^b = \frac{\text{Dose (mg)}}{V_d \text{ (L/kg)} \times \text{Body weight (kg)} \times 10}$$

Average reduction in serum ethanol concentration (elimination phase):

Nontolerant adults: 3.26–4.35 mmol/L/h (15–20 mg/dL/h, 100–125 mg/kg/h)

Tolerant adults: 6.52–8.70 mmol/L/h (30–40 mg/dL/h, 175 mg/kg/h)

For a 70-kg individual:

Dose of Ethanol	Serum Ethanol Concentration <sup>b</sup>
10 mL/kg of 10% (20 proof)	153 mg/dL (36.30 mmol/L)
3 mL/kg of 10% (20 proof)	46 mg/dL (10.87 mmol/L)
1.5 mL/kg of 10% (20 proof)	23 mg/dL (5.43 mmol/L)
150 mL (5 “shots”) of 40% (80 proof)	125 mg/dL (31.09 mmol/L)
30 mL (1 “shot”) of 40% (80 proof)	25 mg/dL (5.87 mmol/L)
One “standard drink” (–0.6 fluid (fl) oz or 14 grams of “pure” ethanol): 1.5 fl oz of 80-proof distilled spirits or “hard liquor” (eg, whiskey, gin, rum, vodka, and tequila), 2–3 fl oz of cordial, liqueur, or aperitif (24% ethanol), 3–4 fl oz of fortified wine (eg, sherry or port, 14% ethanol), 5 fl oz of table wine (12% ethanol), 8–9 fl oz of malt liquor (7% ethanol), or 12 fl oz of regular beer (5% ethanol) <sup>158</sup>	25 mg/dL (9.11 mmol/L)

<sup>a</sup>Specific gravity of ethanol is dependent on its water content and temperature. The specific gravity of 100% ethanol at temperature between 20° and 35°C ranges from 0.78934 to 0.77641 (–0.8) g/mL.

<sup>b</sup>This is the theoretical maximum concentration, based on instantaneous and complete ethanol absorption and no distribution or metabolism. Principle 1 and Principle 2 concentration consistent with legal intoxication = 10.87–17.39 mmol/L (50–80 mg/dL or 0.05–0.08 g/dL %). The legal breath ethanol concentration to serum ethanol concentration ratio has been set at 1:2100; the amount of ethanol in 1 mL of blood is the same amount in 2,100 mL of exhaled air: Measured breath ethanol concentration (mmol/L) × 2,100 = (Calculated) serum ethanol concentration (mmol/L).

death<sup>148</sup> and accounted for an average of 88,129 American deaths per year from 2006 through 2010; 1 in 10 deaths among working-age adults age 20 to 64 years.<sup>32</sup> In 2015, there were 10,265 ethanol-related traffic fatalities in the United States that accounted for 29% of total traffic fatalities; 63% of ethanol-impaired driving fatalities were drivers with serum ethanol concentration 80 mg/dL or higher.<sup>155</sup> Drivers age 21 to 34 years accounted for 27%, and drivers between 16 and 20 years accounted for 16% of all ethanol-impaired drivers in fatal crashes. Among 16- to 20-year-old male drivers, an increase of 20 mg/dL in serum ethanol concentration was estimated to more than double the relative risk of fatal single vehicle crash injury compared with sober drivers of the same age and gender.<sup>240</sup> When the serum ethanol concentration was between 80 and 100 mg/dL (17–22 mmol/L), 100 and 150 mg/dL (22–33 mmol/L), and greater than 150 mg/dL (33 mmol/L), the relative risks of fatal single-vehicle crash injury were 52, 241, and 15,560 respectively.

The Global Burden of Disease Study identified 3 effects of ethanol: harmful effects in relation to injuries, harmful effects in relation to disease, and the protective effect in relation to ischemic heart disease.<sup>157</sup> Overall, ethanol accounted for 3.5% of mortality and disability, 1.5% of all deaths, 2.1% of all life years lost, and 6% of all the years lived with disability.<sup>157</sup> In the United States, according to National Highway Traffic Safety Administration (NHTSA) information, all jurisdictions have enacted per se serum ethanol concentration for adults operating noncommercial motor vehicles.<sup>156</sup> The term “illegal per se” refers to state laws that make it a criminal offense to operate a motor vehicle at or above a specified ethanol concentration in the blood, breath, or urine, which is independent of any determination of clinical impairment (Special Considerations: SC11). For example, although some ethanol-tolerant individuals will not exhibit impairment even at serum ethanol concentrations greater than 300 mg/dL (65 mmol/L), they are still considered impaired with regard to the laws that governs motor vehicle operation.<sup>1</sup>

There is a dose–response relationship between ethanol consumption and risk of death in men age 16 to 34 years and in women age 16 to 54 years. Meta-analysis of aggregate data from epidemiologic dose–response ethanol and mortality cohort studies suggests that the amount of ethanol consumption at which all-cause risk is lowest is approximately 5 g/day and that ethanol exerts a protective effect (J-shaped dose response curve) up to a daily intake of approximately 45 g.<sup>11</sup> “Sensible” or “responsible” drinking of ethanol (not drinking alcohol to excess) for men is 8 to 10 g/d up to age 34 years, 16 to 20 g/d between 34 and 44 years of age, 24 to 30 g/d between 44 and 54 years of age, 32 to 40 g/d up between 54 and 84 years of age, and 40 to 50 g/d over age 85 years. Women are advised to limit their drinking to 8 to 10 g/d up to age 44 years, 16 to 20 g/d between 44 and 74 years of age, and 24 to 30 g/d over age 75 years.<sup>232</sup> However, no safe amount of prenatal ethanol exposure is established. The combination of a national tolerance of drinking and heavy advertising of ethanol makes it especially appealing to young people. In a society increasingly concerned with drug abuse, the excessive use of ethanol constitutes a serious and pervasive problem as well as a major health issue.

## PHARMACOKINETICS AND TOXICOKINETICS

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract, with approximately 20% absorbed from the stomach and the remainder from the small intestine.<sup>162</sup> Factors that enhance absorption include rapid gastric emptying, ethanol intake without food, the absence of congeners, dilution of ethanol (maximum absorption occurs at a concentration of 20%), and carbonation. Under optimal conditions for absorption, 80% to 90% of an ingested dose is fully absorbed within 60 minutes. Factors that delay or decrease ethanol absorption include high concentrations of ethanol (by causing pylorospasm), the presence of food, the coexistence of GI disease, coingestion of xenobiotics such as aspirin and anticholinergics,<sup>105,167</sup> time taken to ingest the drink, and individual variation. When any of these factors is present, absorption may be delayed for 2 to 6 hours. The relative amount of ethanol that is absorbed from the stomach is determined by the presence of an alcohol dehydrogenase (ADH) enzyme in the gastric mucosa, which oxidizes a proportion of the ingested ethanol, thus reducing the amount available for absorption. This effect is more pronounced in men than in women and in nonalcoholics

than in alcoholics.<sup>13,67</sup> However, this gender difference is undetectable after age 50 years.<sup>197</sup> Although histamine<sub>2</sub> (H<sub>2</sub>) receptor antagonists such as cimetidine and ranitidine inhibit gastric ADH, resulting in decreased first-pass metabolism and increased bioavailability of imbibed ethanol,<sup>28,48,60,198</sup> the clinical significance of this effect after a moderate ethanol dose is unclear.<sup>7,24,66,123,218</sup>

After complete distribution, ethanol is present in body tissues in a concentration proportional to that of the tissue water content. Ethanol freely passes through the placenta, exposing the fetus to ethanol concentrations comparable to those achieved in the mother.

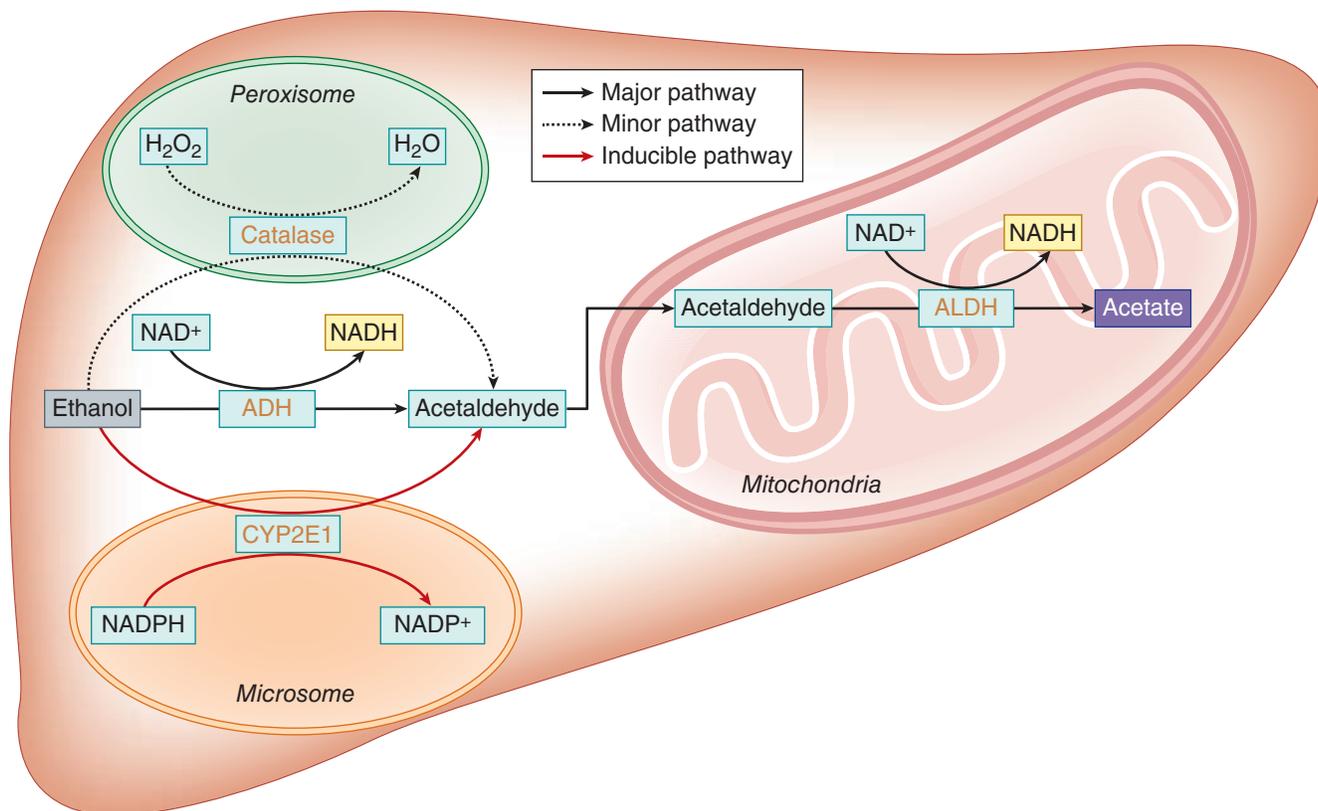

Ethanol is primarily eliminated by the liver, with 2% to 5% excreted unchanged by the kidneys, lungs, and sweat.<sup>98</sup> Ethanol is metabolized via at least 3 different pathways: the aforementioned ADH pathway located in the cytosol of the hepatocytes, cytochrome P450 2E1 (CYP2E1) located on the endoplasmic reticulum, and the peroxidase-catalase system associated with the hepatic peroxisomes (Fig. 76–1).<sup>162</sup>

For a given ethanol dose, 95% to 98% is metabolized in the liver, first to acetaldehyde by ADH and then further to acetic acid by aldehyde dehydrogenase (ALDH).<sup>98</sup> The end products of ethanol oxidation are carbon dioxide and water. The remaining 2% to 5% is excreted unchanged in urine, sweat, and expired air. In addition, less than 0.1% undergoes nonoxidative biotransformation, the products of which include fatty acid ethyl esters (FAEEs), ethyl glucuronide, and ethyl sulfate. Fatty acid ethyl esters are formed by esterification of ethanol with endogenous fatty acids and acyl-CoA fatty acids and is catalyzed by cytosolic FAEE synthases. Whereas ethyl glucuronide is formed by the conjugation of ethanol with glucuronic acid catalyzed by uridine diphosphate-glucuronosyltransferase, ethyl sulfate is formed by the transfer of a sulfur group from 3′-phosphoadenosine-5′-phosphosulfate to ethanol mediated by mitochondrial sulfotransferases.<sup>10,40,84,194</sup>

The ADH system is the main pathway for ethanol metabolism and is also the rate-limiting step. Alcohol dehydrogenase is a zinc metalloenzyme that uses oxidized nicotinamide adenine dinucleotide (NAD<sup>+</sup>) as a hydrogen ion acceptor to oxidize ethanol to acetaldehyde. In this process, a hydrogen ion is transferred from ethanol to NAD<sup>+</sup>, converting it to its reduced form, NADH. Subsequently, hydrogen ion is transferred from acetaldehyde to NAD<sup>+</sup>. Under normal conditions, acetate is converted to acetylcoenzyme A (acetyl-CoA), which enters the citric acid cycle—also historically known as the Krebs cycle—and is metabolized to carbon dioxide and water. The entry of acetyl-CoA into the citric acid cycle is thiamine dependent (Antidotes in Depth: A27). When thiamine is deficient, acetyl-CoA accumulates, and high acetyl-CoA concentration favors formation of acetoacetate and its subsequent reduction to β-hydroxybutyrate in the setting of a high redox state defined by NADH excess.

The *ADH* gene family encodes enzymes that metabolize a wide variety of substrates. There are at least 7 genetic loci that code for human ADH arising from the association of different subunits, and there are more than 20 ADH enzymes.<sup>2</sup> These ADH forms are divided into 5 major classes (I–V) according to their subunit, enzyme composition, and physicochemical properties.<sup>99</sup> Two of these gene loci exhibit polymorphism, and they both involve class I *ADH* genes; 3 alleles exist for *ADH2* (*ADH1B*) *ADH2\*1* (*ADH1B\*1*), *ADH2\*2* (*ADH1B\*2*), and *ADH2\*3* (*ADH1B\*3*) and 3 for *ADH3* (*ADH1C*) *ADH3\*1* (*ADH1C\*1*), *ADH3\*2* (*ADH1C\*2*), and *ADH3\*3* (*ADH1C\*3*).<sup>38</sup> Class I ADH, which are non-inducible hepatic enzymes, play a more substantial role in ethanol metabolism than the ADH isoenzymes in the gastric mucosa.<sup>128</sup> Class IV *ADH6* (σ-ADH) is the major ADH expressed in human gastric mucosa.<sup>13,67</sup> Alcohol dehydrogenase is usually present in non-Asians, but in a majority of Pacific Rim Asians, the enzyme activity is either low or not detectable.<sup>13,14,50</sup> The *ADH1B\*2* allele is present in 90% of Pacific Rim Asians but occurs infrequently in most whites, except for people of Jewish and perhaps Hispanic descent.<sup>233</sup> This allele is responsible for the unusually rapid conversion of ethanol to acetaldehyde. People carrying *ADH1B\*2* alleles are about one-third as likely to be alcoholic compared with people without this allele.<sup>233</sup>

In the liver, ADH metabolizes ethanol to acetaldehyde, which is then converted to acetate by mitochondrial NAD<sup>+</sup>-dependent ALDH. Human ALDH

**FIGURE 76-1.** Ethanol is metabolized in the cytoplasm of hepatocytes to acetaldehyde through major, minor, and inducible pathways. Acetaldehyde is metabolized in the mitochondria to acetic acid.

is divided into 9 major gene families. There is a functional polymorphism of the mitochondrial *ALDH2* gene and expression of an inactive form of the *ALDH2*, glutamate to lysine substitution at position 487 (E487K), results in impaired acetaldehyde metabolizing capacity. The variant allele *ALDH2\*2* encodes a protein subunit that confers low activity to the enzyme, resulting in marked differences in the steady-state kinetic constants, which appears to be most prevalent in Pacific Rim Asians.<sup>2,38,76,212,213</sup> These metabolic polymorphisms contribute to differences in ethanol and acetaldehyde elimination rates; high-activity ADH variants are predicted to increase the rate of acetaldehyde generation, but the low-activity *ALDH2* variant is associated with limited capacity to metabolize this compound and contributes to differences in ethanol-related behavior. Asians possessing an atypical *ALDH2* gene are more sensitive to acute adverse responses to ethanol, which tends to discourage ethanol consumption. Homozygous *ALDH2\*2* individuals are strikingly sensitive to a small dose of ethanol (0.2 g/kg), as evidenced by the intense flushing, pronounced cardiovascular and hemodynamic effects as well as subjective perception of general discomfort.<sup>57,76,171,217,222</sup> This effect is also associated with the *ADH2\*2* and *ADH3\*1* allele and is similar to that induced by disulfiram (Chap. 78). The ethanol flushing response involves prostaglandin and histamine release. Both prostaglandin antagonists (aspirin)<sup>219</sup> and antihistamines (H<sub>1</sub> and H<sub>2</sub>)<sup>145,208,215</sup> attenuate this response.

Cytochrome P450 2E1 is responsible for very little ethanol metabolism in the nontolerant drinker but becomes more important as the ethanol concentration rises or as ethanol use becomes chronic (Fig. 76-1). Cytochrome P450 2E1 uses reduced nicotinamide adenine dinucleotide phosphate (NADPH) as an electron acceptor to oxidize ethanol to acetaldehyde.<sup>117</sup> In this process, electrons are transferred from ethanol to NADPH, converting it to its oxidized form, NADP<sup>+</sup>. Subsequently, acetaldehyde is further oxidized to acetate as hydrogen ion is transferred from acetaldehyde to NAD. The ability of ethanol to induce the CYP2E1 forms the basis for the well-established interactions between ethanol and a host of other xenobiotics metabolized by

this system.<sup>49,65</sup> In alcoholics and those with higher ethanol concentrations, cimetidine also delays ethanol clearance by inhibiting CYP2E1.<sup>80</sup> However, the increase in serum ethanol concentration from such an interaction is of questionable clinical significance.<sup>6,7,24,27</sup>

Alcohol dehydrogenase is saturated at relatively low serum ethanol concentrations; class I ADH is not inducible.<sup>31</sup> As the system is saturated, ethanol elimination changes from first-order to zero-order kinetics (Chap. 9). In adults, the average rate of ethanol metabolism is 100 to 125 mg/kg/h in occasional drinkers and up to 175 mg/kg/h in habitual drinkers.<sup>20,75</sup> As a result, the average-sized adult metabolizes 7 to 10 g/h, and the serum ethanol concentration falls 15 to 20 mg/dL/h (3.26–4.35 mmol/L/h). Tolerant drinkers, by recruiting CYP2E1, increase their clearance of ethanol to 30 mg/dL/h (6.52 mmol/L/h) or even higher.<sup>20,75</sup> Studies of inebriated patients indicate that although the average ethanol clearance rate is about 20 mg/dL/h (4.35 mmol/L/h), there is considerable individual variation (standard deviation of about 6 mg/dL/h (1.30 mmol/L/h)).<sup>20,75</sup>

## XENOBIOTIC INTERACTIONS

Ethanol interacts with a variety of xenobiotics (Table 76-2).<sup>103,227</sup> The most frequent ethanol–drug interactions occur as a result of ethanol-induced increase in hepatic enzyme activity. By contrast, acute ethanol use inhibits metabolism of other xenobiotics due to competitive inhibition of hepatic enzyme activity or a reduction in hepatic blood flow. The interaction between ethanol and disulfiram (Antabuse) is well described and it can be life threatening (Chap. 78).

Concomitant use of cocaine and ethanol leads to the formation of an active metabolite, ethylbenzoylcoquine, through transesterification of cocaine by the liver.<sup>178</sup> Cocaethylene has a longer half-life than cocaine itself (2 hours versus 48 minutes), and this explains some of the delayed cardiovascular effects attributed to cocaine use.<sup>9,234</sup> Both ethanol and cocaethylene inhibit the metabolism of cocaine, thereby prolonging the elimination of cocaine and enhancing its effect (Chap. 75).<sup>168</sup>

**TABLE 76-2 Ethanol–Xenobiotic Interactions**

Xenobiotics	Adverse Effects
Carbamates, cephalosporins, <sup>3</sup> chloramphenicol, chlorpropamide, <i>Coprinus</i> mushrooms, griseofulvin, metronidazole, nitrofurantoin, thiram derivatives	Disulfiramlike effect
Antihistamines (H <sub>1</sub> ), chloral hydrate, cyclic antidepressants, opioids, phenothiazines	Additive sedative effect
Aspirin	Enhance antiplatelet effect
Disulfiram (Antabuse)	Nausea, vomiting, abdominal pain, flushing, diaphoresis, chest pain, headache, vertigo, palpitations
Isoniazid	Increased incidence of hepatitis; increased metabolism <sup>b</sup>
Methadone	Increased methadone metabolism <sup>b</sup>
Oral hypoglycemics	Potentiates hypoglycemic effect
Phenytoin	Increased phenytoin metabolism <sup>b</sup>
Ranitidine, cimetidine	Increased ethanol concentration
Sedative–hypnotics	Additive sedative effect or respiratory depression
Vasodilators	Potentiates vasodilator effect
Warfarin	Increased warfarin metabolism <sup>b</sup>

<sup>a</sup>Those containing a *N*-methylthiotetrazole side chain. <sup>b</sup>Effect possibly associated with chronic ethanol consumption.

The combination of ethanol and chloral hydrate (ie, “Mickey Finn”) has additive central nervous system (CNS) depressant effects. Chloral hydrate competes for ADH, thereby prolonging the half-life of ethanol.<sup>199</sup> The metabolism of ethanol generates NADH, which is a necessary cofactor for chloral hydrate metabolism to trichloroethanol, an active metabolite. In addition, ethanol inhibits the conjugation of trichloroethanol, which in turn inhibits ethanol oxidation.

Case reports and retrospective case series suggest that chronic ethanol consumption predisposes a person to acetaminophen (APAP) hepatotoxicity (Chap. 33)<sup>55,133,141,193,244</sup> even when APAP is taken according to the manufacturer’s recommended dosage.<sup>243</sup> Because ethanol induces CYP2E1, the enzyme involved in the metabolism of APAP to its hepatotoxic intermediate, NAPQI, a theoretical basis for this association exists. However, in randomized, placebo-controlled trials in which people with confirmed alcoholism were given APAP 4 g/day or placebo, there were no differences between the 2 groups with regard to liver enzymes or to their coagulation profile.<sup>187</sup> Recent fasting, common in people with alcoholism, was also associated with a predisposition to APAP hepatotoxicity, likely because of depletion of glutathione (Chap. 33).<sup>231</sup> However, in a retrospective study, heavy drinkers did not develop more severe hepatotoxicity after APAP overdose than nondrinkers.<sup>134</sup>

## PATHOPHYSIOLOGY

Despite the long history of ethanol use and study, no specific receptor for ethanol is identified, and the mechanism of action leading to inebriation remains the subject of debate.<sup>172</sup> Ethanol affects a large number of membrane proteins that participate in signaling pathways such as neurotransmitter receptors, enzymes, and ion channels,<sup>154,224</sup> and there is extensive evidence that ethanol interacts with a variety of neurotransmitters.<sup>59,220,221</sup> The major actions of ethanol involve enhancing the inhibitory effects of  $\gamma$ -aminobutyric acid (GABA) at GABA<sub>A</sub> receptors and blockade of the *N*-methyl-*D*-aspartate (NMDA) subtype of glutamate, an excitatory amino acid (EAA) receptor.<sup>45,115,116,224</sup> Animal studies indicate that the acute effects of ethanol result from competitive inhibition of glycine binding to the NMDA

receptor and disruption of glutamatergic neurotransmission by inhibiting the response of the NMDA receptor. Persistent glycine antagonism and attenuation of glutamatergic neurotransmission by chronic ethanol exposure result in tolerance to ethanol by enhancing EAA neurotransmission and NMDA receptor upregulation.<sup>25,92,95,153,220,221</sup> The latter involves selective increases in NMDA R2B or GluN2B subunit concentrations and other molecular changes in specific brain loci.<sup>4</sup> The abrupt withdrawal of ethanol thus produces a hyperexcitable condition that leads to the alcohol withdrawal and excitotoxic neuronal death.<sup>18,45,221</sup>  $\gamma$ -Aminobutyric acid-mediated inhibition, which normally acts to limit excitation, is eliminated in the absence of ethanol during ethanol withdrawal syndrome and further intensifies this excitation. In addition, NMDA receptors function to inhibit the release of dopamine in the nucleus accumbens and mesolimbic structures, which modulates the reinforcing action of addictive xenobiotics such as ethanol.<sup>22,23,207</sup> By inhibiting NMDA receptor activity, ethanol increases dopamine release from the nucleus accumbens and ventral tegmental area and thus creates dependence. Chronic ethanol administration also results in tolerance, dependence, and an ethanol withdrawal syndrome mediated in part by desensitization and/or downregulation of GABA<sub>A</sub> receptors (Chaps. 13, 14, and 77).

Chronic alcoholism has multiorgan system effects (Table 76-3), and the relationships among ethanol use, nutrition, and liver disease are reviewed elsewhere.<sup>127</sup> In addition to the harmful effects of ethanol itself such as impairment of protein synthesis, its metabolite, acetaldehyde, is inherently toxic to biologic systems.<sup>121,129,223,242</sup> Acetaldehyde directly impairs cardiac contractile function, disrupts cardiac excitation–contractile coupling, inhibits myocardial protein synthesis, interferes with phosphorylation, causes structural and functional alterations in mitochondria and hepatocytes, and inactivates acetyl-coenzyme A. Acetaldehyde also reacts with intracellular proteins to generate adducts. Acetaldehyde–protein and DNA adducts promote oxidative stress, lipid peroxidation, hepatic stellate cell activation-associated inflammation and fibrosis, and mutagenesis. Acetaldehyde adducts are believed to be important in the early phase of alcoholic liver disease, and in advanced liver disease, they contribute to the development of hepatic fibrosis as well as hepatocellular carcinoma.<sup>200</sup>

Ethanol metabolism through the CYP2E1 pathway generates highly reactive oxygen radicals, including the hydroxyethyl radical (HER) molecule. Elevated oxygen radical concentrations generate a state of oxidative stress, which leads to cell damage. Oxygen radicals also initiate lipid peroxidation, resulting in reactive molecules such as malondialdehyde (MDA) and 4-hydroxy-2-nonenal (HNE). These molecules react with proteins or acetaldehyde to form adducts, which contribute to the development of alcoholic liver injury.<sup>46</sup>

Oxidation of ethanol generates an excess of acetyl-CoA and reducing potential in the cytosol in the form of NADH with the ratio of NADH to NAD<sup>+</sup> being dramatically increased. This ratio, also known as the redox potential, determines the ability of the cell to carry on various oxidative processes. The excess acetyl-CoA and the unfavorable change in redox potential caused by ethanol metabolism contribute to the development of metabolic disorders such as impaired gluconeogenesis, alterations in fatty acid metabolism, fatty liver, hyperlipidemia, hypoglycemia, elevated lactate concentration, hyperuricemia (gouty attacks), increased collagen and scar tissue formation, and alcoholic ketoacidosis (AKA) (Fig. 76-2).

Studies in alcoholic liver disease focused on Kupffer cell activation by endotoxin that is released by intestinal bacteria. When Kupffer cells are activated, they produce regulatory nuclear factor  $\kappa$ B (NF $\kappa$ B) and generation of significant amounts of superoxide radicals (O<sub>2</sub><sup>-</sup>) and cytokines (tumor necrosis factor and interleukin-8), which is an essential factor in the injury to hepatocytes associated with alcoholic liver disease.<sup>140,230</sup>

## ACUTE CLINICAL FEATURES

Ethanol is a selective CNS depressant at low doses and a general depressant at high doses. Initially, it depresses the areas of the brain involved with highly integrated functions. Cortical release leads to animated behavior and the

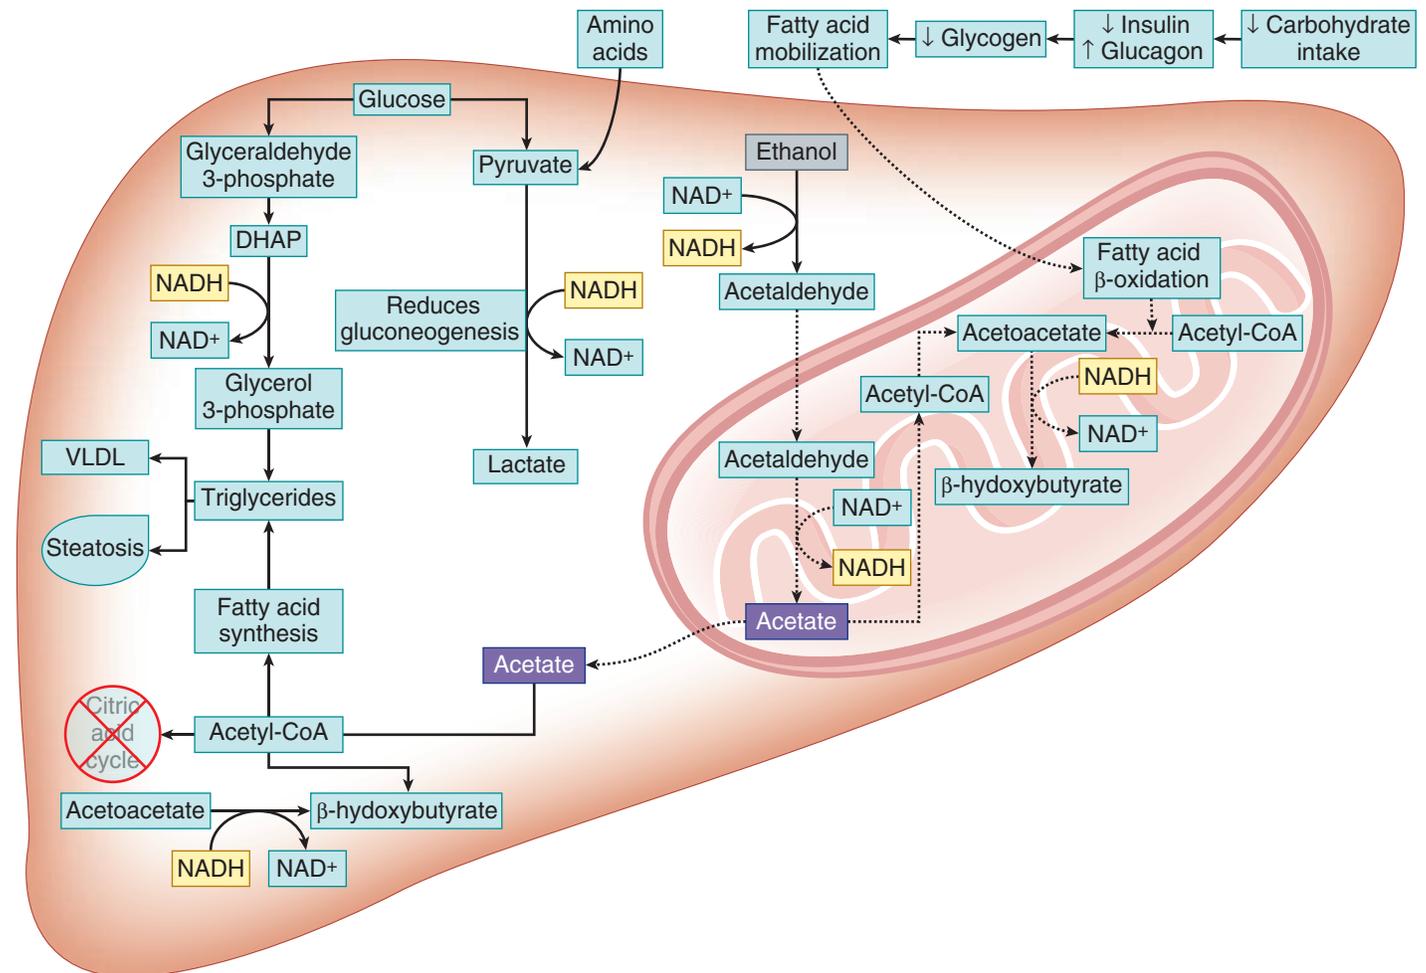

**TABLE 76-3** Systemic Effects Associated With Alcoholism

<b>Cardiovascular</b>	<b>Genitourinary</b>
Cardiomyopathy	Hypogonadism
“Holiday heart” (dysrhythmias)	Impotence
“Wet” beriberi or high-output heart failure (thiamine deficiency)	Infertility
<b>Endocrine and Metabolic</b>	<b>Hematologic</b>
Hypoglycemia	Coagulopathy
Hypokalemia	Folate, B <sub>12</sub> , iron-deficiency anemias
Hypomagnesemia	Hemolysis (Zieve syndrome, stomatocytosis, spur-cell anemia)
Hypophosphatemia	Leukopenia
Hypothermia	Thrombocytopenia
Hypertriglyceridemia	<b>Neurologic</b>
Hyperuricemia	Alcohol amnestic syndrome
Metabolic acidosis	Alcoholic hallucinosis
Malnutrition	Alcohol withdrawal
<b>Gastrointestinal</b>	Cerebellar degeneration
Mouth	Cerebral atrophy (dementia)
Cancer of the mouth, pharynx, larynx	Cerebrovascular accident (hemorrhage, infarction)
Cheilosis	Inebriation
Stomatitis (nutritional)	Korsakoff psychosis
Esophagus	Marchiafava-Bignami disease
Boerhaave syndrome	Myopathy
Cancer of the esophagus	Osmotic demyelination syndrome
Esophageal spasm (diffuse)	Pellagra
Esophagitis	Polyneuropathy
Mallory-Weiss tear	Subdural hematoma
Stomach and duodenum	Wernicke encephalopathy
Diarrhea	<b>Ophthalmic</b>
Gastritis (Acute)	Tobacco-ethanol amblyopia
Gastritis (chronic hypertrophic)	<b>Psychiatric</b>
Hematemesis	Animated behavior
Malabsorption	Loss of self-restraint
Peptic ulcer	Manic-depressive illness
Liver	Suicide and depression
Cirrhosis	<b>Respiratory</b>
Hepatitis	Atelectasis
Steatosis	Pneumonia
Pancreas	Respiratory acidosis
Pancreatitis (acute or chronic)	Respiratory depression

loss of restraint. This paradoxical CNS stimulation is due to disinhibition. The signs of inebriation are quite variable. The patients are energized and loquacious, expansive, emotionally labile, increasingly gregarious or appear to have lost self-control, exhibit antisocial behavior, and are ill tempered. As the degree of inebriation increases, there are successive inhibition and impairment of neuronal activity. Patients become irritable, abusive, aggressive, violent, dysarthric, confused, disoriented, or lethargic. With severe inebriation, there is loss of airway protective reflexes, coma, and increasing risk of death from respiratory depression. An ethanol-naïve adult with a serum ethanol concentration of greater than 250 mg/dL (54 mmol/L) is usually comatose.<sup>1</sup>

However, the acute effects of ethanol ingestion also depend on the habituation of the drinker. This is mainly because of the development of tolerance, which has both a metabolic (pharmacokinetic) and a functional (pharmacodynamic) component.<sup>211</sup> Metabolic tolerance to ethanol is based on enhanced elimination by CYP2E1. Functional tolerance (resistance to the effects of ethanol at the cellular level) is a more important determinant of

habituation and is mediated through alterations in GABA<sub>A</sub> receptor subunits (eg, decrease in  $\alpha_1$  and  $\alpha_2$  subunit, increase in  $\alpha_6$  subunit, glycine antagonism, and glutamatergic neurotransmission attenuation) and upregulation of NMDA receptors (eg, NMDA R2B or GluN2B subunit) as well as interaction between serotonergic (eg, 5HT<sub>1A</sub>) and adrenergic (eg, norepinephrine and dopamine) neurons.<sup>25,92,95,108,109,150,153,176,210,221</sup> Acute ethanol tolerance is demonstrated by the Mellanby effect, which involves the comparison of physiologic responses or behavioral effects at the same serum ethanol concentration on the ascending and descending limbs of the serum ethanol vs time curve. Impairment is greater at a given serum ethanol concentration when it is increasing than for the same serum ethanol concentration when it is falling.<sup>160,226</sup> Although individuals who are acutely inebriated move through a progressive sequence of events, the association of a particular aspect of inebriation with a specific serum ethanol concentration is not usually possible without knowing the pattern of ethanol use of the patient. Acute inebriation occurs in habitual drinkers when they raise their ethanol concentration an equivalent amount above baseline and specific clinical manifestations of

**FIGURE 76-2.** Ethanol metabolism drives reactions towards NADH and acetate. The high cytoplasmic redox state favors the reduction of pyruvate to lactate and diverts pyruvate from being a substrate for gluconeogenesis, favors the reduction of dihydroxyacetone phosphate (DHAP) to glycerol 3-phosphate, and serves as substrate for triglycerides formation. The high cytoplasmic redox state and acetate load limits the citric acid cycle, thus decreasing the supply of NADH for oxidative phosphorylation, resulting in a decrease in adenosine triphosphate (ATP) production and favoring conversion of acetyl-CoA to ketone bodies and fatty acid synthesis. Abrupt discontinuation of ethanol and starvation results in mobilization and oxidation of fatty acids. Fatty acid metabolism results in the formation of acetyl-CoA, which combines with the excess acetate, in the form of acetyl-CoA, that is generated from ethanol metabolism to form acetoacetate. Most of the acetoacetate is reduced to  $\beta$ -hydroxybutyrate because of the high cellular redox state.

inebriation typically occur with significantly higher serum ethanol concentration than nontolerant individuals. Regardless, the absolute change above baseline is an important factor.

Many patients present with obvious signs and symptoms consistent with inebriation that include flushed facies, diaphoresis, tachycardia, hypotension, hypothermia, hypoventilation, mydriasis, nystagmus, vomiting, dysarthria, muscular incoordination, ataxia, altered consciousness, and coma. However, an inebriated patient presenting to an emergency department (ED) has a broad range of diagnostic possibilities and should prompt a careful evaluation for a variety of occult clinical and metabolic disorders. A meticulous and systematic approach to the evaluation and management of an inebriated patient will help avoid the potential pitfalls in such a situation.<sup>69</sup> The presence or absence of an odor of ethanol on the breath is an unreliable means of ascertaining whether a person is inebriated or whether ethanol was recently consumed.<sup>152</sup> Diplopia, visual disturbances, and nystagmus are caused by either the toxic effects of ethanol or represent Wernicke encephalopathy. Hypothermia is exacerbated by environmental exposure, from malnutrition and loss of carbohydrate or energy substrate, and ethanol-induced vasodilation; conversely heat-related illness is exacerbated during a heat wave. Inebriation impairs cardiac output in patients with preexisting cardiac disease<sup>77</sup> and induces dysrhythmias such as atrial fibrillation, atrioventricular block, and nonsustained ventricular tachycardia.<sup>53,78,79</sup> The association between ethanol use and cardiac dysrhythmias, particularly supraventricular tachydysrhythmias, in apparently healthy people is called “holiday heart

syndrome.”<sup>110,118,143</sup> The syndrome was first described in people with consequential ethanol consumption, who typically presented on weekends or after holidays, and it also occurs in patients who binge but who usually drink little ethanol. The most common dysrhythmia is atrial fibrillation, which usually reverts to normal sinus rhythm within 24 hours. Although the syndrome recurs, the clinical course is benign in patients without anatomic cardiac pathology, and specific antidysrhythmic therapy is usually not warranted.<sup>68,79</sup> Acute consequential ethanol drinking precipitates silent myocardial ischemia in patients with stable angina pectoris.<sup>186</sup> A variant form of angina pectoris, or Prinzmetal angina, occurs at rest but not usually with exertion and is associated with transient ST-segment elevation caused by focal spasm of an epicardial coronary artery and is reported to occur in patients after ethanol ingestion at a time when the serum ethanol concentration has decreased almost to zero.<sup>62,102,137,146,166,190,214</sup> Ethanol-related seizures occur as a consequence of ethanol dependence. Most commonly these seizures are caused by alcohol withdrawal and are classically characterized by generalized tonic-clonic activity followed by a brief postictal period. However, a significant percentage of patients with ethanol-related seizures have other identifiable causes, and they include head trauma (eg, intracranial hemorrhage or contusion), idiopathic generalized epilepsy, cerebrovascular accident, intracranial lesions (eg, tumors, infection, and gliosis), and toxic-metabolic (eg, hypoglycemia).<sup>159,179,180</sup> Patients presenting with acute inebriation commonly have decreased serum ionized magnesium concentrations while their total serum magnesium concentration is within the normal range.<sup>239</sup> However,

total-body magnesium depletion occurs because of poor dietary intake, decreased GI absorption secondary to ethanol, and renal wasting caused by ethanol-related diuresis.<sup>63,101,182,201,209</sup>

## DIAGNOSTIC TESTS

There are numerous qualitative and quantitative assays for ethanol in biological fluids and exhaled breath. Immunoassay or gas chromatography is commonly used for determination of ethanol in liquid specimens in most hospitals. Hospital laboratory analysis of blood samples for ethanol content is usually based on serum (liquid portion of whole blood after the cellular components and clotting factors are removed) or rarely plasma (acellular liquid portion of whole blood). By contrast, forensic casework expresses ethanol concentration in terms of ethanol concentration in whole blood (Special Considerations: SC11).

Ethanol saliva testing is a promising alternative to breath ethanol analysis in the rapid assessment of serum ethanol concentrations in patients regardless of their mental status.<sup>43,204</sup> Fatty acid ethyl esters are a highly sensitive and specific test for recent ethanol use.<sup>16,51,205</sup> Because FAEs remain in the system for at least 24 hours, they have a role as a marker of recent ethanol use even after ethanol is completely metabolized. The presence of FAEs in meconium and hair is currently the most used tool to detect prenatal ethanol exposure.<sup>10</sup>

Ethyl glucuronide and ethyl sulfate are nonoxidative direct ethanol metabolites and are excreted for considerably longer time than ethanol.<sup>19,40,83,189,194</sup> Testing for these metabolites in urine has gained popularity as a sensitive method to detect recent ethanol intake and is favored over tests such as  $\gamma$ -glutamyl transferase (GGT) or carbohydrate-deficient transferrin, particularly by agencies concerned with monitoring an individual for recent ethanol consumption or relapse, confirm abstinence in treatment programs, workplaces, and schools, and provide legal proof of drinking.<sup>82,175</sup> The presence of ethyl glucuronide and ethyl sulfate provides a strong indication of recent drinking even when ethanol is no longer detectable.<sup>83</sup> However, caution should be applied in the interpretation of ethyl glucuronide testing results. Ethyl glucuronide is sensitive to degradation or is synthesized by bacteria (eg, *Escherichia coli*) such that infected urine results in either a false-negative or false-positive test result, particularly when specimens are improperly stored; ethyl sulfate degradation or formation is not detected under similar conditions.<sup>85,87</sup> Detection windows for ethyl glucuronide and ethyl sulfate after drinking are limited and dependent on the amount of ethanol consumed. For example, these metabolites are detectable in urine for 24 hours or less after intake of 0.25 g/kg ethanol and 48 hours or less after intake of 0.50 g/kg ethanol.<sup>40,81,83,90,91,237</sup> Depending on the analytical cut-off limit, unintentional exposure to ethanol including mouthwash and hand sanitizers results in a urine positive for ethyl glucuronide or ethyl sulfate.<sup>37,185</sup> There appears to be a marked interindividual variation in the concentration–time profiles for both metabolites. When the times for ethanol intake and urine specimen collection between drinking and sampling are uncertain, it is not possible to link a single ethyl glucuronide and sulfate result to a specific ethanol dose taken at a specific time.<sup>86</sup> A common cut-off or reporting limit has yet to be determined for urinary ethyl glucuronide and ethyl sulfate when used as ethanol biomarkers.

Laboratory investigations that are recommended for inebriated patients include a rapid reagent glucose test, complete blood count, electrolytes, blood urea nitrogen, creatinine, urine, ketones, acetone, lipase, liver enzymes, ammonia, calcium, and magnesium. Patients with an anion gap metabolic acidosis should have urine ketones and a serum lactate concentration determined (Chaps. 12 and 106). Whereas high serum acetone concentrations are indicative of isopropanol toxicity or accelerated fatty acid metabolism, elevated serum or urinary ketones are indicative of AKA, starvation ketosis, or diabetic ketoacidosis (DKA). Because the laboratory nitroprusside reaction detects only ketones (acetoacetate and acetone) and not  $\beta$ -hydroxybutyrate, the assay for urinary ketones is only mildly positive in many patients with AKA.

A serum ethanol concentration will be infrequently necessary in the initial laboratory studies of patients who appear inebriated or have an altered mental status.<sup>93</sup> When performed if the serum ethanol concentration is inconsistent with the patient's clinical condition, prompt reevaluation of the patient is indicated to elucidate the etiology of the altered mental status, including toxic-metabolic (eg, hypoglycemia, electrolyte or acid–base disorder, toxic alcohols, therapeutic or illicit drug overdose, ethanol withdrawal, hepatic encephalopathy, and Wernicke-Korsakoff syndrome), trauma-related, neurologic (eg, postictal condition), and infectious (eg, CNS infections) etiologies. The threshold for head computed tomography (CT) imaging should be low in comatose patients with concentrations below 300 mg/dL (65 mmol/L) and those with values in excess of 300 mg/dL (65 mmol/L) who fail to improve clinically during a limited period of close observation followed by a lumbar puncture if warranted. There should also be a low threshold for head CT imaging in chronically ethanol-tolerant patients because they are prone to trauma and coagulopathies, both of which cause intracranial bleeding.

If the osmol gap, the difference between the measured osmolality and the calculated osmolality, is to be used as a tool to assist in the diagnosis of toxic alcohol ingestion, the presence of ethanol in patients needs to be included in the calculation.<sup>89</sup> Ethanol increases the calculated osmolality, making the osmol gap smaller or even possibly negative. Small osmol gaps cannot be safely used to exclude the possibility of toxic alcohol ingestions, but very large osmol gaps are suggestive of toxic alcohol ingestions.

## MANAGEMENT OF POSSIBLY INEBRIATED PATIENTS

Ethanol is rapidly absorbed from the GI tract. Occasionally, an extremely inebriated or comatose patient will have severe respiratory depression, necessitating endotracheal intubation and ventilatory support. Any patient with an acute altered mental status mandates immediate investigation and treatment of reversible causes such as hypoxia, hypoglycemia, and opioid toxicity. In addition, treatment for presumed thiamine depletion is recommended. Supplemental oxygen should be administered if the patient is hypoxic; intravenous (IV) dextrose (0.5–1.0 g/kg) and naloxone 0.04 mg should be administered as clinically indicated. Abnormal vital signs should be addressed and stabilized. Patients who are combative and violent should be both physically restrained and then chemically sedated (Special Considerations: SC4). Randomized clinical trials suggest both benzodiazepines (ie, midazolam) and antipsychotics (ie, droperidol and haloperidol) are effective as chemical sedation in the ED setting.<sup>96,111,136,161</sup> Midazolam has a more rapid onset of action and a shorter duration of effect than droperidol.<sup>96,111,136,161</sup> Patients receiving midazolam required more additional sedation and required airway management compared with patients receiving droperidol.<sup>96,111,136</sup> Although the efficacy of midazolam and various antipsychotics are confirmed in multiple studies,<sup>96,111,136,161</sup> these studies were not designed to inform about the safety, equivalence, or superiority of midazolam and droperidol. Caution should be taken because of additive effects of ethanol and benzodiazepine on respiratory depression. Attempts by those who are clinically inebriated to sign out against medical advice or attempt to leave should also be prevented. Under these circumstances reevaluation, observation and additional laboratory studies will enhance the assessment to ensure the patient is safe for discharge (Chap. 138 and Special Considerations: SC11). It is reasonable to reassess patient's fluid and electrolyte status and abnormalities corrected. It is reasonable to add multivitamins with folate, thiamine, and magnesium to the maintenance IV solution.

A variety of therapies are advocated either to reverse the intoxicating effects of ethanol or to enhance its elimination. Those proven to be either ineffective or unreliable include caffeine, naloxone, flumazenil, and rapid IV saline loading.<sup>64,126,163,164,184</sup> Hemodialysis is an effective means of enhancing the systemic elimination of ethanol because of the small volume of distribution and low molecular weight of ethanol. In severe ethanol poisoning resulting in respiratory failure or coma, hemodialysis is a reasonable adjunct treatment to supportive care. However, the risks of hemodialysis usually exceed its benefit.

## INDICATIONS FOR HOSPITALIZATION

A patient with uncomplicated inebriation can be safely discharged after a careful observation with social service or psychiatric counseling. An individual should not be discharged while impairment of cognitive and motor function persists. However, it is reasonable to discharge a mildly intoxicated patient to a protected environment under the supervision of a responsible, not intoxicated adult. In all cases except allowing a person to drive, the clinical assessment of the patient is more important than the serum ethanol concentration. Indications for hospital admission include persistently abnormal vital signs, persistently abnormal mental status with or without an obvious cause, an overdose with intended self-harm, concomitant serious trauma, consequential ethanol withdrawal, and those with an associated serious disease process such as pancreatitis or GI hemorrhage.

Chronic alcoholism leads to an organic brain syndrome that is irreversible. The patient's socioeconomic condition, capacity, and lack of ability to comply with a treatment plan are critical in making a disposition. Patients with alcoholism requesting ethanol detoxification should be assisted in finding an appropriate rehabilitation site. Inpatient detoxification programs differ substantially from outpatient programs, but their most consequential advantages are that they enforce abstinence, provide more support and structure, and separate the patient from the social surroundings associated with drinking.<sup>157,225</sup> For patients who are not admitted, a referral should be offered to Alcoholics Anonymous or another suitable ethanol rehabilitation program.

### Ethanol-Associated Hypoglycemia

Hypoglycemia associated with ethanol consumption occurs when ethanol metabolism increases the cellular redox ratio. The higher redox state favors the conversion of pyruvate to lactate, diverting pyruvate from being a substrate for gluconeogenesis (Fig. 76-2).<sup>113,241</sup> Hypoglycemia typically occurs when there is a reduced caloric intake and only after the hepatic glycogen stores are depleted, as in an overnight fast. The mechanism by which hypoglycemia is associated with ethanol consumption in the well-nourished individual is less well defined.

Although the conditions associated with hypoglycemia in adults are also present in infants and children, children with their smaller livers have less glycogen stores than adults and are more likely to develop hypoglycemia. Hypoglycemia associated with ethanol consumption usually occurs in malnourished chronic alcoholics and children (Chap. 47). Hypoglycemia also occurs in binge drinkers who do not have adequate caloric intake. A 22% incidence of hypoglycemia was reported in one retrospective study of children with documented ethanol ingestion.<sup>124</sup> In another retrospective study of children and adolescents, there was a 3.4% incidence of hypoglycemia (serum glucose concentration <67 mg/dL or 3.7 mmol/L);<sup>58</sup> children age younger than 5 years have an increased risk of developing hypoglycemia, and it is the most common reported clinical abnormality related to ethanol ingestion in this age group.<sup>119,120</sup>

### Clinical Features

Patients with ethanol associated hypoglycemia usually present with an altered consciousness 2 to 10 hours after ethanol ingestion. Other physical findings include hypothermia and tachypnea. Laboratory findings, in addition to hypoglycemia, usually include a positive serum ethanol concentration, ketonuria without glucosuria, and mild metabolic acidosis.

### Management

Acute treatment of ethanol-associated hypoglycemia is similar to other causes of hypoglycemia (Chap. 47 and Antidotes in Depth: A8) and should prompt a systematic evaluation for coexisting clinical and metabolic disorders. Hospital admission is reasonable in severe or resistant cases. Because this represents serious metabolic impairment that cannot be rapidly rectified.

### Alcoholic Ketoacidosis

The development of AKA requires a combination of physical (eg, abrupt discontinuation of ethanol and starvation) and physiologic events to occur. The

normal response to starvation and depletion of hepatic glycogen stores is for amino acids to be converted to pyruvate. Pyruvate serves as a substrate for gluconeogenesis and is converted to acetyl-CoA, which can enter the citric acid cycle or is used in various biosynthetic pathways (eg, fatty acids, ketone bodies, cholesterol, and acetylcholine). As described earlier, ethanol metabolism generates an excess of acetate and a high cellular redox potential. This excess acetate is converted to acetyl-CoA by cytoplasmic and mitochondrial adenosine triphosphate (ATP)-dependent acetyl-CoA synthetases (Fig. 76-2). The consequences of increased cellular acetyl-CoA and cellular redox potential include inhibition of pyruvate dehydrogenase complex thus entry of pyruvate into the citric acid cycle, inhibition of the citric acid cycle, and favors formation of the ketone bodies (ie, acetoacetate, beta-hydroxybutyrate, and acetone). The high redox state also favors the conversion of pyruvate to lactate, diverting pyruvate from being a substrate for gluconeogenesis. To compensate for the lack of normal metabolic substrates, the body mobilizes fat from adipose tissue and increases fatty acid metabolism as an alternative source of energy. This response is mediated by a decrease in insulin and an increase in glucagon, catecholamines, growth hormone, and cortisol. Fatty acid metabolism results in the formation of acetyl-CoA. Two molecules of acetyl-CoA condense to form acetoacetyl-CoA, which is metabolized to acetoacetate via the 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) pathway.<sup>30</sup> Similarly, the high acetyl-CoA concentration that is generated from excess acetate favors condensation to acetoacetyl-CoA and metabolism to acetoacetate, both in the mitochondria as well as in the cytoplasm. Most of the acetoacetate is reduced to  $\beta$ -hydroxybutyrate because of the excess reducing potential or high redox state of the cell. Volume depletion interferes with the renal elimination of acetoacetate and  $\beta$ -hydroxybutyrate and contributes to the metabolic acidosis. An elevated lactate concentration results from shunting from pyruvate or from hypoperfusion or infection that may coexist with the underlying ketoacidosis.

### Clinical Features

Patients with AKA are typically chronic ethanol users, presenting after a few days of "binge" drinking, who become acutely starved because of cessation in oral intake due to binging itself or because of nausea, vomiting, abdominal pain from gastritis, hepatitis, pancreatitis, or a concurrent acute illness.<sup>69,70,72</sup> The patient usually appears acutely ill with salt and water depletion, tachypnea, tachycardia, and hypotension. Medical conditions such as sepsis, meningitis, pyelonephritis, or pneumonia occur simultaneously, and ethanol withdrawal subsequently develops.

The serum ethanol concentration is usually low or undetectable because ethanol intake substantially decreased earlier in the clinical course. In one report of 23 episodes of AKA, serum ethanol was undetectable in 13 and above 50 mg/dL in only 5.<sup>70</sup> The hallmarks of AKA include an elevated anion gap metabolic acidosis with an elevated serum lactate concentration. However, some patients will have a normal arterial pH or be even alkalemic because of an associated primary metabolic alkalosis because of vomiting and a compensatory respiratory alkalosis (Chap. 12).<sup>70,72,206</sup> When patients with AKA were compared with patients with DKA, those with AKA tended to have a higher blood pH, lower serum potassium and chloride concentrations, and a higher serum bicarbonate concentration.<sup>71</sup> The etiology of anion gaps in patients with AKA and DKA are very similar with  $\beta$ -hydroxybutyrate being the primary anion in AKA and acetoacetate in DKA.<sup>71</sup>

The nitroprusside test used to detect the presence of ketones in serum and urine is negative or mildly positive in patients with AKA because the nitroprusside reaction only detects molecules containing ketone moieties. This includes acetoacetate and acetone but not  $\beta$ -hydroxybutyrate. Reliance on the nitroprusside test alone underestimates the severity of ketoacidosis. Specific assays for  $\beta$ -hydroxybutyrate are performed in some hospital laboratories and are available as point-of-care testing at bedside. The blood glucose concentration is typically low or mildly elevated. It is postulated that ethanol induced hypoglycemia occurs first, causing increased cortisol, growth hormone, glucagon, and epinephrine concentrations, which mobilizes fatty acids that are then converted to ketone bodies.<sup>44</sup> Therefore, alcoholic

hypoglycemia and AKA frequently are sequential events of the same process depending on the point in this process at which the patient is evaluated.

### Management

Treatment should begin with adequate crystalloid fluid replacement, dextrose, thiamine and folic acid. Supplemental multivitamins, potassium, and magnesium are recommended on an individual basis. The administration of dextrose will stimulate the release of insulin, decrease the release of glucagon, and reduce the oxidation of fatty acids. Exogenous glucose also facilitates the synthesis of ATP, which reverses the pyruvate-to-lactate and NAD<sup>+</sup>/NADH ratios. The provision of thiamine facilitates pyruvate entry into the citric acid cycle, thus increasing ATP production. Volume replacement restores glomerular filtration and improves excretion of ketones and organic acids. Administration of either insulin or sodium bicarbonate in the management of AKA is usually unnecessary.<sup>72</sup>

During the recovery phase of AKA, β-hydroxybutyrate is converted back to acetoacetate. As this process occurs, the nitroprusside test becomes more positive because of higher concentrations of acetoacetate resulting in a hyperketonemia and ketonuria, which represents improvement of the metabolic status.

Patients presenting with AKA are manifesting serious metabolic impairment and frequently require hospital admission. They often succumb to other precipitating or coexisting medical or surgical disorders<sup>69</sup> such as occult trauma, pancreatitis, GI hemorrhage or hepatorenal dysfunction, and infections. However, death is rare from ethanol-induced ketoacidosis.

## ALCOHOLISM

Alcoholism is traditionally defined as a chronic, progressive disease characterized by tolerance and physical dependence to ethanol and pathologic organ changes and is recognized to be a multifactorial, genetically influenced disorder.<sup>38,88,157,171,181,196,216</sup> The most recent edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* integrated alcohol abuse and alcohol dependence into a single disorder called *alcohol use disorder* (AUD) with mild, moderate, and severe subclassifications.<sup>5</sup> The presence of at least 2 of the symptoms (Table 76-4) within 12 months indicates an AUD. The severity of AUD is defined by the number of symptoms present (ie, mild, 2 or 3 symptoms; moderate, 4 or 5 symptoms; and severe, 6 or more symptoms).

Although many people drink in an attempt to ameliorate their depression, all available evidence suggests that alcoholism adversely affects mood and cognitive ability. Research suggests alcoholism is partly under genetic control.<sup>12,106,112,130</sup> Chromosomal linkage analysis has implicated chromosomes 9, 15, and 16 in the genetic predisposition to alcoholism.<sup>15,47,132</sup> Polymorphism in *ADH* and *ALDH* genes appears to be a marker for risk of alcoholism.<sup>34,38,57,216,217</sup> The *ADH1B\*2*, *ADH1C\*1*, and *ALDH2\*2* alleles are associated with reduced risk of alcoholism. Genetic epidemiologic studies

**TABLE 76-5** The Brief Michigan Alcoholism Screening Test

Question	Circle Correct Answer	Points
1. Do you feel you are a normal drinker?	Yes No	N2
2. Do friends or relatives think you are a normal drinker?	Yes No	N2
3. Have you ever attended a meeting of Alcoholics Anonymous?	Yes No	Y5
4. Have you ever lost friends or girlfriends/boyfriends because of drinking?	Yes No	Y2
5. Have you ever gotten into trouble at work because of drinking?	Yes No	Y2
6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking?	Yes No	Y2
7. Have you ever had delirium tremens (DTs) or severe shaking, or heard voices, or seen things that weren't there after heavy drinking?	Yes No	Y2
8. Have you ever gone to anyone for help about your drinking?	Yes No	Y5
9. Have you ever been in a hospital because of drinking?	Yes No	Y5
10. Have you ever been arrested for drunk driving after drinking?	Yes No	Y2

Score 6 = Probable diagnosis of alcoholism.

strongly correlate Asians with homozygous *ADH1B\*2* and *ALDH2\*2* alleles with reduced ethanol consumption and incidence of alcoholism.<sup>38,171,233</sup> The incidence of both homozygous *ADH1B\*1* and *ALDH2\*1* alleles was significantly higher in patients with ethanol dependence and in patients with alcoholic liver disease.

Screening is a preliminary procedure to assess the likelihood that an individual has a substance use disorder or is at risk of negative consequences from alcohol or other xenobiotics use. Whereas screening tools, such as the Brief Michigan Alcoholism Screening Test (MAST)<sup>174</sup> and the CAGE questions<sup>138</sup> (Tables 76-5 and 76-6), were initially developed to identify people with active alcohol dependence for referral to treatment, the screening, brief intervention, and referral to treatment (SBIRT) was developed as a public health model designed to provide universal screening, secondary prevention in detecting risky or hazardous substance use before the onset of abuse or dependence, early intervention, and treatment for people who have problematic or hazardous alcohol problems within health care settings.<sup>8</sup> Based on the Substance Abuse and Mental Health Services Administration (SAMHSA) model, SBIRT allows for universal screening of all patients regardless of an identified disorder, allowing health care professionals to address the spectrum of such behavioral health problems even when the patient is not actively seeking intervention or treatment.

The Alcohol Use Disorders Identification Test (AUDIT) was developed from a 6-country World Health Organization collaborative project as a screening instrument to identify heavy drinkers and explicitly

**TABLE 76-4** DSM-5 Alcohol Use Disorder

Drinking more or longer than intended?
Desire or unsuccessful efforts to control alcohol use?
A lot of time drinking or to recover from alcohol effects?
Craving to use alcohol?
Drinking or sick from drinking interfering with obligations at work, home, or school?
Continued drinking even though it is causing social or interpersonal problems?
Alcohol use reducing social, occupational, or recreational activities?
Recurrent alcohol use in situations where it is physically hazardous?
Continued drinking in spite of physical or psychological problems?
Need for increased drinking to achieve desired effect?
Drinking to relieve or avoid withdrawal symptoms?

Data from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: American Psychiatric Association; 2013.

**TABLE 76-6** The CAGE Questions<sup>138</sup>

1. Have you ever felt you should cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?

Two or more affirmatives = probable diagnosis of alcoholism.

TABLE 76-7 AUDIT-C Alcohol Use Disorders Identification Test-Dealing With Alcohol Consumption

Questions	Scoring <sup>a</sup>				
	0	1	2	3	4
How often do you have a drink containing alcohol?	Never	≤Monthly	2–4 times/mo	2–3 times/wk	≥4 times/k
How many alcohol units do you drink on a typical day when you are drinking?	0–2	3–4	5–6	7–9	≥10
How often have you had ≥6 units if female, or ≥8 units if male, on a single occasion in the past year?	Never	<Monthly	Monthly	Weekly	Daily (almost)

<sup>a</sup>One alcohol unit (10 mL or 8 g of “pure” ethanol) is equal 25 mL of whisky (alcohol by volume 40%), a third of a pint of beer (alcohol by volume, 5%–6%), or a 175-mL glass of red wine (alcohol by volume, 12%).

addresses alcohol-related problems and symptoms of dependence over the past year.<sup>191</sup> It is a 10-item questionnaire that covers the domains of alcohol consumption, drinking behavior, and alcohol-related problems. The AUDIT screen provides a simple method of early detection of hazardous and harmful alcohol use in primary health care settings. A modified version of the AUDIT instrument, the first 3 questions of AUDIT dealing with alcohol consumption (AUDIT-C), is used to help identify patients who are hazardous drinkers or have active alcohol use disorders and performed better than AUDIT for identification of heavy drinkers who might benefit from brief primary care interventions (Table 76-7).<sup>26,114</sup> In addition, there was no significant difference between these screening questionnaires for identification of patients with heavy drinking or active alcohol abuse or dependence. However, AUDIT performed better than AUDIT-C in identifying active alcohol abuse or dependence. The AUDIT-C is scored on a scale of 0 to 12 points; 0 reflect no alcohol use in the past year. In men, a score of 4 points or more is considered positive for alcohol misuse; in women, a score of 3 points or more is considered positive. Generally, the higher the AUDIT-C score, the more likely it is that the drinking is affecting the patient’s health and safety.

The presence of tolerance or dependence is not essential for a diagnosis of alcoholism. Emphasis instead is placed on the social and behavioral concomitants of heavy drinking.<sup>151</sup> In the ED setting, questions concerning the patient’s ability to function physically and psychologically are just as appropriate as quantifying the amount of ethanol consumed per day.

Alcoholism is commonly associated with affective disorders, especially depression.<sup>147,177</sup> There is a higher rate of alcoholism among patients with bipolar disorder than in the general population, and there is evidence for a genetic relationship between alcoholism and depression.<sup>106,165,235,236</sup> Ethanol affects mood, judgment, and self-control and creates a clinical condition conducive to violence directed at self and others and is an important risk factor for suicide.

Various strategies are used to treat alcoholism, including psychosocial interventions, pharmacologic interventions, or both. One psychosocial experiment is the “project-based Housing First” model, the so-called wet houses, in which chronically homeless individuals with alcohol problems are provided food and permanent housing, but unlike other housing agencies or shelters, wet houses do not require participants to observe curfews or abstain from drinking, and they can elect to receive onsite case management and other supportive services.<sup>35,122</sup> Contrary to the enabling hypothesis that provision of non-abstinence-based Housing First would result in stable or increasing levels of alcohol use and alcohol-related problems, residence of project-based Housing First reduced their alcohol use on typical and peak drinking days by 7% and 8%, respectively, for every 3 months of their stay; increased their avoidance in drinking to inebriation at least 1 day in the previous month by 19% at the end of a 2-year stay; and reported a decrease in delirium tremens occurrence by 42% during at the end of 2-year residence. Pharmacologic treatment of ethanol dependence that is of potential collateral toxicologic consequence include opioid antagonists such as naltrexone and nalmefene, disulfiram, serotonergic agents, and topiramate.<sup>73,97</sup>

Although it is a serious disease with important health and economic consequences, alcoholism remains underdiagnosed and remains a treatment challenge.<sup>135,238</sup>

## SUMMARY

- Ethanol is widely used in our society and ethanol use problems impose a staggering personal, social, and economic burden on our society.
- Domestic violence, motor vehicle crashes, child abuse, fires, falls, rape, and other crimes such as robbery and assault and medical consequences such as cancer, liver disease, and heart disease are all associated with ethanol misuse.
- One interesting area in ethanol research is the finding that genetics are an important determinant in vulnerability to ethanol dependence. This finding suggests the biological basis of alcoholism.
- Acute inebriation and alcoholism are among the most common and complex toxicologic and societal problems.
- Patients with acute inebriation or alcoholism present with a diversity of clinical problems (eg, hypoglycemia, AKA, and ethanol withdrawal) that challenge the clinicians to be meticulous and systematic in their evaluation and management of these patients.

## THIAMINE HYDROCHLORIDE

Robert S. Hoffman

## INTRODUCTION

Thiamine (vitamin B<sub>1</sub>) is a water-soluble vitamin found in organ meats, yeast, eggs, and green leafy vegetables that is essential in the creation and utilization of cellular energy. Although there is no toxicity associated with thiamine excess, thiamine deficiency is responsible for “wet” beriberi (congestive heart failure) and “dry” beriberi (Wernicke encephalopathy and the Wernicke-Korsakoff syndrome). Patients at risk include those with malnutrition (HIV/AIDS, cancer, end-stage kidney disease, fad diets, anorexia nervosa, bulimia, cyclic vomiting, hyperemesis gravidarum, and after bariatric surgery), those with impaired absorption (alcoholism, sepsis, bariatric surgery, inflammatory bowel disease), and those with enhanced elimination (high-dose loop diuretic therapy). Typical signs of Wernicke encephalopathy include ataxia, altered mental status, and ophthalmoplegia. Although administration of 100 mg of parenteral thiamine hydrochloride protects against thiamine deficiency for more than 1 week, patients with clinical deficiencies require larger doses for a longer period of time.

## HISTORY

Kanehiro Takaki, a physician in the Japanese navy, first established the relationship between a nutritional deficiency and beriberi in 1884. It was not until 1901 that Gerrit Grijns determined that the nutrient, as yet unnamed, was contained in the outer coat of rice and was lost during the polishing process. Ten years later, Casimir Funk isolated thiamine, and Williams finally determined its structure in 1934. Originally thiamine was called aneurin for “antineuritic vitamin”<sup>22</sup> and was ultimately synthesized by Cline, Williams, and Finkelstein.<sup>28</sup> In 1936, Peters demonstrated that thiamine could reverse neurologic disease in nutritionally deprived pigeons and that improvement was coupled to an enhanced ability to metabolize pyruvate.<sup>109</sup>

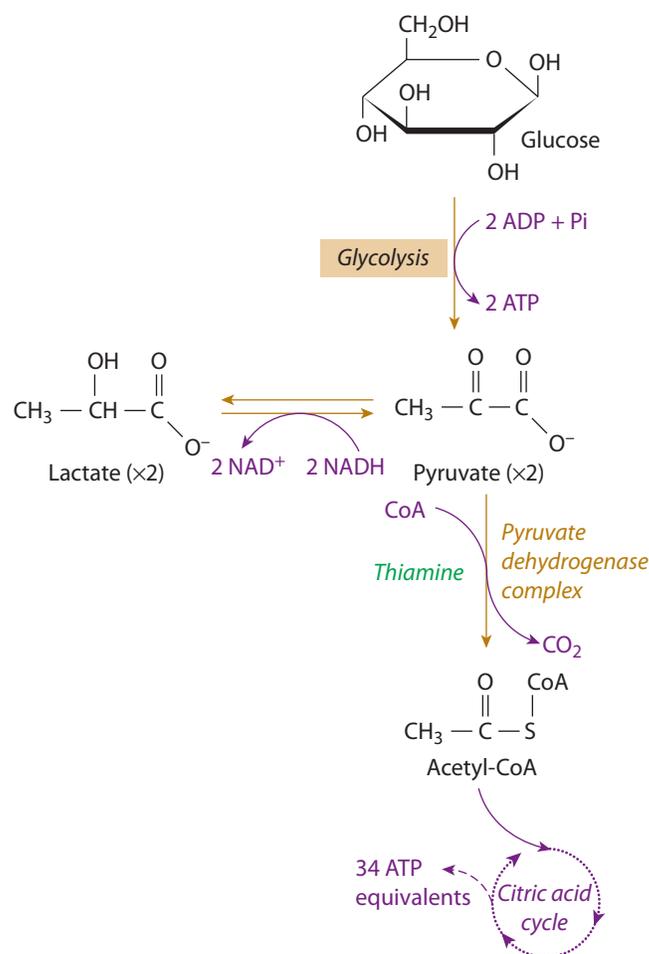

In 1881, Carl Wernicke reported 3 patients with alcoholism who died after developing confusion, ataxia, and ophthalmoplegia.<sup>149</sup> Autopsies showed characteristic hemorrhages surrounding the third and fourth cerebral ventricles. A few years later, Sergei Korsakoff reported amnesia and confabulation in 30 individuals with alcoholism and 16 without alcoholism that was preceded in many by the clinical findings reported by Wernicke.<sup>157</sup> Today, these 2 neurologic disorders are often combined and called the Wernicke-Korsakoff syndrome in recognition that they are a spectrum of the same disease.

## PHARMACOLOGY

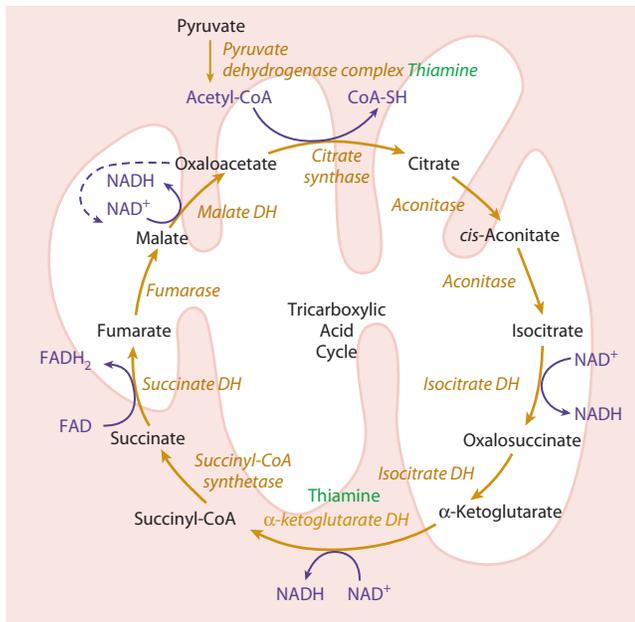

## Biochemistry

As a coenzyme in the pyruvate dehydrogenase complex, thiamine diphosphate (thiamine pyrophosphate), the active form of thiamine, facilitates the conversion (with bound lipoamide and magnesium as cofactors) of pyruvate to acetylcoenzyme A (acetyl-CoA). This reaction occurs at the C2 atom

of thiamine, which is located between the nitrogen and sulfur atoms on the thiazolium ring.<sup>53</sup> In the protein-rich environment of the enzyme complex, this C2 atom is deprotonated to form a carbanion that rapidly attaches to the carbonyl group of pyruvate, thereby stabilizing it for decarboxylation.<sup>73</sup> In a series of subsequent reactions, the hydroxyethyl group that remains bound to thiamine diphosphate is transferred to lipoamide, where an acetyl group is later broken off and attached to coenzyme A (CoA). This overall process links pyruvate production from anaerobic glycolysis to the citric acid cycle, in which the sum of anaerobic and aerobic metabolism produces the equivalent of 36 moles of adenosine triphosphate (ATP) from each mole of glucose (Fig. A27-1). When pyruvate cannot be converted to acetyl-CoA

**FIGURE A27-1.** Thiamine links anaerobic glycolysis to the citric acid cycle. Anaerobic glycolysis only yields 2 moles of adenosine triphosphate (ATP) as each mole of glucose is metabolized to 2 moles of pyruvate. To obtain the 34 additional ATP equivalents that can be derived as the citric acid converts pyruvate to CO<sub>2</sub> and H<sub>2</sub>O, pyruvate must first be combined with coenzyme A (CoA) to form acetylcoenzyme A (acetyl-CoA) and CO<sub>2</sub>. This process is dependent on the thiamine-requiring enzyme system known as pyruvate dehydrogenase complex.

**FIGURE A27-2.** Thiamine is essential for  $\alpha$ -ketoglutarate dehydrogenase activity, which is a rate-limiting step within the citric acid cycle. Thiamine deficiency leads to an accumulation of  $\alpha$ -ketoglutarate, which is shunted to glutamate and causes excitatory neurotoxicity.

because of thiamine deficiency, for example, only 2 moles of ATP are generated by anaerobic metabolism from each mole of glucose. Within the citric acid cycle, thiamine is also required as a cofactor for the  $\alpha$ -ketoglutarate dehydrogenase complex to catalyze the reaction of  $\alpha$ -ketoglutarate to succinyl-CoA (Fig. A27-2), and in the pentose phosphate pathway for transketolase, an enzyme in which nicotinamide adenine dinucleotide phosphate (NADPH) is formed for subsequent use in reductive biosynthesis.<sup>15,172</sup> In addition to its metabolic effects, thiamine also has a role as a neuromodulator, influencing acetylcholine release.<sup>64</sup>

Naturally occurring thiamine is a base composed of a substituted pyrimidine ring and a substituted thiazole ring connected by a methylene bridge. This connection between the 2 rings is weak, and the molecule is unstable in both an alkaline milieu and in a high-temperature environment. In addition, thiamine is highly water soluble, allowing it to leach out of foods following prolonged washing or cooking in water. However, thiamine, which is synthesized as a hydrochloride salt, is usually quite stable. Thiamine requirements are determined by total caloric intake and energy demand, with 0.33 mg of thiamine required for every 4,400 kJ (1,000 kcal) of energy.<sup>132</sup> The recommended daily consumption is 0.5 mg/1,000 kcal to provide a margin of safety.<sup>131</sup>

### Pharmacokinetics

Thiamine is well absorbed from the human gastrointestinal (GI) tract by a complex process.<sup>81,116</sup> At low concentrations, thiamine absorption occurs through a saturable mechanism that is most effective in the duodenum, with absorption occurring to a lesser degree in the large bowel and stomach.<sup>81</sup> As thiamine concentrations increase, however, the majority of absorption occurs through simple passive diffusion. A placebo-controlled human volunteer study evaluated the kinetics of oral administration of 100, 500, and 1,500 mg in healthy participants.<sup>132</sup> After the oral 100-mg dose, peak concentrations occurred in whole blood in 3.43 hours. Although higher doses produced higher peak concentrations with a delay in time, the lack of linearity of the dose–response relationship confirmed complex absorption kinetics.<sup>132</sup> The kinetics of oral and intravenous (IV) thiamine were compared in 6 healthy volunteers after a 50-mg dose.<sup>144</sup> Intravenous administration peaked rapidly and had an apparent elimination half-life of 96 minutes but showed restricted distribution with 53% recovered in the

urine over the next 24 hours. By contrast, oral administration peaked in a mean of 53 minutes, was only 5.3% bioavailable, and had an apparent elimination half-life of 154 minutes, and only 2.5% was recoverable in the urine.<sup>144</sup> The effects of varied rates of infusion were compared in 12 healthy individuals when 150 mg of thiamine was given IV over either 1 hour or 24 hours in a controlled trial.<sup>41</sup> As expected, although the rapid infusion produced a higher peak concentration. However, the slower infusion increased the AUC of thiamine pyrophosphate and decreased the urinary elimination from 83.6% of the dose to 57.6%, suggesting a benefit for slower administration rates.<sup>41</sup> Synthesized analogs such as thiamine propyl disulfide, benfotiamine, and fursultiamine have enhanced bioavailability, but their use remains largely experimental.<sup>53,151,168</sup> Chronic liver disease, folate deficiency, steatorrhea, and other forms of malabsorption all significantly decrease the absorption of thiamine.<sup>33,133</sup> Bariatric surgery also predisposes patients to thiamine deficiency.<sup>1,5,48,125,126</sup> Malabsorption has even greater clinical relevance in patients with alcoholism.<sup>9,148</sup> In experimental studies, when healthy volunteers were given small amounts of ethanol, a 50% reduction in GI thiamine absorption resulted.<sup>148</sup> A rat model confirmed that the simple presence of ethanol in the gut impairs thiamine absorption.<sup>65</sup>

Two genes are involved in the cellular transport of thiamine: a high-affinity thiamine transporter known as THTR1 (SLC19A2) and a low-affinity thiamine transporter known as THTR2 (SLC19A3).<sup>54,55</sup> Variations or mutations in these genes predispose to thiamine deficiency causing thiamine-responsive megaloblastic anemia syndrome. Homozygous or compound heterozygous mutations in THTR2 manifest as 2 distinct clinical phenotypes, thiamine-biotin-responsive basal ganglia disease and Wernicke-like encephalopathy.<sup>169</sup> Experimental evidence suggests that ethanol intake directly alters gene transcription, further increasing risk.<sup>152</sup> These models demonstrate that ethanol reduces the expression of intestinal and pancreatic acinar thiamine transporters at the protein, mRNA, and transcriptional (promoter activity) levels.<sup>140</sup>

Thiamine is eliminated from the body largely by renal clearance, which consists of a combination of glomerular filtration, flow-dependent tubular secretion, and saturable tubular reabsorption.<sup>161</sup> In an animal model, furosemide, acetazolamide, chlorothiazide, amiloride, mannitol, and salt loading all significantly increased urinary elimination of thiamine.<sup>69</sup> This nonspecific flow-dependent elimination was confirmed in humans given small doses of furosemide.<sup>115</sup> Interestingly, spironolactone use is associated with higher thiamine concentrations.<sup>117</sup> Additionally, both furosemide and digoxin appear to inhibit thiamine uptake into myocardial cells.<sup>171</sup>

## THIAMINE DEFICIENCY

### Pathophysiology

Mice develop signs of encephalopathy 10 days after being rendered thiamine deficient. Immunohistochemistry in these animals demonstrates destruction of the blood–brain barrier with resultant extravasation of albumin.<sup>59</sup> Similarly, rats develop symptoms after 10 days of thiamine deficiency and subsequently demonstrate deterioration of the blood–brain barrier with hemorrhage into the mammillary bodies and other areas of the brain.<sup>20</sup> This pattern is similar to findings described in humans with Wernicke encephalopathy (Fig. A27-3).<sup>56,111</sup> Although there are no controlled trials of thiamine deprivation in humans, several unfortunate events support this time course. One report describes 3 patients who were given total parenteral nutrition (TPN) without multivitamins; signs and symptoms developed in 7, 10, and 14 days, respectively.<sup>155</sup> Similar reports confirm this time course with some variability based on the nutritional status of the patients.<sup>6,80,99,105</sup> Infants aged 2 to 12 months given a soy-based formula that lacked thiamine also developed findings consistent with Wernicke encephalopathy, irritability, vomiting, nystagmus, ophthalmoplegia and metabolic acidosis with elevated lactate.<sup>45</sup>

The proximate cause of Wernicke encephalopathy is unclear. In human autopsy studies, brain samples from alcoholic patients with Wernicke-Korsakoff syndrome demonstrate decreased function of pyruvate dehydrogenase,  $\alpha$ -ketoglutarate dehydrogenase, and transketolase compared with control participants.<sup>18</sup> However, a similar decrease in enzyme activity of neuronal

**FIGURE A27-3.** Postgadolinium axial and coronal T1-weighted magnetic resonance image of a patient with Wernicke encephalopathy showing pronounced enhancement of the mammillary bodies (arrows). (Used with permission from Dr. Alexander Baxter, Department of Radiology, New York University School of Medicine.)

tissue was demonstrated in alcoholics who died from hepatic coma without ever manifesting signs of Wernicke encephalopathy.<sup>85</sup> This finding is understandable given that high concentrations of ammonia inhibit  $\alpha$ -ketoglutarate dehydrogenase.<sup>15</sup> Likewise, the activity of thiamine-requiring citric acid cycle enzymes is reduced in thiamine-replete patients with neurodegenerative diseases.<sup>14</sup> Thus, although thiamine deficiency produces deficits in critical enzymes in humans, many have argued that it is unclear whether these deficits are either necessary or sufficient to produce clinical disease.

Animal models offer insight into the mechanisms involved in developing thiamine-deficient neurologic injury. Although the exact chain of events leading to these structural abnormalities is unclear, several models demonstrate key portions of the pathway. Thiamine deficiency in rats produces 200% to 640% increases in concentrations of glutamate,<sup>83,84</sup> which presumably results from blockade of  $\alpha$ -ketoglutarate dehydrogenase. Excess  $\alpha$ -ketoglutarate is shunted away from the citric acid cycle to form glutamate. Astrocytes seem uniquely sensitive to these effects with decreases in both glutamate and glutamate-aspartate transporters noted, which further increase interstitial glutamate concentrations.<sup>23</sup> Rats subsequently develop increases in lactate in vulnerable regions of the brain marked by the induction of the protooncogene *c-fos*. Both the histochemical lesions and the gene induction are blocked by the administration of the calcium channel blocker nifedipine.<sup>98</sup> This suggests a strong role for excitatory amino acid–induced alterations in calcium transport in the genesis of thiamine-deficient encephalopathy.<sup>70</sup> In other animal models of thiamine deficiency, neuronal tissues are also directly injured by oxidative stress and lipid peroxidation.<sup>21,61,62,70</sup> Additional investigations demonstrate roles for triggered mast cell degranulation,<sup>46</sup> histamine,<sup>83</sup> and nitric oxide<sup>51,77</sup> in the generation of neuronal injury. The final common pathway is localized cerebral edema, which appears to result from altered expression of aquaporin.<sup>26</sup>

In what may be the most important finding since Wernicke's original report described 2 healthy nonalcoholic brothers who developed signs, symptoms, and neuroimaging findings consistent with Wernicke encephalopathy despite normal serum thiamine concentrations.<sup>76</sup> Both brothers were confirmed to have compound mutations of the *SLC19A3* gene (K44E and E320Q) encoding for low-affinity thiamine transporter (THTR2). High-dose thiamine (up to 600 mg) was clinically effective. The more severe E320Q homozygous THTR2 mutation manifests as impaired thiamine uptake, progressive brain atrophy, bilateral thalamic and basal ganglia lesions, and epileptic spasms

beginning early in infancy.<sup>169</sup> Several other mutations (including G23V and T422A and those inducing premature termination codons) produce loss of thiamine THTR2 transport function and a spectrum of generalized dystonia; epilepsy; and bilateral striatal, caudate, putamen, and cortical lesions.<sup>35,128,139</sup> Patients may respond to high-dose thiamine (150–300 mg/every 8 hours in adults or 10–40 mg/kg/day in children) or biotin (or both).<sup>128</sup> As demonstrated by magnetic resonance imaging, vasogenic edema is a characteristic finding during the acute crises.<sup>142</sup> When added to the cases in which thiamine was excluded from TPN or infant formula, these findings definitively relate intracellular thiamine concentrations to clinical and anatomical manifestations of Wernicke encephalopathy and thiamine deficiency.

In addition, several human cases and case series suggest an important role for insufficient magnesium (a cofactor) in Wernicke pathogenesis.<sup>37,93,120</sup> The adversely synergistic effects of magnesium and thiamine codeficiency mirrors detrimental effects observed in animal species.<sup>86</sup> Chronic alcoholic patients supplemented with magnesium in addition to thiamine recover their erythrocyte transketolase activity to a greater extent compared with those receiving thiamine alone.<sup>108</sup> Patients with Wernicke encephalopathy may be clinically unresponsive to thiamine treatment in the setting of untreated hypomagnesemia.<sup>47</sup>

### Clinical Manifestations

When thiamine is completely removed from the human diet, tachycardia is often the first sign of deficiency. The clinical symptoms of thiamine deficiency present as 2 distinct patterns: “wet” beriberi or cardiovascular disease and “dry” beriberi, the neurologic disease known as Wernicke-Korsakoff syndrome. Although some patients display symptoms consistent with both disorders, usually either the cardiovascular or the neurologic manifestations predominate. A genetic variant of transketolase activity, combined with low physical activity and low-carbohydrate diet, predisposes to neurologic symptoms, but high-carbohydrate diets and increased physical activity lead to cardiovascular symptoms.<sup>13,165</sup> Thus, cardiovascular disease is more common in the Asian population, and neurologic disease predominates in the northern European population.

Wet beriberi results from high-output cardiac failure induced by peripheral vasodilation and the formation of arteriovenous fistulae secondary to thiamine deficiency. These patients complain of fatigue, decreased exercise tolerance, shortness of breath, and peripheral edema. Myocardial edema is reported.<sup>43</sup> Patients with congestive heart failure seem to have an analogous worsening cardiac function caused by diuretic-associated thiamine use, which improves with thiamine supplementation.<sup>39,146</sup> Fulminant cardiovascular beriberi (Shoshin beriberi) presents as shock and cardiovascular collapse.<sup>32,95</sup> The classic triad of oculomotor abnormalities, ataxia, and global confusion defines dry beriberi or Wernicke encephalopathy. Other manifestations include hypothermia and the absence of deep-tendon reflexes.<sup>44,160</sup> Vomiting and anorexia are common<sup>45,155</sup> and are presumed to be related to increases in intracranial pressure. Additionally, patients develop a peripheral neuropathy with paresthesias, hypesthesias, and an associated myopathy, all related to axonal degeneration.<sup>131</sup> Laboratory studies may reflect a metabolic acidosis with elevated lactate concentration brought on by excessive anaerobic glycolysis resulting from blocked entry of substrate into the Krebs cycle.<sup>25,27,74,75,82,106,118,160</sup> Interestingly, a primary respiratory alkalosis of unclear etiology seems to be simultaneously present.<sup>40</sup> Korsakoff psychosis, a frequently irreversible disorder of learning and processing of new information characterized by a deficit in short-term memory and confabulation, often occurs together with Wernicke encephalopathy.<sup>157</sup> A 10% to 20% mortality rate is associated with Wernicke encephalopathy, with survivors having an 80% risk of developing Korsakoff psychosis.<sup>114</sup> Only about 21% of patients with Korsakoff psychosis will have a complete recovery, with others having variable degrees of improvement that typically take months.<sup>156</sup>

A clinical tool for identifying patients with Wernicke encephalopathy used 4 signs: dietary deficiencies, oculomotor abnormalities, cerebellar dysfunction, and either an altered mental status or mild memory impairment. When 2 or more signs were present, the tool was highly sensitive and

specific.<sup>19</sup> Despite this tool, autopsy studies suggest that Wernicke encephalopathy remains underrecognized in the critically ill patients.<sup>47</sup>

### Epidemiology: Populations at Risk

In the United States, a healthy diet and mandatory thiamine supplementation of numerous food products protect most people from the manifestations of thiamine deficiency. Despite this, the prevalence of Wernicke encephalopathy in the general US population is estimated to be between 0.2% and 2.2%, although only 20% of these cases are estimated to be diagnosed during their lifetime.<sup>90,138</sup> This is, unfortunately, not true in other countries. A survey of the 17 major public hospitals in the Sydney, Australia, area identified more than 1,000 cases of either acute Wernicke encephalopathy or Korsakoff psychosis between 1978 and 1993.<sup>91</sup> Similarly, a single Australian hospital identified 32 cases of Wernicke encephalopathy during a 33-month period.<sup>166</sup> In Australia, mandatory supplementation of flour with thiamine in 1991 resulted in a dramatic reduction in hospitalized cases during 1992 and 1993,<sup>91</sup> as well as of the percentage of cases diagnosed by postmortem studies.<sup>60</sup> Other countries at risk include Ireland and New Zealand, where lack of a mandatory thiamine supplementation program is correlated with a high prevalence of biochemical evidence of thiamine deficiency.<sup>102,103</sup> In countries where bread is not a major dietary staple, alternative supplemental strategies such as adding thiamine to fish sauce seem promising.<sup>163</sup>

Alcoholic patients, whose consumption of ethanol is their major source of calories, are the best described and most easily recognized patients at risk for thiamine deficiency.<sup>114</sup> In Scotland, 21% of alcoholics requiring emergency admission to the hospital were thiamine deficient, as determined by erythrocyte transketolase activity.<sup>68</sup> The prevalence in US alcoholics is estimated to be 12.5%.<sup>138</sup> In patients with sepsis, thiamine deficiency rates are between 20% and 70%.<sup>30</sup> Likewise, in patients with congestive heart failure, thiamine deficiency is reported to range from just a few percent to over 90% depending on the population studied and the use of diuretics.<sup>39,146</sup>

Consequential thiamine deficiency is also described in the following settings: incarceration,<sup>69</sup> drug rehabilitation,<sup>49</sup> hemodialysis,<sup>36</sup> hyperemesis gravidarum or anorexia nervosa,<sup>147</sup> parenteral nutrition,<sup>6,23,24,27,80,82,105,106,141,155,158</sup> acquired immunodeficiency syndrome (AIDS),<sup>7,16,17,124</sup> malignancies,<sup>11,66,78,119,135,153</sup> institutionalized older adults,<sup>79,102-104</sup> critically ill children,<sup>72,88</sup> sepsis,<sup>40</sup> congestive heart failure on furosemide therapy,<sup>79</sup> malabsorption secondary to diarrhea,<sup>33,170</sup> eating disorders,<sup>113,159</sup> the refeeding syndrome,<sup>92</sup> and patients who had undergone bariatric surgery.<sup>1,5,48,52,96,125</sup> Thus, despite routine dietary supplementation, many people are still at risk because of dietary limitations, alcohol abuse, or underlying medical or surgical conditions. Additionally there is some evidence to suggest that the use of metformin is associated with thiamine deficiency which contributes to neuropathies in patients with diabetes.<sup>87</sup>

### ROLE IN PREVENTION AND TREATMENT OF WERNICKE ENCEPHALOPATHY

Thiamine hydrochloride is included in the initial therapy for any patient with an altered mental status, potentially acting as both treatment and prevention of Wernicke encephalopathy. Many patients with altered levels of consciousness have had or will have a poor nutritional status or will be hospitalized and deprived of oral intake for a number of days because of GI disorders or altered mental status. Although thiamine concentrations can be either directly measured or functionally assessed by measuring erythrocyte transketolase activity at baseline and in response to thiamine diphosphate administration,<sup>63</sup> these determinations are unavailable for clinical use and do not correlate with disease severity.<sup>90</sup> Likewise, although clinical prediction models exist, they are cumbersome and unvalidated.<sup>129</sup> Glucose loading increases thiamine requirements, which can exacerbate marginal thiamine deficiencies, elevate lactate concentrations,<sup>101</sup> or precipitate coma in the absence of parenteral thiamine supplementation.<sup>114</sup> Although it is commonly believed that acute glucose loading, in the form of a bolus of hypertonic dextrose, can precipitate Wernicke encephalopathy over several hours in normal individuals, there is evidence to support this effect only in patients

who already have grave manifestations of thiamine deficiency or exaggerated delay in the provision of thiamine.<sup>94,121,160</sup> Previously healthy patients require prolonged dextrose administration in the absence of thiamine to develop Wernicke encephalopathy. Because the morbidity and mortality associated with Wernicke encephalopathy are so severe and underdiagnosed and treatment is both benign and inexpensive, parenteral thiamine hydrochloride should be included in the initial therapy for all patients who receive dextrose, all patients with altered consciousness, and every potential alcoholic or nutritionally deprived individual who presents to the emergency department or other clinical setting.

### ROLE IN THE TREATMENT OF OTHER DISORDERS

A supplementary indication for the administration of thiamine hydrochloride occurs in patients with ethylene glycol poisoning. As shown in Fig. 106-2, a minor pathway for the elimination of glyoxylic acid involves its conversion to  $\alpha$ -hydroxy- $\beta$ -ketoacid by  $\alpha$ -ketoglutarate: glyoxylate carboligase, a thiamine and magnesium-requiring enzyme. There are no data to support an increase in  $\alpha$ -hydroxy- $\beta$ -ketoacid formation after thiamine administration in ethylene glycol-poisoned animals or humans. However, animal models of primary hyperoxaluria show increases in urinary oxalate during thiamine deficiency, suggesting at least a potential importance of this pathway.<sup>58,143</sup> Because therapy is benign and inexpensive, it is reasonable to administer standard doses of thiamine to patients with suspected or confirmed ethylene glycol poisoning.

Standard doses of thiamine are also recommended for patients with alcoholic ketoacidosis (AKA) and starvation ketoacidosis. Glucose is required to stimulate insulin secretion, which subsequently terminates ketogenesis. Because by definition, AKA occurs in malnourished alcoholics who are at risk for Wernicke encephalopathy, parenteral thiamine administration is recommended (Chap. 76).<sup>10</sup>

It is also reasonable to include routine thiamine administration in patients with congestive heart failure treated with long-term use of loop diuretics. Diuretics enhance renal thiamine elimination.<sup>127</sup> In one randomized trial, 200 mg of daily IV thiamine was able to increase cardiac ejection fraction by 22% at 7 weeks.<sup>130</sup> Another study showed that a daily oral dose of 300 mg of thiamine in patients with chronic heart failure was able to increase left ventricular ejection fraction by 10% over placebo.<sup>123</sup> Repletion of thiamine and other water soluble vitamin repletion is common practice in clinical dialysis centers.

### ADVERSE EFFECTS

Very few complications are associated with the parenteral administration of thiamine. A single case of repeated angioedema was reported with oral thiamine.<sup>107</sup> The older literature emphasized intramuscular (IM) administration because of numerous reports of anaphylactoid reactions associated with IV thiamine delivery.<sup>42,112,122,137,162</sup> It is generally believed that these reactions resulted from responses to contaminants rather than thiamine itself. Despite the availability of purer, aqueous preparations of thiamine, rare adverse reports still occur.<sup>8,71,97,110,136</sup> Although the IM route is theoretically comparably efficacious in a healthy individual, many patients requiring thiamine have diminished muscle mass or a coagulopathy, exacerbating the potential for pain and unpredictable absorption. The safety of thiamine use was evaluated in a large case series in which nearly 1,000 patients received parenteral doses of up to 500 mg of thiamine without significant complications.<sup>167</sup> This study suggests that if anaphylaxis to thiamine exists, its occurrence is exceedingly rare, permitting the safe IV administration of thiamine to most patients.

### PREGNANCY AND LACTATION

Thiamine hydrochloride is listed in Pregnancy Category A and is also considered safe for use in lactating mothers. When the use of oral thiamine supplementation was studied in thiamine-deficient Cambodian mothers, a significant increase in breast milk concentrations was noted, but these concentrations were insufficient to correct deficiencies in their children over the 5-day study period.<sup>29</sup> Over the course of study, the median breast

milk thiamine concentration increased from 180 nmol/L to 503 nmol/L (360–808 nmol/L) on day 6, which is within the reported values of American breast milk. Although the infants' thiamine concentration increased from 3.0 nmol/L to 5.6 nmol/L, these values still qualified as deficient.

## DOSING AND ADMINISTRATION

For prevention of Wernicke encephalopathy, initial therapy usually consists of the immediate parenteral administration of 100 mg of thiamine hydrochloride. This can be given either intramuscularly or intravenously, but the oral route should be avoided because of its unpredictable absorption. In countries where thiamine propyl disulfide (a lipid-soluble thiamine preparation) is available, the oral route is equally efficacious for the replacement of serious thiamine deficiencies.<sup>9,151</sup> Although there are no dose finding studies, some authorities recommend daily doses as high as 250 mg/day in high-risk patients without signs and symptoms of Wernicke encephalopathy.<sup>150</sup> Current recommendations also exist for patients on TPN (3–3.5 mg/d), enteral feeding (2.2–2.9 mg/1,500 kcal), and renal replacement therapy (100 mg/d).<sup>134</sup> Unfortunately, despite consensus statements and guidelines, evidence suggests that clinicians uniformly fail to protect their patients appropriately<sup>34,67</sup> and that there will likely be public health benefits to increasing the duration of parenteral thiamine administration to patients at risk.<sup>164</sup>

The practice of requiring the administration of parenteral thiamine before hypertonic dextrose in patients with altered consciousness is illogical.<sup>57</sup> Besides the fact that the first dose of dextrose is unlikely to cause thiamine deficiency, thiamine uptake into cells and activation of enzyme systems is slower than that of glucose uptake, which suggests that even pretreatment with thiamine offers little benefit over posttreatment.<sup>145</sup> Despite these limitations, it is prudent to administer at least 100 mg of parenteral thiamine at the time of initial dextrose administration. The biochemical link between dextrose and thiamine is obvious, which demonstrates to the clinician the scientific basis for the administration of thiamine. Although thiamine is unlikely to offer immediate benefits for patients with altered consciousness, it will offer some long-term protection for these individuals at risk and initiate therapy for a serious, insidious, and easily overlooked disorder.

For treatment of Wernicke encephalopathy, in some patients, symptoms such as ophthalmoplegia are reported to respond rapidly to as little as 2 mg of thiamine; however, the other neurologic and cardiovascular manifestations of thiamine deprivation necessitate higher doses and generally respond more slowly, if at all. Although many sources recommend that daily doses of 100 mg of thiamine are sufficient as in preventive therapy, others recommend initial doses of at least 200 or 250 mg<sup>4,153</sup> based on limited data. We agree with current guidelines recommended by the British National Formulary and the Royal College of Physicians, British Association for Psychopharmacology, the European Federation of Neurological Societies (EFNS), and the National Institute for Health and Clinical Excellence (NICE) guidelines, all of which suggest that the initial thiamine regimen for patients with Wernicke encephalopathy is 500 mg intravenously 3 times daily for 2 to 3 days and 250 mg intravenously daily for the next 3 to 5 days.<sup>50,89</sup> This increase over formerly recommended regimens is reflective of reports of patients failing standard therapy and the safety of parenteral thiamine.<sup>31</sup> As stated earlier, because there is pharmacokinetic evidence favoring slow infusions over bolus therapy, this practice is reasonable after the first dose.<sup>41</sup> Additionally, because data suggest that transketolase activity is improved when magnesium supplementation is routinely added to thiamine administration,<sup>108</sup> we recommend administering 2 g of magnesium sulfate IV to patients with normal kidney function.

Because of the safety of thiamine hydrochloride and the urgency to correct the manifestations of thiamine deficiency, up to 1,000 mg of thiamine hydrochloride is reasonable for use in the first 12 hours if a patient demonstrates persistent neurologic abnormalities.<sup>100</sup>

Dosing in other disorders is less well defined. In patients with congestive heart failure, regimens have varied from 100 mg twice per week to 300 mg/day,<sup>38,39</sup> but for sepsis, single doses of 200 mg were given.<sup>12</sup> For ethylene glycol poisoning and AKA, we recommend a dose of 100 mg intravenously.

For all these disorders, strong evidence to favor one regimen over alternatives is lacking.

## FORMULATION AND ACQUISITION

Multiple manufacturers formulate thiamine hydrochloride for IV or IM administration. Typical concentrations are either 50 or 100 mg/mL. Although more concentrated solutions are available, their use is usually reserved for preparation of TPN solutions. Thiamine available in the United States is formulated in 0.5% (5 mg/mL) chlorobutanol as a preservative. In the United Kingdom, the formulation Pabrinex is chlorobutanol free. Chlorobutanol is a sedative with a long elimination half-life, but doses of 600 mg were given to human volunteers without complication.<sup>154</sup> Thus, following UK and EFNS recommendations of 1,500 mg/day of thiamine would only deliver 75 to 150 mg of chlorobutanol depending on which preparation was used. Even with the long elimination half-life, many days of high dose thiamine could be administered without delivering a single sedating dose.

## SUMMARY

- Thiamine is an essential water-soluble vitamin for cellular energy.
- Thiamine deficiency can present as either Wernicke encephalopathy or high output cardiac failure (wet beriberi).
- Wernicke encephalopathy manifests as ataxia, ophthalmoplegia, altered mental status, decreased deep tendon reflexes, metabolic acidosis with elevated lactate, and hypothermia.
- Parenteral administration of 100 mg of thiamine is required to protect an individual at risk for 1 to 2 weeks.
- When Wernicke encephalopathy is present or suspected, higher doses of thiamine are recommended. The exact dose and speed of administration of thiamine has yet to be established for these patients, but we favor the higher dosing regimens that are proposed.
- Although thiamine requirements are based on caloric intake, there is no evidence that thiamine must be given before dextrose administration.

# ALCOHOL WITHDRAWAL

Jeffrey A. Gold and Lewis S. Nelson

## HISTORY AND EPIDEMIOLOGY

The medical problems associated with alcoholism and alcohol withdrawal were initially described by Pliny the Elder in the first century B.C. In his work *Naturalis Historia*, the alcoholic and alcohol withdrawal were described as follows: “drunkenness brings pallor and sagging cheeks, sore eyes, and trembling hands that spill a full cup, of which the immediate punishment is a haunted sleep and unrestful nights.”<sup>74</sup> Initial treatments as described by Osler at the turn of the 20th century were focused on supportive care, including confinement to bed, cold baths to reduce fever, and judicious use of potassium bromide, chloral hydrate, hyoscine, and possibly opium.<sup>18</sup>

Some of the initial large series of alcohol related complications in the early 20th century describe alcohol use as a major public health concern. At Bellevue Hospital in New York City, there were 7,000 to 10,000 admissions per year for alcohol-related problems from 1902 to 1935, with an estimated rate of 2.5 to 5 admissions per 1,000 New York City residents.<sup>45</sup> Many of these patients were described as having “alcoholomania” or “acute alcoholic delirium.”

A similar number of admissions to Boston City Hospital was also reported, with up to 10% of people with alcoholism admitted with evidence of delirium tremens (DTs).<sup>69</sup> The mortality rate at the beginning of the study among patients with DTs was 52% (1912), and DTs was the leading cause of death among admitted people with alcoholism. Over the ensuing 20 years, this rate declined to approximately 10% to 12%, a decrease believed to be secondary to improved supportive care and nursing.

Although people with alcoholism were widely recognized as having a high incidence of delirium and psychomotor agitation, whether this was caused by ethanol use, ethanol abstinence, or coexisting psychological disorders was debated. Isbell and colleagues performed a highly controversial study in 1955, proving that abstinence from alcohol was responsible for DTs when they subjected 9 male prisoners to chronic alcohol ingestion for a period of 6 to 12 weeks followed by 2 weeks of abstinence.<sup>43</sup> During the abstinence phase, 6 of the 9 men developed tremor, elevations in blood pressure and heart rate, diaphoresis, and varying degrees of either auditory or visual hallucinations, consistent with the diagnosis of DTs. In addition, 2 of the 9 men developed convulsions, further linking alcohol abstinence to seizures. However, it should be noted that the high rate of development of DTs (67%) is atypical and does not represent the true prevalence found in later epidemiologic studies.<sup>16</sup>

Alcoholism and the various manifestations of the alcohol withdrawal syndrome (AWS) still represent major problems in both the inpatient and outpatient setting. Ethanol is responsible for approximately 3.8% of all deaths worldwide (6.3% of men and 1.1% of women) and accounts for 4.6% of the global burden of disease (7.6% of men and 1.4% of women).<sup>79</sup> The lifetime risk of alcohol use disorders in men is more than 20%, with a risk of about 15% for alcohol abuse and 10% for alcohol dependence.<sup>88</sup>

Alcohol-related complications accounted for 21% of all medical intensive care unit (ICU) admissions, with alcohol withdrawal being the most common alcohol-related diagnosis.<sup>61</sup> Further, the presence of any alcohol use disorder (alcohol abuse, dependence or harmful alcohol use) was associated with a 2-fold increase in mortality amongst ICU patients with organ failure.<sup>66</sup> In other studies, 8% of all general hospital admissions, 16% of all postsurgical patients, and 31% of all trauma patients developed alcohol withdrawal.<sup>29</sup> The development of alcohol withdrawal in postsurgical and trauma patients is associated nearly threefold increase in mortality in this population.<sup>5</sup>

## PATHOPHYSIOLOGY

Intensive research over the past 2 decades provides valuable insight into the mechanism of alcohol withdrawal, allowing for better understanding of both the clinical spectrum of the disorder and potential therapeutic interventions (Chap. 14). Alcohol withdrawal syndrome is a neurologic disorder with a continuum of progressively worsening effects caused by the reduction or discontinuation of ethanol in a person who has developed ethanol dependence following chronic and heavy ethanol use. Alcohol withdrawal syndrome is often exacerbated by the clinical manifestations of heavy alcohol intake (eg, nutritional depletion, impaired immunity, anemia, cirrhosis, and head trauma).

The effects of chronic alcohol consumption on neurotransmitter function best explains the clinical findings. Persistent stimulation of the inhibitory  $\gamma$ -aminobutyric acid (GABA) receptor chloride channel complex by ethanol leads to downregulation.<sup>14</sup> This allows the alcohol user to maintain a relatively normal level of consciousness, as well as cognitive and motor function despite the presence of sedative concentrations of ethanol in the brain. A continued escalation of the steady-state serum ethanol concentration is required to achieve euphoria due to the development of tolerance, which results from progressive desensitization of the GABA receptor chloride channel complex.<sup>53</sup> The exact mechanism by which this adaptive change occurs is incompletely understood but involves in part substitution of an  $\alpha_4$  for an  $\alpha_1$  receptor subunit on the GABA<sub>A</sub> receptor (Chaps. 13 and 14). A converse series of events occurs at the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Binding of ethanol to the glycine binding site of this receptor inhibits the NMDA receptor function, resulting in compensatory quantitative upregulation of these excitatory receptors (as opposed to a subunit component change in the GABA receptors).<sup>36</sup> Thus withdrawal of alcohol is associated with both a decrease in GABAergic activity and an increase in glutamatergic activity.<sup>14</sup> This phenomenon of a concomitant loss of inhibition and increased excitation results in the clinical manifestations of autonomic excitability and psychomotor agitation associated with alcohol withdrawal (Figs. 14-1 and 14-2).<sup>73</sup>

Repeated episodes of alcohol withdrawal lead to permanent alterations in neurotransmitters and their receptors. In rats, repeated episodes of alcohol withdrawal leads to persistent and progressive electroencephalographic abnormalities, with subsequent episodes of withdrawal becoming increasingly resistant to benzodiazepines. Both clinical observation and in vitro data also suggest permanent dysregulation of GABA receptors, and thiamine and other nutritional deficiencies are implicated in structural brain changes in animal models.<sup>70</sup> These effects are proposed explanation for both the “kindling phenomenon,” which is the clinical observation of an increasing severity of alcohol withdrawal among individual subjects, and the development of benzodiazepine-resistant alcohol withdrawal.<sup>106</sup>

## CLINICAL MANIFESTATIONS

Alcohol withdrawal is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-V*) as the cessation of heavy or prolonged alcohol use resulting, within a period of a few hours to several days, in the development of 2 or more of the clinical findings listed in Table 77-1. Alcohol withdrawal can be qualitatively classified both by timing (eg, early versus late) and severity (eg, mild, moderate, severe). However, despite the availability of scoring systems (see next paragraph), there are no adequate or fully accepted criteria by which to define these categorizations, and many of the components require subjective interpretation. Furthermore, the clinical

**TABLE 77-1 Diagnostic Criteria for Alcohol Withdrawal Syndrome<sup>4</sup>**

A.	Cessation of or reduction in alcohol intake, which has previously been prolonged or heavy.
B.	Criterion A, plus any 2 of the following symptoms developing within several hours to a few days: Anxiety Autonomic hyperactivity Hallucinations Insomnia Nausea and vomiting Psychomotor agitation Seizures (generalized tonic–clonic) Tremor (worsening)
C.	The above symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D.	The above symptoms are not attributable to other causes; for example, another mental disorder, intoxication, or withdrawal from another substance. Specify if hallucinations (usually visual or tactile) occur with intact reality testing, or if auditory, visual, or tactile illusions occur in the absence of a delirium.

course of alcohol withdrawal varies widely among patients, and progression of individual patients through these different stages is also highly variable.<sup>100</sup> In fact, some extensive alcohol users experience no significant withdrawal after the cessation of alcohol consumption. Recognizing these limitations, this conceptual framework still proves helpful in the clinical management of patients with alcohol withdrawal.

One of the more commonly used means for accurately assessing the severity of alcohol withdrawal is the Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) score.<sup>95</sup> This scoring system contains 10 clinical categories and requires less than 5 minutes to complete. In an attempt to improve the specificity and simplicity of the score, the Glasgow Modified Alcohol Withdrawal Scale (GMAWS) was developed and validated, demonstrating clinical comparability to the CIWA-Ar.<sup>15</sup> However, use of either CIWA or GMAWS is limited by the requirement of subjective assessments by the patient; they cannot be adequately performed in highly agitated or sedated patients and are difficult to use in situations with language barriers. For these reasons, we prefer the use of general alertness scales such as the Richmond Agitation Sedation Scale (RASS) or Riker Sedation Anesthesia Scale (SAS), which are observer based.<sup>81,90</sup> In one study, use of the SAS was associated with a reduction in intensive care unit (ICU) length of stay and reduction in sedative use compared with use of the CIWA.<sup>89</sup> Scoring systems are essential not only for symptom-triggered therapy, but they also provide a basis for comparative analysis of clinical trials in ethanol withdrawal. Greater use of semiobjective CIWA-Ar, GMAWS, RASS, SAS, or a comparable validated scale remain essential for interpretation of both genetic and treatment trials.

### Early Uncomplicated Withdrawal

Alcohol withdrawal begins as early as 6 hours after the cessation of drinking. Early withdrawal is characterized by autonomic hyperactivity, including tachycardia, hypertension, fine tremor, and diaphoresis, as well as psychological changes such as emotional lability, anxiety, insomnia, and psychomotor agitation. This constellation of findings is sometimes called *alcoholic tremulousness*.<sup>98</sup> Although these clinical effects are uncomfortable, they are not generally harmful. Most patients who ultimately develop severe manifestations of AWS initially develop these findings, but this is not universal. At this “stage” of AWS, the clinical effects are still readily amenable to treatment with ethanol, as is done daily by many patients with alcohol use disorder when they take an “eye opener.”

### Alcoholic Hallucinosi

Nearly 25% of patients with alcohol withdrawal will develop transient hallucinations, and a subset of these patients will develop alcoholic hallucinosis, which is characterized by vivid hallucinations that are generally transient but do infrequently last several weeks.<sup>31,99</sup> Although classically

these hallucinations are tactile or visual (“pink elephants”), other types of hallucinations, particularly auditory and persecutory, are described. Tactile hallucinations include formication, or the sensation of ants crawling on the skin, which can result in repeated itching and excoriations. However, as opposed to DTs, patients with alcoholic hallucinosis have a clear sensorium. The presence of alcoholic hallucinosis is neither a positive nor a negative predictor of the subsequent development of DTs.<sup>32</sup>

### Alcohol Withdrawal Seizures

Approximately 10% of patients with alcohol withdrawal develop seizures, or “rum fits.” For many patients, a generalized seizure is the first manifestation of the alcohol withdrawal.<sup>98</sup> Approximately 40% of patients with alcohol withdrawal seizures have isolated seizures, and 3% develop status epilepticus.<sup>100</sup> Alcohol withdrawal seizures often occur in the absence of other signs of alcohol withdrawal and are characteristically brief, generalized, tonic–clonic events with a short postictal period. However, for approximately one-third of patients with DTs, the sentinel event is an isolated alcohol withdrawal seizure.<sup>65</sup> Rapid recovery and normal mental status initially minimize the seriousness of an alcohol withdrawal seizure.<sup>100</sup> Finally, clinicians should be cognizant that many people with alcoholism are prescribed antiepileptics because they have a preexisting seizure disorder, often related to repetitive brain trauma.<sup>42</sup> Conversely, the use of antiepileptics does not unequivocally indicate the presence of a preexisting seizure disorder because of the difficulty in differentiating these seizures from those of alcohol withdrawal.

### Delirium Tremens

Delirium tremens is the most serious manifestation of alcohol withdrawal and generally occurs between 48 and 96 hours after the cessation of drinking.<sup>98</sup> Many of the clinical characteristics of DTs are similar to those of uncomplicated early alcohol withdrawal, differing only in severity, and include tremors, autonomic instability (hypertension and tachycardia), and psychomotor agitation. However, unlike the other forms of alcohol withdrawal, DTs is defined by either (1) disturbance of consciousness (eg, reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention, delirium, confusion, and frank psychosis, or (2) a change in cognition (eg, memory deficit, disorientation, and language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.<sup>4</sup> Unlike the early manifestations of alcohol withdrawal, which typically last for 3 to 5 days, DTs often lasts for up to 2 weeks.

## RISK FACTORS FOR THE DEVELOPMENT OF ALCOHOL WITHDRAWAL

Factors determining whether an individual will develop withdrawal and to what severity are not well identified. As already mentioned, the development of alcohol dependence is a prerequisite, and this requires several days or longer of nearly continuous consumption of alcohol. The strongest predictor for the development of alcohol withdrawal is a history of prior episodes of withdrawal or DTs or a family history of alcoholic withdrawal.<sup>34,49</sup> These factors, in addition to a select number of clinical and biochemical variables, were combined to create the Prediction of Alcohol Withdrawal Severity Scale (PAWSS), which demonstrated a 93% sensitivity for predicting complicated alcohol withdrawal among hospitalized patients.<sup>60</sup>

The influence of family history on the development of withdrawal suggests a strong role for genetic factors. A growing number of studies have identified associated polymorphisms, including genes involved in dopaminergic neurotransmission, glutamate signaling, cannabinoid receptors, serotonin signaling, and neuropeptide Y.<sup>97</sup> However, these findings must be interpreted with caution. First, whether these findings represent a predisposition to greater ethanol consumption because of an enhanced mesolimbic reward system or some other underlying pathophysiologic effect is unclear. Second, many of the studies do not systematically discriminate among alcoholic tremulousness, alcoholic hallucinosis, withdrawal seizures, and DTs, all of which are potentially regulated by different pathways. Finally, almost uniformly these

studies are small (fewer than 200 participants) and are racially homogenous, making it imperative that these be replicated on a larger scale and among different racial groups. Larger and more varied patient cohorts that include both women and nonwhite ethnic groups are required before any definitive conclusions can be drawn. Racial predisposition to the development or severity of alcohol withdrawal is not definitive, but the experience at our institution suggests that African American patients are at lower risk of developing severe DTs than whites.<sup>19</sup>

## DIAGNOSTIC TESTING

### Clinical and Biochemical Predictors

Numerous attempts have been made to develop biochemical predictors for the presence or severity of alcohol withdrawal. Although consistent abnormalities in readily obtained laboratory values are observed in patients with alcohol withdrawal (eg, aminotransferases, magnesium, mean corpuscular volume), their role in predicting the severity is poorly understood. In one study, an alanine aminotransferase of greater than 50 U/L, a serum chloride less than 96 mEq/L, and a serum potassium less than 3.6 mEq/L were all associated with the development of alcohol withdrawal in patients admitted to a detoxification center.<sup>104</sup> Another study noted that risk factors for DTs included a significant hypokalemia, thrombocytopenia, and prevalence of structural brain lesions.<sup>27</sup> However, the varied and generally low specificity of these derangements makes it difficult to assess their predictive value, especially when accounting for other clinical characteristics such as prior history, initial ethanol concentration, and admission CIWA-Ar or RASS score. In addition, there is a negative association between the presence of severe alcohol withdrawal and histopathologic cirrhosis, further clouding the usefulness of routine laboratory testing for prognostication.<sup>6</sup>

Other investigators have focused specifically on blood ethanol concentration as a predictor for the severity of alcohol withdrawal in at-risk subjects. In one study of patients entering a detoxification program, an admission blood ethanol concentration of greater than 150 mg/dL had a 100% sensitivity and a 57% specificity for the need for treatment of alcohol withdrawal.<sup>101</sup> At a different treatment facility, an ethanol concentration of greater than 150 mg/dL had an 81% positive predictive value for the need to use more than a single dose of chlordiazepoxide.<sup>101</sup> In a third study, an ethanol concentration of greater than 200 mg/dL was a factor in predicting complicated alcohol withdrawal.<sup>60</sup> In addition, admission blood ethanol concentrations in patients with alcohol withdrawal seizures were twofold higher than in those without seizures, irrespective of whether or not they had a history of prior withdrawal seizures. However, these results should be interpreted with caution and in the context of the clinical presentation because other studies yield conflicting results. For example, in one study, an admission ethanol concentration of lower than 100 mg/dL was associated with an increased risk of recurrent alcohol withdrawal seizures, and in another study, admission ethanol concentrations failed to predict the development of DTs.<sup>20,77</sup> There are many potential explanations, including differences in patient population, differences in cohort size, and the late onset of DTs, at a time when ethanol concentrations would be extremely low or nonexistent.

Homocysteine and B vitamin concentrations as well as hepatic function tests are associated with the development of alcohol withdrawal, although there are several contradictory study results.<sup>38,49</sup> Because many studies are based on small numbers of often highly selected subjects and some are promising but not prospectively validated, their generalizability is typically poor.<sup>104</sup> Numerous reports document hyperhomocysteinemia in alcoholism, presumably caused by a deficiency of dietary folic acid. Furthermore, homocysteine and its metabolites act as excitatory neurotransmitters at the NMDA receptor and cause seizures and excitatory neuronal death. In one study, serum homocysteine concentrations were predictive of the development of alcohol withdrawal seizures.<sup>11</sup> However, in this study, there was very strong correlation ( $r^2 = 0.7666$ ;  $P < 0.001$ ) between admission blood ethanol concentrations and homocysteine concentrations and the development of seizures, raising doubts as to whether the determination of homocysteine concentration holds any advantage over blood ethanol concentrations.

## MANAGEMENT

### Alcohol Withdrawal Seizures

Alcohol withdrawal seizures are perhaps the most rigorously studied complication of alcohol withdrawal. They are generally self-limited, and if treatment is needed, benzodiazepines are preferred. In a randomized, placebo-controlled trial of 229 participants with alcohol withdrawal seizures, 2 mg of intramuscular lorazepam reduced the risk of recurrent seizure from 24% to 3% ( $P < 0.001$ ) at 6 hours and the need for hospital admission from 42% to 29% ( $P = 0.02$ ).<sup>23</sup> However, whether this interrupts the natural history of progression to DTs is not known. There is no role for phenytoin in either treatment or prevention of alcohol withdrawal seizures. In multiple trials, phenytoin was ineffective in preventing recurrent seizures.<sup>2,76</sup> The most likely explanation for the failure of phenytoin is its inability to regulate  $\gamma$ -aminobutyric acid (GABA) or *N*-methyl-D-aspartate (NMDA) receptors, the principal mediators of seizures in alcohol withdrawal. One exception to this lack of usefulness occurs in alcoholic patients with a non-alcohol withdrawal-mediated seizure (eg, traumatic injury) or a history of underlying seizure disorders.

### Alcohol Withdrawal

In the early stages of alcohol withdrawal, many patients are able to self-medicate with additional ethanol consumption. Among those who seek medical attention, many patients with alcohol withdrawal can be safely managed as outpatients. Outpatient management has significant cost savings with little effect on treatment outcome.<sup>92</sup> In one study, patients who were not clinically intoxicated, had no history of either DTs or alcohol withdrawal seizures, had no comorbid psychiatric or medical disorders, and had a CIWA-Ar score of less than 8 were safely managed as outpatients.<sup>3</sup> Patients not meeting these criteria were referred to inpatient detoxification centers or medical units, depending on the severity of withdrawal and other comorbid conditions.

For all patients with alcohol withdrawal, the initial stages of therapy remain the same and should include a thorough assessment to identify a coexisting medical, psychiatric, or toxicologic disorder. In particular, an assessment for CNS trauma and infection should include the use of computed tomography and lumbar puncture as indicated. Patients with altered cognition and an elevated body temperature should receive antibiotics, pending the results of a lumbar puncture. In concert with this approach, adequate supportive care should be instituted, including maneuvers to address any abnormal vital signs such as body temperature.

Chronic ethanol consumption leads to severe vitamin and nutritional deficiencies and electrolyte disturbances that should be corrected. Specifically, thiamine is recommended for all patients to prevent the development of Wernicke encephalopathy.<sup>25</sup> It was historically suggested that thiamine should be given before the administration of dextrose to prevent precipitation of Wernicke encephalopathy.<sup>64,102</sup> This is a highly unlikely event, and it will suffice to administer the thiamine simultaneously or shortly after the dextrose.

A systematic review of all articles related to nutritional and electrolyte deficiencies in patients with alcohol use disorders and not specific to alcohol withdrawal suggests that the typical “banana bag” be abandoned in lieu of specific nutritional supplementation.<sup>28</sup> The recommendations, which are not subsequently validated, suggest that there is strong support for the administration of thiamine, 200 to 500 mg intravenously every 8 hours in the first day. In addition, the authors suggest that there is reasonable support for the administration of magnesium sulfate, 64 mg/kg intravenously and folic acid, 400 to 1,000 mcg intravenously over this same time period. We believe that these higher doses of thiamine are appropriate in the range of therapy for Wernicke-Korsakoff syndrome. We recommend an initial dose of parenteral thiamine of 100 mg in the management of the patient with alcohol withdrawal.

In addition, there is a high incidence of intravascular volume depletion among people with alcoholism, volume resuscitation is recommended in patients with clinically significant alcohol withdrawal. Of 39 deaths between 1915 and 1936 attributed to DTs in which volume status was recorded, all

participants were volume depleted.<sup>69</sup> Finally, for patients with AWS, prevention of nosocomial complications is paramount for reducing hospital stays. Currently, in addition to adequate volume replacement, we recommend that all patients (1) be kept with the head of the bed elevated to prevent aspiration and (2) that deep vein thrombosis prophylaxis be given if the patient is bed bound for an extended period.

The association of alcohol withdrawal with severe psychomotor agitation led to early use of sedative-hypnotics. In a landmark study, 547 patients were randomized to one of 4 drugs (chlordiazepoxide, chlorpromazine, hydroxyzine, or thiamine) or to placebo for the treatment of alcohol withdrawal.<sup>46</sup> Patients receiving chlordiazepoxide had the lowest incidence of both alcohol withdrawal seizures and DTs, establishing benzodiazepines as a first-line agent for treatment of alcohol withdrawal. Of note, use of chlorpromazine, an antipsychotic, is associated with a significant increase in the incidence of seizures in both humans and animal models.<sup>13,46</sup>

Since this study, numerous trials have compared different routes of administration among various sedative-hypnotics, both to each other and to placebo. Because of the historical use noted earlier, chlordiazepoxide remains widely used in outpatient clinics and inpatient detoxification services. Oral benzodiazepine administration is generally effective in patients with early or mild alcohol withdrawal, although initial rapid titration with an intravenous (IV) regimen may be more efficient. Benzodiazepines administered intravenously have a rapid onset of action and among the benzodiazepines, IV diazepam offers the most rapid time to peak clinical effects, which limits the oversedation that may occur after the administration of lorazepam, which has a slower onset to the peak drug effect. Because of the delayed peak clinical effect of lorazepam of approximately 10 to 20 minutes, several doses may be administered in rapid succession with little clinical effect followed by the appearance of the sedative effect of the cumulative doses. Midazolam may be administered intramuscularly if IV access is not available.<sup>91</sup> Although no significant differences are observed among benzodiazepines and barbiturates in terms of mortality or the duration of delirium, the improved pharmacokinetic and safety profile as well as the ease of administration favor benzodiazepines over barbiturates when an IV medication is required.<sup>3,50</sup>

Other pharmacokinetic factors and experience confirm that diazepam is the preferred benzodiazepine for initial IV use in patients with moderate to severe alcohol withdrawal. Diazepam has a long half-life and 2 active metabolites (desmethyldiazepam and oxazepam). The prolonged half-life (48–72 hours) of desmethyldiazepam further extends the effective duration of action of the initial dose of diazepam.<sup>111</sup> A study comparing oral diazepam with oral lorazepam found that the former was associated with a more comfortable recovery, likely because of the active metabolites.<sup>82</sup> A retrospective review reported that the use of a single benzodiazepine rather than multiple benzodiazepines was a marker for treatment success in surgical patients experiencing alcohol withdrawal during surgical admission.<sup>72</sup> These data suggest that it is more important to sedate the patient rapidly with adequate doses of a single benzodiazepine than to use multiple treatments in hopes of finding an effective regimen. Finally, it should be noted that in patients with advanced liver disease, the use of diazepam may result in a very prolonged period of sedation because of impaired clearance of the parent compound and its metabolites. Consequently, in these patients, a benzodiazepine without active metabolites, such as lorazepam, is recommended.

The initial management of patients with AWS should include rapid titration with a benzodiazepine to achieve sedation.<sup>71</sup> An oral benzodiazepine, such as chlordiazepoxide or diazepam, should be sufficient, but certain patients require IV medication. The goal of therapy is to have the patient sedated but breathing spontaneously, with normal vital signs. Although normalization of vital signs is not a mandatory therapeutic endpoint, abnormal vital signs despite adequate sedation should prompt a search for comorbidities. In many patients, attaining complete sedation using a loading protocol allows for autotitration; that is, as alcohol withdrawal resolves, the blood concentrations of the benzodiazepine decrease, allowing gradual clinical recovery.<sup>59</sup> In practicality, most patients need periodic symptom triggered redosing with benzodiazepines to maintain adequate sedation. This

is particularly important in patients develop withdrawal with alcohol withdrawal a concomitantly elevated blood alcohol concentration. Their benzodiazepine requirements using symptom-triggered therapy typically parallel the decline in their blood alcohol concentration.

Multiple studies suggest that if additional doses are required, they should be administered based on symptoms (“symptom triggered”) as opposed to on a fixed dosing schedule.<sup>17</sup> In 2 randomized controlled trials, administration of benzodiazepine in a symptom-triggered fashion reduced both the total amount of benzodiazepine and the duration of treatment.<sup>24,85</sup> In these trials, benzodiazepines were administered every hour as long as the CIWA-Ar score remained greater than 8 to 10. In both trials, symptom-triggered therapy resulted in a 4- to 6-fold reduction in the duration of therapy and a 4- to 5-fold reduction in the total amount of benzodiazepine administered, with no increase in withdrawal seizures or adverse events. Symptom-triggered doses in patients with moderate or severe alcohol withdrawal using IV diazepam 10 to 20 mg or lorazepam 2 to 4 mg. For less symptomatic patients, oral chlordiazepoxide 50 to 100 mg is recommended. However, it is important to note that the decision to treat in the symptom-triggered group was made based on CIWA-Ar score (usually >8), which demonstrates the usefulness of standardized scoring and evaluation tools. It should also be noted that in both these trials, patients had very mild withdrawal symptoms, with mean CIWA-Ar scores of 9 to 11. Although experience suggests that this same regimen is also effective in patients with more severe withdrawal or DTs, it has not been validated in this population. Furthermore, it must be emphasized that protocolized use of the CIWA-Ar score depends on a significant history of recent heavy drinking and a communicative subject. A prospective analysis of complex medical-surgical patients enrolled in a CIWA-Ar protocol suggested that more than 50% of the patients failed to have recent alcohol use and could not communicate, leading to unnecessary treatment.<sup>37</sup> Consequently, we agree with studies that use generalized sedation or agitation scales such as the SAS or RASS in these populations. Using the SAS was associated with reduced ICU length of stay compared with CIWA in ICU admitted patients with withdrawal/DTs.<sup>89</sup>

### Resistant Alcohol Withdrawal and Delirium Tremens

There is a subgroup of patients with alcohol withdrawal who require very large doses of diazepam or another comparable drug to achieve initial sedation.<sup>35</sup> This same group often has exceedingly high benzodiazepine requirements to maintain this degree of sedation. Patients with resistant alcohol withdrawal and DTs are often have benzodiazepine requirements that exceed 2,600 mg of diazepam within the first 24 hours and generally require admission to an ICU or step-down unit.<sup>86,106</sup> Patients admitted to the Bellevue hospital medical ICU for resistant alcohol withdrawal had very high diazepam requirements, with a mean of 234 mg (range, 10–1,490 mg) required in the first 24 hours and individual doses of diazepam that often exceeded 100 mg to control their agitation. These patients comprised approximately 5% of all ICU admissions, with nearly 40% of patients requiring mechanical ventilation and a mean ICU length of stay of 5.7 days.<sup>33</sup>

The approach to the management of patients with resistant alcohol withdrawal depends on several factors, including the availability of an ICU bed. In the ICU, despite the perception of failure of high benzodiazepine requirements, we recommend administration of benzodiazepines in a symptom-triggered fashion. This approach was confirmed in a study of patients who developed AWS postoperatively in the ICU.<sup>93</sup> In this study, a symptom-triggered strategy resulted in a shorter length of stay and a lower incidence of mechanical ventilation than did continuous infusion of midazolam. Patients who receive this therapy generally respond to doses of diazepam, which results in a brief period of sedation followed by recrudescence of their symptoms. However, the dose range and other sedative-hypnotics required to achieve this may be dramatically different than that which is observed in subjects with nonresistant alcohol withdrawal. In another study, use of escalating doses of diazepam, up to 200 mg as an individual dose, combined with phenobarbital in participants with continued benzodiazepine

resistance (defined as the requirement for bolus doses more frequently than every hour), reduced the need for mechanical ventilation by nearly 50%.<sup>33</sup> In non-ICU settings, the ability to administer frequent IV doses of diazepam is limited.

In instances of extreme benzodiazepine resistance, patients often receive a second GABAergic drug because of “failure” of benzodiazepine therapy. Phenobarbital, given in combination with a benzodiazepine, in IV doses of up to 260 mg, is recommended.<sup>33</sup> Caution is required to avoid stacking doses of phenobarbital because the onset of clinical effect takes approximately 20 to 40 minutes.<sup>37</sup> With the growing use of phenobarbital in resistant cases, a number of studies have now documented its safety and efficacy, even as a first-line therapy.<sup>62</sup> Furthermore, when administered in a symptom-triggered fashion, administration of a single loading dose of 10 mg/kg of phenobarbital, compared with administration of lorazepam according to a CIWA protocol, reduced the need for ICU admission for alcohol withdrawal from 25 to 8%.<sup>39,50,83</sup> Combined, these data suggest that phenobarbital is the preferred adjunct to benzodiazepines for cases of resistant alcohol withdrawal.<sup>68</sup> Although studies and reviews suggest its use as initial therapy,<sup>62</sup> additional prospective studies are needed before it can be routinely recommended as primary therapy (as opposed to benzodiazepines) for routine management.

Alternatively, propofol, either as individual bolus or as an infusion (in standard ICU dosing regimens, 10–50 mcg/kg/min), can serve as an adjunct to benzodiazepines for patients with resistant alcohol withdrawal. Although propofol has a rapid onset, it is difficult to titrate, and high-dose or long-term use is associated with profound metabolic consequences.<sup>21</sup> However, in an observational study, propofol was safely administered to 21 patients intubated for severe benzodiazepine-resistant DTs.<sup>33</sup> The main drawback to the use of propofol and barbiturates are their narrow therapeutic indices, with the potential for profound respiratory depression. This is especially true for propofol, which should generally only be used in the setting of mechanical ventilation. Both of these sedative–hypnotics can act synergistically with benzodiazepines to enhance GABA-induced chloride channel opening. In addition, propofol antagonizes NMDA receptors, thus reducing the excitatory component of alcohol withdrawal. The safety concerns with propofol were highlighted in a recent retrospective study that compared patients treated with escalating doses of benzodiazepine with or without propofol. The addition of propofol led to longer ICU length of stay and need for mechanical ventilation.<sup>108</sup> Given the uncontrolled nature of the data, it is difficult to make definitive safety claims based on this study, but given the known adverse effects of intubation and mechanical ventilation, relegating propofol to patients with RAW is judicious.<sup>33,94</sup> Therefore, based on best available data we recommend against using propofol as a primary therapeutic and only recommend using it after patients have failed escalating doses of oral or IV benzodiazepines.

## Ethanol

Ethanol consumption is a common and effective means by which people with alcoholism can self-medicate to treat or prevent mild alcohol withdrawal. Consequently, some hospitals still administer ethanol for either prophylaxis or treatment of alcohol withdrawal. In one survey, 72% of 122 hospitals surveyed had administered either IV or oral ethanol for these indications; in another, 25% of Veterans Administration Hospitals allowed consumption of alcoholic beverages.<sup>12,87</sup> Despite its widespread use, little randomized controlled data supports its use. In one trial, 39 trauma patients without hepatic or CNS disease were successfully treated with 10% ethanol infusion for treatment of presumed alcohol withdrawal.<sup>17,22</sup> Conversely, IV ethanol was no more effective than flunitrazepam in one trial and inferior to diazepam in another in the prevention of alcohol withdrawal in postoperative surgical patients.<sup>26,103</sup> Although the authors did not report any adverse effects in these trials, the necessity for frequent blood alcohol monitoring, unpredictable elimination kinetics, potential for significant hepatic complications, postulated adverse effects of ethanol on wound healing, and difficulty in safely administering this therapy make it inappropriate to recommend the use of ethanol for the medical treatment of alcohol withdrawal.<sup>40</sup>

## Adrenergic Antagonists

Numerous studies have investigated the use of sympatholytics to control the autonomic symptoms of alcohol withdrawal. Both  $\beta$ -adrenergic antagonists and clonidine reduced blood pressure and heart rate in randomized, placebo-controlled trials.<sup>8,51</sup> However, the inability of these xenobiotics to address the underlying pathophysiologic mechanism of alcohol withdrawal and subsequently control the neurologic manifestations makes them suboptimal as the sole therapeutic. Additionally, by altering the physiologic parameters that serve as classic markers for the severity of withdrawal, there is a risk of under administering necessary amounts of benzodiazepines.<sup>110</sup> This was observed in a randomized controlled trial of the central  $\alpha_2$ -agonist lofexidine, and it is particularly complicated if using the peripheral manifestations to assess alcohol withdrawal severity as is done with CIWA.<sup>47</sup> There are a growing number of reports documenting the use of the central  $\alpha$ -adrenergic agonist dexmedetomidine as an adjuvant to benzodiazepines for treatment of alcohol withdrawal.<sup>9,10,57,78</sup> The majority of observational studies document an improvement in CIWA or RASS score with dexmedetomidine administration and with a subsequent reduction in the amount of benzodiazepine administered.<sup>109</sup> This is also associated with a reduction in global adrenergic tone, manifest by reductions in heart rate and blood pressure.<sup>78</sup> However, the impact on global outcomes remains mixed, with studies reporting increased or decreased duration of hospitalization with dexmedetomidine use.<sup>9,10</sup> Consequently, with the high cost of dexmedetomidine, the unclear efficacy, and the potential for bradycardia, we recommend not to use it for the routine primary treatment of alcohol withdrawal. In the setting in which standard therapies, such as escalating doses of benzodiazepines and barbiturates, fail to provide adequate sedation (eg, RASS) or control of the alcohol withdrawal (eg, CIWA), a trial of dexmedetomidine seems reasonable while continuing the therapies.

## Magnesium

The theoretical benefits of magnesium supplementation are based both on the high prevalence of magnesium deficiency in people with alcoholism, its ability to block NMDA receptors, and its usefulness in preventing seizures in other disorders, including eclampsia.<sup>41,44,84</sup> Furthermore, magnesium deficiency has many clinical similarities to alcohol withdrawal, clouding the differential diagnosis. Numerous studies have evaluated the efficacy of magnesium supplementation.<sup>75</sup> However, in a randomized, placebo-controlled trial, magnesium had no effect on either the incidence of withdrawal seizures or severity of alcohol withdrawal.<sup>105</sup> Consequently, aside from repletion of electrolyte abnormalities as part of routine patient care, we recommend against the routine administration of magnesium for the treatment of alcohol withdrawal.

## Antiepileptics

Carbamazepine has been used in multiple trials for treatment of mild alcohol withdrawal, more commonly in Europe, where an IV preparation is available. In animal studies, carbamazepine increases both the CNS GABA concentrations and the seizure threshold in alcohol withdrawal models. However, there are insufficient data to recommend the use of carbamazepine in lieu of benzodiazepines in patients with either alcohol withdrawal or DTs.<sup>7,67</sup> Valproic acid appears to have a benzodiazepine-sparing effect in patients with mild withdrawal, but the true clinical benefit is unclear.<sup>2</sup> In contrast, a recent randomized placebo-controlled study of the newer epileptic, oxcarbazepine, showed no difference between this xenobiotic and placebo in inpatient detoxification.<sup>48</sup> Consequently, although this class of drugs may be reasonably recommended as an adjunct to benzodiazepines, we recommend against using antiepileptics as monotherapy or primary therapy for treatment of patients with moderate or severe alcohol withdrawal.

## Gabapentin

Gabapentin, originally introduced as an antiepileptic, has been used extensively for treatment of neuropathic pain and delirium. Contrary to its name, its primary mechanism of action appears to be inhibition of the voltage-gated

calcium channel, which inhibits the activity of stimulatory neurotransmitters, such as glutamate.<sup>52</sup> An extensive literature demonstrates that gabapentin, administered in doses up to 2,400 mg/day is extremely effective in treatment of alcohol dependence, reducing alcohol cravings in people with alcoholism, and promoting abstinence.<sup>63</sup> However, literature related to its use for the treatment of established alcohol withdrawal remains mixed. Currently, the only studies have focused on its outpatient use for mild alcohol withdrawal. When pooled, these studies confirm a reduction in alcohol use when the withdrawal has resolved but also suggest a potential increase in the rate of seizures (6%) and potential worsening of delirium in patients with severe alcohol withdrawal. Therefore, although it may be appropriate for mild alcohol withdrawal, its use, especially as monotherapy, cannot be recommended for patients with severe alcohol withdrawal, DTs, or a history of seizures.<sup>55</sup>

### Other Therapeutics

Recently there has been growing attention toward the use of baclofen, a GABA<sub>B</sub> receptor agonist, because of its purported ability to reduce alcohol cravings and treat alcohol withdrawal. However, data from 3 randomized controlled clinical studies have failed to demonstrate clinical benefit. In one study, baclofen was found to be equivalent to placebo, but in another, no difference was found between baclofen and benzodiazepines, with one of the studies demonstrating inferiority to chlordiazepoxide.<sup>1,30,58</sup> Based on these data and a recent Cochrane review we recommend against using baclofen for monotherapy at this time, although its use as an adjunctive therapy deserves further study.<sup>56</sup>

Ketamine is also proposed as an adjunct for treatment of severe alcohol withdrawal or DTs. Ketamine is an NMDA receptor antagonist, already used in the emergency department and ICU for procedural sedation and more recently as a continuous infusion for sedation, particularly in mechanically ventilated patients.<sup>54,80,96</sup> A recent retrospective study of the use of ketamine in 23 ICU patients with alcohol withdrawal<sup>107</sup> found that it was associated with a reduction in the need for diazepam. However, the uncontrolled use of multiple other adjuncts combined with a lack of a controlled comparator group makes it difficult to assess the true clinical benefit. Psychological adverse effects are common, and their effects on an inadequately sedated patient with alcohol withdrawal are unknown. Therefore, pending more controlled clinical data, ketamine is only reasonable in cases of severe benzodiazepine-resistant alcohol withdrawal for whom other more established adjuncts, including phenobarbital and possibly propofol, have either failed or are unable to be tolerated.<sup>107</sup>

### SUMMARY

- Ethanol withdrawal is a complex physiologic process involving both enhanced neuronal excitation and reduced inhibition.
- The manifestations of greatest concern are neurologic and include altered mental status and seizures, but the autonomic excess is always of great concern.
- Treatment includes supportive care and sedation with benzodiazepines in escalating doses in a symptom-triggered fashion.
- When benzodiazepines cannot produce adequate sedation, sedative-hypnotics such as phenobarbital or propofol are recommended.

# DISULFIRAM AND DISULFIRAMLIKE REACTIONS

Amit K. Gupta

## HISTORY AND EPIDEMIOLOGY

Disulfiram, tetraethylthiuram disulfide (TETD), was synthesized from thiocarbamide in the 1880s to accelerate the vulcanization (stabilization) of rubber by the addition of sulfur.<sup>108</sup> Sixty years later, it was the first Western medication used to treat alcohol dependence. By the turn of the 20th century, most rubber factory workers exposed to disulfiram found that they were intolerant to alcohol.<sup>3,34</sup> E.E Williams, a rubber factory occupational physician, wrote, “If the chemical compound disulfiram is not harmful to man, one wonders if one has discovered a cure for alcoholism.” Apart from its use in the rubber industry, beginning in the early 1940s, disulfiram was also used in medicine as a scabicide. Two scientists, Hald and Jacobsen, were exploring the antiparasitic effects of disulfiram when they made the rediscovery that ingesting alcohol after loading doses of disulfiram was “quite unpleasant.”<sup>799</sup> Subsequently, in 1951, the US Food and Drug Administration approved disulfiram for the treatment for alcoholism. Disulfiram is typically prescribed at an initial dose of 500 mg/day for 1 to 2 weeks followed by a maintenance dose of 125 to 500 mg/day.

Disulfiram was never widely used clinically, and its use further declined after several studies revealed no significant difference in drinking outcomes between unsupervised disulfiram administration and placebo.<sup>33</sup> Studies evaluating the efficacy of disulfiram that span nearly 60 years yielded mixed results, with many studies having small sample sizes, nonrandomization, unblinded conditions, short follow-up periods, and no measurement of treatment adherence. With the worldwide approval of naltrexone in 1993 and later acamprosate, the clinical use of disulfiram declined. More recent interest in disulfiram for treating cocaine and other stimulant dependence has provided some renewed clinical interest.<sup>35,82,85</sup> Disulfiram is being studied for its possible antineoplastic properties, which include the induction of oxidative stress, leading to copper-dependent cytotoxicity, proteasome inhibition, and nuclear factor-κB inhibition.<sup>15,38</sup> Oxidative stress is enhanced by the presence of the disulfiram-copper chelation complex, and copper-binding drugs inhibit proteasome activity and generate reactive oxygen species.<sup>90</sup> Disulfiram is undergoing clinical trials for the treatment of various cancers, including melanoma and liver, lung, and prostate cancers.

In considering disulfiram toxicity, a distinction must be made between the clinical manifestations of a disulfiram-ethanol reaction and the toxic effects of disulfiram itself. Direct disulfiram toxicity can be further classified as acute or chronic poisoning. Although life-threatening effects associated with disulfiram are rare, clinicians should be aware of proper diagnosis and management of patients with disulfiram-associated toxicity.

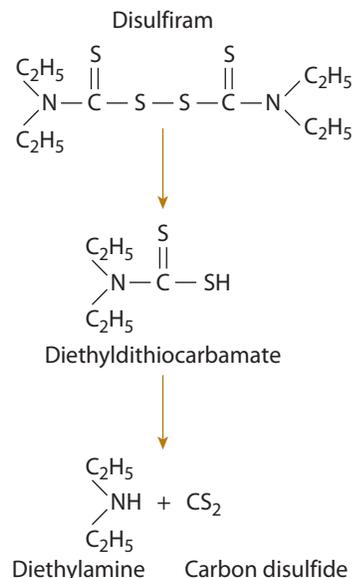

Specific epidemiologic information about the 3 different forms of disulfiram toxicity is difficult to elucidate, even from an analysis of the American Association of Poison Control Centers (AAPCC). Data from the National Poison Data System from 2015 revealed 221 exposures to disulfiram, with the majority of cases being in adults and classified as unintentional. No deaths and only one major adverse outcome was reported. Since 1982, 14 deaths associated with disulfiram were reported to the AAPCC, most involving a disulfiram-ethanol reaction (Chap. 130). Serious adverse effects associated

with both therapeutic use of disulfiram and with disulfiram overdose continue to be reported mostly in case reports and case series. As such, these reports are difficult to interpret because of complications and comorbidities associated with alcohol use; the potential effects of polypharmacy; and the difficulty in relating the adverse effect to disulfiram, alcohol, or a disulfiram-ethanol reaction.

## PHARMACOLOGY AND PHARMACOKINETICS OF DISULFIRAM

Approximately 70% to 90% of disulfiram is absorbed from the gastrointestinal (GI) tract after oral administration.<sup>13</sup> Upon absorption, disulfiram is immediately converted to diethyldithiocarbamate (DDC) followed by rapid conversion to carbon disulfide and diethylamine.<sup>24</sup> Diethyldithiocarbamate also chelates copper to form a bis(DDC)-copper complex.<sup>13</sup> Bis(DDC)-copper is absorbed from the small intestine. Peak serum concentrations of disulfiram and DDC are achieved 8 to 10 hours after a 250-mg dose, and that for carbon disulfide occurs 5 to 6 hours.<sup>24</sup> In one study, the mean serum disulfiram concentration in humans after a 250-mg dose was reported to be  $0.38 \pm 0.03$  mcg/mL.<sup>24</sup>

Within 5 to 10 minutes after absorption, disulfiram is rapidly reduced to DDC via glutathione reductase, which then can undergo nonenzymatic degradation to diethylamine and carbon disulfide or chelate copper to form a bis(DDC)-copper complex (Fig. 78-1).<sup>13</sup> As such, it is difficult to detect the parent drug blood concentrations. Metabolism of disulfiram occurs primarily in the liver and the erythrocyte. The oxidation of DDC in the liver is catalyzed by at least 4 enzymes of cytochrome P450 (CYP3A4, CYP1A2, CYP2A6, CYP 2D6) and to a minor extent by human flavin monooxygenase.<sup>63</sup> Diethyldithiocarbamate is also metabolized by glucuronidation, methylation, and oxidation. Methylation of DDC produces diethyldithiomethylcarbamate (MeDDC).<sup>17</sup> Diethyldithiomethylcarbamate is oxidized primarily to the intermediate metabolite MeDDC sulfine, which is ultimately converted to MeDDC sulfoxide.<sup>63</sup> Genetic differences in various enzymatic activity among

**FIGURE 78-1.** Disulfiram metabolism occurs in the liver and in the erythrocyte. The most consequential metabolites are diethyldithiocarbamate and carbon disulfide.

**TABLE 78–2** Xenobiotics Reported to Cause a Disulfiramlike Reaction With Ethanol<sup>8,14,23,41,55,56,72,76,99,113,119,122</sup>

Antimicrobials
Cephalosporins, especially those that contain an nMTT side chain, such as cefotetan, cefoperazone, cefamandole, and cefmenoxime
Metronidazole
Moxalactam
Trimethoprim–sulfamethoxazole
Possible reactions with chloramphenicol, furazolidone, griseofulvin, nitrofurantoin, procarbazine quinacrine, sulfonamides
Calcium carbimide (citrated)
Carbon disulfide
Carbon tetrachloride
Chloral hydrate
Dimethylformamide
Mushrooms
<i>Coprinus</i> mushrooms, including <i>C. atramentaria</i> , <i>C. insignis</i> , <i>C. variegatus</i> , and <i>C. quadrididus</i> , <i>Boletus luridus</i> , <i>Clitocybe clavipes</i> , <i>Polyporus sulphureus</i> , <i>Pholiota squarosa</i> , <i>Tricholoma aurantum</i> , <i>Verpa bohemica</i>
Nitrofurantoin
Phentolamine
Procarbazine
Sulfonylurea oral hypoglycemics
Chlorpropamide
Tolbutamide
Tacrolimus
Thiram analogs (fungicides)
Copper, mercuric, and sodium diethyldithiocarbamate
Zinc and ferric dimethyldithiocarbamate
Zinc and disodium ethylenebis (dithiocarbamate)
Thiuram analogs
Tetraethylthiuram monosulfide and disulfide (disulfiram)
Tetramethylthiuram disulfide (thiram)
Tolazoline
Trichloroethylene

nMTT = *N*-methylthiotetrazole.

Disulfiram-like reactions occur when ethanol is ingested with xenobiotics other than disulfiram. Symptoms are similar to those of disulfiram–ethanol reactions. Health care providers should warn patients of such reactions when prescribing certain medications that cause this adverse effect. Unfortunately, these reactions are idiosyncratic and are not been studied extensively.<sup>116</sup> **Table 78–2** lists xenobiotics reported to cause disulfiramlike reactions.

## MANAGEMENT OF DISULFIRAM–ETHANOL REACTIONS

The duration of the disulfiram–alcohol reaction varies from 30 to 60 minutes in mild cases to several hours and is largely dependent on the amount of alcohol absorbed and its metabolism. Because of vomiting and volume depletion, serum glucose, electrolytes, and kidney function should be evaluated. Because only small amounts of ethanol precipitate a disulfiram–ethanol reaction, it is useful to quantify the presence of ethanol with a blood concentration. Patients with cardiovascular instability should have an ECG and attached to continue cardiac monitoring. Symptomatic and supportive care is the mainstay of treatment. Most patients with hypotension respond to intravenous (IV) 0.9% sodium chloride. Refractory hypotension is rare, but if necessary, a vasopressor should be administered. A direct-acting adrenergic agonist such as norepinephrine is recommended because disulfiram inhibits DBH, an enzyme necessary for norepinephrine synthesis. As such, indirect vasopressors, such as dopamine, that require functioning norepinephrine synthesis are less effective.

For further symptomatic care, antiemetics are reasonable, and for cutaneous flushing, a histamine (H<sub>1</sub>) receptor antagonist, such as diphenhydramine, is useful.<sup>105</sup> Most patients with a disulfiram–ethanol reaction have mild symptoms, are hemodynamically stable, and should safely discharged after resolution of symptoms.

Fomepizole halts the accumulation of acetaldehyde and thus halts the severity of disulfiram–ethanol reactions. Fomepizole, an inhibitor of alcohol dehydrogenase, limits the progression of the disulfiram reaction by blocking ethanol metabolism to acetaldehyde (Antidotes in Depth: A33). In a study of patients with alcoholism, fomepizole decreased acetaldehyde concentrations and improved clinical symptoms in those experiencing a disulfiram–ethanol reaction.<sup>62</sup> A case series reported 2 patients who developed severe disulfiram–ethanol reactions with hypotension and tachycardia unresponsive to fluids who were treated successfully with a single dose of fomepizole.<sup>101</sup> One patient improved clinically 90 minutes after administration of fomepizole and the other within 30 minutes. Fomepizole is only be recommended for patients experiencing a severe disulfiram–ethanol reaction leading to cardiogenic or distributive shock.

## CLINICAL MANIFESTATIONS OF DISULFIRAM TOXICITY

### Acute Disulfiram Toxicity

Reported cases of acute disulfiram overdose are infrequent and typically do not cause life-threatening toxicity. Most patients rapidly develop GI symptoms within 1 to 2 hours that include nausea, vomiting, and abdominal pain. Neurologic symptoms are present after acute disulfiram overdose, including lethargy and coma.<sup>61</sup> Dysarthria and movement disorders, including myoclonus, ataxia, dystonia, and akinesia, usually take 3 or more days to develop, occur rarely, and are related to direct effects of carbon disulfide on the basal ganglia.<sup>59,60,64</sup> Hypotonia is present in children.<sup>6</sup> Persistent neurologic abnormalities, such as paresis, myoclonus, and neuropathy, lasting weeks to months, are reported in both children and adults but are rare.<sup>95,124</sup>

### Chronic Disulfiram Toxicity

The disulfiram–ethanol reaction, characterized by tachycardia, hypotension, diaphoresis, and facial erythema, is familiar to most physicians. However, the toxic effects of disulfiram alone, including depression, lethargy, loss of libido, psychosis, delirium, meningeal signs, unilateral weakness, optic neuritis, and peripheral neuropathy, are not well recognized by most clinicians, perhaps because the behavioral symptoms confused with manic-depressive or schizophrenic psychoses and the neurologic findings with the sequelae of alcoholism.<sup>19,23,27,57,81,91,100</sup>

The only significant adverse event reported in a placebo-controlled trial of abstinent individuals with oral disulfiram 250 mg/day versus placebo was drowsiness.<sup>33</sup> Over a 23-year period (1968–1991), 155 adverse drug events (ADEs) were reported for disulfiram, giving it an ADR rate of 1 per 200 to 2,000 patients per year (categorized as an “intermediate” rate of ADRs for a medication). Hepatic reactions were the most frequent ADR (34%) followed by neurologic (21%), cutaneous (15%), psychiatric (4%), and other (26%).<sup>23</sup>

Disulfiram-induced hepatitis was first reported in 1974.<sup>50</sup> In 1977, 6 additional cases were reported; 5 of the patients died.<sup>92</sup> Incidence of disulfiram-induced fatal hepatitis is reportedly 1 in 30,000 patients treated per year.<sup>16</sup> The onset of symptoms of hepatotoxicity caused by disulfiram occurs within 4 to 6 weeks (range, 2–24 weeks) after initiating treatment.<sup>16,29,92</sup> Signs and symptoms include fatigue, headache, fever, pruritus, rash, myalgias, malaise, anorexia, nausea, vomiting, abdominal pain, jaundice, light stools, dark urine, and hepatomegaly. Symptoms usually resolve within 2 weeks of stopping disulfiram, but liver function requires up to 12 weeks to normalize.<sup>16,29,92</sup> Liver biopsy demonstrates a predominantly hepatocellular degeneration with focal or extensive hepatocellular necrosis as well as portal and periportal eosinophilic infiltration.<sup>16,29</sup> Although the exact mechanism of disulfiram-induced liver damage is unclear, most reports suggest an idiosyncratic hypersensitivity reaction as the primary mechanism involved.<sup>16,29,92</sup> Alternatively, a carbon disulfide–induced hepatic injury resulting from covalent binding of electrophilic oxides or carbene derivatives of these oxides to macromolecules is considered responsible.<sup>30</sup>

Asymptomatic elevations in aminotransferase concentrations, up to 3 times the upper limits of normal, associated with disulfiram therapy are reported to range from 6% to 30% in alcoholics.<sup>37,110,121</sup> Although hepatic effects are most commonly reported with oral dosage forms, they also occur with implantable depot disulfiram.<sup>69</sup>

Liver transplantation for disulfiram-induced liver failure was first reported in 1989.<sup>114</sup> Since then, several case reports of liver transplantation for disulfiram-induced liver failure are noted<sup>71</sup>; the first North American case was performed in 1998.<sup>89</sup> A 5-year review from a hospital in Denmark revealed that disulfiram was the most common cause of idiosyncratic drug-induced liver failure, accounting for 13 of the 43 cases (30%).<sup>2</sup>

Disulfiram induces a peripheral neuropathy characterized by distal sensory impairment with loss of coordination, painful paresthesias, and distal weakness with foot drop.<sup>1,31</sup> The severity of the neuropathy is directly related to dose and duration of exposure.<sup>81,118</sup> If disulfiram is not discontinued, sensory and motor impairment progresses proximally.<sup>7,98</sup> Wallerian-type axonal degeneration, intermediate filament accumulation, and marked loss of larger myelinated fibers are the pathological hallmarks of disulfiram toxicity.<sup>10,79</sup> Experiments in animals showed that disulfiram causes Schwann cell damage and demyelination of peripheral nerves.<sup>111,112</sup> In addition, isolated descriptions of both axonal and myelin involvement are reported.<sup>78</sup>

The mechanisms underlying disulfiram-induced parkinsonism and catatonia are still controversial. One of the main hypotheses is that the lesions result from the toxicity of the disulfiram metabolite, carbon disulfide.<sup>49,91</sup> Histopathologic lesions of the globus pallidus and substantia nigra are observed after chronic exposure to carbon disulfide in animals.<sup>97</sup> Other research suggest involvement of brain dopaminergic transmission in disulfiram neurotoxicity.<sup>17,44</sup> This is supported by an experiment in mice, in which the toxic effects of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine on nigrostriatal dopaminergic systems were enhanced by pretreatment with disulfiram.<sup>18</sup>

The exact mechanism of disulfiram-mediated encephalopathy is not known. However, both DDC and carbon disulfide are implicated, and both inhibit the activity of DBH, leading to the accumulation of dopamine, producing a relative deficiency of adrenaline and noradrenaline in the area of the basal ganglia.<sup>42</sup> Dopamine-mediated cellular injury is related to its ability to induce excitatory toxic effects of glutamate and calcium-mediated cell death and to impair the cellular ability to eliminate free oxygen radicals.<sup>98</sup>

### Disulfiram and Carbon Disulfide

Carbon disulfide is a colorless volatile liquid and a commonly used nonpolar chemical solvent. The principal industrial use of carbon disulfide is the manufacture of viscose rayon. In addition, carbon disulfide is used as an insecticide for the fumigation of grains, nursery stock, in fresh fruit conservation, and as a soil pesticide against insects and nematodes.<sup>21</sup> The clinical, biochemical, and pathological neurotoxic effects of disulfiram are similar to those of carbon disulfide. Both are associated with depression, lethargy, loss of libido, psychosis, ataxia, incoordination, and peripheral neuropathy.<sup>91</sup> Both inhibit DBH in vitro and produce increased brain dopamine and decreased brain norepinephrine, demyelination, and denervation in vivo.<sup>104</sup> Acute exposure to carbon disulfide causes a rapid onset of headache, confusion, nausea, hallucinations, delirium, seizures, coma, and death.<sup>4</sup> Chronic carbon disulfide exposure causes pyridoxine deficiency and interacts with pyridoxal-5-phosphate, a cofactor in the production of  $\gamma$ -aminobutyric acid (GABA) from glutamate, thereby depleting GABA concentrations in the brain and leading to benzodiazepine-resistant seizures.<sup>88</sup> These findings suggest that disulfiram induced seizures are similar to that of carbon disulfide. However, there is no evidence that administering pyridoxine to a patient with disulfiram-induced seizure is of any benefit.

Although patients with occupational exposure to carbon disulfide have an increased risk of atherosclerosis and ischemic heart disease, this has not been proven for patients using disulfiram.<sup>108</sup> Disulfiram therapy increases serum cholesterol concentration.<sup>65</sup>

### Disulfiram and Pediatrics

The presence of this drug in the household makes it a potential xenobiotic encountered in unintentional poisonings; however, reports of significant toxicity are rare. One case report details a 5-year-old girl with exposure to 19 tablets of disulfiram, who subsequently developed dystonia, complete loss of developmental milestones, and spastic tetraparesis over a 2-year follow-up period.<sup>64</sup> A 2-year-old child who developed an encephalopathy and dystonia after exposure to disulfiram brain magnetic resonance imaging showed edema and symmetrical hyperintense signal changes involving the globus pallidus and substantia nigra.<sup>117</sup>

### Disulfiram and Pregnancy

There is a paucity of information regarding the teratogenic effects, if any, of disulfiram in humans or animals. Case reports suggest congenital defects, and one spontaneous miscarriage occurred.<sup>25,43,77</sup> A confounder could be the combination of disulfiram and alcohol itself, which enhances the incidence of birth defects. The embryotoxic properties of disulfiram could be related because of its lead- and copper-chelating properties.<sup>20</sup>

## DIAGNOSTIC TESTING

### Acute Disulfiram Toxicity

Serum concentrations of disulfiram and its metabolites, including diethyldithiomethylcarbamate acid and diethyldithiomethylcarbamate acid, can be measured but are not useful when managing most patients with suspected acute or chronic disulfiram overdose, disulfiram toxicity, or a disulfiram-ethanol reaction. Other markers of ingestion include carbon disulfide in the breath and diethylamine in the urine.<sup>28</sup> Because of rapid metabolism, only a small proportion of ingested disulfiram reaches the blood as the parent drug.<sup>46</sup> Leukocyte ALDH correlates most closely with hepatic mitochondrial ALDH. Decreased erythrocyte ALDH1 and leukocyte ALDH2 activity are markers of disulfiram exposure, but neither enzyme assay is commonly available. Elevated acetaldehyde concentrations in the blood will occur but are not readily available and thus also not clinically useful in managing patients.

### Chronic Disulfiram Toxicity

The development of hepatotoxicity is a concern with chronic disulfiram administration. Two common strategies used for detecting and preventing severe hepatotoxicity include routine clinical monitoring for signs or symptoms of hepatic injury as well as periodic monitoring of biomarkers, including alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and total bilirubin.<sup>120,121</sup>

There is no agreement on when disulfiram therapy should be modified or discontinued based on the finding of mildly elevated aminotransferase concentrations. There is much greater agreement that the development of an aminotransferase concentration greater than 3 times the upper limit of the reference range in combination with evidence of impaired hepatic synthetic function, elevated total bilirubin greater than 2 times the upper limit of the reference range, or international normalized ratio greater than 1.5 is suggestive of more severe drug-induced liver injury. In such situations, the mortality rate may be 16% or higher and necessitate discontinuing disulfiram.<sup>9,102</sup>

## MANAGEMENT OF DISULFIRAM TOXICITY

### Acute Disulfiram Toxicity

There is no antidote for acute disulfiram overdose. No specific studies have evaluated GI decontamination for acute overdose. Unless otherwise contraindicated, activated charcoal at a dose of 1 g/kg is recommended. Induced emesis is not indicated, and orogastric lavage or whole-bowel irrigation is not required.

### Chronic Disulfiram Toxicity

Most patients receiving disulfiram will not develop hepatotoxicity, but those who develop mild increase in their aminotransferases will likely normalize with continued disulfiram therapy.<sup>102</sup> Continued periodic monitoring of liver

function tests should be performed, and therapy should be discontinued with symptoms of hepatic injury such as jaundice, abdominal pain, nausea, vomiting, or fever.

Treatment of hepatotoxicity is supportive and usually resolves after discontinuation of disulfiram therapy. Liver transplantation was successfully performed for disulfiram-induced hepatic failure in both adults and children.<sup>71,89</sup>

## DISULFIRAM AS AN ANTIDOTE

Disulfiram is used for the treatment of nickel dermatitis. However, a small double-blind, placebo-controlled study of patients with hand eczema and nickel allergy did not find a clinically significant difference between those treated with disulfiram and those treated with placebo.<sup>48</sup> In fact, the conditions of some patients worsened after disulfiram therapy.<sup>54</sup>

Diethyldithiocarbamate is available as the chelator dithiocarb. Although animal studies suggest that DDC is effective for nickel-carbonyl poisoning, there are no human studies to confirm this<sup>12,107</sup> (Chap. 96).

## SUMMARY

- Although the role of disulfiram in treating alcoholism is diminishing, its use for the treatment of cocaine dependence is gaining interest.
- It is critical to understand the distinction among the different forms of disulfiram toxicity, including toxicity from an acute overdose, from chronic therapy, and from a disulfiram-ethanol reaction.
- Disulfiram and its metabolites both irreversibly inhibit ALDH. This leads to accumulation of acetaldehyde and is responsible for many of the symptoms produced by the disulfiram-ethanol reaction. Symptoms are typically self-limiting and include facial and generalized body warmth and flushing, pruritus, urticaria, diaphoresis, lightheadedness, vertigo, headache, nausea, vomiting, and abdominal pain.
- Treatment for the disulfiram-ethanol reaction is mostly supportive and includes IV crystalloid administration, antiemetics, and histamine receptor antagonists. Fomepizole, an alcohol dehydrogenase inhibitor, is appropriate for more serious reactions when the serum ethanol concentration remains elevated.
- Disulfiram toxicity after an acute overdose is unlikely to be life threatening. Early symptoms are mostly GI. Rarely, persistent neurologic symptoms occur and include myopathy, movement disorders, ataxia, parkinsonism, and psychosis.
- Hepatotoxicity is the most common ADE associated with chronic disulfiram therapy. Neurotoxicity is also reported with chronic disulfiram toxicity, and symptoms are similar to those of acute disulfiram toxicity.

# HALLUCINOGENS

Mark J. Neavyn and Jennifer L. Carey

## HISTORY

A “hallucination” is defined as a false perception that has no basis in the external environment. The term is derived from the Latin “to wander in mind.” Hallucinations differ from illusions, which are distorted perceptions of objects based in reality. Although the term *psychedelic* has been used for years to refer to the recreational and nonmedical effects of hallucinogens, other terms, such as *entheogen* and *entactogen*, frequently appear in discussions. Entheogens are “substances that generate the god or spirit within,” and entactogens create an awareness of “the touch within.”<sup>50</sup> These terms all refer to the same xenobiotics, used with differing intent or in varying settings.

Hallucinogens are a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium. Hallucinogens are categorized by their chemical structures and are further divided into natural and synthetic members of each family. The major structural classes of hallucinogens include the lysergamides, tryptamines (indolealkylamines), amphetamines (phenylethylamines), arylhexamines, cannabinoids, harmine alkaloids, belladonna alkaloids, and tropane alkaloids. In addition, there are several unclassified hallucinogens, such as *Salvia divinorum*, nutmeg (*Myristica fragrans*), kratom (*Mitragyna speciosa*), and kava kava (*Piper methysticum*). This chapter focuses on lysergamides, tryptamines, phenylethylamines, and the aforementioned “unclassified” hallucinogens. The other classes are found in Chaps. 71, 73, 74, and 83 (Table 79-1).

Hallucinogens have been used for thousands of years by many different cultures, largely during religious ceremonies. The ancient Indian holy book, *Rig-Veda*, written more than 3,500 years ago, describes a sacramental substance called Soma both as a god and as an intoxicating substance. Although debated for many years, the source of Soma is now believed to be an extract of the mushroom *Amanita muscaria*.<sup>121,129</sup> The Aztecs used the psilocybin-containing mushroom *Psilocybe mexicana*, termed “teonanacatl” (flesh of the gods), and the lysergic acid amide-containing morning glory plant, *Turbina corymbosa*, known as “Ololiuqui” in their religious ceremonies. The Native American Church in the United States uses peyote in religious ceremonies.<sup>28,31,116</sup> In South America, ayahuasca, a tea made of dimethyltryptamine-containing plants (eg, *Psychotria viridis*), is famous for its use in shamanistic rituals.<sup>94</sup>

From medieval times through recent years, several large-scale epidemics of vasospastic ischemia, gangrene and hallucinations (collectively called ergotism) resulted from *Claviceps purpurea* contamination of cereal crops.<sup>164</sup> The hallucinations from *Claviceps* ingestion is attributed to the ergot alkaloid lysergic acid amide from which lysergic acid diethylamide (LSD) was chemically synthesized. *Claviceps purpurea* has been suggested, but subsequently disproved, as the cause of the mass hysteria leading up to the Salem witch trials. Many of these adverse effects after ingestion of *C. purpurea* are attributed to the serotonergic agonist effects of the ergot alkaloids (Chap. 52).<sup>47</sup>

Synthetic hallucinogen use is often said to have begun in 1938 when Albert Hofmann, a Swiss chemist, synthesized LSD while performing extensive research on the medicinal uses of ergot alkaloids derived from the fungus, *Claviceps purpurea*. Five years later, LSD was “tested” when Hofmann exposed himself in his laboratory and subsequently developed hallucinations.<sup>76,141</sup> Soon thereafter, Sandoz laboratories began marketing LSD under the trademark *Delysid* as an adjunct for analytic psychotherapy. In the 1950s, a small number of psychiatrists began using LSD to release the repressed memories of patients and as an experimental model for schizophrenia.<sup>149</sup> The Central Intelligence Agency experimented with the use of LSD as a tool for interrogating suspected communists and as a mind-control agent.<sup>27,141</sup>

Lysergic acid diethylamide (also called acid) became a fashionable recreational drug. In the 1960s, the concept of the “fifth freedom” emerged as

the “right” for individuals to alter their consciousness as they saw fit. In one of the most famous slogans of the 1960s, Timothy Leary popularized LSD as a way to “tune in, turn on, drop out.”<sup>141</sup> By 1966, federal law banned the use of LSD.<sup>112</sup> Initial reports of LSD-induced chromosomal damage appeared in the 1960s, including fetuses in utero.<sup>36,78,90</sup> However, further studies of pregnant women who had taken LSD did not demonstrate an increased risk of abortions or birth defects.<sup>53,87</sup> Lysergic acid diethylamide use diminished in the late 1970s and early 1980s, perhaps because of users’ concerns regarding potential health risks of brain damage, “bad trips,” and flashbacks.<sup>120</sup> Recurrent visual hallucinations after LSD are known to cause significant anxiety in some users, and this phenomenon is now recognized as “hallucinogen persisting perception disorder” (HPPD).<sup>72</sup>

In the meantime, there was a rise in the use of the “designer” hallucinogens. Exploiting a loophole in drug enforcement laws, these designer synthetic tryptamine and amphetamine hallucinogens are chemically similar to, but legally distinct from, their outlawed counterparts and therefore not subjected to legislative drug control. These are often referred to as “legal highs.” A bill sponsored by Rep. Charles Dent of Pennsylvania in 2016 aimed to place additional synthetic hallucinogens, opioids, and cannabinoids in Schedule I status, but it has yet to pass in the US Senate.<sup>37</sup>

The Internet is now a vehicle for the rapid and facile sharing of information on the synthesis of emerging drugs, user experiences, and adverse effects. Encyclopedic content on recreational drug use is found on Erowid.org, and additional crowd-sourcing information is found on drug forums hosted on Bluelight.org, Reddit.com, and many others. Additionally, many “herbal” hallucinogens are widely available for purchase via unregulated websites.<sup>41</sup> Hidden “cryptomarkets” are found on the dark web, content on the Internet that requires encryption software or prior authorization to access and is not searchable through common Internet search engines.<sup>156,157</sup> A search on one such cryptomarket Alphabay found 120 vendors selling novel psychoactive substances to users.<sup>157</sup> All-night dance clubs host “rave parties” at which emerging hallucinogens are popular.<sup>16</sup> Although the impact of these parties on the growth of hallucinogens in the United States is unclear, many of the newer hallucinogens are christened “club drugs” because of this association.<sup>64</sup> A survey of dance club patrons in South London suggests that novel psychoactive substances supplement established recreational drugs like 3,4-methylenedioxyamphetamine (MDMA).<sup>107</sup>

Although much of the research involving psychedelic drugs was halted in the 1960s, clinical investigations for the treatment of various psychiatric disorders, with emphasis on treatment of anxiety and addictions is reemerging. Currently, psilocybin is being evaluated for the treatment of the existential anxiety associated with end-stage cancer and obsessive-compulsive disorders, and MDMA is studied as an adjunct to psychotherapy for treatment-resistant posttraumatic stress disorder.<sup>69,106,108,123</sup> This clinical or research use of psychedelic drugs remains highly controversial.

## EPIDEMIOLOGY

Resurgence in LSD use was reported among high school teens in the late 1990s, with more prevalent use in the suburbs than the cities.<sup>113,130</sup> In 1997, 2 studies of adolescents showed a lifetime prevalence of LSD use at 13% and 14%.<sup>80,120</sup> In 2000, Drug Enforcement Administration (DEA) agents seized an LSD-production lab and apprehended 2 men involved in massive production of LSD in Kansas. The seizure of more than 40 kg of LSD in this case was considered the largest LSD lab seizure in DEA history.<sup>3</sup> Their incarceration resulted in a 95% decrease in LSD availability nationwide.<sup>4</sup>

From 2006 to 2015, the National Survey on Drug Use and Health (NSDUH) reported the following trends in hallucinogen use: lifetime LSD use among

TABLE 79–1 Structural Classifications of Hallucinogens

## Lysergamides

- D-Lysergic acid diethylamide (LSD)
- Lysergic acid hydroxyethylamide
  - Morning glory (*Ipomoea violacea*)
  - South American morning glory (*Ololiuqui*)
- Ergine
  - Woodrose (*Argyreia nervosa*)

## Indolealkylamines and Tryptamines

- 5-Methoxy-*N,N*-dimethyltryptamine (5-MeO-DiPT, Foxy Methoxy)
- N,N*-Dimethyltryptamine (DMT)
- Psilocin  $\alpha$ -methyltryptamine (AMT)
- Psilocybin

## Phenylethylamines

- Mescaline
- 3,4-Methylenedioxyamphetamine (MDMA)
- 2C-B
- 2C-T-7

## Tetrahydrocannabinoids

- Marijuana
- Hashish

## Belladonna Alkaloids

- Jimsonweed (*Datura stramonium*)
- Henbane (*Hyoscyamus niger*)
- Deadly nightshade (*Atropa belladonna*)
- Brugmansia* spp

## Miscellaneous

- Kava Kava (*Piper methysticum*)
- Kratom (*Mitragyna speciose korth*)
- Nutmeg (*Myristica fragrans*)-myristicin, elemicin, safrole
- Phencyclidine (PCP), ketamine
- Salvia divinorum*

Americans over the age of 12 years increased from 23 to 25 million, lifetime phencyclidine (PCP) use decreased from 6.6 to 6.3 million, and lifetime MDMA use increased from 12 million to 18 million. Additionally, lifetime ketamine use increased from 2.3 to 3 million people, and lifetime reported use of  $\alpha$ -methyltryptamine (AMT), dimethyltryptamine (DMT), or 5-methoxydimethyl tryptamine (5-MeO-DMT) tripled from 700,000 to 2.1 million. About 1.8 million people reported use of *S. divinorum* during their lifetime in 2006, and 5.1 million people reported lifetime use in 2015.<sup>117</sup> In the reported results, the 18- to 25-year-old age group was most likely to report use of any of these hallucinogens within the previous year.<sup>143</sup> In 2010, the

NSDUH reported that 1.2 million Americans older than the age of 12 years were current users of hallucinogens.<sup>152</sup>

## LYSERGAMIDES

Lysergamides are derivatives of lysergic acid, a substituted tetracyclic amine based on an indole nucleus (Fig. 79–1). Naturally occurring lysergamides are found in several species of morning glory (*Rivea corymbosa*, *Ipomoea violacea*) and Hawaiian baby woodrose (*Argyreia nervosa*).<sup>71</sup> Morning glory seeds contain multiple alkaloids, including lysergic acid hydroxyethylamide and ergonovine. Morning glory seeds were called *ololiuqui* in ancient Mexico, where Aztecs and other indigenous populations used them in religious rites.<sup>145</sup> However, in one volunteer study, *ololiuqui* caused sedation rather than hallucinations.<sup>77</sup> Hawaiian baby woodrose seeds contain the alkaloid ergine (D-lysergic acid amide).<sup>7</sup> Both morning glory and Hawaiian baby woodrose seeds are legally purchased for planting in garden stores and on the Internet.

The synthetic lysergamide, LSD, is derived from an ergot alkaloid of the fungus, *Claviceps purpurea*. Although 4 LSD isomers exist, only the D-isomer is active. Lysergic acid diethylamide is a water-soluble, colorless, tasteless, and odorless powder. Lysergic acid diethylamide is typically sold as liquid-impregnated blotter paper, microdots, tiny tablets, “window pane” gelatin squares, liquid, powder, or tablets.<sup>130</sup> Of note, the traditional “blotter paper” associated with LSD is commonly found to have other synthetic hallucinogens, particularly *N*-benzyl-oxy-methyl (NBOME).<sup>44,59</sup> Lysergic acid diethylamide users typically experience heightened awareness of auditory and visual stimuli with size, shape, and color distortions. Auditory and visual hallucinations occur, as well as synesthesia, a confusion of the senses, in which users report “hearing colors” or “seeing sounds.” Other more complex perceptual effects include depersonalization and a sensation of enhanced insight or awareness. A “bad trip” or dysphoric reaction is said to occur when LSD use produces anxiety, bizarre behaviors, and combativeness.

Lysergic acid diethylamide is classified by the DEA as a Schedule I drug, which is defined as having a high abuse potential, lack of established safety even under medical supervision, and no known use in medical treatment.

## INDOLEALKYLAMINES (TRYPTAMINES)

Indolealkylamines, or tryptamines, represent a class of natural and synthetic compounds that structurally share a substituted monoamine group (Fig. 79–2). Endogenous tryptamines include serotonin and melatonin. Naturally occurring exogenous tryptamines include psilocybin, bufotenine and *N,N*-dimethyltryptamine (DMT). Psilocybin is found in three major genera of mushrooms: *Psilocyba*, *Panaeolus*, and *Conocybe*.<sup>129</sup> Other psychoactive mushrooms include *Amanita muscaria* and *Amanita pantherina*, which contain ibotenic acid, muscimol, and muscazone, which are unrelated to the tryptamines.<sup>71</sup> Hallucinogenic mushrooms are discussed at length in Chap. 117. Psilocybin-containing mushrooms, or “magic mushrooms,” are indigenous to the Pacific Northwest and southern United States, usually

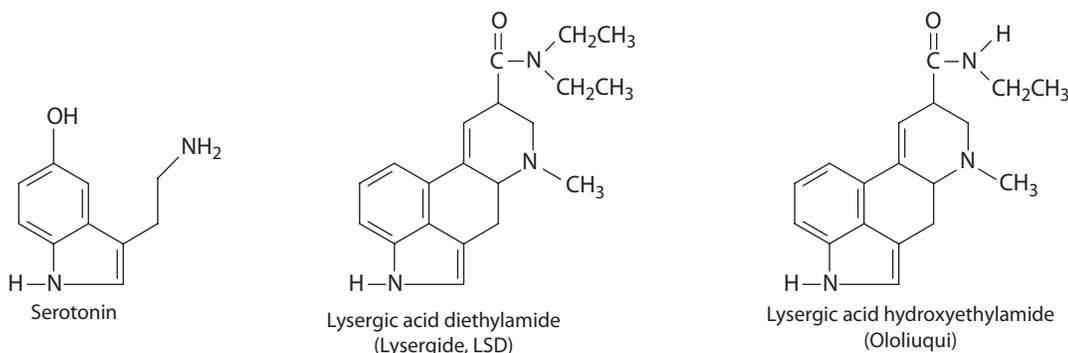

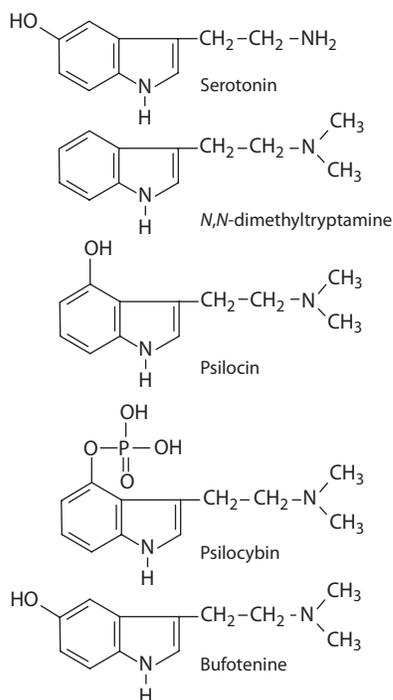

FIGURE 79–1. Hallucinogens of the lysergamide chemical class and their chemical similarity to serotonin.

**FIGURE 79-2.** Hallucinogens of the indolealkylamine chemical class and their chemical similarity to serotonin.

found in cow pastures. The mushroom is recognizable by a green-blue color that it assumes after bruising, but misidentification is common.<sup>14</sup>

*N,N*-dimethyltryptamine a 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and 5-HT<sub>1A</sub> receptor agonist, is a potent short-acting hallucinogen found naturally in the bark of the Yakee plant (*Virola calophylla*), a species of the Myristicaceae family, which grows in the Amazon basin. It is used by shamans as a hallucinogenic snuff to “communicate with the spirits.”<sup>129</sup> *N,N*-dimethyltryptamine is also found in the hallucinogenic tea ayahuasca, which originates in the Amazon Basin and used by indigenous healers during religious ceremonies.<sup>94</sup> In ayahuasca, DMT-containing plants (eg, *Psychotria viridis*) are combined with plants containing harmine alkaloids (eg, *Banisteriopsis caapi*), which inhibit hepatic monoamine oxidases to increase the oral bioavailability of DMT (Chap. 71).<sup>102</sup>

The use of toads in religious ceremonies and witchcraft dates back thousands of years. All species of the toad genus *Bufo* have parotid glands on their backs that produce a variety of xenobiotics, including dopamine, epinephrine, and serotonin.<sup>93</sup> Many of these toads produce bufotenine, a tryptamine, which causes hypertension but does not cross the blood–brain barrier. Interest in bufotenine grew out of reports of a toad-licking fad in the 1980s, in which individuals would reportedly lick toads for recreational purposes.<sup>92</sup> However, further review suggests that bufotenine is not the hallucinogenic substance found in toad secretions. Instead, 5-methoxydimethyl tryptamine (5-MeO-DMT), was identified as the psychoactive substance.<sup>162</sup> 5-Methoxydimethyl tryptamine is only found in one species of toad, *Bufo alvarius* (Sonoran Desert toad or Colorado River toad).<sup>92</sup> Although bufotenine was classified as a Schedule I drug by the DEA for many years, 5-MeO-DMT was not scheduled until 2009.<sup>109</sup> Like DMT, 5-MeO-DMT is rapidly metabolized by intestinal monoamine oxidase enzymes; oral ingestion of toad venom or skins would thus have limited potential as a route of recreational use.<sup>25</sup> Methods for extracting and drying *B. alvarius* secretions for smoking and insufflation are available on the Internet. The toad venom glands also produce cardioactive steroids, called bufadienolides, which cause digoxinlike cardiac toxicity (Chap. 62) and in some species can secrete tetrodotoxin.<sup>104,167</sup> Death results from ingestion of *Bufo* secretions for purposes of aphrodisia.<sup>34,67</sup>

Two of the more important synthetic tryptamines include *N,N*-diisopropyl-5-methoxytryptamine (5-MeO-DiPT, Foxy Methoxy), and  $\alpha$ -methyltryptamine (AMT, IT-290). Since 2001, law enforcement authorities

in more than ten states seized large amounts of 5-MeO-DiPT and AMT. These xenobiotics are often sold surreptitiously as MDMA. 5-MeO-DiPT was listed as Schedule I in 2004.<sup>154</sup>  $\alpha$ -Methyltryptamine (AMT or IT-290) is a monoamine oxidase inhibitor that was sold as an antidepressant in the former Soviet Union.<sup>135</sup>  $\alpha$ -Methyltryptamine was listed as Schedule I by the DEA in 2004.<sup>154</sup> Since 2011, AMT exposures reported to the United Kingdom Poisons Information Service are increasing.<sup>81</sup> This mirrors the experience in the United States as reported by the NSDUH data documenting tripling of reported lifetime use to 2.1 million people in 2015.<sup>117</sup>

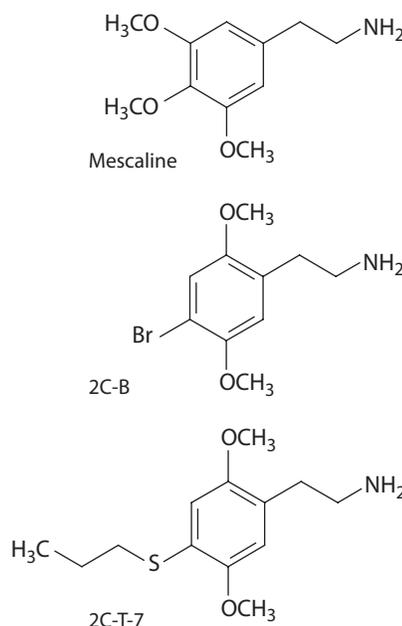

## PHENYLETHYLAMINES (AMPHETAMINES)

Dopamine, norepinephrine, and tyrosine are endogenous phenylethylamines. Exogenous phenylethylamines stimulate catecholamine release and cause a variety of physiologic and psychiatric effects, including hallucinations. Substitution on the phenylalkylamine structure has important effects on both the hallucinogenic and stimulant potential of the drug. The presence of a methyl group in the side chain of the phenylethylamines is associated with a higher degree of hallucinogenic effect (Fig. 79-3).<sup>83</sup> 3,4-Methylenedioxyamphetamine, amphetamine, and methamphetamine are well-known members of this family and are discussed in detail in Chap. 73.

The best recognized of the naturally occurring psychoactive phenylethylamines is mescaline. Mescaline is found in Peyote (*Lophophora williamsii*), a small blue-green spineless cactus that grows in dry and rocky slopes throughout the southwestern United States and northern Mexico. Peyote buttons are the round, fleshy tops of the cactus that are sliced off and dried. The legal use of peyote in the United States is restricted to members of the Native American Church, for whom peyote buttons are used for both religious ceremonies and medical treatment for physical and psychological ailments.<sup>28,31,116</sup>

Other nonindigenous cactus species containing significant amounts of mescaline include the San Pedro cactus (*Trichocereus pachanoi*) and Peruvian torch cactus (*Trichocereus peruvianus*). These plants can be purchased for ornamental purposes in garden stores and on the Internet.<sup>71</sup>

The synthesis and effects of hundreds of other hallucinogenic amphetamines are well described, including 4-bromo-2,5-dimethoxyphenethylamine (2C-B, Nexus, Bromo, Spectrum) and 2,5-dimethoxy-4-*N*-propylthiophenethylamine (2C-T-7, Blue Mystic).<sup>134</sup> During the 1980s, 2C-B gained popularity as a legal alternative to MDMA. When 2C-B became a Schedule I drug in 1995, 2C-T-7 emerged as another legal designer amphetamine.<sup>12</sup> In 2004, 2C-T-7 became a Schedule I drug.<sup>39</sup> 5-Methoxydimethyl tryptamine is a

**FIGURE 79-3.** Hallucinogens of the phenylethylamine chemical class.

Schedule I controlled drug since 2011. Under Food and Drug Administration Safety and Innovation Act of 2012, the compounds 2C-D, 2C-C, 2C-E, 2C-I, 2C-T-2, 2C-T-4, and 2C-P are all now Schedule I drugs.<sup>66</sup>

### SALVIA DIVINORUM

*Salvia divinorum* is a perennial herbaceous member of the mint family. Although there are more than 500 species of *Salvia*, *S. divinorum* is most recognized for its hallucinogenic properties.<sup>155</sup> *Salvia divinorum* is a native to areas of Oaxaca, Mexico, and grows well in sunny, temperate climates. Plants, leaves, and extracts are typically purchased online, and advice for cultivation of plants is easily accessible.

Since the 16th century, the Mazatec Indians have used *S. divinorum* as a hallucinogen in religious rites as a means of producing “visions.”<sup>155</sup> The Mazatecs continue to revere *S. divinorum* as an incarnation of the Virgin Mary, referring to the plant as “ska Maria.” Currently, although the federal Controlled Substances Act does not prohibit use of *S. divinorum* or its psychoactive extracts, the possession and sale of *S. divinorum* is illegal in several states, including Louisiana,<sup>151</sup> Missouri,<sup>43</sup> Delaware,<sup>150</sup> and Florida.<sup>42</sup> The United States is limited to local regulation in certain municipalities where *S. divinorum* use among teenagers is rampant.<sup>153</sup> There is wide variability among state laws against *S. divinorum*, and there continues to be widespread marketing of this hallucinogen on the Internet as a “legal hallucinogen.”

### KRATOM

Kratom, or *Mitragyna speciosa* Korth, is derived from the leaves of a tree native to Asia and Africa.<sup>133</sup> Kratom has dual properties, producing stimulant effects and opioidlike analgesic effects. It was used in Southeast Asia to enhance productivity in manual laborers. The kratom alkaloids mitragynine and 7-hydroxymitragynine are reported to activate  $\mu$ -,  $\delta$ -, and  $\kappa$ -opioid receptors. It is used as a substitute for opium; although hallucinogenic effects are uncommon, they are reported after heavy use.<sup>144</sup> Kratom has been illegal in Thailand since 1946 and Australia since 2005. Although there are import bans on kratom as an adulterant because it was not approved as a supplement before 1994, it is currently legal to possess and use in the United States, where it is adopted by some patients for self-treatment of chronic pain and to modulate opioid withdrawal symptoms.

### NUTMEG

Nutmeg is derived from *Myristica fragrans*, an evergreen tree native to the Spice Islands. The fruits of the tree contain a central kernel called the nutmeg; the surrounding red aril is used to produce a spice called mace.<sup>119</sup>

Although nutmeg is commonly available as a cooking spice, it has been used medicinally for centuries as an antidiarrheal and abortifacient.<sup>70</sup> It is a recreational herbal that is used to produce euphoria and hallucinations; it is more likely to be abused by adolescents because of its low cost and accessibility.<sup>40,119,126</sup>

### BELLADONNA ALKALOIDS

The belladonna alkaloids, including the tropane alkaloids atropine, hyoscyamine, and scopolamine, are isolated from a number of plants. Deadly nightshade (*Atropa belladonna*), a perennial plant, grows throughout the United States, areas of Europe, and Africa. Belladonna alkaloids are isolated from both the leaves and berries of this perennial plant. Jimson weed (*Datura stramonium*), also called locoweed, grows throughout warm and moist areas of the world. This bush contains pods full of small black seeds that are ingested or brewed as a tea for their hallucinogenic properties. The common name Angel’s trumpet is used for plants of the Solanaceae family with large trumpet-shaped white flowers (*Brugmansia* or *Datura*) (Chap. 118). Given their wide availability, in the wild and over the Internet, these plants are frequently used as hallucinogens by adolescents.<sup>65</sup> Unfortunately, they produce significant morbidity from anticholinergic toxicity in unwary users.<sup>61</sup> Moonflower, a common name given to several plants, including *Datura innoxia*, was responsible for anticholinergic poisoning of more than a dozen adolescents in one series.<sup>35</sup> Additionally, epidemics of unintentional poisoning were reported among drug users who received heroin adulterated with scopolamine<sup>74</sup> (Antidotes in Depth: A11).

### TOXICOKINETICS

Lysergic acid diethylamide (LSD) is the most studied hallucinogen for which there is extensive information about its pharmacokinetic data (Table 79–2). Ingestion is the most common route of exposure, and the gastrointestinal (GI) tract rapidly absorbs LSD. Other reported routes of administration include intravenous, intramuscular, intranasal, parenteral, sublingual, smoking, and conjunctival instillation. Plasma protein binding is over 80% and the volume of distribution is 0.28 L/kg. It is concentrated within the visual cortex, as well as the limbic and reticular activating systems. Metabolism takes place in the liver via hydroxylation and glucuronidation and LSD is excreted predominantly as a pharmacologically inactive compound. Lysergic acid diethylamide has an elimination half-life of about 2.5 hours. Only small amounts are eliminated unchanged in the urine. The minimum effective oral dose is 25 mcg.<sup>84</sup> The onset of effects generally occurs 30 to 60 minutes after exposure, with a duration of 10 to 12 hours.

TABLE 79–2 Pharmacology of Selected Hallucinogens

Drug Name or Source	Psychoactive Component (if Different)	Typical Oral Dose	Onset	Duration
Bufo species toads	5-MeO-DMT	5–15 mg (smoked)	Immediate (smoked)	5–20 min (smoked)
DMT	—	15–60 mg	5–20 min	30–60 min
“Foxy Methoxy”	5-MeO-DIPT	6–10 mg	20–30 min	3–6 h
Woodrose ( <i>Argyrea nervosa</i> )	Ergine	5–10 seeds	minutes	6–8 h
Jimson weed ( <i>Datura stramonium</i> )	Atropine, hyoscyamine, scopolamine	10 seeds	20–30 min	2–3 h
Kratom ( <i>Mitragyna speciosa</i> Korth)	Mitragynine, 7-hydroxy-mitragynine	2–6 g (stimulant); >7 g (sedative)	10–15 min	4–6 h
LSD	Lysergic acid diethylamide	50–100 mcg	30–60 min	10–12 h
“Magic mushrooms” ( <i>Psilocybe</i> spp)	Psilocybin, psilocin	5 g mushrooms	30 min–2 h	4 h
Nutmeg ( <i>Myristica fragrans</i> )	Myristicin, elemicin	20 g	1 h	24 h
Peyote ( <i>Lophophora williamsii</i> )	Mescaline	6–12 buttons, 270–540 mg mescaline	1–3 h	10–12 h
<i>Salvia divinorum</i>	Salvinorin A	—	30 min (inhaled); 1 h (PO)	15–20 min (inhaled); 2 h (PO)
2C-B	—	16–30 mg	1 h	6–10 h

PO = oral.

Ingestion of 200 to 300 morning glory seeds is required to achieve hallucinogenic effects. Only 5 to 10 seeds of Hawaiian baby woodrose are required to produce hallucinations. After ingestion of woodrose seeds, the effects typically last for 6 to 8 hours and produce tranquility without marked euphoria.<sup>7</sup>

Peyote buttons are very bitter and are eaten whole or dried and crushed into a powder, which is reconstituted as tea.<sup>71</sup> Nausea, vomiting, and diaphoresis often precede the onset of hallucinations, which begin at 1 to 3 hours after ingestion and last for up to 12 hours.<sup>119</sup> About 6 to 12 peyote buttons, or 270 to 540 mg of mescaline, are commonly required to produce hallucinogenic effects.<sup>128</sup> Ingestion of up to 5 g of psilocybin-containing mushrooms is typically required to produce hallucinogenic effects.

After ingestion of *Psilocybe* spp mushrooms, psilocybin is converted to psilocin, the active hallucinogen in the GI tract.<sup>68</sup> The effects of psilocin are similar to LSD but have a shorter duration of action of about 4 hours.

For recreational purposes, DMT is typically smoked, insufflated, or injected. Hallucinogenic effects peak in 5 to 20 minutes, with a duration of 30 to 60 minutes. 5-Methoxy-*N,N*-dimethyltryptamine (5-MeO-DiPT) is usually ingested by mouth and less commonly smoked or insufflated. Effects begin 20 to 30 minutes after ingestion and include disinhibition and relaxation. There is a dose-dependent response, and at higher ranges, symptoms include mydriasis, euphoria, auditory and visual hallucinations, nausea, diarrhea, and jaw clenching.<sup>111,136</sup> The hallucinogenic effects last from 3 to 6 hours.<sup>103,136</sup> Other substances such as sildenafil,  $\gamma$ -hydroxybutyrate, benzodiazepines, and marijuana are used to heighten or prolong the hallucinogenic effects of 5-MeO-DiPT.  $\alpha$ -Methyltryptamine is available as a white powder, which is ingested, smoked, or insufflated. Hallucinations typically occur within 30 minutes and last from 12 to 16 hours.<sup>89</sup>

Amphetamine, methamphetamine, and MDMA are well absorbed through the GI tract. The elimination half-life ranges from 8 to 30 hours for members of this class and is dependent on urine pH.<sup>15,38</sup> Amphetamines are weak bases and undergo more rapid elimination in acidic urine.<sup>131</sup> The volume of distribution ranges from 3 to 5 L/kg for amphetamine, 3 to 4 L/kg for methamphetamine, and likely more than 5 L/kg for MDMA.<sup>15,38,88,131</sup> Elimination of other amphetamines occurs through multiple mechanisms, including aromatic hydroxylation, aliphatic hydroxylation, and *N*-dealkylation.<sup>88</sup> Tolerance occurs with chronic amphetamine use.<sup>85</sup> There is little information about 2C-B and 2C-T-7 in the medical literature. Both drugs are used via oral, intranasal, and rectal routes. Both 2C-B and 2C-T-7 exert their hallucinogenic effects within 1 hour of use, and physiologic and psychologic effects persist for 6 to 10 hours. Additional information on the kinetics of amphetamine and congeners can be found in Chap. 73.

*Salvia divinorum* is chewed, smoked, or ingested as tea. Hallucinations occur rapidly after exposure and are typically quite vivid. Synesthesia is reported among *Salvia* users. Hallucinogenic effects after *S. divinorum* use are typically brief, lasting only 1 to 2 hours. Pharmacokinetic data for *S. divinorum* and its primary psychoactive, salvinorin A, were described in a volunteer study.<sup>137</sup> Psychoactive effects were typically experienced 5 to 10 minutes after absorption of salvinorin A via the buccal mucosa, reaching a plateau during the first hour after exposure and resolving within 2 hours. Vaporization and inhalation of salvinorin A led to more rapid effects beginning at 30 seconds after exposure. These effects plateaued at 5 to 10 minutes and typically subsided after 20 to 30 minutes. In this study, ingestion of *S. divinorum* leaves did not produce the same effects as buccal or inhalational administration, leading to the theory that GI deactivation of salvinorin A occurs after ingestion.<sup>137</sup>

Kratom leaves are decocted into tea, chewed, or smoked.<sup>79</sup> Kratom leaves contain approximately 0.8% mitragynine by weight but can vary by geographic origin of trees, as well as season.<sup>132</sup> In addition, several commercially available kratom products have excessive quantities of 7-hydroxymitragynine, suggesting that many of these products are likely being artificially adulterated with this alkaloid.<sup>91</sup> Neuropsychiatric effects are dose dependent and occur within 5 to 10 minutes of exposure, with effects lasting 4 to 6 hours.<sup>144</sup> Stimulant effects predominate at doses of 2 to 6 g, and sedation becomes more pronounced at doses above 7 g.

Nutmeg is usually ingested as a paste or mixed in a beverage; 15 to 20 g is required for clinical effects.<sup>119</sup> This dose is often unpalatable, and a case report of recreational use of encapsulated nutmeg is described.<sup>126</sup> Clinical effects begin 1 hour after nutmeg ingestion and persist for more than 24 hours after exposure.<sup>119</sup>

The belladonna alkaloids are most concentrated in the seeds of *Datura stramonium* (Jimson weed); each seed contains approximately 0.1 mg of atropine.<sup>139</sup> Ingestion of as few as 10 seeds produces hallucinations within 20- to minutes; these effects can last for 2 to 3 hours. Although the roots and seeds of *Brugmansia arborea* (Angel's trumpet) contain the highest alkaloid concentrations, users most often brew the blossom into a tea. Each blossom contains approximately 0.3 mg of atropine and 0.65 mg of scopolamine.<sup>65</sup> The elimination half-lives of atropine and hyoscyamine are 2.5 and 3.5 hours, respectively, and the elimination half-life of scopolamine is considerably longer, at 8 hours.<sup>18</sup>

## PHARMACOLOGY

Although the lysergamide, indolealkylamine, and phenylethylamine hallucinogens are structurally distinct, the similarities in their effects on cognition support a common site of action on central serotonin receptors.<sup>5,24,30,75,148</sup> Serotonin modulates many psychological and physiologic processes, including mood, personality, affect, appetite, motor function, sexual activity, temperature regulation, pain perception, sleep induction and antidiuretic hormone (ADH) release. There are more than 14 known 5-HT receptor subtypes (Chap. 13); differing affinity for these subtypes occurs based on the structure of the hallucinogen and accounts for the subtle differences between their effects.

The lysergamide, indolealkylamine, and phenylethylamine hallucinogens all bind to the 5-HT<sub>2</sub> class of receptors. There is a good correlation between the affinity of both indolealkylamine and phenylethylamine hallucinogens for 5-HT<sub>2</sub> receptors in vitro and hallucinogenic potency in humans.<sup>5,63,118,148</sup> The 5-HT<sub>2A</sub> receptor subtype has the highest density in the cerebral cortex and represents the binding site for hallucinogens.<sup>96</sup> This is bolstered by an animal study that shows that a selective 5-HT<sub>2A</sub> antagonist inhibit the effects of LSD and a phenylethylamine, 2,5-dimethoxy-4-iodo-amphetamine (DOI).<sup>97</sup> The response to high doses of LSD and DOI suggest that both lysergamides and phenylethylamines are partial agonists at cortical 5-HT<sub>2A</sub> receptors.<sup>62,96,125</sup>

Although the majority of investigations have focused on the role of serotonin in drug-induced hallucinations, other neurotransmitters are also involved. Stimulation of 5-HT<sub>2A</sub> receptors enhances release of glutamate in the cortical layer V pyramidal cells.<sup>5,11</sup> Lysergic acid diethylamide and other lysergamides stimulate both D<sub>1</sub> and D<sub>2</sub> dopamine receptors.<sup>10,60,161</sup> In animal models, LSD and phenylethylamine hallucinogens modulate NMDA receptor-mediated effects and are suggested to have a protective effect against neurotoxicity secondary to PCP and ketamine.<sup>11,52</sup>

Another theory that incorporates these other neurotransmitters involves the concept of "thalamic filtering."<sup>58</sup> The thalamus receives input and output from the cortex and reticular activating system and functions to filter relevant sensory input. This theory has been explored as an explanation for organic psychosis and the effects of hallucinogenic xenobiotics. Multiple neurotransmitters, including dopamine, acetylcholine,  $\gamma$ -aminobutyric acid (GABA), and glutamate, exert their actions on the thalamus. Increased excitatory or decreased inhibitory neurotransmitters in this region of the brain leads to "sensory overload," which manifests itself clinically as symptoms of psychosis.<sup>58</sup> Experimental evidence also demonstrates electroencephalographic (EEG) abnormalities after administration of hallucinogens, confirming a cortical, rather the ophthalmologic, etiology for hallucinations.<sup>51</sup>

Salvinorin A, the psychoactive component of *S. divinorum*, is one of the most potent natural hallucinogens. The effect of Salvinorin A occurs via binding at the  $\kappa$ -opioid receptor, making it structurally and mechanistically unique (Fig. 79–4).<sup>166</sup> The  $\kappa$ -opioid receptor is distinct from the mu opioid receptor, stimulation of which generally causes euphoria and analgesia (Chap. 36). Salvinorin A does not have any serotonergic activity.<sup>166</sup>

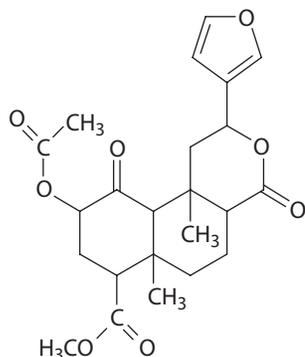

FIGURE 79-4. Structure of Salvinorin A.

The opioid effects of kratom are attributed to mitragynine.<sup>132,165</sup> The most prevalent of the kratom alkaloids, mitragynine, shares a structural similarity with yohimbine.<sup>13</sup> In vitro, mitragynine is active at both supraspinal opioid  $\delta$  and  $\mu$  receptors.<sup>147</sup> This  $\mu$ -receptor activity results in analgesia and efficacy in treating opioid withdrawal symptoms. Additionally, mitragynine activates noradrenergic and serotonergic pathways.<sup>100</sup> Another kratom alkaloid, 7-hydroxymitragynine, has antinociceptive effects and high affinity for opioid receptors.<sup>101</sup> In animal studies, 7-hydroxymitragynine has more analgesic potency than morphine, even after oral administration.<sup>99</sup> This compound was found in commercial kratom products at concentrations that far exceed its natural occurrence in the plant, suggesting surreptitious adulteration of many these kratom products.<sup>91</sup>

Nutmeg contains a number of purportedly psychoactive compounds, including myristicin, elemicin, and safrole (Fig. 79-5). The psychoactive components of nutmeg include terpenes and alkyl benzyl derivatives (myristicin, elemicin, and safrole).<sup>119</sup>

It is theorized that the aromatics found in nutmeg are metabolized to amphetaminelike compounds that create hallucinogenic effects.<sup>119</sup> However, this mechanism is not supported in animal data.<sup>126</sup> Nutmeg contains myristicin and elemicin, both weak monoamine oxidase inhibitors that also demonstrate serotonergic activity, which likely accounts for the clinical effects of nutmeg.<sup>126</sup>

The pharmacology of atropine, a competitive central and peripheral antimuscarinic, and the most well-studied belladonna alkaloid, is discussed in detail in Antidotes in Depth: A35. Like atropine, scopolamine and hyoscyamine are tertiary amines that cross the blood-brain barrier. Scopolamine causes more sedation than atropine, and its transdermal availability led to its use in motion sickness patches. Hyoscyamine is more potent than atropine; it is used as an antispasmodic for GI conditions.

## CLINICAL EFFECTS

Physiologic changes accompany and often precede the perceptual changes induced by lysergamides, tryptamines, and phenylethylamines. The physical effects are caused by direct drug effect or by a response to the disturbing or enjoyable hallucinogenic experience. Sympathetic effects mediated by the locus coeruleus include mydriasis, tachycardia, hypertension, tachypnea, hyperthermia, and diaphoresis. They occur shortly after ingestion and often precede the hallucinogenic effects. Other clinical findings that are reported include piloerection, dizziness, hyperactivity, muscle weakness,

ataxia, altered mental status, coma, and hippus (rhythmic pupillary dilation and constriction).<sup>86</sup> Nausea and vomiting often precede the psychedelic effects produced by psilocybin and mescaline. Potentially life-threatening complications, such as hyperthermia, hypertension, tachycardia, coma, respiratory arrest, and coagulopathy, were described in a report of 8 patients with a massive LSD overdose.<sup>82</sup> Sympathomimetic effects are generally less prominent in LSD toxicity than in phenylethylamine toxicity. Similar sympathetic symptoms are described after the use of 2C-B and 2C-T-7. Whereas low doses of 2C-B and 2C-T-7 produce hypertension, tachycardia, and visual hallucinations, larger doses are associated with shifts in color perception and enhanced auditory and visual stimulation. Three deaths are associated with 2C-T-7 use; in one case, death resulted from seizures or aspiration.<sup>39,48</sup> An analog of 2C-B, called 2C-B-FLY, or Bromo-dragonFLY, is implicated in finger necrosis requiring amputation secondary to potent peripheral vasospastic activity and sudden cardiac death.<sup>114</sup> Similar vasoconstrictive effects resulting in limb ischemia is induced by exposure to ergot containing alkaloids. Bromo-dragonFLY, like other 2-C compounds, is associated with agitated delirium and delayed onset of seizures.<sup>163</sup>

The psychological effects of hallucinogens seem to represent a complex and elusive interaction between different neurotransmitters, including the serotonergic and dopaminergic systems. Based on this serotonergic mechanism, serotonin toxicity could theoretically occur after the use of any of the lysergamide, indolealkylamine, or phenylethylamine hallucinogens. Animal studies documented LSD and tryptamine-induced serotonin toxicity.<sup>138,158</sup> Case reports link phenylethylamine use to fatal serotonin syndrome in recreational users.<sup>20,110,160</sup>

Tolerance to the psychological effects of LSD occurs within 2 or 3 days with daily dosing but rapidly dissipates if the drug is withheld for 2 days. Psychological cross-tolerance among mescaline, psilocybin, and LSD is reported in humans.<sup>17</sup> There is no evidence for physiologic tolerance, physiologic dependence, or a withdrawal syndrome after LSD use. Limited cross-tolerance is demonstrated between psilocybin and cannabinoids such as marijuana.<sup>26</sup>

*Salvia divinorum* use results in vivid hallucinations and synesthesia.<sup>137</sup> Additionally, its use causes diuresis, nausea and dysphoria. These aversive effects limit its long-term use.<sup>13</sup>

The dual stimulant and sedative properties of kratom contributed to its traditional use among manual laborers. However, its opioidlike activity led to a surge in contemporary use as an herbal treatment for opioid withdrawal among patients with chronic pain.<sup>22,23</sup> Anorexia, weight loss, and insomnia are reported among kratom-dependent individuals. Hyperpigmentation of the cheeks is also described among chronic users.<sup>144</sup>

Recreational nutmeg use results in the desired effects of euphoria and hallucinations, as well as the adverse effects of nausea, vomiting, dizziness, flushing, tachycardia, and hypotension. Two fatalities from nutmeg ingestion are reported.<sup>33,140</sup>

The belladonna alkaloids produce classic signs of anticholinergic toxicity, including hyperthermia, tachycardia, mydriasis, flushing, anhidrosis, urinary retention, and ileus. The central effects include restlessness, hallucinations, agitation, delirium, seizures, and coma.<sup>35</sup> The psychosis produced by belladonna alkaloids are profound; in one case, a young man autoamputated his tongue and penis after ingestion of tea made from *Brugmansia arborea*.<sup>98</sup>

The vast majority of morbidity from hallucinogen use stems from trauma. Hallucinogen users frequently report lacerations and bruises sustained during their "high." Additionally, dysphoria drives patients to react to stimuli with unpredictable and occasionally aggressive behavior. Many websites regarding hallucinogen use advise readers to take hallucinogens only while under the supervision of an observer.<sup>79</sup>

The psychological effects of hallucinogens are dose related and affect changes in arousal, emotion, perception, thought process, and self-image. The response is related to the person's mindset, emotions, or expectations at the time of exposure and are altered by the group or setting.<sup>1</sup> The person experiencing the effects of a hallucinogen is usually fully alert, oriented, and aware that he or she is under the influence of a drug. Euphoria, dysphoria, and emotional lability occur.

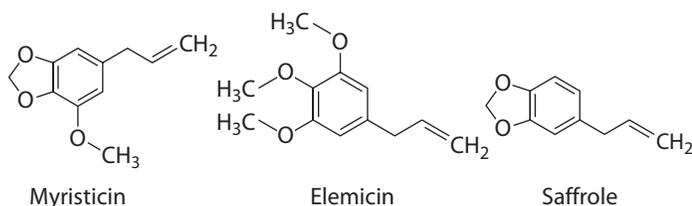

FIGURE 79-5. Structure of myristicin.

Illusions are common, typically involving distortion of body image and alteration in visual perceptions. Hallucinogen users display acute attention to details with excessive attachment of meaning to ordinary objects and events. Usual thoughts seem novel and profound. Many people report an intensification of their sensory perceptions such as sound magnification and distortion. Colors often seem brighter with halo-like lights around objects. Frequently, hallucinogen users relate a sense of depersonalization and separation from the environment, commonly called an “out-of-body” experience. Synesthesias, or sensory misperceptions, such as “hearing colors” or “seeing sounds” are commonly described. Hallucinations are visual, auditory, tactile, or olfactory.

Acute adverse psychiatric effects of hallucinogens include panic reactions, psychosis, and major depressive dysphoric reactions. Acute panic reactions, the most common adverse effect, present with frightening illusions, tremendous anxiety, apprehension, and a terrifying sense of loss of self-control.<sup>46</sup> These psychiatric effects cause patients to seek care in the emergency department (ED).

## LABORATORY

Routine urine drug-of-abuse immunoassay screens do not detect LSD or other hallucinogens. Although LSD can be detected by radioimmunoassay of the urine, confirmation by high-performance liquid chromatography (HPLC) or gas chromatography is necessary for reliability. These tests are rarely used in the clinical setting but are commonly available for forensic purposes.<sup>17,46</sup> False-positive urine immunoassay test results for LSD are reported after exposure to several medications, including fentanyl, sertraline, haloperidol, and verapamil.<sup>56,122</sup>

Depending on their structure, phenylethylamines cause positive qualitative urine test results by immunoassay for amphetamines. However, amphetamine drug screening is associated with numerous false-positive results, particularly after the use of nonprescription medications that contain ephedrine, pseudoephedrine, or phenylpropanolamine.<sup>142</sup> Urine immunoassays do not detect 5-Meo-DiPT, DMT, AMT, 2C-T-7, and 2CB, but gas chromatography–mass spectrometry testing methods for detection of these compounds is available.<sup>146</sup> There are several websites that monitor the content of MDMA pills that are in distribution, such as pillreports.net and partyflock.nl, but these sites are inaccurate and fail to report contamination with other drugs.<sup>159</sup> Organizations such as DanceSafe promote safe drug use through user test kits, but it is unclear if this practice increases drug use or reduces harm.<sup>45</sup>

Routine urine drug immunoassay screens do not detect salvinorin A, mitragynine, or myristicin. High-performance liquid chromatography and liquid chromatography–mass spectrometry protocols are used for quantitative analysis of salvinorin A and B in plant matter and in ex vivo animal studies. Gas chromatography–mass spectrometry identified salvinorin A in urine and saliva obtained from 2 human volunteers who had smoked *S. divinorum*.<sup>115</sup> Myristicin testing is not widely available.<sup>140</sup>

## TREATMENT

Most hallucinogen users rarely seek medical attention because either they experience only the desired effect of the drug or they minimize or cannot perceive the adverse effects. It is rare that hallucinogens produce life-threatening toxicity. Autonomic instability, seizures, hyperthermia, and excited delirium during severe hallucinations result in self harm and death. For any hallucinogen user presenting to the ED, initial treatment must begin with attention to airway, breathing, circulation, level of consciousness, and abnormal vital signs. Even in those in whom exposure to a hallucinogen is suspected, the basic approach for altered mental status should include dextrose, naloxone, and oxygen therapy as clinically indicated, as is the vigorous search for other etiologies. Because of their rapid absorption, GI decontamination with activated charcoal is of little value after clinical symptoms appear, and attempts may lead to further agitation. Sedation with benzodiazepines is usually sufficient to treat the hypertension, tachycardia, and hyperthermia which occur. The patient with a dysphoric reaction should be placed in a quiet location

with minimal stimuli. A nonjudgmental advocate should attempt to reduce the patient’s anxiety, provide reality testing, and remind the individual that a drug was ingested and that the effect will dissipate in several hours. We recommend avoiding use of physical restraint when possible to prevent hyperthermia and rhabdomyolysis. Benzodiazepines remain the cornerstone of therapy for both autonomic instability and dysphoria because the sedating effect diminishes both endogenous and exogenous sympathetic effects.<sup>105</sup> Autonomic instability and hyperthermia are a feature of phenylethylamine use, as well as tryptamine use or massive LSD overdose.<sup>55,82,105</sup> Hyperthermia resulting from agitation or muscle rigidity requires urgent sedation with benzodiazepines and rapid ice bath cooling. Although CNS depression is unlikely to be severe enough to require endotracheal intubation in a patient with a pure hallucinogen exposure, intubation and paralysis are recommended in patients with life threatening hyperthermia.<sup>19</sup> Seizures that occur with tryptamine or phenylethylamine use should be initially treated with benzodiazepines. Seizures also result from hyponatremia in MDMA users and treatment with 3% (hypertonic) saline is recommended (Chap. 73).

The treatment of anticholinergic toxicity from the belladonna alkaloids involves several critical components: correction of abnormal vital signs, management of delirium, and rapid intervention for seizures or dysrhythmias. The mainstays of therapy are fluid resuscitation and benzodiazepines; however, physostigmine is recommended as antidotal therapy in cases of belladonna alkaloid poisoning. Physostigmine is efficacious in decreasing morbidity and length of hospital stay compared with benzodiazepines alone.<sup>29,124</sup> Based on the strength of this evidence, physostigmine is recommended for patients with evidence of anticholinergic delirium or agitation if there are no contraindications. More information on physostigmine is found in Antidotes in Depth: A11.

Morbidity and mortality typically result from the complications of hyperthermia, including rhabdomyolysis and myoglobinuric acute kidney injury, hepatic necrosis, and disseminated intravascular coagulopathy. For the most part, however, hydration, sedation, a quiet environment, and meticulous supportive care prove adequate to prevent morbidity or mortality in recreational use or overdose.<sup>32</sup> Treatment of serotonin toxicity from phenylethylamine use is largely supportive and includes the avoidance of further administration of serotonergic medications. Specific therapy with cyproheptadine is recommended (Chap. 69).<sup>21</sup>

The role of antipsychotics in controlling hallucinogen-induced agitation is defined in detail in Chap. 26 and Special Considerations: SC4. Haloperidol, risperidone, and ziprasidone have utility in controlling the acutely agitated patient. However, haloperidol and risperidone worsen panic and visual symptoms and increase the incidence of HPPD (see later).<sup>2</sup> The safety of ziprasidone in hallucinogen users has not yet been reported yet. Although further study of these drugs is required, prolonged psychosis requires treatment with long-term antipsychotic therapy.

## LONG-TERM EFFECTS

Long-term consequences of LSD use include prolonged psychotic reactions, severe depression, and exacerbation of preexisting psychiatric illness.<sup>73,127</sup> When LSD was initially popularized, some patients behaved in a manner similar to schizophrenia and required admission to psychiatric facilities. In volunteer studies, panic reactions, HPPD, and extended psychoses were noted. When the drug was used for alleviation of anxiety and personality abnormalities, flashbacks and extended psychosis were reported.<sup>54</sup> It is suggested that these individuals had preexisting compensated psychological disturbances.<sup>5,95</sup>

Flashbacks are reported in up to 15% to 80% of LSD users.<sup>8</sup> Anesthesia, alcohol intake, and medications precipitate flashbacks.<sup>57</sup> These perceptions are triggered during times of stress, illness, and exercise and are often a virtual recurrence of the initial hallucinations. Hallucinogen persisting perception disorder is a chronic disorder in which flashbacks lead to impairment in social or occupational function. According to the *Diagnostic and Statistical Manual*, fifth edition, the diagnosis of HPPD requires the recurrence of perceptual symptoms that were experienced while intoxicated with the hallucinogen that causes functional impairment and is not due to a medical

condition.<sup>9</sup> The etiology of HPPD is still unknown, and the reported incidence varies widely. Symptoms are primarily visual, and reality testing is typically intact in HPPD. Common perceptual and visual disturbances in HPPD include geometric forms; false, fleeting perceptions in the peripheral fields; flashes of color; intensified color; and halos around objects.<sup>95</sup> One finding described after LSD use is palinopsia, or “trailing,” which refers to the continued visual perception of an object after it has left the field of vision. These visual perceptions are associated with normal ophthalmologic examinations and abnormal EEG evaluations, suggesting a cortical cause for the visual symptoms. Lysergic acid diethylamide causes psychological but not physical dependence; therefore, it does not cause any physical withdrawal symptoms.

## SUMMARY

- Hallucinogens are a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium.
- The lysergamide, phenylethylamine, and tryptamine hallucinogens share a serotonergic mechanism of action; however, other neurotransmitters are responsible for the complex effects of these hallucinogens.
- Acute adverse psychiatric effects of hallucinogens include panic reactions, true hallucinations, psychosis, and major depressive dysphoric reactions.
- With severe poisoning, hallucinogens cause autonomic instability, seizures, and hyperthermia.
- Meticulous supportive care with attention to abnormal vital signs and sedation with a benzodiazepine are often the only therapies required.

# $\gamma$ -HYDROXYBUTYRIC ACID ( $\gamma$ -HYDROXYBUTYRATE)

Rachel Haroz and Brenna M. Farmer

## HISTORY AND EPIDEMIOLOGY

$\gamma$ -Hydroxybutyric acid (GHB) was discovered in 1960 while searching for an analog for  $\gamma$ -aminobutyric acid (GABA).<sup>38</sup> Because of its central nervous system (CNS) depressive and amnestic properties, GHB was initially used as an anesthetic adjunct, especially in Europe, but never gained favor in the United States for this indication. Outside of the United States, GHB is still used for anesthesia or as an adjunct sedative for therapeutic hypothermia and wound care in children.<sup>50,61</sup> During the 1970s, a Food and Drug Administration (FDA) investigational new drug application (NDA) was submitted to test the use of GHB as a treatment for sleep disturbances. In the 1980s and 1990s, body builders popularized GHB as an anabolic dietary supplement because of its purported release of growth hormone. Its euphoric effects were recognized at this time, and it rapidly gained favor as a “club drug.” Because it can cause coma and profound amnesia, GHB was reportedly used in drug-facilitated sexual assault, and in 1990, the FDA banned all use of non-prescription GHB because of this concern.<sup>70</sup>

Following the ban, the analogs  $\gamma$ -butyrolactone (GBL) and 1,4-butanediol (BD) were quickly substituted for GHB in dietary supplements. After the Samantha Reid and Hillory J. Farias Date-Rape Prevention Act of 1999 was passed in 2000, the Drug Enforcement Administration (DEA) classified GHB and its analogs as Schedule I substances, claiming that GHB was a hazard to public safety.<sup>54,70</sup> Also in 2000, an NDA was submitted to the FDA for GHB—under the generic name sodium oxybate and the trade name Xyrem—to reduce the incidence of cataplexy and improve the symptoms of daytime sleepiness in patients with narcolepsy.<sup>35</sup> This latter indication was approved in 2002 and given a Schedule III designation by the DEA,<sup>83</sup> which was expanded, in 2005, to include the treatment of excessive daytime sleepiness in patients with narcolepsy. In 2017, the generic sodium oxybate was approved for the same use. It is now also used “off label” for fibromyalgia, chronic fatigue syndrome, and depressive disorders, and shows promising results in treating spasmodic dysphonia.<sup>6,63,65,74</sup> However, in 2010 the FDA declined to approve GHB for fibromyalgia because of a lack of evidence of efficacy and concerns for safety, citing specifically concerns for respiratory depression, abuse or misuse, and potential unintentional exposure and overdose in children. In the case of narcolepsy, these medications are subject to a Risk Evaluation and Mitigation Strategy (REMS). This requires prescribers to be certified and that patients must be enrolled in certified pharmacies. These pharmacies ship the medications directly to the patients.<sup>23,36</sup> In Europe, specifically Austria and Italy, sodium oxybate is used both for alcohol withdrawal syndrome and for relapse prevention.<sup>10</sup>

In 2007, during an epidemic largely in England and Australia, 1,4-BD was identified in the sticky surface material of toy beads marketed under the names Bindeez or Aquadots. This led to inadvertent toxicity in children ingesting these beads.<sup>30,64</sup>

National statistics demonstrated a trend of escalating GHB abuse and poisoning throughout the 1990s. However, exposures reported to poison control centers has declined in recent years. In 2002, there were 1,386 exposures with GHB and its analogs and precursors reported to the American Association of Poison Control Centers (AAPCC)—Toxic Exposure Surveillance

System, representing more than a twofold increase from approximately 600 GHB cases reported in 1996. Among these, 1,181 exposures (85%) required treatment in a health care facility and resulted in 272 major outcomes and 3 deaths (Chap. 130).<sup>82</sup> From the 2015 the AAPCC, National Poison Data System (NPDS) reports 620 exposures involved GHB and its analogs and precursors. In 379 of these cases, GHB, its analogs and precursors were the single xenobiotic of exposure. Of the reported cases, 318 were treated in a health care facility, and 201 of the cases had moderate or major outcomes.<sup>9</sup> The Drug Abuse Warning Network’s 2010 estimates revealed 1,787 emergency department (ED) visits for GHB exposures, similar to the number of visits from 2004 to 2009 with a range of 1,036 to 2,207 ED visits.<sup>75</sup> A retrospective review of deaths in 2011 related to GHB, GBL, and 1,4-BD showed that death from GHB toxicity was more likely to occur in men in their 20s. Thirty-four percent of these deaths were caused by GHB alone.<sup>87</sup>

The apparent trend of decreased GHB exposures in the United States after 2000 contrasts starkly with the increased use reported in some European countries and Australia.<sup>14,17,37</sup>  $\gamma$ -Hydroxybutyrate recently was found to be the fourth most common drug found in ED cases in a recent European publication.<sup>21</sup> More recent reports of large criminal seizures of GBL from Europe indicate the presence of large-scale manufacturing, shipment, and distribution concentrated in the Netherlands and associated with other synthetic drugs such as 3,4-methylenedioxy methamphetamine (MDMA).<sup>20</sup>

In Spain, a study of 505 consecutive GHB-poisoned patients presenting to one hospital from 2001 to 2007 revealed that these patients came to the hospital on the weekends in the early morning hours and require more treatment if ethanol, amphetamines or their derivatives, or cocaine was used concomitantly.<sup>26</sup>

A growing trend in South London coined “chemsex” refers to the recreational use of GHB, methamphetamine, and mephedrone to enhance sexual encounters. Described primarily among men who have sex with men, this practice is associated with an increase in GHB-related deaths. There were 61 deaths in London related to GHB between 2011 and 2015, which includes an increase of 119% between 2014 and 2015.<sup>7,33</sup>

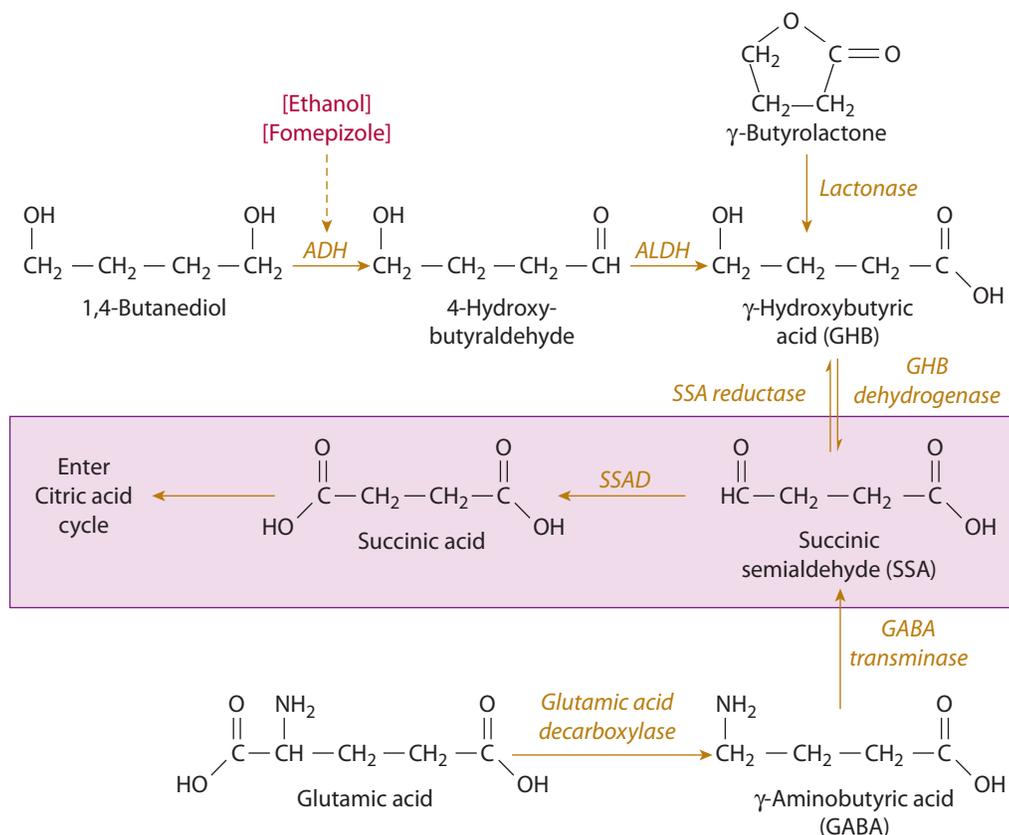

## PHARMACOLOGY

$\gamma$ -Hydroxybutyrate is both a precursor and degradation product of GABA.<sup>72</sup> It has a dual pharmacologic profile, with the neuropharmacology of endogenous GHB being distinct and divergent from that of exogenously administered GHB. Whereas the principal difference is that the activity of endogenous GHB is mediated by the GHB receptor, the activity of exogenously administered GHB is most likely mediated by intrinsic activity at the GABA<sub>B</sub> receptor.<sup>71,73</sup>

## ENDOGENOUS $\gamma$ -HYDROXYBUTYRIC ACID

$\gamma$ -Hydroxybutyrate is formed from GABA by the enzymes GABA transaminase and succinic semialdehyde reductase (Fig. 80–1).<sup>46</sup>  $\gamma$ -Hydroxybutyrate is also endogenously transformed from GBL by lactonases and from 1,4-BD by alcohol and aldehyde dehydrogenase. Endogenous GHB acts as a putative neurotransmitter and is found in highest concentrations in the hippocampus, basal ganglia, hypothalamus, striatum, and substantia nigra.<sup>46,48,80</sup> It has subcellular systems for synthesis, vesicular uptake, and storage in presynaptic terminals. It is released in a Ca<sup>2+</sup>-dependent manner following depolarization of neurons.

After release, GHB binds to GHB-specific receptors that modulate other neurotransmitter systems. As noted, endogenous GHB acts predominantly on the GHB receptor, which is a G protein–linked receptor located presynaptically.<sup>15,46,71</sup> The GHB receptor is located in the synaptosomal membranes of neuronal cells, most highly concentrated in the pons and hippocampus followed by

**FIGURE 80-1.** The synthesis and metabolism of  $\gamma$ -hydroxybutyric acid (GHB). ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; SSAD = succinic semialdehyde dehydrogenase.

the cerebral cortex and caudate. The GHB receptor has no affinity for typical GABA<sub>A</sub> or GABA<sub>B</sub> agonists such as GABA and baclofen, respectively. Localized application of GHB produces a response that mimics the action of endogenous GHB.<sup>4,51</sup>  $\gamma$ -Hydroxybutyrate receptors are highly associated with dopaminergic neurons and increase the concentration of dopamine by stimulating tyrosine hydroxylase to synthesize dopamine.<sup>46,73,77</sup>  $\gamma$ -Hydroxybutyrate is also a neuro-modulator of dopamine, acetylcholine, endogenous opioids, and glutamate.<sup>46</sup> It either increases (concentrations below 1 mM) or decreases (at higher concentrations) the release of dopamine throughout the mesolimbic system.<sup>13</sup> By contrast, GHB increases dopamine concentrations in the striatum and cortex in a dose-dependent manner by stimulating tyrosine hydroxylase to synthesize dopamine.<sup>46,47,73</sup>  $\gamma$ -Hydroxybutyrate also increases the turnover of serotonin in the brain by stimulating both serotonin synthesis and breakdown.<sup>29,32</sup> Furthermore, GHB decreases acetylcholine in the brain stem and corpus striatum, as well as in the hippocampus (via GABA<sub>B</sub> receptors).<sup>52,73</sup>  $\gamma$ -Butyrolactone, but not GHB itself, increases total-brain acetylcholine concentrations by decreasing firing of cholinergic neurons.<sup>28,39,67</sup>

Through an unclear mechanism, GHB increases the release of growth hormone by promoting slow-wave sleep without affecting total sleep time, and additional GHB release is enhanced.<sup>79,81</sup> Although GHB has no effect on total sleep time, it decreases latency to slow-wave sleep while also decreasing the time spent in stages 1 and 2 of the sleep cycle.<sup>40</sup>  $\gamma$ -Hydroxybutyric acid activity is terminated by active uptake from the synaptic cleft for metabolism by specific cytosolic and mitochondrial enzymes.

### EXOGENEOUS $\gamma$ -HYDROXYBUTYRIC ACID

Exogenous GHB, which produces supraphysiologic GHB concentrations, acts predominantly on the GABA<sub>B</sub> receptor, which is found throughout the cerebral cortex, cerebellum, and thalamus.<sup>27,62,84</sup> Presynaptically and postsynaptically, these receptors signal the adenylate cyclase system to activate calcium channels and G protein-coupled inwardly rectifying K<sup>+</sup> channels.<sup>5</sup> Through GABA<sub>B</sub> receptor signaling pathways, both dopamine and

acetylcholine pathways are altered, leading to decreased dopamine release and decreased acetylcholine concentrations.<sup>13,52</sup> These effects of GHB are potentiated by baclofen, a GABA<sub>B</sub> receptor agonist. Further discussion of these receptors and pathways is found in Chap. 13.

### $\gamma$ -HYDROXYBUTYRIC ACID ANALOGS

$\gamma$ -Butyrolactone, like GHB, exists in the mammalian brain.<sup>16</sup> Its pharmacologic properties are only evident after conversion to its active metabolite, GHB. Like GBL, 1,4-BD occurs naturally in the brain and exerts its pharmacologic and toxicologic properties only when converted to GHB by alcohol dehydrogenase (ADH).<sup>59</sup>

Table 80-1 lists other GHB analogs known to result in similar toxicity and lists synonyms for GHB, GBL, and 1,4-BD that are often found on the labels of commercial and illicit products.

### PHARMACOKINETICS AND TOXICOKINETICS

The endogenous production and metabolism of GHB is shown in Figure 80-1. Exogenous GHB is typically ingested in its sodium salt form. Oral bioavailability of exogenous GHB is approximately 60% in rats.<sup>41,42</sup> It is rapidly absorbed from the gastrointestinal (GI) tract in 15 to 45 minutes and displays 2-compartment distribution in animals with an initial volume of distribution of 0.4 L/kg and final volume of distribution 0.6 L/kg.<sup>18,41-43</sup> It is lipid soluble and crosses the blood-brain barrier rapidly. It does not bind significantly to any plasma proteins.<sup>55</sup>  $\gamma$ -Hydroxybutyrate is metabolized mainly by succinic semialdehyde reductase (also known as GHB dehydrogenase) to succinic semialdehyde, which is subsequently metabolized to succinate and enters the citric acid cycle (Fig. 80-1).  $\gamma$ -Hydroxybutyrate is also metabolized directly to succinate via  $\beta$  oxidation in the liver.<sup>57</sup>  $\gamma$ -Hydroxybutyrate is subject to first-pass metabolism by the cytochrome P450 system. However, the specific enzyme is not known.<sup>41</sup> In adult volunteers, the elimination half-life is 20 to 53 minutes. Less than 5% of GHB is excreted unchanged in the urine.<sup>55</sup> In patients with HIV taking protease inhibitors, GHB first-pass metabolism is

TABLE 80–1 Common Synonyms for  $\gamma$ -Hydroxybutyric Acid and Analogs

GHB ( $\gamma$ -Hydroxybutyrate)	GBL ( $\gamma$ -Butyrolactone)	1,4-BD (1,4-Butanediol)	GHV ( $\gamma$ -Hydroxyvaleric Acid)	GVL ( $\gamma$ -Valerolactone)	THF Tetrahydrofuran
4-Hydroxybutanoic acid	1,4-Butanolide	1,4-Butylene glycol	$\gamma$ -Methyl-GHB	4,5-Dihydro-5-methyl-2(3H)-furanone	No other synonyms
4-Hydroxybutyric acid sodium salt	4-Butanolide	1,4-Dihydroxybutane		4-Hydroxypentanoic acid lactone	
$\gamma$ -Hydroxybutyric acid	Butyric acid lactone	1,4-Tetramethylene glycol		$\gamma$ -Methyl-GHB	
$\gamma$ -Hydroxybutyric acid sodium salt	Butyrolactone				
Sodium 4-Hydroxybutyrate	Butyrolactone- $\gamma$				
Sodium oxybate	4-Butyrolactone				
	Butyryl lactone				
	4-Deoxytetronic acid				
	Dihydro-2(3H)-Furanone				
	2(3H)-Furanone				
	2(3H)-Furanone dihydro				
	Tetrahydro-2-furanone				
	4-Hydroxybutyric acid lactone				
	$\gamma$ -Hydroxybutyric acid lactone				
	1,4-Lactone				

altered such that low doses of GHB produce more toxic manifestations. This results from the interactions of the protease inhibitors on the cytochrome P450 system.<sup>1,31</sup>

$\gamma$ -Butyrolactone undergoes conversion to GHB by a lactonase.<sup>59,60</sup> Compared with GHB, GBL is more rapidly absorbed from the GI tract and has a longer duration of action, both of which result from higher lipid solubility. 1,4-Butanediol exerts its effects after conversion to GHB by ADH.<sup>11,58</sup> Coingestion with ethanol can therefore prolong the onset of clinical effects because of competitive inhibition of ADH.<sup>53,66</sup>

## CLINICAL MANIFESTATIONS

The clinical manifestations of GHB are mainly caused by its effects on the CNS. Initial clinical effects of ingested GHB occur in 15 to 20 minutes and peak in 30 to 60 minutes.<sup>8</sup> The clinical manifestations of GHB follow a steep dose-response curve. Doses of 20 to 30 mg/kg create euphoria, memory loss, and drowsiness, and doses of 40 to 60 mg/kg result in coma.<sup>24,48</sup> Doses of 25 mg/kg given to naïve healthy participants result in mean serum GHB concentrations of  $39.4 \pm 25.2$  mcg/mL (range, 4.7–76.3 mcg/mL).<sup>8</sup> Vital sign changes include bradycardia, hypotension, bradypnea, and hypothermia. Pupils are typically miotic and poorly responsive to light. Acute toxicity typically results in CNS depression or coma, respiratory depression, salivation, vomiting, and sometimes myoclonus.<sup>18,45</sup> Of these findings, the most concerning is respiratory depression because apnea is the primary cause of death.<sup>12,44,86</sup> Salivation and vomiting can complicate the respiratory and CNS depression and lead to pulmonary aspiration. Case series also report aggressive and combative behavior, which is characteristically exacerbated when assessing the airway and initiating endotracheal intubation in those patients with compromised consciousness.<sup>18,85</sup> Motor manifestations can be confusing. Although GHB induces seizures (electroencephalographic changes and convulsions) in animal models, this has never been demonstrated in humans. More commonly, in humans, GHB induces myoclonus, which is confused with seizures because of the altered consciousness.<sup>22</sup>

Other findings reported in patients taking prescribed therapeutic doses for narcolepsy include confusion, abnormal thought processes, and depression.<sup>35</sup> The most common adverse effects reported in these patients using prescribed GHB include nausea, dizziness, headache, vomiting, and urinary incontinence.<sup>35</sup>

Recovery from overdose occurs rapidly, typically in less than 6 to 8 hours, and patients often extubate themselves after rapid improvement of their level of consciousness. No sequelae should be expected if hypoxia or aspiration did not occur.

Frequent GHB users develop both tolerance and dependence to GHB.<sup>25,70</sup> In rats receiving doses of GHB every 3 hours for up to 6 days, tolerance was observed.<sup>2</sup> Dependent patients typically use GHB or one of its analogs every

2 to 4 hours over a prolonged period of time, with cumulative daily doses in the range of 10 g or more.<sup>49</sup> The majority of patients with dependence use GHB for its purported anabolic rather than for its psychoactive effects. In patients with dependence, withdrawal symptoms occur after discontinuation or a reduction in dose (see later).

## DIAGNOSTIC TESTING

Routine “screens” for drugs of abuse do not typically include analysis for GHB. Specific testing for GHB and its related analogs usually is not requested unless there is suspicion of its use associated with drug-facilitated sexual assault. However, urine and serum testing can also be performed if needed for other forensic purposes. Gas chromatography–mass spectrometry is the test of choice for both urine and serum.  $\gamma$ -Hydroxybutyrate is typically detected in the urine up to 12 hours after use.<sup>8</sup> Interpretation of these tests must include cutoff concentrations because GHB and 1,4-BD also occur endogenously.  $\gamma$ -Butyrolactone does not occur endogenously. These cutoff concentrations must be able to distinguish endogenous production and therapeutic use (as in patients using prescribed GHB for narcolepsy) from abuse or misuse. Attempts to correlate concentrations with clinical effects in any individual are not valid when used chronically because of tolerance. Because of rapid metabolism and elimination, concentrations return to baseline shortly after drug-naïve patients become clinically normal. Normal urinary concentrations of endogenous GHB are less than 5 to 10 mcg/mL, and serum concentrations of endogenous GHB are less than 5 mcg/mL.<sup>8</sup> In patients receiving a 25-mg/kg dose of GHB, serum GHB concentrations ranged from 4.7 mcg/mL to 76.3 mcg/mL 20 to 45 minutes after administration, and urine concentrations ranged from below the detection limit to 840 mcg/mL. In general, loss of consciousness occurs when serum concentrations rise above 50 mcg/mL, and deep coma occurs when concentrations rise above 260 mcg/mL.<sup>68</sup>

Screening for GHB is also routinely performed when specific genetic or metabolic disorders are of concern. In particular, elevated GHB concentrations on a urinary organic acid screen in a child is indicative a succinic semialdehyde dehydrogenase deficiency. These children have developmental delay, seizures, hypotonia, and elevated GHB concentrations in the blood, urine, and cerebrospinal fluid.<sup>56</sup> One case report describes a child with a serum GHB concentration of 775 mcg/mL, significantly higher than most patients with exogenous GHB poisoning.<sup>34</sup>

Other routine tests in patients with depressed levels of consciousness include a rapid evaluation of blood glucose, an ethanol concentration as clinically indicated, and an electrocardiogram (ECG). Electrocardiogram findings in reported GHB overdose include sinus bradycardia and prominent U waves, which may be related to the sinus bradycardia. Other standard laboratory test results are typically normal.<sup>12</sup> When intentional overdose or

self-harm is suspected, a determination of serum acetaminophen concentration is also recommended. Other studies should be obtained based on the clinical condition of the patient.

## MANAGEMENT

Supportive care is the mainstay of therapy for patients with GHB toxicity. All patients presenting to the hospital should have their airway, breathing, and circulation assessed immediately. Some patients with GHB toxicity require airway protection in the presence of profound coma and respiratory depression or apnea. However, many become combative during the intubation process. Supportive care with a nasal airway is often sufficient in a snoring patient who has an appropriate gag and respiratory function. The need for endotracheal intubation is a bedside clinical decision and should be based on the patient's ability to oxygenate and ventilate, especially when the diagnosis is known or highly suspected, as recovery is expected shortly. An intravenous (IV) catheter should be established and IV fluids infused as necessary for hypotension. It is reasonable to give atropine for severe bradycardia that results in hemodynamic compromise. However, in most instances, the bradycardia will not necessitate treatment in otherwise healthy patients. Patients should be warmed if they are hypothermic.

There is no role for gastric decontamination in patients with isolated GHB toxicity because GHB is rapidly absorbed from the GI tract. The increased risk of vomiting and aspiration also limits any beneficial role of gastric decontamination. If a coingestant is present, decontamination with activated charcoal is reasonable if there are no contraindications (Chap. 5).

Other therapies such as dextrose and thiamine should be administered as clinically indicated. Some proposed antidotes include physostigmine, naloxone, and flumazenil. All of these antidotes lack a pharmacologic basis for use and likely place the patient at increased risk because other drugs of abuse commonly used with GHB may interact with these xenobiotics. An animal model did not support the use of physostigmine in GHB toxicity,<sup>3</sup> nor did a systematic literature review.<sup>78</sup> Naloxone is recommended for patients with respiratory and CNS depression in the setting of unknown or presumed overdose. However, in patients with known GHB toxicity, naloxone administration is largely unsuccessful at improving clinical status and therefore is not recommended.<sup>44</sup>

Patients whose symptoms resolve are safe for discharge from the hospital after appropriate psychosocial evaluation for abuse and dependency. All patients who do not follow the expected course of resolution of their clinical manifestations (in ~6 hours) should be admitted to the hospital and investigated for other potential etiologies.

## $\gamma$ -HYDROXYBUTYRIC ACID WITHDRAWAL

Patients who use GHB or its analogs daily in large quantities develop tolerance and dependence.<sup>25</sup> Such patients are prone to withdrawal if they abruptly cease or decrease their daily dose. In patients prescribed GHB for narcolepsy, withdrawal rarely develops when the GHB is used as prescribed because the recommended doses are low and given only at night.<sup>35,76</sup>

$\gamma$ -Hydroxybutyrate withdrawal is similar to ethanol and benzodiazepine withdrawal (Chap. 14). It can be severe and potentially life threatening. The onset of withdrawal typically occurs 1 to 6 hours after last use. In a descriptive analysis of patients with GHB withdrawal, 64% were male.<sup>49</sup> Manifestations of withdrawal include tachycardia, hypertension, tremors, agitation, dysphoria, nausea, vomiting, auditory and visual hallucinations, and seizures.<sup>19,25,49,76</sup>

For acute withdrawal symptoms, benzodiazepines and supportive care are the recommended mainstays of therapy<sup>49,76</sup> (Antidotes in Depth: A26). Rapid cooling, IV fluids, and evaluation for other medical or traumatic illnesses should be performed. Some patients require large doses of benzodiazepines to control symptoms. In patients with withdrawal symptoms refractory to benzodiazepines, barbiturates and propofol are reasonable.<sup>49,69,76</sup> Baclofen, a GABA<sub>B</sub> receptor agonist, is also a reasonable treatment choice in patients with severe GHB withdrawal, although research must be done to determine appropriate dosing and escalation of dosing.

## SUMMARY

- $\gamma$ -Hydroxybutyrate is a unique xenobiotic because it occurs naturally as an endogenous neurotransmitter and is both a licensed pharmaceutical (Schedule III) and a drug of abuse (Schedule I).
- $\gamma$ -Hydroxybutyrate, GBL, and 1,4-BD result in GHB toxicity through complex neuropharmacological effects to rapidly produce CNS and respiratory depression that is characteristically of short duration.
- $\gamma$ -Hydroxybutyrate toxicity rarely results in death when patients are treated with supportive care.
- In patients who are dependent on GHB or its analogs, a life-threatening withdrawal syndrome occurs with cessation or decreased use. This withdrawal syndrome should be treated in a manner similar to ethanol or sedative-hypnotic withdrawal.
- With appropriate care of both acute toxicity and withdrawal, patients recover without sequelae, but psychosocial care and referral for management of abuse or dependency are essential.

## INHALANTS

Heather Long

### HISTORY AND EPIDEMIOLOGY

Inhalant use is defined as the deliberate inhalation of vapors for the purpose of changing one's consciousness or becoming "high." It is also referred to as volatile substance use, which was first described in medical literature in 1951.<sup>43</sup> Inhalants are appealing to adolescents because they are inexpensive, readily available, and sold legally. Initially, inhalant use was viewed as physically harmless, but reports of "sudden sniffing death" began to appear in the 1960s.<sup>13</sup> Shortly thereafter, evidence surfaced of other significant morbidities, including organic brain syndromes, peripheral neuropathy, and withdrawal.

The demographics of inhalant use differ markedly from those of other traditional substances of use.<sup>160</sup> Age at initiation of illicit drug use is youngest for those choosing inhalants, and among students, the reported use of inhalants peaked among eighth graders.<sup>117,159</sup> For the first time since conducting its drug use survey, the Substance Abuse and Mental Health Services Administration (SAMSHA) reported a second peak in use among 18- to 25-year-old individuals; this may be because of inclusion of a new question specifically asking about inhalation of computer dusters (see later).

In the United States, the problem is greatest among children of lower socioeconomic groups. Non-Hispanic white adolescents are the most likely and black adolescents the least likely to use inhalants. Use among girls equals or surpasses boys.<sup>160</sup> Although inhalant use is a problem in both urban and rural communities, it is more prevalent in rural settings.<sup>113,154</sup> This may relate to the easier access that teens in urban areas have to other drugs of use. Disturbingly, a study of 279 youths who were lifetime inhalant users found 37% perceived experimental inhalant use of slight or no risk.<sup>134</sup>

Inhalant use includes the practices of sniffing, huffing, and bagging. *Sniffing* entails the inhalation of a volatile substance directly from a container, as occurs with modeling glue or rubber cement. *Huffing* involves pouring a volatile liquid onto fabric, such as a rag or sock, and placing it over the mouth, nose, or both while inhaling and is the method used by more than 60% of volatile-substance users.<sup>113</sup> *Bagging* refers to instilling a solvent into a plastic or paper bag and rebreathing from the bag several times; spray paint is among the inhalants commonly used with this method.

### COMMON INHALANTS

There are myriad xenobiotics used as inhalants (Table 81-1). Hydrocarbons are organic compounds composed of carbon and hydrogen atoms and are divided into 2 basic categories: aliphatic (straight, branched, or cyclic chains) and aromatic. Most of the commercially available hydrocarbon products are mixtures of hydrocarbons; for example, gasoline is a mixture of aliphatic and aromatic hydrocarbons that consists of more than 1,500 compounds. Substituted hydrocarbons contain halogens or other functional groups such as hydroxyl or nitrite that are substituted for hydrogen atoms in the parent structure. Solvents are themselves a heterogeneous group of xenobiotics that are used to dissolve other chemical compounds or provide a vehicle for their delivery.

The most commonly inhaled hydrocarbons are fuels, such as gasoline, and solvents, such as toluene.<sup>154</sup> Other commonly inhaled hydrocarbon-containing products include spray paints, lighter fluid, air fresheners, and glue. In most reported cases of inhalant use, the inhalant is identified not by its chemical name (eg, butane, toluene) but rather by its intended use (eg, lighter fluid, paint thinner). Because exact components may vary among products, identification by the intended commercial use of the product is inaccurate and imprecise. The choice of xenobiotic used likely reflects its availability: cases from the 1970s frequently reported use of antiperspirants

and typewriter correction fluid; computer and electronics cleaners have largely replaced these products.

*Dusting* refers to the inhalation of compressed air cleaners containing halogenated hydrocarbons like 1,1-difluoroethane (eg, CRC Dust Off), marketed for cleaning computer keyboards and electronics equipment. Reports of such exposures, including deaths and ventricular dysrhythmias, have dramatically increased. From 2008 to 2012 at the San Diego County Medical Examiner's Office, 1,1-difluoroethane was detected in 17 postmortem tissues and cited as the cause of death in 13.<sup>170</sup> Of the 56 deaths attributed to recreational inhalant use in Washington State between 2003 and 2012, 54% involved difluoroethane from computer dusters, yet dusting is not perceived to be harmful by users, and surprisingly, many users do not consider it a form of inhalant use.<sup>112,128</sup>

Although intentional inhalation of the inert gas helium for its voice-altering effects is common, it has not traditionally been inhaled for potential euphoric effects. Among 723 adolescents, however, 11.5% reported inhaling helium with the intention of getting high, and of them, 34% reported they did get high from inhaling helium.<sup>180</sup>

Although volatile alkyl nitrites are technically substituted hydrocarbons, they have pharmacologic and behavioral effects, as well as patterns of use, that are distinct from the other volatile hydrocarbons. For this

**TABLE 81-1 Common Inhalants and the Constituent Xenobiotics**

Inhalant	Chemical
Carburetor cleaner	Methanol, methylene chloride, toluene, propane
Cigarette lighter fluid	Butane
Computer keyboard duster	Difluoroethane, tetrafluoroethane
Deodorizers (room)	Butyl nitrite, isobutyl nitrite, cyclohexyl nitrite
Dry cleaning agents, spot removers, degreasers	Tetrachloroethylene, trichloroethane, trichloroethylene
DVD and video cassette recorder head cleaner	Ethyl chloride
Freon (refrigerants)	Hydrofluorocarbons
Gasoline	Aliphatic and aromatic hydrocarbons
Glues and adhesives	Toluene, <i>n</i> -hexane, benzene, xylene, trichloroethane, trichloroethylene, tetrachloroethylene, ethyl acetate, methylethyl ketone, methyl chloride
Hair spray, deodorants, air fresheners	Butane, propane, fluorocarbons
Nail polish remover	Acetone
Paint thinner	Toluene, methylene chloride, methanol
"Poppers"	Amyl nitrite, isobutyl nitrite
Paints, lacquers, varnishes	Trichloroethylene, toluene, <i>n</i> -hexane
Spray paint	Toluene, butane, propane
Typewriter correction fluid	Trichloroethane, trichloroethylene
Whipped cream dispensers, "whippits"	Nitrous oxide

reason, researchers usually classify them as a separate category among used inhalants. Amyl nitrite is the prototypical volatile alkyl nitrite.<sup>11</sup> Amyl nitrite became popular in the 1960s with the appearance of “poppers,” small glass capsules containing the chemical in a plastic sheath or gauze. When crushed, the ampules release the amyl nitrite. When nonprescription sales of amyl nitrite were restricted in 1968, sex and drug paraphernalia shops began selling small vials of butyl and isobutyl nitrites marketed as room deodorizers or liquid incense.<sup>11,108</sup> Because of further restrictions on sales of alkyl nitrites, most of these products now contain chemicals that are not technically alkyl nitrites, such as cyclohexyl nitrite.<sup>11</sup>

The most commonly used nonhydrocarbon inhalant is nitrous oxide (N<sub>2</sub>O). Nitrous oxide, or “laughing gas,” is used medicinally as an inhalational anesthetic. It is the propellant in supermarket-bought whipped cream canisters, and cartridges of the compressed gas are sold for home use in whipped cream dispensers. These battery-sized metal containers of compressed gas are known as “whippits.” The container is punctured using a device known as a “cracker,” and the escaping gas is either inhaled directly or collected in a balloon and then inhaled.

## PHARMACOLOGY AND PHARMACOKINETICS

Although chemically heterogeneous, inhalants are generally highly lipophilic and gain rapid entrance into the central nervous system (CNS). Little is known about the cellular basis of the effects of inhalants. Evidence to date shows the most commonly used hydrocarbons have molecular mechanisms similar to those of other classic CNS depressants, frequently with common cellular sites of action. Their effects are probably best represented by the model for ethanol in which multiple different cellular mechanisms explain diverse pharmacologic and toxicologic effects.<sup>11</sup>

### Volatile Hydrocarbons

The clinical effects of the volatile hydrocarbons are likely mediated through stimulation of inhibitory neurotransmission and antagonism of excitatory neurotransmission within the CNS. Like ethanol, toluene, trichloroethane (TCE), and trichloroethylene enhance  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor-mediated synaptic currents as well as glycine receptor-activated ion function. Stimulation of these receptors acts to increase chloride permeability, hyperpolarizing the neuronal cell membrane and inhibiting excitability.<sup>17,80,148,156</sup> Like inhaled anesthetics, these inhalants act presynaptically on the GABA nerve terminals. Toluene-induced increases in inhibitory synaptic current are blocked by dantrolene and ryanodine, suggesting toluene effects release of calcium from intracellular nerve terminal stores.<sup>107</sup> Despite very different molecular structures, ethanol, enflurane, chloroform, toluene, and TCE compete for binding sites at  $\alpha_1$  glycine receptors.<sup>16</sup> Like ethanol and subanesthetic concentrations of isoflurane, toluene, TCE, and benzene all interfere with glutamate-mediated excitatory neurotransmission by inhibiting *N*-methyl-D-aspartate (NMDA) receptor-mediated currents in a concentration dependent manner.<sup>10,44,136,147</sup> Furthermore, repeated toluene exposure increases NMDA receptors, suggesting that chronic exposure leads to upregulation of excitatory neurotransmission as occurs with ethanol.<sup>10,184</sup>

Toluene is the prototypical volatile hydrocarbon and the best studied. In animal models, differences in pharmacologic action are demonstrated between toluene and other alkylbenzenes, halogenated hydrocarbons such as TCE, and acetone (Chap. 105).<sup>23,44,100,149,166</sup> These differences represent evidence that specific cellular sites for their actions exist. Additionally, these differences may explain the variation in their use potential or their clinical effects.<sup>11</sup> Despite these distinctions, there are marked similarities in the behavioral and pharmacologic effects of the volatile hydrocarbons. Moreover, the clinical effect profile shared by the volatile hydrocarbons, subanesthetic concentrations of general anesthetics, ethanol, and benzodiazepines suggests that they share cellular mechanisms. Shared clinical effects include anxiolysis,<sup>28</sup> anticonvulsant effects,<sup>187</sup> impaired motor coordination,<sup>120</sup> and physical dependence upon withdrawal.<sup>54,55</sup>

Most research on inhalants has focused on the neural basis of their effects, yet it is the cardiotoxicity that is responsible for the majority of their lethal effects. In vivo, toluene reversibly inhibits myocardial voltage-activated sodium channels.<sup>45</sup> Similarly, it inhibits muscle sodium channels but with less potency.<sup>63</sup> Ethanol and toluene have opposite effects on potassium channels in vivo; whereas ethanol potentiates the large conductance, calcium-activated potassium channels, and certain G protein-coupled inwardly rectifying potassium channels, toluene inhibits them.<sup>46</sup> The combined inhibition of the sodium channels and the inwardly rectifying potassium channels is postulated to play a role in cardiac dysrhythmias and sudden sniffing death associated with the aromatic and halogenated hydrocarbons. Animal studies show toluene and 1,1,1-trichloroethane produce biphasic dose-response curves for motor activity: low concentrations yield motor excitation, and high concentrations produce sedation, motor impairment, and anesthesia.<sup>24,178</sup> Molecular mechanisms underlying motor excitation and cardiac dysrhythmias may maximize the risk and explain the observed clinical phenomenon described in sudden sniffing death (see below).

There are scant data on the pharmacokinetics of the inhalants. Most data are derived from studies on occupational and environmental exposures and have limited applicability to intentional inhalation. More relevant to the understanding of inhalants are the similarities with the inhalational anesthetics, many of which are also halogenated hydrocarbons. Factors determining pharmacokinetic and pharmacodynamic effects of a given inhalational anesthetic include its concentration in inspired air; partition coefficient; interaction with other inhaled substances, ethanol, and drugs; the patient's respiratory rate and blood flow; percent body fat; and individual variation in drug metabolism (Chap. 65).<sup>67</sup>

Partition coefficients measure the relative affinity of a gas for two different substances at equilibrium and are used to predict the rate and extent of uptake of an inhaled substance. The blood:gas partition coefficient is most commonly referenced. The higher the number, the more soluble the substance is in blood. Substances with a low blood:gas partition coefficient, like N<sub>2</sub>O, are rapidly taken up by the brain and, conversely, are rapidly eliminated from the brain once exposure is ended (Table 81–2).

In a rodent model of inhalation use of toluene and acetone, the rapidity of onset and the extent of CNS depression were dependent on the concentration of the solvent inhaled.<sup>32</sup> There was a parallel relationship between brain concentration and pharmacologic effect during induction (inhalation) and postexposure. Brain and liver concentrations dropped rapidly after exposure; concentration in blood decreased at the slowest rate. Elimination was biphasic: rapid elimination during the first step was a result of tissue redistribution, alveolar ventilation, and metabolic clearance. During the second phase, there was a slow decrease in tissue concentrations as a result of the gradual mobilization from adipose tissue with subsequent exhalation or metabolism. Acetone, which is more water soluble than toluene, is less potent and slower acting than toluene but is eliminated much more slowly than toluene and has a much longer duration of action.<sup>32</sup> In a rat study designed to mimic use, initial distribution of 1,1-difluoroethane (DFE) was rapid with an average half-life during the uptake phase of 9 seconds, 18 seconds, and 27 seconds for blood, brain, and heart, respectively. Average elimination half-lives were 86 seconds, 110 seconds, and 168 seconds in the blood, brain, and heart, respectively. After a burst exposure mimicking inhalant use, all animals demonstrated CNS toxicity within 20 seconds with no detectable toxicity by 8 minutes and brain and serum concentrations nearing zero.<sup>7</sup> Positron emission tomography (PET) studies using (<sup>11</sup>C) radiolabeled toluene, butane, and acetone in nonhuman primates showed rapid uptake of radioactivity in striatal and frontal regions of the cortex followed by rapid clearance from the brain.<sup>64</sup> Whole-body PET scans in mice showed excretion through the kidneys and liver.<sup>65</sup>

The inhalants are eliminated unchanged by the lungs, undergo hepatic metabolism, or both (Table 81–2). For some, the percentage that is metabolized versus eliminated unchanged varies with the exposure dose. Nitrous oxide and the aliphatic hydrocarbons are frequently eliminated unchanged in the expired air. The aromatic and halogenated hydrocarbons are metabolized

**TABLE 81–2** Blood:Gas Partition Coefficients, Routes of Elimination, and Important Metabolites of Selected Inhalants

<i>Xenobiotic</i>	<i>Blood:Gas Partition Coefficient (98.6° F {37° C})</i>	<i>Routes of Elimination</i>	<i>Important Metabolites</i>
Acetone	243–300	Largely unchanged via exhalation 95% and urine 5%	None
<i>n</i> -Butane	0.019	Largely unchanged via exhalation	Metabolized to 2-butanol and 2-butanone
Carbon tetrachloride	1.6	50% unchanged via exhalation; 50% hepatic metabolism and urinary excretion	CYP2E1 to trichloromethyl radical, trichloromethyl peroxy radical, phosgene
<i>n</i> -Hexane	2	10%–20% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to 2-hexanol, 2,5-hexanedione, $\gamma$ -valerolactone
Methylene chloride	5–10	92% exhaled unchanged; hepatic metabolism and urinary excretion	1. CYP2E1 to CO and CO <sub>2</sub> 2. Glutathione transferase to CO <sub>2</sub> , formaldehyde, and formic acid
Nitrous oxide	0.47	>99% exhaled unchanged	None
Toluene	8–16	<20% exhaled unchanged; >80% hepatic metabolism and urinary excretion	CYP2E1 to benzoic acid, then 1. Glycine conjugation to form hippuric acid (68%) 2. Glucuronic acid conjugation to benzoyl glucuronide (insignificant pathway except after large exposure)
1,1,1-Trichloroethane	1–3	91% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to trichloroethanol, then 1. Conjugated with glucuronic acid to formurochloral acid or 2. Further oxidized to trichloroacetic acid
Trichloroethylene	9	16% exhaled unchanged; 84% hepatic metabolism and urinary excretion	CYP2E1 to epoxide intermediate (transient); chloral hydrate (transient); trichloroethanol (45%), trichloroacetic acid (32%). Urinary trichloroacetic acid peaks 2–3 days postexposure
1,2-Dichloro-1,1-difluoroethane	NA	NA	CYP2E1 to 2-chloro-2,2-difluoroethyl glucuronide, 2-chloro-2,2-difluoroethyl sulfate, chlorodifluoroacetic acid, chlorodifluoroacetaldehyde hydrate, chlorodifluoroacetaldehyde-urea adduct, and inorganic fluoride; no covalently bound metabolites to liver proteins

NA = not applicable.

extensively via the cytochrome P450 (CYP) system, particularly CYP2E1, which has a substrate spectrum that includes a number of aliphatic, aromatic, and halogenated hydrocarbons.<sup>21,75,76,189</sup> Extrahepatic expression of CYP2E1 occurs to a lesser extent but is of toxicologic significance, particularly in the kidneys and the dopaminergic cells of the substantia nigra.<sup>22,82,172</sup> In humans, there appears to be no significant gender difference in CYP2E1 activity; however, it is polymorphic, and as such, allelic distributions vary among different human populations.<sup>22,151</sup> Moreover, this polymorphism explains the varying degrees of toxicity exhibited after inhalant use.

Reward and reinforcement effects of inhalants are readily demonstrated. Although the mechanisms underlying their reinforcement behavior remain poorly studied, activation of the dopaminergic neurons of the ventral tegmental area is thought to play an important role in solvent use, similar to more commonly studied drugs of use.<sup>65,126,140,168,188</sup> Interestingly, the reward and reinforcement effects of the toluene appear to vary with age of exposure, suggesting that physiologic as well as psychosocial factors play a role in the prevalence of inhalant use among adolescents compared with adults.<sup>14,26,127</sup> Furthermore, age at exposure differentially affects dendritic growth in the brain as well as subunit expression of both NMDA and GABA<sub>A</sub> receptors, suggesting that the adolescent brain is at greater risk for cognitive impairment after inhalant use.<sup>61,127,130</sup>

### Volatile Alkyl Nitrites

Little still is known about the molecular basis of use of the volatile alkyl nitrites. Their effects are thought to be mediated through smooth muscle relaxation in the central and peripheral vasculature, and they share a common cellular pathway with other nitric oxide (NO) donors similar to nitroglycerin and sodium nitroprusside.<sup>11,92</sup> As occurs with other used substances, a rodent study found elevated dopamine release after exposure to isobutyl nitrite.<sup>83</sup> In rats, chronic exposure to alkyl nitrites impaired motor

coordination as well as memory acquisition and retention.<sup>40</sup> A rat model of inhalation of isobutyl nitrite found a half-life of 1.4 minutes with almost 100% biotransformation to isobutyl alcohol. Bioavailability after inhalation was estimated to be 43%.<sup>91</sup>

### Nitrous Oxide

The pharmacokinetics and pharmacodynamics of N<sub>2</sub>O use are derived from its use as an inhalational anesthetic (Chap. 65). In contrast to toluene and other used volatile solvents, N<sub>2</sub>O mediates its stimulant effects through inhibition of excitatory NMDA-activated currents; in animal models, it does not have an effect on GABA-activated currents.<sup>84,138,176</sup> Nitrous oxide also stimulates dopaminergic neurons, but the significance of this in mediating its anesthetic effects remains unclear.<sup>89,121</sup>

Animal studies suggest the analgesic effects (or more accurately, the antinociceptive effects because it refers to animals) of N<sub>2</sub>O appear to be mediated through  $\kappa$ -opioid receptors in the midbrain.<sup>60</sup> These antinociceptive effects can be reversed by the opioid antagonist naloxone.<sup>19</sup> However, in humans, the anesthetic effects are not attenuated by naloxone, nor are the subjective and psychomotor effects of N<sub>2</sub>O extinguished.<sup>152,191</sup>

### CLINICAL MANIFESTATIONS

Signs and symptoms of inhalant use may be subtle, tend to vary widely among individuals, and generally resolve within several hours of exposure. After acute exposure, there may be a distinct odor of the used inhalant on the patient's breath or clothing. Depending on the inhalant used and the method, there may be discoloration of skin around the nose and mouth. Mucous membrane irritation causes sneezing, coughing, and tearing. Patients may complain of dyspnea and palpitations. Gastrointestinal complaints include nausea, vomiting, and abdominal pain. After an initial period of euphoria, patients have residual headache and dizziness.

## Volatile Hydrocarbons

The CNS is the intended target of the inhalants and is most susceptible to its adverse effects. Initial CNS effects include euphoria and hallucinations, that are both visual and auditory, as well as headache and dizziness. As toxicity progresses, CNS depression worsens, and patients develop slurred speech, confusion, tremor, and weakness. Transient cranial nerve palsies are reported.<sup>162</sup> Further CNS depression is marked by ataxia, lethargy, seizures, coma, and respiratory depression. These acute encephalopathic effects generally resolve spontaneously, and associated neuroimaging abnormalities are not reported.<sup>57</sup>

As can be expected, given the high lipophilicity of most inhalants, toxicity is manifested most strikingly in the CNS. Chronic users demonstrate impaired executive function compared with control participants.<sup>163,164</sup> Toluene leukoencephalopathy, characterized by dementia, ataxia, eye movement disorders, and anosmia, is the prototypical manifestation of chronic inhalant neurotoxicity. Patients with toluene leukoencephalopathy display characteristic neurobehavioral deficits reflecting white matter involvement, including inattention, apathy, and impaired memory and visuospatial skills with relative preservation of language.<sup>57</sup> Autopsy studies reveal white matter degeneration, including cerebral and cerebellar atrophy and thinning of the corpus callosum.<sup>194,141</sup> On microscopy, there is diffuse demyelination with relative sparing of the axons. Abundant perivascular macrophages containing coarse or laminar myelin debris found in areas of the greatest myelin loss is a characteristic pathologic feature.<sup>157</sup> This targeting of myelin, which is 70% lipid, is explained by the lipophilicity of toluene.<sup>57</sup> Because myelination continues at least through the second decade of life, the typical toluene user who begins inhaling during adolescence will be particularly susceptible to its toxic CNS effects.<sup>56</sup> Advances in magnetic resonance imaging (MRI) with gadolinium, which allow enhanced visualization of the cerebral white matter, demonstrate that the extent of white matter injury in the brain directly corresponds to the clinical severity of toluene leukoencephalopathy.<sup>57</sup> Younger age at onset of use is associated with decreased frontal white-matter integrity on MRI.<sup>190</sup> Chronic inhalant use is associated with altered concentrations of antioxidant enzymes, including erythrocyte superoxide dismutase and plasma glutathione peroxidase, and it is postulated that reactive oxygen species generated either by toluene or its metabolite benzaldehyde induce lipid peroxidation in the brain.<sup>51,110,139</sup> Genetic polymorphisms and host susceptibility among chronic users are also hypothesized to play a role.<sup>70</sup>

Acute cardiotoxicity associated with hydrocarbon inhalation is manifested most dramatically in “sudden sniffing death.” In witnessed cases, sudden death occurred when sniffing was followed by some physical activity. Examples include running or wrestling or a stressful situation such as being caught sniffing by parents or police.<sup>13</sup> It is thought that the inhalant “sensitizes the myocardium” by blocking the potassium current ( $I_{Kr}$ ), thereby prolonging repolarization.<sup>124</sup> This produces a substrate for dysrhythmia propagation; the activity or stress then causes a catecholamine surge that initiates the dysrhythmia (Chap. 15).<sup>124</sup> Cardiac dysrhythmias after the inhalation of hydrocarbons were documented with the halogenated inhalational anesthetics in the early 1900s, and this association was subsequently confirmed in both animal and human studies.<sup>58,165</sup>

More typically, the clinical presentation of a patient with hydrocarbon cardiotoxicity includes palpitations, shortness of breath, syncope, and electrocardiographic (ECG) abnormalities, including atrial fibrillation, premature ventricular contractions, QT interval prolongation, and U waves.

Multiple case reports of ventricular fibrillation and torsade de pointes follow intentional inhalation of other hydrocarbons such as butane fuel,<sup>72,183</sup> fluorinated hydrocarbons such as DFE,<sup>8,38</sup> and Glade Air Freshener (SC Johnson), which contains a mixture of short-chain aliphatic hydrocarbons.<sup>103</sup> Among 44 patients with a history of inhalant use, specifically toluene exposure, the QT interval and QT interval dispersion were significantly greater than in healthy control participants. Furthermore, the QT interval and QT interval dispersion were significantly greater in the 20 toluene users with a history of unexplained syncope than in asymptomatic users and control participants.<sup>3</sup> Although cardiotoxic effects

of inhalant use are generally acute, myocarditis and dilated cardiomyopathy are reported with use of toluene, trichloroethylene, and DFE.<sup>31,38,48,114,186</sup> Microscopy reveals evidence of chronic myocarditis with fibrosis.<sup>186</sup>

The most significant respiratory complication of inhalational use is hypoxia, which is either caused by displacement of inspired oxygen with the inhalant, reducing the fraction of inspired oxygen ( $F_{iO_2}$ ), or by rebreathing of exhaled air, as occurs with bagging. Direct pulmonary toxicity associated with inhalants is most often a result of inadvertent aspiration of a liquid hydrocarbon (Chap. 105). Aspiration injury is associated with the acute respiratory distress syndrome (ARDS), a continuum of lung injury characterized by increased permeability of the alveolar–capillary barrier and the resulting influx of edema into the alveoli, neutrophilic inflammation, and an imbalance of cytokines and other inflammatory mediators.<sup>177</sup> Chronic use of volatile solvents induces increased lung epithelial permeability, suggesting pulmonary alveolar–capillary membrane dysfunction independent of aspiration injury.<sup>39</sup> Reports of asphyxiation initially ascribed to inhalant use were later found caused by suffocation by a plastic bag, mask, or container pressed firmly to the face and not specifically by toxicity of the inhaled vapor.<sup>13,35,175</sup>

Irritant effects on the respiratory system are frequently transient, but some patients progress to chemical pneumonitis. This syndrome is characterized by tachypnea, fever, tachycardia, crackles, rhonchi, leukocytosis, and radiographic abnormalities, including perihilar densities, bronchovascular markings, increased interstitial markings, infiltrates, and consolidation. Acute eosinophilic pneumonia after use of a fabric protector containing 1,1,1-trichloroethane is also reported.<sup>90</sup> Barotrauma, from deep inhalation or breath-holding, presents as pneumothorax, pneumomediastinum, or subcutaneous emphysema.<sup>143</sup>

Hepatotoxicity is associated with exposure to halogenated hydrocarbons, particularly carbon tetrachloride ( $CCl_4$ ), but also chloroform, trichloroethane, trichloroethylene, and toluene.<sup>109</sup> Intentional inhalation of ( $CCl_4$ ) is rarely reported, but its toxic metabolite, the trichloromethyl radical, created by the cytochrome CYP2E1, can covalently bind to hepatocyte macromolecules and cause lipid peroxidation<sup>137</sup> (Chap. 105). Two cases of centrilobular hepatic necrosis are reported after inhalation of trichloroethylene. In a case series of 34 serum-confirmed inhalant deaths, 2 of the 3 who died from trichloroethane and trichloroethylene inhalation had cirrhosis of the liver at autopsy. None of the victims of other inhalants had cirrhosis.<sup>62</sup> Inhalation of either toluene or one of the many halogenated hydrocarbons is associated with elevated liver enzymes and hepatomegaly that generally return to pre-exposure condition within 2 weeks of abstinence.<sup>9,79,87,102</sup>

Most reported kidney toxicity is associated with toluene inhalation. Prolonged toluene inhalation was said to cause a distal renal tubular acidosis (RTA), resulting in hypokalemia. However, whereas distal RTA is typically associated with a hyperchloremic metabolic acidosis and a normal anion gap, toluene use is associated with both normal and increased anion gap acidosis. Production of hippuric acid, a toluene metabolite, plays an important role in the genesis of the metabolic acidosis.<sup>37</sup> Hippurate excretion, usually expressed as a ratio to creatinine, rises dramatically with toluene inhalation.<sup>115</sup> The excretion of abundant hippurate in the urine unmatched by ammonium mandates an enhanced rate of excretion of sodium and potassium cations. Continued loss of potassium in the urine leads to hypokalemia. Toluene is rapidly metabolized to hippuric acid, and the hippurate anion is swiftly cleared by the kidneys, leaving the hydrogen ion behind. This prevents the rise in the anion gap that would normally occur with an acid anion other than chloride, resulting in a normal anion gap. In some cases, the loss of sodium causes extracellular fluid volume contraction and a fall in the glomerular filtration rate, which transforms the metabolic acidosis with a normal anion gap into one with a high anion gap caused by the accumulation of hippurate and other anions.<sup>37</sup> Other renal abnormalities of uncertain etiology are associated with toluene inhalation, including hematuria, albuminuria, and pyuria. Glomerulonephritis associated with hydrocarbon inhalation is also reported and is a result of antiglomerular basement membrane antibody-mediated immune complex deposition.<sup>18,123,171,192</sup>

Toluene using patients often present with profound hypokalemic muscle weakness. In a study of 25 patients admitted to the hospital after inhalant use, 9 presented with muscle weakness. The mean serum potassium concentration was 1.7 mEq/L, and 6 of these patients also had rhabdomyolysis. Four patients were quadriplegic on presentation, and initially, 2 of these were misdiagnosed with Guillain-Barré syndrome. The patients had inhaled toluene 6 to 7 hours per day for 4 to 14 days before presentation.<sup>157</sup> In a prospective study of 20 patients presenting to a single emergency department (ED) with acute toluene toxicity, 15 (75%) had had muscle weakness or paralysis. Three patients died from cardiac dysrhythmias, all of whom presented with altered mental status, hypokalemia, marked acidemia, and acute kidney injury.<sup>36</sup>

Acute dermatologic and upper airway toxicity is associated with the inhalation of fluorinated hydrocarbons. This is caused by the cooling of the gas as it rapidly expands on release from its pressurized container. First- and second-degree burns of the face, neck, shoulder and chest are reported in a 12-year-old-girl inhaling a computer duster containing difluoroethane.<sup>118</sup> Vesicular lesions of frostbite affect the tongue, lips, oral mucosa, airway, and hands as well as other areas that come in contact with dropped or discarded containers.<sup>2,74,93,97</sup> Massive, potentially life-threatening edema of the oropharyngeal, glottic, epiglottic, and paratracheal structures is also reported.<sup>95,96,112,135,185</sup> With chronic use of volatile hydrocarbons, some patients develop severe drying and cracking around the mouth and nose as a consequence of a defatting dermatitis known as “huffer’s eczema” or “glue sniffer’s rash.” Other manifestations of chronic irritation include recurrent epistaxis, chronic rhinitis, conjunctivitis, halitosis, and ulceration of the nasal and oral mucosa.<sup>115</sup>

Bone mineral density was significantly lower in 25 adolescent chronic glue sniffers compared with that of healthy control participants.<sup>50</sup> In a mouse model, chronic exposure to toluene significantly reduced bone

mineral density.<sup>6</sup> Skeletal fluorosis, manifested clinically by pain in affected bones and joints, hypertrophic nodules (Figs. 81–1 and 81–2), and decreased joint mobility, is reported following use of fluoride-containing inhalants (Fig. 8–13).<sup>42,74,169</sup>

Ophthalmologic toxicity, although more commonly associated with use of alkyl nitrites (see later), is reported in 2 men with chronic toluene use. Both had gradual vision loss, bilateral optic atrophy, and characteristic white matter changes on MRI.<sup>73</sup>

Methylene chloride (dichloromethane), most commonly found in paint removers and degreasers, is unique among the halogenated hydrocarbons in that it undergoes metabolism in the liver by CYP2E1 to carbon monoxide (CO).<sup>12</sup> In addition to acute CNS and cardiac manifestations, inhalation of methylene chloride is associated with delayed onset and prolonged duration of signs and symptoms of CO poisoning. The CO metabolite is generated 4 to 8 hours after exposure and its apparent half-life is 13 hours, significantly longer than that of CO following inhalation (Chap. 122).<sup>12,158</sup> Methanol toxicity is reported after intentional inhalation of methanol-containing carburetor cleaners and paint strippers.<sup>59,101,104,111</sup> Significant findings include hyperemic optic discs on funduscopic examination, metabolic acidosis, and CNS and respiratory depression (Chap. 106). Methanol-containing carburetor cleaners also contain significant amounts of toluene (43.8%), methylene chloride (20.5%), and propane (12.5%). These xenobiotics potentiate CNS depression and contribute to the toxicity associated with these products.

Chronic inhalation of the solvent *n*-hexane, a petroleum distillate found, for example, in rubber cement, causes a sensorimotor peripheral neuropathy. Toxicity is mediated via a metabolite, 2,5-hexanedione, which interferes with glyceraldehyde-3-phosphate dehydrogenase–dependent axonal transport, resulting in axonal death.<sup>49</sup> Numbness and tingling of the fingers and toes is the most common initial complaint; progressive, ascending loss of motor function with frank quadriplegia may ensue<sup>41</sup> (Chap. 105).

Reports of polyneuropathy associated with chronic gasoline inhalation date to the 1960s and describe a symmetric, progressive, sensorimotor neuropathy with occasional superimposed mononeuropathies.<sup>33,88</sup> Initially, these deficits were attributed to the presence of tetraethyl lead as an “antiknocking” agent in gasoline, but cases after use of unleaded gasoline are also reported.<sup>33,144</sup> *n*-Hexane is present in gasoline in concentrations up to 3% and is thought to be the likely mediator of gasoline neuropathy.<sup>179</sup>

### Teratogenicity

Fetal solvent syndrome (FSS) was first reported in 1979.<sup>167</sup> The authors described a 20-year-old primigravida with a 14-year history of solvent use defined as “daily” and “heavy” who gave birth to an infant exhibiting facial dysmorphism, growth retardation, and microcephaly, a constellation of findings that resembles fetal alcohol syndrome (FAS). A number of cases and case series were subsequently reported.<sup>5,78,142,182</sup> A general limitation of these case series is their reliance on self-reporting of substance use. In a number of cases included for analysis of teratogenic effects, mothers admit to use during pregnancy of other potential teratogens, including ethanol, cocaine, heroin, and phenobarbital.<sup>5,182</sup> Cases purported to represent inhalant use in the absence of other drug use, particularly ethanol, are not verified by laboratory testing. A small study of infants born to mothers with a self-reported history of chronic solvent use found 16% had major anomalies, 12.5% had facial features resembling FAS, and 3.6% had cleft palate.<sup>142</sup> Craniofacial abnormalities common to both FAS and FSS include small palpebral fissures, a thin upper lip, and midfacial hypoplasia. Features of FSS that distinguish it from FAS include micrognathia, low-set ears, abnormal scalp hair pattern, large anterior fontanelle, and downturned corners of the mouth.<sup>167</sup> Hypoplasia of the philtrum and nose are more characteristic of FAS.<sup>131</sup> Compared with matched control participants, infants born to mothers who report inhalant use are more likely to be premature, have low birth weight, have smaller birth length, and have small head circumference.<sup>5,182</sup> Follow-up studies of these infants

show developmental delay compared with children matched for age, race, sex, and socioeconomic status.<sup>5,78</sup> A rat model of toluene use embryopathy found a significant reduction in the number of neurons within each cortical layer, as well as abnormal neural migration.<sup>69</sup> In animal models of inhalant use, exposure to brief, repeated, high concentrations of toluene significantly increases rates of low birth weight, growth restriction, minor malformations, and impaired motor development as well as changes in regulation of metabolism, body composition, food intake, and weight gain.<sup>25,81,85</sup> In another rat model of maternal inhalant use, toluene concentrations in fetal brain tissue, the placenta, and amniotic fluid increased in a concentration-dependent manner.<sup>27</sup>

### Withdrawal

Observed similarities in the acute effects of inhalants compared with other CNS depressants suggest similar patterns of tolerance and withdrawal. Rodent models of inhalant use with toluene and TCE show evidence of physical dependence that manifests as an increase in handling-induced seizures on cessation of inhalation.<sup>55,181</sup> Additionally, these studies demonstrate cross-tolerance of the benzodiazepine diazepam with the motor-stimulating effects of TCE and, to a lesser degree, with toluene. Inhalant users describe tolerance with weekly use in as little as 3 months.<sup>71</sup> Withdrawal symptoms, including irritability, both hypersomnia and insomnia, fatigue, craving, nausea, tremor, and dry mouth lasting 2 to 5 days after last use, are described.<sup>133,146</sup>

### Volatile Alkyl Nitrites

Methemoglobinemia caused by inhalation of amyl, butyl, and isobutyl nitrites is well reported.<sup>29,106</sup> Nitrites are strong oxidants that induce hemoglobin oxidation from the ferrous ( $\text{Fe}^{2+}$ ) to the ferric ( $\text{Fe}^{3+}$ ) state. Patients with methemoglobinemia present with signs and symptoms that include shortness of breath, cyanosis, tachycardia, and tachypnea (Chap. 124). “Poppers retinopathy” characterized by eye pain; transient increased intraocular pressure; and central,

bilateral visual loss is reported after use of alkyl nitrites. Optical coherence tomography, the preferred diagnostic modality, demonstrates disruption of the inner and outer segment layers of the fovea.<sup>105,129,173</sup>

### Nitrous Oxide

Reported deaths associated with use of N<sub>2</sub>O appear to be caused by secondary effects of N<sub>2</sub>O, including asphyxiation and motor vehicle collisions while under the influence, and not a direct toxic effect.<sup>161,175</sup> Investigations after deaths associated with N<sub>2</sub>O have found many of the dead were discovered with plastic bags over their heads in an apparent attempt to both prolong the duration of effect and increase the concentration of the inhalant.<sup>175</sup> Autopsy findings in these cases are consistent with asphyxiation, including ARDS, cardiac petechiae, and generalized visceral congestion.<sup>161,175</sup> Laboratory simulation of a reported death in which the victim was found with a plastic bag over his head with a belt fastened loosely around his neck and a spent whipped cream canister within the plastic bag showed that N<sub>2</sub>O displaces oxygen in a closed space.<sup>175</sup> Additionally, N<sub>2</sub>O concentrations in this simulation were greater than 60%; at concentrations of N<sub>2</sub>O greater than 50%, the normal hypoxic response is diminished.<sup>175</sup> The combined effects of displaced oxygen and a blunted hypoxic drive likely increase the risk of asphyxia.

Chronic use of N<sub>2</sub>O is associated with neurologic toxicity mediated via irreversible oxidation of the cobalt ion of cyanocobalamin (vitamin B<sub>12</sub>). Oxidation blocks formation of methylcobalamin, a coenzyme in the production of methionine and S-adenosylmethionine, required for methylation of the phospholipids of the myelin sheaths. Additionally, cobalamin oxidation inhibits the conversion of methylmalonyl to succinyl coenzyme A. The resultant accumulation of methylmalonate and propionate results in synthesis of abnormal fatty acids and their subsequent incorporation into the myelin sheath (Chap. 65).<sup>132</sup> Case reports and small case series in humans after self-reported chronic, heavy use of N<sub>2</sub>O found development of a myeloneuropathy resembling the subacute combined degeneration of the dorsal columns of the spinal cord of classic vitamin B<sub>12</sub> deficiency.<sup>20,99,174</sup> Presenting signs and symptoms reflect varying involvement of the posterior columns, the corticospinal tracts, and the peripheral nerves. Numbness and tingling of the distal extremities is the most common presenting complaint. Physical examination reveals diminished sensation to pinprick and light touch, vibratory sensation and proprioception, gait disturbances, the Lhermitte sign (electric shock sensation from the back into the limbs with neck flexion), hyperreflexia, spasticity, urinary and fecal incontinence, and extensor plantar response.<sup>34,132</sup> Among reported patients with N<sub>2</sub>O-associated neurotoxicity who had documented concentrations of vitamin B<sub>12</sub>, approximately 50% were low.<sup>4,20,52,99,145,155,174</sup> Results were normal in the few patients who underwent a Schilling test, which evaluates the capacity to absorb vitamin B<sub>12</sub> from the bowel using radiolabeled vitamin B<sub>12</sub>.<sup>99,174</sup> Elevated concentrations of methylmalonic acid and homocysteine are often reported, even when vitamin B<sub>12</sub> concentrations are normal.<sup>4,52,145</sup> Magnetic resonance imaging of the spinal cord may reveal symmetric enhancement and edema of the dorsal columns, referred to as the inverted V-sign (Fig. 65-3).<sup>52,153</sup> Nerve conduction studies and electromyography typically reveal a distal, axonal sensorimotor polyneuropathy.<sup>34,99,174</sup>

### LABORATORY AND DIAGNOSTIC TESTING

Routine urine toxicology screens do not detect inhalants or their metabolites. Most volatile inhalants can be detected using gas chromatography as well as nuclear magnetic resonance spectroscopy (MRS). The likelihood of detection is limited by the dose, time to sampling, and method of specimen storage. Blood is the preferred specimen, but urinalysis for metabolites, including hippuric acid (the toluene metabolite) and methyl hippuric acid (the xylene metabolite), extend the time until the limit of detection is reached.<sup>30,98</sup> Furthermore, urinary hippuric acid is not specific for toluene exposure; the ratio of urine hippuric acid to urine creatinine must be considered. Specimens should be stored at a temperature between 23°F (−5°C) and 39.2°F (4°C).<sup>30</sup> Testing is not readily available at most institutions, and the need to send the specimen to a reference laboratory limits

TABLE 81-3 Inhalants With Unique Clinical Manifestations

Inhalant	Clinical Manifestations
Toluene	Hypokalemia Hepatotoxicity Leukoencephalopathy (chronic)
Difluoroethane, tetrafluoroethane	Frostbite Skeletal fluorosis (chronic)
1,1,1-Trichloroethane, trichloroethylene	Hepatotoxicity
Methylene chloride	Carbon monoxide poisoning
Carburetor cleaner	Methanol poisoning
n-Hexane	Peripheral neuropathy (chronic)
Alkyl nitrites (amyl, butyl, isobutyl)	Methemoglobinemia Vision loss
Nitrous oxide	Myeloneuropathy (chronic) Megaloblastic anemia (chronic) Skin hyperpigmentation (chronic)

the clinical utility in most situations. A thorough history and physical examination and careful questioning of the patient's friends and family are probably more helpful in cases of suspected inhalant use.

Depending on the patient's signs and symptoms, additional diagnostic testing is recommended, including an ECG, radiograph, electrolytes, liver enzymes, carboxyhemoglobin and blood pH. Inhalation of some xenobiotics presents unique diagnostic considerations (Table 81-3 and Fig. 81-2). Routine laboratory testing, including cerebrospinal fluid analysis, is unremarkable in patients with inhalant-induced leukoencephalopathy. A computed tomography (CT) scan of the head is generally normal until late in the disease, when diffuse hypodensity of white matter becomes evident. T2-weighted MRI with its superior resolution of white matter is the diagnostic study of choice. Standard MRI does not detect initial changes caused by toluene leukoencephalopathy; measurement of N-acetyl aspartate (NAA), a marker of CNS axons, with MRS assists with earlier detection. A decrease in NAA concentration, usually expressed as the ratio of NAA to creatinine (NAA:Cr), is suggested as a marker of axonal damage.<sup>57</sup> It is not currently routine or definitively valuable.

### MANAGEMENT

Management begins with assessment and stabilization of the patient's airway, breathing, and circulation (the "ABCs"). The patient should be attached to a pulse oximeter and cardiac monitor. Oxygen should be administered if indicated. Early consultation with a regional poison control center or medical toxicologist is recommended to assist with identification of the xenobiotic and patient management.

Cardiac dysrhythmias associated with inhalant use carry a poor prognosis. Sudden death after use is not limited to novices, and there appears to be no premonitory signal.<sup>13,68</sup> Dysrhythmias, including ventricular fibrillation have been observed in the ED after witnessed exposures suggesting an ill-defined period of observation on cardiac monitor is warranted after initial exposure to inhalant. An evaluation for life-threatening electrolyte abnormalities is indicated and rapid correction is recommended in the patients presenting with dysrhythmias. Patients with nonperfusing rhythms should be managed after standard management with defibrillation. There are no evidence-based treatment guidelines for the management of inhalant-induced cardiac dysrhythmias, but β-adrenergic antagonists are thought to offer some cardioprotective effects to the sensitized myocardium.<sup>124</sup> Treatment with either propranolol or esmolol would be reasonable choices in managing ventricular dysrhythmias after inhalant use.<sup>66,119</sup>

Other complications, including methemoglobinemia, elevated carboxyhemoglobin, and methanol toxicity, should be managed with the appropriate

antidotal therapy when present. Patients with respiratory symptoms that persist beyond the initial complaints of gagging and choking should be evaluated for hydrocarbon pneumonitis and treated supportively (Chap. 105).

With abstinence, cognitive and neuroimaging changes associated with toluene-induced leukoencephalopathy are initially partially reversible; beyond a poorly defined period, these changes are irreversible.<sup>47,57</sup> Cessation of use is the most important therapeutic intervention in patients with *n*-hexane-induced neuropathy and N<sub>2</sub>O-induced myeloneuropathy; limited evidence supports the co-administration of vitamin B<sub>12</sub> (1,000 mcg intramuscularly) and methionine (1 g orally) and 30 mg IV folic acid in cases of N<sub>2</sub>O induced myeloneuropathy and is a reasonable therapeutic intervention.<sup>34,145,155</sup>

Agitation, either from acute effects of the inhalant or from withdrawal, is safely managed with a benzodiazepine. In the vast majority of patients, symptoms resolve quickly, and hospitalization is not required. The potential toxicity of inhalants should be reinforced, and patients should be referred for counseling. Subsets of users, meeting the criteria for inhalant dependence and inhalant-induced psychosis, require inpatient psychiatric care. Pharmacotherapy with carbamazepine or the antipsychotics haloperidol, risperidone, and aripiprazole are reasonable for some patients with an inhalant-induced psychotic disorder.<sup>53,77,116</sup> Case reports suggest treating patients with inhalant dependence with lamotrigine, which inhibits excitatory glutamatergic tone, or with buspirone, an atypical anxiolytic.<sup>123,150</sup> There are limited data, suggesting that patients with inhalant withdrawal can be treated with baclofen in either single or divided doses of up to 50 mg/day.<sup>86,122</sup> Drug use treatment programs for inhalant use are scarce, and few providers have special training in this area.<sup>15</sup> Unfortunately there is limited evidence to support these therapeutic interventions and our standard approaches to psychosis will typically be the initial strategies.

## SUMMARY

- Inhalants are a heterogeneous group of xenobiotics that include volatile hydrocarbons, the alkyl nitrites, and N<sub>2</sub>O.
- The incidence of inhalant use is greatest among adolescents.
- The CNS is the intended target for the inhalant users; early effects include euphoria, hallucinations, headache, and dizziness.
- Chronic neurotoxicity, described best with toluene leukoencephalopathy, is characterized by dementia and ataxia.
- Muscle weakness, even paralysis, secondary to marked hypokalemia occurs with toluene use.
- Acute cardiotoxicity is manifested most dramatically in “sudden sniffing death.”
- Diagnosis is largely clinical; further diagnostic testing should be guided by the patient’s presenting complaint.
- Management begins with basic life support, and care is generally supportive.
- Cessation of use is the only known treatment for many manifestations of chronic toxicity.

Nicotine

MW = 162 Da

## HISTORY AND EPIDEMIOLOGY

Nicotine is the principal alkaloid derived from plants of the genus *Nicotiana*, collectively known as the tobacco plant, in the family *Solanaceae*. Other fruits and vegetables from the *Solanaceae* family, such as tomatoes, potatoes, eggplant, and cauliflower, also contain nicotine in amounts ranging from 3.8 to 100 ng/g.<sup>29</sup> The source of greatest toxicologic importance in human use is *Nicotiana tabacum*, and the primary method of exposure is cigarette smoking.

The tobacco plant is native to the Americas, and its use most likely predates the Mayan empire. In 1492, Christopher Columbus and his crew were given tobacco by the Arawaks but reportedly threw it away, not knowing any use for it. Ramon Pane, a monk who accompanied Columbus on his second voyage to America, is credited with introducing tobacco to Europe.<sup>99</sup>

Because of the highly addictive properties of nicotine, the global disease burden related to cigarette use today is staggering. Cigarette smoking increases rates of illnesses, such as chronic obstructive pulmonary disease (COPD), cardiovascular disease, pulmonary infections, macular degeneration, and cancers, and tobacco use causes more than 5 million deaths worldwide per year.<sup>101</sup> Chronic nicotine exposure causes cardiovascular damage related to catecholamine release and vasoconstriction and directly promotes angiogenesis, neuroteratogenicity, and possibly some cancers.<sup>64</sup> However, there are more than 3,000 components to tobacco smoke, and nicotine per se may not be the crucial determinant of the total health burden associated with its use.

Although the long-term effects of tobacco dependency are significant, this chapter is concerned with the sources, effects, and management of acute toxicity referable to nicotinic receptor stimulation and cholinergic activation. Compared with other xenobiotics, exposure to nicotine-containing products is a relatively rare cause of acute poisoning. For example, reviews of case data from the National Poison Data System (NPDS) suggest that cigarettes are by far the most common vehicle implicated in acute nicotine exposures and poisoning in the United States,<sup>22</sup> yet over a period of 27 years from 1983 to 2009, tobacco products accounted for 217,340 calls, or 0.37%, of all pediatric exposures reported to poison control centers in the United States<sup>2</sup> and accounted for only 0.7% of all unintentional poisoning cases in children treated in US hospital emergency departments.<sup>36</sup> More current data suggest that electronic cigarettes and liquid nicotine exposures are on the rise. In 2014, pediatric exposures to e-cigarettes and liquid nicotine accounted for approximately 59% of all calls reporting these exposures, a percentage that rose to 70% in 2015.<sup>41</sup> Consequential poisoning occurs, but most patients with nicotine exposure from tobacco products have a benign course, with only mild to moderate symptoms, and an infrequent need for hospitalization.

The frequency and severity of nicotine poisoning is changing with the rise of e-cigarette use, and associated increase in topical and oral exposures of more highly concentrated liquid nicotine preparations. According to NPDS data, pediatric nicotine exposure via e-cigarettes rose by more than 1,000% between 2012 and 2015.<sup>52</sup> During this time, cigarettes, other forms of tobacco, and e-cigarettes accounted for 60.1%, 16.4%, and 14.2% of pediatric nicotine exposure, respectively.<sup>52</sup> Other smoking cessation products containing

nicotine or nicotinlike compounds are also increasingly available. Some of the more novel smokeless tobacco products have the appearance and flavor of candy, raising concern about the potential for unintentional poisoning of young children, in particular.<sup>22</sup>

Nicotine receptor partial agonists/antagonists are a relatively new class of drug mimicking the physiologic effects of nicotine. A 2-year review of poison control center data from the California Poison Control System found 36 calls regarding human exposures to varenicline which was approved in 2006 by the US Food and Drug Administration (FDA) as a smoking cessation aid.<sup>58</sup> Of these, 17 cases had no outcome data or involved coingestions. Nine of the remaining cases involved unintentional exposure in children younger than 6 years of age, one of whom was hospitalized; none experienced major adverse events. However, postmarketing safety reports of seizures<sup>93</sup> and neuropsychiatric effects, including anxiety, depression, and suicidal ideation,<sup>100</sup> drove the FDA to place a black box warning on varenicline in 2009.

Dermal exposure to tobacco plants during harvest remains an important source of occupational nicotine toxicity, known as green tobacco sickness (GTS). Green tobacco sickness was first reported in 1970 among tobacco workers in Florida.<sup>105</sup> In 1992, the US Centers for Disease Control and Prevention estimated the crude 2-month incidence rate of hospital treated GTS was 10 per 1,000 workers in a 5-county area in Kentucky.<sup>77</sup> Overall prevalence estimates among seasonal and migrant farmworkers are as high as 25% to 40% of workers.<sup>3,5,88</sup>

Insecticides containing nicotine and neonicotinoid compounds are also implicated in acute poisoning. These products and their role in human poisoning are discussed in Chap. 111 and are only briefly mentioned here. Tobacco extracts were first reported as effective for pest control in 1690, and in 1886, a mixture of tobacco and soapsuds was advocated for aphid control. The first commercial nicotine insecticides were developed in 1912. Crop dusting with nicotine sulfate began in 1917, although at the time, it was mostly accomplished by horse-drawn carriage.<sup>84</sup> The most widely known application of 40% nicotine sulfate, BlackLeaf 40, was discontinued in 1992. Nicotine-based insecticides are now restricted in the United States, although they are used in other countries, and a 14% preparation of nicotine is still marketed as a greenhouse smoke fumigator.<sup>82</sup> Because nicotine pesticides are highly concentrated, the ingestion of even small amounts produces serious toxicity, including catastrophic brain injury<sup>90</sup> and death.<sup>60</sup>

The neonicotinoids are a relatively new class of insecticide developed in the last quarter century, and epidemiologic data about their role in acute pesticide poisoning are still limited. A retrospective review of poison control center data from Thailand found no reports of neonicotinoid exposures before 1993.<sup>86</sup> Between 1993 and 2007 there were a total of 70 cases, including 2 deaths. The number of exposures reported annually increased dramatically after 2002, suggesting that neonicotinoid insecticides will likely continue to be an emerging cause of acute pesticide poisoning. However, in the year with the highest case incidence, these insecticides still represented fewer than 3% of all pesticide exposures reported. Neonicotinoid insecticides also carry environmental implications and are detrimental to pollinating insects such as bees.<sup>42</sup>

## PHARMACOLOGY AND PHARMACOKINETICS

The pharmacologic characteristics of nicotine are listed in Table 82–1. Nicotine is well absorbed from the respiratory tract, mucosal surfaces, skin, and intestines. Nicotine is a weak base (pKa = 8.0) and is more readily absorbed in an alkaline environment. Many tobacco and nicotine replacement products are therefore buffered to alkaline pH to facilitate absorption.

Absorption	Lungs, oral mucosa, skin, intestinal tract; increased in more alkaline environments
Volume of distribution	2.6 L/kg
Protein binding	5%
Metabolism	80%–90% hepatic via CYP2A6 and CYP2D6, aldehyde oxidase, flavin monooxygenase, and by glycosylation; remainder in lung, kidney; principal (inactive) metabolite is cotinine
Half-life	Nicotine: 1–4 h, decreases with repeated exposure Cotinine: 20 h
Elimination	2%–35% excreted unchanged in urine

Nicotine from cigarette or cigar smoke is carried on inhaled tar particles into the lungs, where the pulmonary circulation rapidly absorbs the inhaled nicotine. After inhalation, studies show that peak nicotine concentration occurs within minutes. After 9 minutes of cigarette smoking, the nicotine concentration in the blood peaks within 10 minutes after cessation of use.<sup>6</sup> With e-cigarette use, nicotine concentrations peak within 5 minutes in naïve users; after more chronic use, peak nicotine concentrations rise along a similar timeline but surpass the concentration reached by naïve users.<sup>45</sup>

In the bloodstream, nicotine is about 69% ionized at a pH of 7.4, and less than 5% is bound to plasma proteins. Distribution to body tissues is rapid and extensive, with an average volume of distribution of about 2.6 L/kg.<sup>12</sup> Nicotine readily crosses the placental barrier and is secreted in breast milk. Metabolism occurs primarily in the liver via CYP2A6 and CYP2D6, aldehyde oxidase, flavin monooxygenase, and by glycosylation. About 70% of circulating nicotine is metabolized to cotinine, and much smaller amounts to nor-nicotine, nicotine-1-*N*-oxide, nicotine glucuronide, and 2'-hydroxynicotine.

Peak plasma concentrations of nicotine and cotinine are influenced most strongly by individual variations in clearance.<sup>10,11</sup> Hepatic nicotine metabolism is inducible and nicotine-dependent individuals metabolize the drug more rapidly than naïve ones.<sup>48</sup> Nicotine metabolism is also linked to race and sex. Asians and African Americans metabolize nicotine more slowly than whites, and they have prolonged cotinine clearance in the urine.<sup>11,65,83</sup> Women metabolize nicotine faster than men, which is further accelerated by oral contraceptive use and pregnancy, and is most likely mediated by an influence of estrogen on CYP2A6 activity.<sup>48</sup>

Renal excretion of unchanged nicotine accounts for 2% to 35% of total nicotine elimination,<sup>14</sup> and this is pH dependent. Nicotine is reabsorbed in the proximal tubule and acidification of the urine enhances elimination. The half-life of nicotine in the body is 1 to 4 hours, and it decreases with repeated nicotine exposure such as is associated with habitual cigarette smoking. Cotinine and trans-3'-hydroxycotinine are eliminated in the urine as glucuronide esters independent of urine pH. The elimination half-life of cotinine is approximately 20 hours, and therefore urinary cotinine is a more useful marker of nicotine exposure. The apparent elimination half-life of nicotine after transdermal patch removal is longer than that noted with nicotine exposure by other routes,<sup>53</sup> but this is most likely because a dermal reservoir of drug is established during patch use, from which absorption continues after removal.

Cigarette smoking modulates the bioavailability and effectiveness of numerous medications through effects on drug absorption, metabolism, or pharmacodynamics. Cigarette smoking induces CYP1A2 and accelerates the metabolism of caffeine, clozapine, olanzapine, tacrine, theophylline, and erlotinib.<sup>46,51</sup> This is not an effect of nicotine. For example, intravenous (IV) nicotine administration does not alter theophylline metabolism.<sup>8</sup> Smokers also have diminished effectiveness of opioids, benzodiazepines,  $\beta$ -adrenergic antagonists, and nifedipine<sup>21</sup> and are more likely to fail antacid and H<sub>2</sub>-antagonist therapy for peptic ulcer disease.<sup>8</sup> However, an effect of nicotine is not clearly linked to these interactions.

The LD<sub>50</sub> of nicotine is usually estimated at 0.5 to 1 mg/kg in adults<sup>38,40,65</sup> but is much higher at about 6.5 to 13 mg/kg according to some reports.<sup>70,71</sup> Severe toxicity is reported with ingestion of less than 2 mg in a child,<sup>74,94</sup> and this dose is sufficient to produce mild symptoms in an unhabituated adult. However, the reported doses associated with toxicity varied widely. Children younger than 6 years of age who ingest one or more cigarettes, or 3 or more cigarette butts, generally develop symptoms of nicotine toxicity.<sup>94</sup> A retrospective review of 10 children who ingested cigarettes found that of the 4 patients with symptoms requiring medical evaluation and treatment, all ingested at least 2 entire cigarettes.<sup>67</sup> Two pediatric deaths associated with e-cigarettes (unknown nicotine doses) are also reported as well as a suicidal ingestion of up to 3 g of nicotine liquid by an adult.<sup>17</sup>

Acute tolerance to nicotine develops in smokers who take in small doses of nicotine regularly throughout the day. Sensitization to the effects of nicotine is restored with overnight abstinence.<sup>6,48</sup> Tolerance also develops in tobacco workers with regular exposure to tobacco plant leaves. However, the phenomenon of acute tolerance, along with considerable genetic variability in nicotine metabolism, implies a range of susceptibility to drug effect.

## SOURCES AND USES OF NICOTINE

### Cigarettes and Cigars

The amount of nicotine contained in a single cigarette is highly variable, ranging from less than 10 mg in a “low-nicotine” cigarette to 30 mg in some European cigarettes (Table 82–2). Because most nicotine is either lost in the sidestream (secondhand) smoke or left in the filter, the absorbed nicotine yield from a smoked cigarette is much less than this, on the order of 0.05 to 3 mg per cigarette.<sup>35</sup> The amount of nicotine absorbed by a particular individual from a single smoked cigarette is highly variable among smokers and depends on the puff rate, volume, the depth and duration of inhalation, and size of the residual.<sup>68</sup> Cigars have higher nicotine content than cigarettes (Table 82–2) and potentially greater absorption because cigar and pipe tobacco is typically air cured to achieve a high pH.

The potential for nicotine toxicity from smoking is limited because peak effects by this route occur within seconds and tend to limit further intake of drug. Most reports of acute nicotine toxicity referable to cigarette exposure are associated with cigarette and cigarette butt ingestion, usually by young children.<sup>78,85,86</sup> Although uncommon, severe toxicity from cigarette<sup>13,94</sup> ingestion is well reported and at least 3 deaths are associated with liquid nicotine.<sup>17,54</sup> Ingesting cigarette soakage water is recommended on the Internet as a “safe and effective” means of suicide, and several cases are reported.<sup>24,91</sup> Intravenous injection of cigarette soakage is also reported.<sup>44</sup>

**TABLE 82–2 Commercial Sources of Nicotine**

Source	Content (mg)	Delivered (mg)
1 cigarette	10–30	0.05–3
1 cigarette butt	5–7	—
1 cigar	15–40	0.2–1
1 g snuff (wet)	12–16	2–3.5
1 g chewing tobacco	6–8	2–4
1 piece nicotine gum	2 or 4	1–2
1 nicotine patch	8.3–114	5–22 over 16–24 h
1 nicotine lozenge	2 or 4	2–4
1 nicotine nasal spray	0.5	0.2–0.4
30-mL bottle of 3.6% nicotine liquid refill for e-cigarette cartridges (30-, 50-, and 100-mL bottles also sold)	36 mg/mL	<43.2 mcg/100 mL “puff” of nicotine mist

## Waterpipes, Hookah, and Shisha

Although the use of cigarettes has decreased in the United States, waterpipe use has become popular especially among college students with hookah bars opening all around the country. Waterpipes, also called hookah or shisha, refer to tobacco smoked through a pipe filled with water. A container holding 10 to 20 g of tobacco, often fruit flavored, is connected to the pipe and covered with aluminum foil paper.<sup>50</sup> Coal is used as a heat source and placed on top of the foil paper. The user then inhales the smoke produced from a mouthpiece at the end of a hose attached to the waterpipe. Waterpipes are perceived to be safer than smoking cigarettes, with 10% to 20% of US college students reporting its use.<sup>32,87</sup>

Toxins associated with waterpipe use include carbon monoxide, nicotine, and carcinogens. In a study including 16 participants who smoked a waterpipe with up to 32 mg of nicotine for a mean of 39 minutes, plasma nicotine concentrations peaked to 11.7 ng/mL and 28.4 ng/mL in waterpipe-only smokers and mixed tobacco users, respectively, 45 minutes after use.<sup>50</sup> These participants reached a systemic dose of 2.5 mg equal to that achieved after smoking 2 or 3 cigarettes, and the average carboxyhemoglobin in the waterpipe-only smokers was 6.2%. Several reports demonstrate overt carbon monoxide poisoning associated with waterpipes. In one case, a 24-year-old man who worked lighting hookahs at a hookah bar became unconscious with a carboxyhemoglobin level of 33.8% and an abnormal electrocardiogram.<sup>75</sup>

Given rising health concerns based on similar studies, in 2016, the FDA included waterpipes under the *Family Smoking Prevention and Tobacco Control Act of 2009*, which restricts tobacco sale to minors younger than 18 years of age, requires packaging to contain health warnings and product ingredients to be evaluated, and mandates FDA premarket review and authorization.<sup>41,92</sup>

## Oral Tobacco

Snuff and chewing tobacco are still widely employed by users of smokeless tobacco products<sup>22</sup> despite clear associations with periodontal disease, dental cavities, and up to a 48 times greater risk of oropharyngeal cancers compared with people who do not use tobacco products.<sup>23</sup> Snuff, or dip, is a finely ground and sometimes flavored tobacco preparation often sold in small teabag-like pouches that users insert between their lower lips and gums. Chewing tobacco consists of shredded, twisted, or “bricked” dried tobacco leaves. Because nicotine is a weak base, smokeless tobacco is buffered to facilitate buccal absorption.

In one survey of major US brands, the pH of marketed oral tobacco products ranged from 5.24 to 8.35, and the nicotine content ranged from 3.37 to 11.04 mg/g.<sup>76</sup> Acute nicotine toxicity from smokeless tobacco is rarely reported in adults. A 14-month-old boy had muscle fasciculations and lethargy after ingesting material taken from his father’s spittoon but recovered within 24 hours with supportive care.<sup>40</sup> Rectal administration of moist snuff as a treatment for migraine headache resulted in significant toxicity in one patient.<sup>56</sup> Presumably, the relatively alkaline environment of the rectum facilitated absorption of a high dose.

Oral tobacco has been popular on baseball fields for many decades. Despite a push to ban smokeless tobacco from baseball fields, the Major League Baseball organization has not prohibited its use. Recently, city and state governments have banned smokeless tobacco from baseball-related events and venues in 5 cities: San Francisco, Boston, Los Angeles, Chicago, and New York City.<sup>55</sup>

## Gum

Nicotine gum has been available without a prescription as an aid to smoking cessation in the United States since 1996. It is sold in 2-mg and 4-mg strengths per piece. Approximately 53% to 72% of the nicotine in the gum is absorbed. It is buffered to an alkaline pH to facilitate buccal absorption. The gum is supposed to be chewed until mouth and throat tingling and a peppery taste develop, signaling the release of nicotine. The gum is then “parked” in the cheek until the sensation subsides, at which time it may be chewed again to release more drug.<sup>81</sup> If used correctly, serum nicotine concentrations rise gradually to a level slightly lower than normally achieved by cigarette

smoking.<sup>81</sup> If the gum is swallowed whole, then serum concentrations rise even more slowly because the acidic environment of the stomach delays absorption.<sup>8</sup> Conversely, if the gum is chewed vigorously and saliva is swallowed, then nicotine concentrations rise rapidly, and adverse reactions occur.<sup>94</sup>

## Lozenges

Nicotine lozenges containing 2 and 4 mg of nicotine are available for purchase without a prescription in the United States. The potential for rapid absorption of nicotine as a bolus dose from chewing the lozenge is a concern.

## Transdermal Patches

Nicotine patches have been FDA approved for purchase without prescription in the United States since 1996. Most nicotine transdermal delivery systems are designed to deliver 7, 14, or 21 mg of nicotine over 24 hours.<sup>43</sup> Because many patch users have difficulty sleeping, experience vivid dreams, or have nightmares if they wear the patch overnight, systems designed to be applied for only 16 hours are now available. Several reports document consequential nicotine toxicity related to nicotine patch misuse. Toxicity occurs in people who continue to smoke cigarettes after beginning therapy with the nicotine patch. Children developed symptoms after exploratory self-application of one or more patches to the skin,<sup>104,106</sup> and concurrent use of multiple patches is used as a means of suicide.<sup>59,95,105</sup> Severe toxicity also occurs if patches are punctured—for example, by biting or tearing—thus allowing delivery of excessive quantities of nicotine.<sup>106</sup> The patch reservoirs contain an estimated 36 to 114 mg per patch.<sup>80</sup>

## Spray or Inhaler

A nicotine spray has been available since 1996 to aid efforts at smoking cessation. The most commonly reported adverse effects during initiation of therapy are due to local irritation and include rhinorrhea, lacrimation, sneezing, and nasal and throat irritation.<sup>49</sup> One spray delivers 0.5 mg of nicotine and the recommended dose is 2 sprays every 30 to 60 minutes as needed. The absorption is about 50% of the delivered dose and is diminished or delayed by rhinitis or by  $\alpha$ -adrenergic agonist decongestants.<sup>63</sup> No report of acute nicotine toxicity from nicotine inhalers has been published to date.

## Electronic Cigarettes

Electronic cigarettes, or e-cigarettes, are a relatively new nicotine delivery product now widely available in various strengths and flavors.<sup>20</sup> The devices resemble cigarettes and contain a rechargeable battery pack along with a small heating element or atomizer attached to a reservoir of liquid nicotine. Currently, there are multiple generations of e-cigarettes with newer models combining the atomizer and the nicotine reservoir into one piece. An electronic airflow sensor activates the heating element when the user inhales, allowing release of a “puff” of nicotine-containing vapor.

An FDA analysis of cartridges found that identically labeled products contained variable amounts of nicotine and a number of potentially harmful contaminants.<sup>98</sup> Personal vaporizers are newer models that allow nicotine delivery to be titrated based on the concentration of the liquid nicotine preparation being used.<sup>96</sup> Liquid nicotine is sold in different formulations with the highest strength preparations (3.6% nicotine) containing more than 1 g of nicotine per 30-mL bottle. This raises serious concerns about the risk of both unintentional and intentional toxic exposures. Additionally, large-volume liquid nicotine replacement fluid bottles (used to refill e-cigarette cartridges) are available, augmenting e-cigarettes’ potential for harm.

Deaths from unintentional and intentional ingestion of e-cigarette liquid are reported.<sup>17,92</sup> Analysis of calls to US poison control centers about e-cigarette exposures shows a substantial increase between the years 2010 and 2014, with significantly greater adverse effects reported compared with calls about cigarette exposures.<sup>16</sup> Before 2016, the sale and use of e-cigarettes were not regulated in the United States. E-cigarette use increased in popularity among adolescents, both who had and those who had not smoked traditional cigarettes.<sup>31</sup> A study found that adolescents who use e-cigarettes are also more likely to try other tobacco products, including traditional cigarettes.<sup>62</sup>

In 2016, the rising concern for e-cigarettes' toxic potential led the FDA to include e-cigarettes under the *Family Smoking Prevention and Tobacco Control Act of 2009*, thus regulating its sale to minors and requiring FDA approval for new e-cigarette products before entering the market.<sup>92</sup>

### Partial Nicotine Receptor Agonists (Varenicline, Cytisine)

Partial nicotine receptor agonists are used to aid smoking cessation. Theoretically, they work by reducing smoking satisfaction (agonist/antagonism effect) while helping to maintain moderate concentrations of central dopamine release (partial agonist effect). Cytisine is a plant-derived xenobiotic with a chemical structure similar to nicotine that is used in East and Central Europe as a smoking cessation drug since the 1960s under the trade name Tabex (Sopharma Pharmaceuticals). Despite its widespread use, the safety, efficacy, pharmacokinetics, and pharmacodynamics of cytisine in humans are not well studied.<sup>33</sup> Varenicline was approved as a prescription-only aid to smoking cessation in 2006. Several randomized controlled trials demonstrated efficacy in controlling nicotine cravings and evidence suggests that varenicline increases the probability of successful abstinence from smoking.<sup>15</sup>

In 2009, the FDA mandated a black box warning due to an association with increased risk of depression or suicidal behavior. In 2011, the FDA updated the drug label for varenicline to include warning of its interaction with ethanol, including its association with decreased ethanol tolerance and increased aggressive behavior, as well as its potential to cause seizures.<sup>34</sup> There is now increasing experience with acute varenicline overdose, including effects such as nausea, vomiting, tachycardia, and hypertension, and one reported fatality after intentional overdose.<sup>47,97</sup>

### Plants and Leaves

Green tobacco sickness (GTS) refers to nicotine-induced symptoms, including nausea, vomiting, headache, and dizziness, that occur when nicotine is topically absorbed during the handling of tobacco plants. Residual moisture or dew drops on tobacco leaves contains as much as 9 mg of nicotine per 100 mL.<sup>39</sup> Tobacco workers' hands tested for nicotine had concentrations between 4.1 and 27.1 mcg/cm<sup>2</sup> in one study.<sup>25</sup>

Tobacco workers are most at risk when their clothing comes in contact with moisture on the tobacco plants. Sweat wrung out of the shirts worn by workers during tobacco harvest in one study contained up to 98 mg/mL of nicotine.<sup>39</sup> Risk factors for GTS include decreased tolerance reflected by younger age and a relative lack of work experience as well as extent of exposure which increases with working with wet tobacco.<sup>3,5,73,77</sup> The use of impermeable garments or other barrier protection is the only protective factor consistently noted to be useful across multiple studies.<sup>4,73,77</sup>

### Miscellaneous

In the pre-Columbian Americas, many tribes used tobacco extract and tobacco smoke enemas for both medicinal and spiritual purposes. They are still recommended by some naturopaths and folk healers as remedies for constipation, urinary retention, pinworm, and "hysterical convulsions." Nicotine was also recommended as a treatment for migraine on the basis of its vasoconstrictive properties.<sup>103</sup> "Therapeutic misadventures" resulted in nicotine poisoning in several documented cases.<sup>38,56,57</sup> For example, acute nicotine toxicity occurred in an 8 year-old boy after application of a home-made remedy for eczema made from a mixture of tobacco leaves, lime juice, and freeze-dried coffee.<sup>27</sup>

## PATHOPHYSIOLOGY

Nicotine mimics the effects of acetylcholine by binding to nicotinic receptors (nAChRs) in the brain, spinal cord, autonomic ganglia, adrenal medulla, neuromuscular junctions, and chemoreceptors of the carotid and aortic bodies (Chap. 13). Activation of nAChRs in the CNS directly stimulates neurotransmitter release. When nicotine binds to this receptor, an ion channel opens, allowing an influx of cations, mostly sodium and calcium. Voltage-gated calcium channels are then activated, leading to further influx of calcium, and a variety of downstream effects, including depolarization.

At doses generally produced by cigarette smoking there is stimulation of the reticular activating system and an alerting pattern on the electroencephalogram.<sup>107</sup> Nicotine-stimulated release of dopamine occurs in the mesolimbic area, the corpus striatum, the prefrontal cortex, and in the nucleus accumbens; it is an important mediator of nicotine addiction.<sup>69</sup> Nicotine also stimulates glutaminergic activation and the GABA ( $\gamma$ -aminobutyric acid)-ergic inhibition of dopaminergic neurons in the hippocampus, basal forebrain, and ventral tegmental area of the midbrain.<sup>7,30</sup> These pathways, along with endogenous cannabinoid and opioid systems, are important neuromodulatory pathways for drug-induced reward, dependence, and withdrawal.<sup>66,69,72</sup> Norepinephrine, acetylcholine, GABA, serotonin, glutamate, and endorphins are all released by nicotine and are associated with cognitive and mood enhancement as well as appetite suppression, increased basal energy expenditures, and anxiety reduction.<sup>7</sup>

The clinical effects of nicotine are dose dependent. Low doses of nicotine and related compounds stimulate nicotinic receptors centrally and in autonomic and somatic motor nerve fibers, resulting in sympathetic agonism. At toxic concentrations, prolonged or excessive nicotinic stimulation ultimately leads to receptor blockade (Chap. 66), with parasympathetic and neuromuscular-blocking effects.

At very high doses, nicotine induces seizures. In a mouse model, nicotine-induced seizures are blocked by the nicotine-receptor antagonists mecamylamine, methyllycaconitine citrate, and hexamethonium.<sup>26</sup> However, when given to mice at slightly higher doses, these nicotine receptor antagonists are epileptogenic. The specific mechanisms by which nicotine produces seizures are unknown. A disinhibition model is proposed in which desensitization or antagonism of central nicotinic cholinergic neurons blocks excitatory input to GABAergic neurons and reduces inhibitory GABAergic input to pyramidal cells, resulting in increased excitability and seizures.<sup>1,18,28,37</sup> An alternative hypothesis is that high doses of nicotine cause synchronous GABA-receptor mediated depolarization in hippocampal neurons to generate seizures.<sup>28</sup>

## CLINICAL MANIFESTATIONS

Patients with nicotine exposure rarely display more than mild symptoms and typically have a benign course.

Exposure to nicotine in low doses comparable to cigarette smoking in nicotine-naïve patients produces fine tremor; cutaneous vasoconstriction; increased gastrointestinal motility; nausea; and increases in heart rate, respiratory rate, and blood pressure. Low-dose nicotine also increases mental alertness and produces euphoria. Because nicotine is poorly absorbed in the acid environment of the stomach, symptom onset occurs 30 to 90 minutes after ingestion of nicotine-containing products.

Early signs and symptoms of nicotine toxicity are referable to nicotinic cholinergic excess; increased salivation, nausea, vomiting, diaphoresis, and diarrhea all occur within minutes of systemic absorption. Vasoconstriction manifests with pallor and hypertension. Tachycardia also occurs, and nicotine gum chewing is implicated in the development of atrial fibrillation in several cases.<sup>19,89</sup> Neurologic signs and symptoms include headache, dizziness, ataxia, confusion, and perceptual distortions. Nicotine is an irritant, and ingestion of nicotine, including use of nicotine gum, causes a burning sensation and pain in the mouth, and constriction of the pharyngeal muscles. Similarly, application of nicotine patches generally results in dermal irritation.

Vomiting is the most common adverse effect reported, although agitation also commonly occurs. The relative rarity of life-threatening symptoms is caused by part to autodecontamination from vomiting. In addition, because most reported cases involve unintentional tobacco ingestion by young children, there is significant selection bias.

Data from poison control centers in the United States suggests that the increased availability of e-cigarettes and liquid nicotine is associated with an increased incidence of consequential poisoning. Most liquid nicotine exposures occur in children younger than 5 years of age,<sup>102</sup> and children exposed to liquid nicotine have 2.6 times higher odds of having severe outcomes than children exposed to traditional cigarettes including one reported death.<sup>52</sup> This is likely caused by larger nicotine concentrations available in

TABLE 82–3 Signs and Symptoms of Acute Nicotine Poisoning

	Gastrointestinal	Respiratory	Cardiovascular	Neurologic
Early (0.25–1 h)	Nausea	Bronchorrhea	Hypertension	Agitation
	Vomiting	Hyperpnea	Tachycardia	Anxiety
	Salivation		Pallor	Dizziness
	Abdominal pain			Blurred vision
				Headache
				Hyperactivity
				Confusion
				Tremors
				Fasciculations
				Seizures
Late (0.5–4 h)	Diarrhea	Hypoventilation	Bradycardia	Lethargy
		Apnea	Hypotension	Weakness
			Dysrhythmias	Paralysis
			Shock	

liquid nicotine. Although less common, ingestion of novel smokeless tobacco preparations, such as gums and lozenges, is more likely to produce symptoms compared to cigarette ingestion because these are buffered to promote more rapid nicotine release.<sup>94</sup>

Because nicotine is rapidly metabolized, patients who develop only mild symptoms are expected to recover quickly. Most patients recover fully within 12 hours. An important exception to this rule is noted in patients with symptoms of nicotine toxicity after transdermal nicotine patch application because a reservoir of drug persists in the subcutaneous tissue after patch removal and can serve as a source of ongoing absorption. Removal of the patch and decontamination of these patients should remain paramount to limiting further absorption.

Clinical manifestations of severe poisoning are classically biphasic, reflecting early central stimulation followed by depression. Initial signs include cardiac dysrhythmias, seizures, and muscle fasciculations in addition to the cholinergic features described earlier. Bradycardia, hypotension, coma, and neuromuscular blockade with respiratory failure from muscular paralysis are a more delayed development (Table 82–3).

Exposure to fresh tobacco leaves produces GTS, which is likened to the experience of seasickness typically occurring within 3 to 17 hours after exposure. This syndrome, characterized by dizziness, headache, weakness, nausea, vomiting, diarrhea, abdominal cramps, chills, and in severe cases, signs of autonomic instability, often has a duration of several days.<sup>72</sup>

## DIAGNOSTIC TESTING

Determination of serum or urinary concentrations of nicotine or its metabolites is unlikely to be helpful in the management of the acutely poisoned patient. Measurement can be made for confirmation purposes using various chromatographic techniques. Cigarette smokers typically maintain serum nicotine concentrations around 30 to 50 ng/mL during the day but can achieve concentrations as high as 100 ng/mL.<sup>79</sup> Postmortem analyses of nicotine concentrations in blood after fatal acute toxicity range from 5.5 to 800 mg/L.<sup>24</sup>

The presence of measurable concentrations of nicotine or cotinine in biologic samples often reflects coincidental or chronic exposure and does not necessarily imply acute toxicity. Urinary cotinine has a longer detection window than nicotine and is often used to document exposure to nicotine containing products, including exposure to secondhand smoke, or to guide dosage adjustments in nicotine replacement therapy.<sup>7,61,79</sup> Conversely, the absence of cotinine in the urine is used to document abstinence from tobacco products.

## MANAGEMENT

Most patients with unintentional or low-dose nicotine exposures do not require medical treatment. Patients should be immediately referred for evaluation if they are symptomatic or have ingested any amount of nicotine- or neonicotinoid-containing liquid. Children who ingest one or more cigarettes or 3 or more cigarette butts should also be referred for evaluation without delay. Patients with mild or no symptoms can be observed for several hours and safely discharged home if there are no complicating circumstances such as significant comorbid cardiovascular illness or intent to self-harm.

Patients with dermal exposure to wet tobacco leaves or pesticides should be undressed completely and the skin washed thoroughly with soap and copious amounts of water. Medical staff charged with handling both clothing and patients before decontamination should wear personal protective gear and dispose of materials safely. Symptomatic patients should have any nicotine dermal patches removed immediately and the skin washed with soap and water.

Vomiting is the most commonly reported adverse effect in patients with acute nicotine toxicity and limits absorption in some cases. Induction of emesis because it is unlikely to be of added benefit and has the potential for harm. Orogastric lavage is reasonable in patients who present immediately after large intentional and potentially life-threatening ingestions of nicotine-containing products with the exception of liquid nicotine. Liquid nicotine formulations are more rapidly absorbed, making orogastric lavage less useful. Activated charcoal adsorbs nicotine and can reduce absorption, and therefore we recommend for consequential ingestions.

There is no specific antidote for nicotine toxicity. Treatment of acute nicotine toxicity is symptomatic and supportive. The first priority is to ensure airway protection and respiratory support. Atropine is used to treat symptoms associated with parasympathetic stimulation such as excess salivation, wheezing, or bradycardia. Endotracheal intubation is required for airway protection or to assist ventilation in severely poisoned patients. Seizures are treated with a benzodiazepine. Hypotension is treated with fluid boluses and infusion of 0.9% NaCl initially. Patients who fail to respond to volume infusion require treatment with a vasopressor such as norepinephrine. Dysrhythmias should be treated according to standard advanced cardiac life support protocols. Nicotine elimination is enhanced in acidic urine,<sup>9</sup> but the potential risks outweigh the benefits of this elimination strategy, so we recommend against this approach.

## SUMMARY

- The primary source of nicotine is tobacco made from the leaves of *Nicotiana* species, but chemically related tobacco substitutes and pesticides are becoming increasingly available.
- Nicotine is well absorbed after inhalation, mucosal, or dermal exposure. It is rapidly distributed to the brain where it activates nicotinic acetylcholinergic receptors, stimulates the reticular activating system, and facilitates neurotransmitter release.
- Metabolism via the hepatic cytochrome oxidase system produces pharmacologically inactive metabolites slowly excreted in urine. The half-life of nicotine in the body is about 1 to 4 hours, with more rapid clearance in individuals who are chronically exposed.
- Clinical manifestations of nicotine toxicity are those of nicotinic cholinergic excess, most commonly including vomiting and agitation. Severe poisoning causes seizures, cardiac dysrhythmias, hypotension, and neuromuscular blockade with respiratory failure from muscular paralysis.
- There are no antidotes for nicotine, and acute toxicity should be managed with symptom directed, supportive care.

## HISTORY AND EPIDEMIOLOGY

Phencyclidine (PCP) was discovered in 1926 but was not developed as a general anesthetic until the 1950s. At that time, the Parke Davis drug company was searching for an ideal intravenous (IV) anesthetic to rapidly achieve analgesia and anesthesia with minimal cardiovascular and respiratory depression.<sup>39</sup> Phencyclidine was marketed under the name Sernyl because it rendered an apparent state of serenity when administered to laboratory monkeys. Its human surgical use began in 1963, but it was rapidly discontinued when a 10% to 30% incidence of postoperative psychoses and dysphoria was documented over the subsequent 2-year period.<sup>88</sup> By 1967, the use of PCP was limited exclusively to veterinary medicine as a tranquilizer marketed under the name Sernylan.

Simultaneously, in the 1960s, PCP emerged as a street drug in San Francisco called “the PeaCe Pill.”<sup>74</sup> Numerous street names have since been given to PCP: on the West Coast, it was called “angel dust,” PCP, “crystal,” “crystal joints” (CJs); Chicago called it “THC” or “TAC”; the East Coast opted for “the sheets,” “Hog,” or “elephant tranquilizer.”<sup>137</sup> Ironically, PCP had limited popularity among drug users because of its dysphoric effects and unpredictable oral absorption.<sup>177</sup> However, with time, its use spread in a similar geographic pattern to that of marijuana and lysergic acid diethylamide (LSD), from the coastal United States to the Midwest region.<sup>74</sup>

Phencyclidine abuse became widespread during the 1970s.<sup>28,207</sup> The relatively easy and inexpensive synthesis coupled with the common marketing of PCP as LSD, mescaline, psilocybin, cocaine, amphetamine, or “synthetic THC” (tetrahydrocannabinol) added to its allure and consumption.<sup>137</sup> By the late 1970s, PCP abuse reached epidemic proportions.<sup>10</sup> The Drug Abuse Warning Network (DAWN) reported that the number of PCP-related emergencies and deaths had more than doubled from 1975 to 1977. In 1978, the National Institute of Drug Abuse reported that 13.9% of young adults (18–25 years old) had used PCP.<sup>56</sup> The manufacture of PCP was ultimately prohibited in 1978 when it was added to the list of federally controlled

substances. Classifying PCP as a Schedule II drug led to its decrease in availability and, consequently, a decrease in its use. Although the 1980s brought about a cocaine epidemic that eclipsed PCP, PCP has remained consistently available, primarily regionalized to large cities in the northeastern United States and in the Los Angeles area,<sup>112</sup> where PCP use continues to rise and fall with societal trends. Because many of the PCP congeners made during the manufacturing process were being abused in place of PCP, the Controlled Substance Act of 1986 made these derivatives illegal and established that the use of the precursor of PCP, piperidine, necessitated mandatory reporting. With this new law in place, those possessing similar but not identical illegal substances could be prosecuted. This led to a further decline in the popularity of PCP. Beginning in 1984, the overall use of PCP declined sharply, reaching a nadir in 1994.<sup>188,203</sup> However, during the 8 years that followed, there was a small resurgence in reported PCP use but never reaching the epidemic proportions of the 1970s. Peak reported use reached an annual prevalence rate of 2.6% in 1996 among 12th graders. The Drug Abuse Warning Network reported that the highest number of PCP-related emergencies occurred in Washington, DC; Philadelphia; Los Angeles; Chicago; and Newark.<sup>188,190,191</sup> Since 2003, the use of PCP has declined, and its prevalence has remained low. During these years, the National Survey on Drug Use and Health (NSDUH) reported that the annual prevalence rate of PCP use for 12th graders fluctuated between 0.7% and 1.4% with the latest report of 1.4% in 2015. Lifetime prevalence of PCP use was highest among adults aged 29 to 30 years (3.9%).<sup>113</sup>

Laboratory investigation of PCP derivatives led to the discovery of ketamine, a chloroketone analog. Ketamine was introduced for general clinical practice in 1970 and was marketed for humans as Ketalar and Ketaject and for veterinary use as Ketavet. Because ketamine has approximately 10% of the potency of PCP and has a much shorter duration of action, it provides greater control in clinical use.<sup>123,227</sup> Forty-five years of clinical experience has established that ketamine provides adequate surgical anesthesia, a rapid recovery, and less prominent emergence reactions than PCP.<sup>66,87,180,222</sup> Because of the simplicity and efficacy of its use, it is regularly used in operating rooms, emergency departments (EDs), and throughout the developing world, where little clinical monitoring is available during surgical and emergency procedures.<sup>60,86–89,181,221</sup>

Abuse of ketamine was first noted in urban areas on the West Coast in 1971.<sup>198</sup> During the 1980s, there were reports of its abuse internationally, including among physicians.<sup>6,76</sup> The nonmedical use of dissociative anesthetics has continued to increase throughout the 1990s and into the 2000s despite the common complications associated with their use.<sup>188,192</sup> Unfortunately, these same pharmacologic qualities that make ketamine more popular than PCP clinically are responsible for its nonmedical popularity. Ketamine is regularly consumed at all-night “rave parties” and in nightclubs because of its “hallucinatory” and “out-of-body” effects, relatively inexpensive price, and short duration of effect: a single insufflation lasts between 15 and 20 minutes.<sup>15,49,102,105,223</sup>

The use of ketamine is not limited to the inner city. In the past 2 decades, the media reported police arrests for possession and sale of ketamine in affluent suburban communities, which is coupled to more in-depth and frequent reporting of its toxicity among users.<sup>49,102,178,223</sup> By contrast to PCP, ketamine is not manufactured illegally; rather, it is diverted from legitimate medical, dental, and veterinary sources. Additionally, with the advent of the Internet in the 1990s, its availability has dangerously grown nationwide from diverted legal or illicit international pharmaceutical companies; a sham “biotech” Internet company was seized by New York City police in 2000 for selling so-called date-rape drugs, including ketamine.<sup>11</sup>

TABLE 83–1 Common Phencyclidine (PCP) and Ketamine Analogs

Name	Chemical Name	Other Name
<b>PCP Analogs</b>		
PCE	<i>N</i> -ethyl-1-phenylcyclohexylamine	Cyclohexamine
TCP	(1-(1-(Thiophen-2-yl)cyclohexyl)piperidine)	Tenocyclidine
PCPy	1-(1-Phenylcyclohexyl)pyrrolidine	Rolicyclidine, PHP
<b>Ketamine Analogs</b>		
3-MeO-2-oxo-PCE	2-(3-Methoxyphenyl)-2-(ethylamino)cyclohexanone	Methoxetamine
3-MeO-PCE	2-(3-Methoxyphenyl)-2-(ethylamino)cyclohexane	Methoxieticyclidine
2-MK	2-(2-Methylphenyl)-2-(methylamino)cyclohexanone	2-MeO-ketamine
N-EK	2-(2-Chlorophenyl)-2-(ethylamino)cyclohexanone	<i>N</i> -ethylnorketamine

Adverse reactions do occur, although there are few reports of fatalities secondary to ketamine, even during this period (1990s and 2000s) of increased use.<sup>80,125,131,156</sup> Because of its abuse potential, ketamine was placed in Schedule III of the Controlled Substance Act in 1999.<sup>180</sup> The Drug Abuse Warning Network reported that there was a more than 2,000% increase in ketamine-related ED visits between 1994 and 2001. Despite any clear reason, after peaking in 2001, there was a decline in ketamine-related ED visits in the United States in 2002.<sup>189,192</sup> The use of ketamine has remained very low since 2006 with an annual prevalence rate at or below 1.4% for high school students and 0.7% for young adults in 2015.<sup>113</sup> The 2011 Central Registry of Drug Abuse by the government of Hong Kong reported that ketamine remained the most common psychotropic substance used among youth since 2001. The Hong Kong Poison Information Centre reported that ketamine drug-related ED visits rose from 16% in 2005 to 40% in 2008.<sup>117</sup>

In the past decade, several other PCP and ketamine analogs (eg, arylcyclohexylamines) were manufactured for their psychoactive effects (Table 83–1). These designer drugs have been synthesized as a means of evading law enforcement. There are several reports of toxicity and fatalities from the ketamine analog methoxetamine, (2-{3-methoxyphenyl}-2-{ethylamino} cyclohexanone or 3-MeO-2-oxo-PCE) since its production in 2010 by an underground pharmaceutical chemist. It is advertised as having less renal and hepatic adverse effects than ketamine. Toxicity and fatalities from methoxetamine are reported throughout Europe and Asia (Hong Kong, Taiwan, Korea, and Japan).<sup>4</sup> In the United States, its abuse was first reported in 2011; however, its prevalence is unknown.<sup>55</sup> The ban of arylcyclohexylamines in the United Kingdom in 2013 led to the use diarylethylamines as the next class of dissociatives to be abused.<sup>163</sup>

## PHARMACOLOGY

### Chemistry

The chemical name of PCP, 1-(1-phenylcyclohexyl)piperidine, provided the basis for its street acronym PCP. During its unlawful chemical synthesis, numerous analogs are made that have similar effects on the central nervous system (CNS) and are used as PCP substitutes. These “designer” arylcyclohexylamines are aliphatic- or aromatic-substituted amines, ketones, or halides and appear similar to the parent compound. More than 60 psychoactive analogs are known. These initial PCP analogs used piperidine as the synthetic precursor. They most likely resulted from a poor manufacturing process of legitimate research using piperidine as a synthetic precursor.<sup>197</sup> The most commonly available derivatives on the street as a white powder indistinguishable from PCP were TCP (1-(1-(Thiophen-2-yl)cyclohexyl)piperidine), PCE *N*-ethyl-1-phenylcyclohexylamine, and PCPy 1-(1-phenylcyclohexyl)pyrrolidine.<sup>197</sup> Phencyclidine, PCE, and PCPy are classified as Schedule I drugs, and the analog PCC is classified as a Schedule II drug.

Ketamine and tiletamine, two legal analogs of PCP, are used clinically for sedation and anesthesia. In larger quantities, both are also used in veterinary medicine for animal sedation. Tiletamine, in combination with zolazepam (Telazol), is commonly used for animal procedures in veterinary medicine. Ketamine is the only dissociative anesthetic product manufactured for human use for the purposes of anesthesia, conscious sedation, and the treatment of bronchospasm. The development of a mechanistic approach to pain therapy in the past 30 years has brought a renewed interest in the use of ketamine as an adjuvant to multimodal pain treatment. Ketamine is used therapeutically in children and adults in the management of postoperative pain. For the treatment of pain, ketamine is administered intravenously (median dose, 0.4 mg/kg; range, 0.1–1.6), orally, intramuscularly, rectally, subcutaneously, intraarticularly, caudally, epidurally, transdermally, or intranasally or added to a patient-controlled analgesia device.<sup>69,90,98,119,184</sup>

In the past 15 years, clinical studies support the rapid antidepressant effect of ketamine. Subanesthetic doses of 0.25 mg/kg to 0.5 mg/kg administered intravenously for 40 to 60 minutes to patients with refractory major depressive disorder provide a 25% to 85% antidepressant response lasting 3 to 7 days postinfusion. Positive results are also encountered in patients with bipolar depression, anxious depression, depression not responsive to electroconvulsive therapy, and posttraumatic stress disorder. The use of repeated infusions is also under investigation to measure the extended antidepressant effects of ketamine.<sup>3</sup> Although these studies report only transient neurocognitive and psychotomimetic effects with ketamine infusions, the dosing, maintenance of response, mode of delivery, and risk-to-benefit ratio of treatment sustainability are under investigation.<sup>1</sup>

The molecular structure of ketamine (2-{ortho-chlorophenyl}-2-methylaminocyclohexanone) contains a chiral center, producing a racemic mixture of 2 resolvable optical isomers or enantiomers, the S(+)-isomer and R(–)-isomer. Commercially available preparations of ketamine contain equal concentrations of the 2 enantiomers. These 2 molecules differ in their pharmacodynamic effects. In a randomized, double-blind evaluation of patients undergoing surgery, the S(+)-isomer of ketamine was a more effective anesthetic but manifested a higher incidence of psychotic emergence reactions than the R(–)-isomer. In other studies, the S(+)-isomer caused a greater increase in both blood pressure and pulse than the R(–)-isomer and had more bronchodilatory effects.<sup>181,222</sup> The R(–) ketamine enantiomers produce longer lasting antidepressant effects than the S(+) enantiomers.<sup>234</sup>

Ketamine analogs are “designer” dissociatives made by clandestine chemists. These new arylcyclohexylamides belong to the subclassification anisylcyclohexylamine and are more difficult to synthesize than the initial PCP analogs. Methoxetamine is a derivative of ketamine that is suggested to have a decreased anesthetic effect because of its 3-methoxy group. The addition of an ethyl group to its cyclic ring is thought to diminish urologic toxicity. However, because it is not a legally manufactured pharmaceutical, the only human experience is derived from its nonmedical reports. Less reported anisylcyclohexylamines are 3-MeO-PCE (2-(3-methoxyphenyl)-2-{ethylamino}cyclohexane), 2-MK (2-MeO-deschloroketamine), and N-EK (*N*-ethylnorketamine). Diphenidine (1-{1,2-diphenethyl}piperidine) and 2-Me-O-diphenidine (1-{1-(2-methoxyphenyl)-2-phenylethyl}piperidine) are examples of diarylethylamines that have *N*-methyl-D-aspartate (NMDA) activity used in research.<sup>163</sup>

### Pharmacokinetics and Toxicokinetics

Phencyclidine is a white, stable solid that is readily soluble in both water and ethanol. It is a weak base with a  $pK_a$  between 8.6 and 9.4 with a high lipid-to-water-partition coefficient ( $\log D = 3.63$ ). It is rapidly absorbed from the respiratory and the gastrointestinal (GI) tracts; as such, it is typically self-administered by the oral, nasal, inhalational, IV, or subcutaneous routes.

The effects of PCP are dependent on routes of delivery and dose. Its onset of action is most rapid from the IV and inhalational routes (2–5 minutes) and slowest (30–60 minutes) after GI absorption.<sup>47,48</sup> Sedation is commonly produced by doses of 0.25 mg intravenously; ingestion typically requires 1 to 5 mg to produce similar sedation. Signs and symptoms of toxicity usually last

4 to 6 hours, and large overdoses generally resolve within 24 to 48 hours, but effects persist in chronic users.<sup>20,62,65,136,161,177</sup> However, in PCP-toxic patients, the relationships between dose, clinical effects, and serum concentrations are neither reliable nor predictable.

There are several explanations for the protracted CNS effects of PCP. The large volume of distribution of 6.2 L/kg<sup>47,230</sup> and high lipid solubility account for its entry and storage in adipose and brain tissue. Also, on reaching the acidic cerebrospinal fluid (CSF), PCP becomes ionized, producing CSF concentrations approximately 6 to 9 times greater than those of serum.<sup>153</sup>

Phencyclidine undergoes first-order elimination over a wide range of doses. It has an apparent terminal elimination half-life of  $21 \pm 3$  hours under both control and overdose settings.<sup>47</sup> Ninety percent of PCP is metabolized in the liver and 10% is excreted in the urine unchanged. Phencyclidine undergoes hepatic oxidative hydroxylation into 2 monohydroxylated and one dihydroxylated metabolites.<sup>48</sup> All 3 compounds are subsequently conjugated to form the more water-soluble glucuronide derivatives and then excreted in the urine. A variety of isoforms of CYP3A and CYP2B are involved in the metabolism of PCP. Hydroxylation at the piperidine ring is carried out by CYP1A and at the cyclohexyl ring by CYP3A.<sup>130</sup> Thiol adducts of PCP inactivate CYP2B6 in a mechanism-based manner.<sup>115</sup>

Urine pH is an important determinant of renal elimination of PCP. In acidic urine, PCP becomes ionized and then cannot be reabsorbed. Acidification of the urine increased renal clearance of PCP from  $1.98 \pm 0.48$  L/h to  $2.4 \pm 0.78$  L/h.<sup>47</sup> If the urine pH is decreased to less than 5.0, even higher renal clearance ( $8.04 \pm 1.56$  L/h) was noted.<sup>14</sup> Although this accounts for a 23% increase in the renal clearance, it only represents a 1.1% increase of the total clearance, and therefore we recommend against acidification. Additionally, in an agitated patient with rhabdomyolysis, acidification of the urine will worsen myoglobin clearance and therefore kidney function.

Ketamine is water soluble (log P 2.6) and has a high lipid solubility (log D = 2.01) that enables it to distribute to the CNS readily.<sup>45</sup> It has a  $pK_a$  of 7.5 and a volume of distribution of  $1.8 \pm 0.7$  L/kg. Ketamine has approximately 10% of the potency of PCP.<sup>87,106</sup> Human trials demonstrate that similar to PCP, the clinical effects of ketamine are both route and dose dependent.<sup>51,54,66,204</sup> Peak blood concentrations occur within 1 minute of IV administration and within 5 minutes of a 5-mg/kg intramuscular (IM) injection.<sup>222,235</sup> Ketamine distributes rapidly into the CNS with the duration of its hypnotic and anesthetic effects extended by its slow redistribution from the brain to other tissues.<sup>222</sup> Recovery time averages 15 minutes for IV administration but is 30 and 120 minutes after IM administration. Oral and rectal doses are not well absorbed and undergo substantial first-pass metabolism.<sup>181,222</sup> In contrast to oral administration of ketamine in which clinical effects persist for 4 to 8 hours, after nasal administration, they last for 45 to 90 minutes.

Ketamine is extensively metabolized in the liver by CYP2B6 and to a lesser extent by CYP3A4 and CYP2C9.<sup>232</sup> Its biotransformation is complex with numerous metabolites described.<sup>5,181,222</sup> The major pathway involves its *N*-demethylation to norketamine, a metabolite with one-third the anesthetic potency of ketamine. Norketamine is hydroxylated at different sites within its hexanone ring, producing varying second chiral centers. The majority of these diastereoisomers are glucuronidated to more water-soluble derivatives that are then excreted in the urine.<sup>87,181</sup> Ketamine also undergoes ring hydroxylation before *N*-demethylation as a minor metabolic pathway. The elimination half-life, which reflects both metabolic and excretory phases, is  $2.3 \pm 0.5$  hours and is prolonged when xenobiotics requiring hepatic metabolism are coadministered.<sup>133</sup> Because of the enzymatic metabolism, both tolerance and enzyme induction are reported after chronic administration.<sup>87,181</sup>

Methoxetamine is a white solid demonstrating aqueous and lipid solubility. Pharmacokinetic data for methoxetamine are obtained from in vivo animal studies and from in vitro studies with human hepatocytes and microsomes. The major metabolic pathway of methoxetamine is *N*-deethylation by cytochromes CYP2B6 and CYP3A4 into normethoxetamine. Minor pathways include *O*-demethylation (CYP2B6, and CYP2C19), hydroxylation (CYP2B6) and reduction reactions into the respective

metabolites *O*-desmethyloxetamine, hydroxymethoxetamine, and dihydromethoxetamine. Urine analysis from patients with methoxetamine toxicity confirm these metabolites.<sup>151</sup>

### Available Forms

Phencyclidine is available illicitly in a variety of forms, including powder, liquid, tablets, leaf mixtures, and rock crystal. Because of its uncontrolled illegal manufacture, the contents of products sold as PCP vary considerably, with powder often the purest form. A typical dose consumed contains approximately 5 mg.<sup>175</sup> Leaf mixtures are made by sprinkling approximately 1 to 10 mg of PCP onto parsley, oregano, mint, tobacco, or marijuana. A PCP joint (known as “crystal joint,” “KJ,” or “supergrass”) is developed for smoking and contains about 1 mg of PCP/150 mg of plant product.<sup>9</sup> Mentholated cigarettes dipped into liquid PCP are known as “supercools.”

Phencyclidine is included in the federal Controlled Substance Act of 1970, reducing its availability for incorporation into marijuana cigarettes. There are reports of marijuana cigarettes being adulterated with PCP and sold on the street under varying names such as “Illy” in Connecticut, “Hydro” in New York City, “Dip” in New Jersey, “Wet” in Philadelphia, and “Fry” in Texas.<sup>100</sup>

The cigarettes are purportedly treated with “embalming fluid,” which allegedly enhances the euphoric effects of the drug. Rather, the embalming fluid or another organic solvent is used as a medium to allow a uniform distribution of PCP in these cigarettes.<sup>100</sup> Furthermore, the organic solvent is thought to be the remnant of the organic solvent used in the synthesis of PCP or one of its analogs. In either case, the ability to smoke the cigarette before drying after dipping in the solvent-PCP (nonaqueous) mixture accounts for some of its various names (eg, wet hydro). In most cases, this “enhanced” mixture appears to be purchased intentionally rather than having the PCP placed in these cigarettes surreptitiously.

On the street and on the Internet, ketamine is known as “vitamin K,” “Special K,” “Super K,” “Ket,” or simply “K.” It is available in a liquid form that is dried into a pure-white crystalline powder and is typically self-administered by ingestion or insufflation in a fashion similar to PCP. It is rarely injected IV or IM in aqueous form.

When used by injection, there is an observed demographic and behavioral difference among those who initiate drug injection use with ketamine and those who initiate injection use with another xenobiotic and later transition into ketamine injection.<sup>128</sup> The majority of individuals whose initial injection drug use was ketamine administered it intramuscularly. These individuals almost solely used the liquid form. Those who initiated injection drug use with drugs other than ketamine did so intravenously.

Ketamine is primarily sold as tablets, capsules, or powder. These formulations are often adulterated with caffeine, methylenedioxymethamphetamine (MDMA), ephedrine, methamphetamine, heroin, and cocaine (a mixture known as CK or Calvin Klein).<sup>63,185</sup> In fact, in addition to ethanol, MDMA (39%), heroin (17%), and cocaine (14%) are the most frequently mentioned xenobiotics used with ketamine.<sup>211</sup> Exemplifying the commercial growth of ketamine, some of the tablets are even found to contain a “K” logo.<sup>63</sup> Common sedating doses are 75 to 300 mg orally (30–75 mg for insufflation). Higher doses, ranging between 300 and 450 mg orally (100–250 mg for insufflation), result in substantial CNS toxicity. These manifestations are similar to the clinical “emergence reactions” that patients experience after ketamine anesthesia.

New designer dissociatives (methoxetamine, 2-MK and N-EK) are currently sold through the Internet internationally as powders that are ingested, insufflated, or injected. Methoxetamine is used extensively in the United Kingdom and is referred to by various names, including MXE, M-ket, Kmax, Mexxy, Special-M, MEX, legal ketamine, and Minx. Case reports indicate that the clinical symptoms of patients with methoxetamine toxicity are similar to those reported from ketamine.<sup>55,99,218,229</sup> After the ban on arylcyclohexylamines in 2012 in the United Kingdom, the beige crystalline solid, 2-MK, and the white powder, N-EK, became available online in many countries where they are unscheduled.<sup>163</sup>

## PATHOPHYSIOLOGY

The arylcyclohexylamines, are a group of anesthetics that functionally and electrophysiologically “dissociate” the somatosensory cortex from higher centers.<sup>51,221</sup> The precise mechanisms by which they achieve these effects are complex and not fully understood; however, investigation of the nature of PCP-induced psychosis has led to a substantial identification of the various sites of PCP activity.

Most studies demonstrate that arylcyclohexylamines bind with high affinity to sites located in the cortex and limbic structures of the brain.<sup>140</sup> They block the NMDA receptors at serum concentrations encountered clinically.<sup>215,236</sup> Analogs of PCP (TCP, PCE, PHP, ketamine) and the most potent, dizocilpine (MK-801), also interact with the NMDA receptors in a dose–response manner that corresponds with their neurobehavioral effect.<sup>29,187,194,224</sup> Binding to the NMDA receptor occurs at a site independent of glutamate.<sup>106,111,140,187,226</sup> This site is located within the ionotropic channel, partially overlapping the Mg<sup>2+</sup> binding site, and it is often termed the PCP binding site. As such, they antagonize the action of glutamate on this channel and noncompetitively block Ca<sup>2+</sup> influx (Fig. 13–14).

Arylcyclohexylamines also bind to the biogenic amine reuptake complex but with 10% to 20% of the affinity to which they bind to the NMDA receptor. Binding occurs at physiologic concentrations that normally take place after subanesthetic doses.<sup>7,171</sup> This weak inhibition of the catecholamine reuptake accounts for the respective sympathomimetic and psychomotor effects. An increase in blood pressure and heart rate is induced. Rapid IV infusion produces a more pronounced effect than by IM injection, with the S(+)-isomer having a greater effect than the R(–)-isomer.<sup>222</sup>

In large overdoses, arylcyclohexylamines also stimulate  $\sigma$  receptors at concentrations generally associated with coma, although with lower affinity than NMDA receptors.<sup>205,225</sup> Both D<sub>2</sub> and  $\sigma$  receptors have an inhibitory effect on the cholinergic receptor pathways.<sup>225</sup> At the higher concentrations, typically associated with death, arylcyclohexylamines bind to the nicotinic, opioid, and muscarinic cholinergic receptors.<sup>214</sup>

N-methyl-D-aspartate receptor antagonists produce effects on behavior, sensation, and cognition that resemble aspects of endogenous psychoses, particularly schizophrenia.<sup>107,168</sup> These behavioral abnormalities were first observed in studies in the late 1950s when PCP, administered to healthy volunteers, generated an organic psychosis that mimicked schizophrenia. When PCP was administered to patients with schizophrenia, it uniformly intensified their primary symptoms of profound disorganization, and some of these symptoms lasted for weeks.<sup>136</sup> Phencyclidine psychosis has such similarity clinically to schizophrenia that many psychiatrists cannot distinguish the entities without a prior indication of drug abuse history.<sup>203</sup> The multireceptor action of PCP and its link to schizophrenia are made more intriguing because various antipsychotics (eg, phenothiazines, thioxanthenes, and butyrophenones) are also  $\sigma$  agonists.<sup>83</sup>

Current interest in the role of excitatory neurotransmitter systems in the pathophysiology of schizophrenia produced similar observations in patients after ketamine administration. Subanesthetic doses of ketamine administered to both healthy and schizophrenic volunteers induced a mild, dose-related, short-lasting increase in psychotic symptoms. Although the normal and schizophrenic volunteers had different levels of baseline psychosis, the magnitude, time course, and dose–response changes in positive symptoms were similar between the 2 populations. Both groups experienced thought disorganization, such as concreteness and loose association, hallucinations, and delusions of varying intensity.<sup>123,125-127</sup>

There is a connection between PCP psychosis and sensory processing. Arylcyclohexylamines inhibit sensory perception in a dose-dependent manner. This processing in sensory information corresponds to their relative affinities to the NMDA receptor and not to the  $\sigma$  receptor.<sup>9,171</sup> Clinically, the impairment of sensory input produced by PCP resembles that of patients who are deprived of sensory stimulation.<sup>147</sup> When external stimulation was reduced by environmental sensory deprivation, the psychotomimetic effects of PCP were diminished,<sup>44</sup> giving credence to the theory that it is not anxiety that causes perceptual dysfunction in schizophrenia but the converse.

Many of the NMDA receptor antagonists have a negative effect on cognition and memory. Repeated administration of arylcyclohexylamines in many animal models results in cognitive and memory impairment.<sup>95,109</sup> They impair concentration, recall, learning, and retention of new information.<sup>18,32,59,62,81,94-96,123,144,155,165</sup> In human volunteers, ketamine selectively impairs explicit,<sup>80</sup> episodic,<sup>58,158</sup> and procedural memory<sup>158</sup> and disrupts frontal cortical function, as measured by the Wisconsin Card Sorting Task and verbal fluency,<sup>123,144</sup> in a dose-dependent manner. Learning and memory impairment in volunteers who were administered subanesthetic doses of ketamine (0.65 mg/kg) are independent of the subject’s attention and related psychosis.<sup>144</sup> Testing performed on chronic ketamine users produces similar results that are long lasting and have more marked effects on semantic and episodic memory.<sup>58,60,159,160</sup> Accordingly, it is presumed that the acute and repeated NMDA receptor antagonism interferes with the functions that integrate interoceptive and exteroceptive input in which goal-directed action becomes possible, similar to the organic psychosis in schizophrenia. Because the rapid antidepressant effects have the potential for either continuous or repeated dosing, current research will of necessity address the long-term adverse effects.

Hypofunction of the NMDA receptor causes neuroanatomical and neurobehavioral effects. Animals exposed to NMDA antagonists such as PCP and dizocilpine transiently demonstrated neuronal vacuolar degeneration in the retrosplenial cortex and the posterior cingulate areas of the brain.<sup>166,167</sup> The major function of cingulate cortical neurons is to mediate affective responses to pain.<sup>216</sup> Single high doses (PCP, 18 mg/kg; ketamine, 40 mg/kg; tiletamine, 20 mg/kg) or repeated exposures to NMDA receptor antagonists are associated with a higher incidence of cellular death.<sup>50,70,71,166</sup> This injury seems to be related to the induction of selective expression of individual heat shock proteins in this anatomical area.<sup>195</sup> Such results raise concern over the use of ketamine for procedural sedation. However, several converging factors indicate its safety in humans. Doses used in animal studies are much higher than those used clinically. When higher doses are used clinically (ie, anesthesia), the sedating effects of ketamine occur as  $\gamma$ -aminobutyric acid (GABA) and  $\sigma$  receptors are activated, decreasing excitation. Also, human elimination kinetics of ketamine differ from those in animal studies. Excitatory amino acids are neurotransmitters responsible for mediating seizure activity in the brain. As NMDA inhibitors, the anticonvulsant properties of the arylcyclohexylamines are inconclusive. Animals administered PCP or PCP analogs progress through dose-related clonic activity followed by tonic-clonic convulsions, as is typical of classic convulsants.<sup>171</sup> Animal research also demonstrates wide interspecies variability of the electroencephalographic (EEG) effects of PCP.<sup>65</sup> In a murine seizure model, ketamine possessed selective anticonvulsant properties.<sup>33</sup> In addition, ketamine preserves learning proficiency in rats when administered shortly after onset of status epilepticus, an effect that is useful in the clinical setting when combined with conventional antiepileptics.<sup>206</sup>

In humans, although these dissociatives induce excitatory activity in the thalamus and limbic areas, they do not affect cortical regions.<sup>53,54,66,77</sup> Excitation, muscle twitching, posturing,<sup>154</sup> and tonic-clonic motor activity with or without EEG changes are reported with these subcortical EEG alterations.<sup>36,52,77,154</sup> In the clinical setting, many report ketamine to possess antiepileptic properties at clinically relevant doses that may be explained by an NMDA inhibitory effect.<sup>36,52</sup> This effect was used to treat patients with refractory status epilepticus in the critical care setting.<sup>210</sup>

The NMDA receptor is also responsible for the development of the neuronal organization of the CNS.<sup>103,199,200</sup> It is linked to hypoxic–ischemic brain injury by mediating calcium influx, a final pathway in cell death. The uninhibited firing of NMDA afferent neurons secondary to brain injury causes their death, as well as the death of efferent neurons downstream. In neonatal rats, ketamine increases the rate of neuronal apoptosis.<sup>194</sup> N-methyl D-aspartate receptor antagonists such as PCP block hypoxic brain injury from stroke and trauma.<sup>21,135</sup> In a rat model of ischemic stroke, PCP had a protective effect on the brain, demonstrated by a decreased rate of seizure activity.<sup>21</sup> This effect is transient and has not been studied in humans.

Neuronal development, plasticity, and connectivity are modulated by NMDA receptors. The phenotypic outcome of receptor malfunction is indicated by genetics, the extent and duration of malfunction (ie, from xenobiotic toxicity or illness), and neuroanatomical location (pre- and postsynaptic neuronal interactions or both). Polymorphisms of GRIN2B (encoding NMDA receptor's GluN2B subunit) are associated with schizophrenia. Animal studies using high doses of an NMDA receptor antagonist resulted in deleterious neuronal effects.<sup>70,71,166</sup> Postmortem and in vivo structural neuroimaging studies in patients with schizophrenia demonstrate a decreased number of dendritic spines, decreased axon dendrite arborization, reduced neuropil volume, and disarray of neuronal orientation in the cortex. It is thought that NMDA receptor hypofunction in mesolimbic areas of these patients leads to an excitatory feedback in the prefrontal cortex via GABAergic interneurons. This disrupted mesocorticolimbic connectivity underlies the cognitive and psychotomimetic impairment of this disease.<sup>121</sup> Stress and major depressive disorders also produce continuous glutaminergic states that cause neuronal atrophy, dendritic retraction, decreased spine density, reduced dendritic arborization, and synaptic strength in the prefrontal cortex. Treatment of depression with low dose ketamine is based on the premise that by blocking presynaptic disinhibition of glutamatergic neurons, a glutamate surge occurs that through a cascade of cellular events (involving postsynaptic  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA] receptors, extrasynaptic NMDA receptors and brain-derived neurotrophic factors [BDNF], and mammalian target of rapamycin [mTORC1]) restore prefrontal connectivity.<sup>3</sup>

## CLINICAL MANIFESTATIONS

The reported signs and symptoms of arylcyclohexylamine toxicity are variable. The variations are a result of differences in dosage, the multiple routes of administration, concomitant xenobiotic use, and other associated medical conditions. In accordance with their pharmacologic effect, arylcyclohexylamine toxicity is relatively similar producing signs and symptoms consistent with PCP but differing in potency and duration of action. Additionally, individual differences in xenobiotic susceptibility, the development of tolerance in chronic users, and contaminants in the drug manufacture account for erratic clinical findings.

### Vital Signs

Body temperature is rarely affected directly by arylcyclohexylamines. In one large series of patients with PCP toxicity, only 2.6% demonstrated hyperthermia, defined as a temperature greater than 101.8°F (38.8°C).<sup>148</sup> In an experimental animal model, PCP failed to increase body temperature.<sup>38,65</sup> When hyperthermia does occur from agitation, all the known complications, including encephalopathy, rhabdomyolysis, myoglobinuria, acute kidney injury, electrolyte abnormalities, and liver failure, occur (Chap. 29).<sup>12,22,43,173</sup>

Most arylcyclohexylamine-toxic patients demonstrate mild sympathomimetic effects secondary to their monoamine reuptake inhibition.<sup>138,139,181</sup> Phencyclidine consistently increases both the systolic blood pressure (SBP) and diastolic blood pressure (DBP) in a dose-dependent fashion.<sup>38,65</sup> Doses of 0.06 mg/kg of IV PCP increased the SBP and DBP by 8 mm Hg, and 0.25 mg/kg produce a 26 and 19 mm Hg increase in SBP and DBP, respectively. Phencyclidine also inconsistently increases the heart rate.<sup>92</sup> Ketamine also produces mild increases in blood pressure, heart rate, and cardiac output via this same mechanism.<sup>54,139,204,212,222</sup> In fact, tachycardia was the most common finding on physical examination in a case series of ketamine users presenting to the ED.<sup>220</sup>

### Cardiopulmonary

Cardiovascular catastrophes are rarely encountered in patients with PCP toxicity.<sup>68,149</sup> These complications result from direct vasospasm,<sup>8,37</sup> causing severe systemic hypertension, pulmonary edema, hypertensive encephalopathy,<sup>69</sup> and cerebral hemorrhage.<sup>25</sup> Hypertension, along with abnormal behavior, miosis, and nystagmus in children, strongly suggest toxicity caused by a dissociative anesthetic.<sup>116</sup>

The effect of PCP and ketamine on cardiac rhythm is controversial. Dysrhythmias are only observed in animals poisoned with very large doses of PCP. Ketamine both enhances and diminishes epinephrine-induced dysrhythmias in animals.<sup>24,67,93,118</sup> The considerable experience in the use of ketamine anesthesia on humans undergoing surgery or cardiac catheterization has not demonstrated prodysrhythmic effects.<sup>73,162</sup>

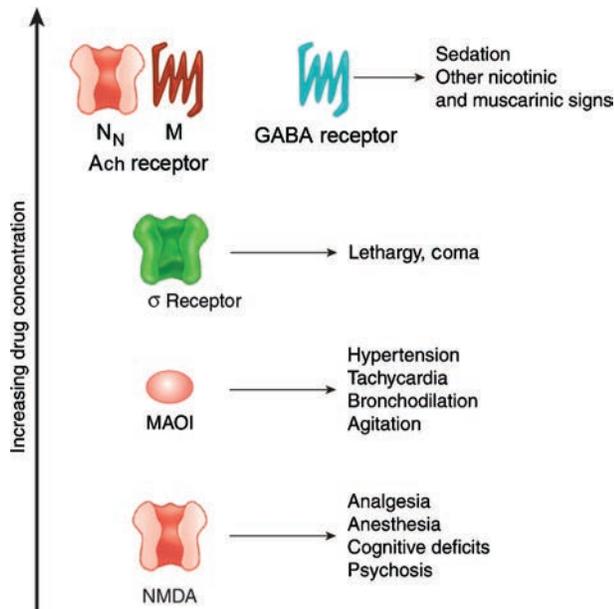

Because these dissociative anesthetics were designed to retain normal ventilation, hypoventilation is uncommon. In clinical studies, PCP increased the minute ventilation, tidal volume, and respiratory rate of volunteers.<sup>92</sup> Clinically, in PCP-toxic patients, irregular respiratory patterns occur with tachypnea much more often than with bradypnea.<sup>12,148</sup> Hypoventilation, when present, is usually secondary to the use of particularly high doses of PCP. Pulmonary edema secondary to respiratory depression is also a rare occurrence but was reported postmortem.<sup>68</sup> Large doses of PCP (20 mg/kg) administered to laboratory animals produced respiratory depression.<sup>38</sup> Although respiratory depression in humans is an uncommon event, it is reported with fast or high-dose infusions of ketamine.<sup>85,222</sup> A total of 8.3% of patients in whom ketamine was used for sedation in EDs needed to be intubated.<sup>182</sup> In fact, ketamine is successfully used to prevent intubation in patients with refractory asthma. Ketamine relaxes bronchial smooth muscles, decreases mean airway pressure and PaCO<sub>2</sub>, and increases PaO<sub>2</sub>.<sup>79,183,209,222</sup>

## Neuropsychiatric

Most patients with arylcyclohexylamine toxicity who are brought to medical attention manifest diverse psychomotor abnormalities.<sup>16,22,30,76,109,220</sup> These xenobiotics impair responses to external stimuli by separating various elements of the mind. Consciousness, memory, perception, and motor activity appear dissociated from each other. This dissociation prevents the user from attaining cognition and properly assembling all information to construct “reality.” Clinically, the person appears inebriated, either calm or agitated, and sometimes violent. In patients with large overdose, the anesthetic effect causes patients to develop stupor or coma. In recreational use, “dissociatives” are not taken for these effects but rather for out-of-body experiences. In addition, patients often have disordered thought processes (including disorientation as to time, place, and person) or amnesia, paranoia, and dysphoria.<sup>75</sup>

These manifestations of arylcyclohexylamine toxicity are better illustrated by the results of their effects in controlled human studies. Volunteers who took oral doses of up to 7.5 mg/d of PCP or 0.1 mg/kg of ketamine exhibited clinical toxicity, but higher doses (PCP >10 mg/d; ketamine 0.5 mg/kg) generally caused a more severe impairment of mental function.<sup>65,123</sup> Intravenous doses of 0.1 mg/kg of PCP<sup>20,62,79,136,161,186</sup> or 0.5 mg/kg of ketamine<sup>123,171</sup> diminish all sensory modalities (pain, touch, proprioception, hearing, taste, and visual acuity) in a dose-dependent fashion. Both xenobiotics also cause feelings of apathy, depersonalization, hostility, isolation, and alterations in body image.<sup>20,62,78,110,143,160</sup> The deficits in sensory modalities are evident before the development of the psychological effects of PCP, with pain perception disappearing first. This alteration in analgesic perception is caused by a blocking action on the thalamus and midbrain (Fig. 83-1).<sup>161</sup>

Abnormal stereognosis and proprioception occur in a dose-dependent manner. This disturbed perception results in body image distortions described as “numbness,” “sheer nothingness,” and “depersonalization.” The decrease of proprioceptive sensation to gravity probably gives the sensation of “tripping” or “flying.” Because all sensory modalities are affected, visual, auditory, and tactile illusions and delusions are common. This lack of stimuli from the surrounding environment is responsible for the “near-death experience” or the “near-birth experience” patients describe as their awareness wanes. Hallucinations are typically auditory rather than visual, which are more common with LSD use. The hallucinogenic effects of ketamine on healthy human volunteers are linearly related to steady-state concentrations between 50 and 200 ng/mL.<sup>26</sup> Ketamine users report experiencing a “k-hole” (“m-hole” in methoxetamine), a slang term for the intense psychological and somatic state experienced while under the influence of ketamine. This experience varies with the individual but can include buzzing, ringing,

**FIGURE 83-1.** Clinical effects of the arylcyclohexylamines. The arylcyclohexylamines bind to different receptors in the central nervous system with varying degrees of affinity; that is, an increasing concentration is necessary to achieve the various clinical effects. ACh = acetylcholine; GABA =  $\gamma$ -aminobutyric acid; MAOI = monoamine oxidase inhibitor;  $N_N$  = nicotinic receptor; M = muscarinic receptor; NMDA = *N*-methyl-D-aspartate.

or whistling sounds; traveling through a dark tunnel; intense visions; and out-of-body or near-death sensations.<sup>64,196</sup>

The reaction to the misperceived or disconnected reality results in unintentional actions and violent behavior. The hallmark of PCP toxicity is the recurring delusion of superhuman strength and invulnerability resulting from both its anesthetic and dissociative properties. There are case reports of patients presenting with trauma from jumping from significant heights, fighting large crowds or the police, or self-mutilation. The true extent and incidence of violence is probably less than previously suggested.<sup>27</sup> These feelings of unreality and sedation are encountered in the clinical setting more commonly when low-dose ketamine is administered as an IV push as opposed to a low-dose infusion.<sup>164</sup>

Typical neurologic signs include horizontal, vertical, or rotatory nystagmus; ataxia; and altered gait. Initially, except for ataxia, movement is not impaired until the patient becomes unconscious. On physical examination, use of dissociative anesthetics typically produces relatively small pupils, nystagmus, and diplopia. In the largest case series reported to date, nystagmus and hypertension were noted in 57% of patients who had taken PCP.<sup>148</sup> Smaller and more limited studies found an incidence of nystagmus of 89% or higher.<sup>22</sup> In comparison, nystagmus was only found in 15% of patients with ketamine abuse.<sup>220</sup> Other cerebellar manifestations were also encountered, most notably dizziness, ataxia, dysarthria, and nausea. A pooled data compilation of 35 reports demonstrated that emesis occurred 8.5% of the time.<sup>85</sup> In fact, Internet chat groups devoted to substance abuse commonly direct users to “mix dissociatives with marijuana” for its antiemetic effect.

Larger doses of PCP produce loss of balance and confusion, the latter characterized by inability to repeat a set of objects, frequent loss of ideas, blocking, lack of concreteness, and disordered linguistic expression.<sup>43,58,123,136,186</sup> Similarly, ketamine users report a high incidence of incoordination, confusion, unusual thought content, and an inability to speak.<sup>64</sup> In general, dissociative anesthetics stimulate the CNS, but seizures rarely occur, except at high doses. The largest case series of PCP-toxic patients reported a 3.1% incidence of seizures.<sup>148</sup>

Although arylcyclohexylamine toxic patients also present with motor disturbances, it is unclear to what extent these dissociative drugs are actually responsible for these manifestations. The most common of the reported

disturbances are dystonic reactions: opisthotonos, torticollis, tortipelvis, and risus sardonicus (facial grimacing). Myoclonic movements, tremor, hyperactivity, athetosis, stereotypies, and catalepsy also occur.<sup>16,31,76,148</sup> A slight increase in muscle tone results from a dopaminergic effect.<sup>136</sup> Laryngospasm requiring intubation is reported after the use of ketamine anesthesia. The incidence of this complication is less than 0.017%.<sup>87</sup> In comparison, the incidence of laryngospasm after traditional general anesthesia is 2%.<sup>169</sup>

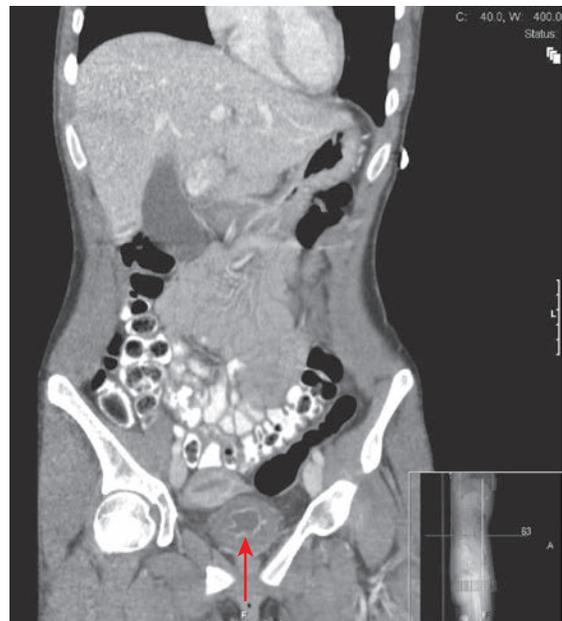

### Cholinergic and Anticholinergic Effects

Both cholinergic and anticholinergic clinical manifestations occur in patients manifesting arylcyclohexylamine toxicity. Miosis or mydriasis, blurred vision, profuse diaphoresis, hypersalivation, bronchospasm, bronchorrhea, and urinary retention are reported.<sup>16,22,132,147,148</sup> Ketamine stimulates salivary and tracheobronchial secretions, both of which are equally and effectively inhibited by atropine and glycopyrolate.<sup>157</sup> Furthermore, in a randomized, double-blind trial, after infusion of 1.5 mg/kg of ketamine in healthy volunteers, physostigmine decreased nystagmus, blurred vision, and the time to recovery.<sup>211</sup>

### Urologic and Hepatobiliary

Intense abdominal and pelvic pain is regularly reported in habitual ketamine users.<sup>233</sup> In the majority of cases, the cause is urologic. The first case series describing ketamine-associated urological dysfunction was reported in 2007. Symptoms consisted of a severe lower urinary tract syndrome (LUTS), including dysuria, frequency, urgency, urge incontinence, and painful hematuria (Fig. 83-2). When investigated by cystoscopy, patients with hematuria were frequently found to have ulcerative cystitis.<sup>193</sup>

Subsequent reports established LUTS as a complication in both recreational ketamine users as well as in a patient receiving ketamine therapeutically for chronic regional pain syndrome.<sup>40,91,104</sup> The incidence of ketamine-induced urologic dysfunction is not well established: whereas studies from the United Kingdom report an incidence of 20%, a study from Hong Kong reports the incidence of 32% and 92% in acute and chronic ketamine users, respectively.<sup>146,228,233</sup>

**FIGURE 83-2.** Ketamine-associated lower urinary tract syndrome. This abdominal-pelvic computed tomography (CT) scan was obtained in an 18-year-old girl who presented to the hospital with complaints of severe abdominal pain and hematuria. The image demonstrates a small bladder ( $\uparrow$ ) volume with an irregular thickened mucosal surface that enhances with contrast. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

The symptoms of ketamine-induced urologic dysfunction are secondary to an inflammatory process that reduces bladder size. Patients develop diminished voiding capacity of 20 to 200 mL, decreased bladder compliance, and detrusor overactivity as measured by urodynamic testing. A thickened bladder wall, a small bladder volume, and perivesicular stranding are usually detected by ultrasonography and computed tomography (CT) of the lower urological tract.<sup>146</sup> Cystoscopy demonstrates an erythematous bladder mucosa with various degrees of ulcerations. Bladder biopsies confer epithelium denudation and ulcerative cystitis. There is a marked lymphocytic infiltration with a variable number of eosinophils and fibrosis as well as squamous metaplasia and nephrogenic metaplasia. The loss of architectural reorganization encountered in fibrosis may be caused by a loss of expression of adhesion proteins in proximal tubule epithelial cells that is reported.<sup>97</sup> The exact mechanism by which ketamine or one of its metabolites causes the destruction of the urinary tract remains unknown.<sup>40,41,228,233</sup>

There is a substantially lower incidence of LUTS reported in the United Kingdom (13%) compared with 51% in Hong Kong. The lower incidence is thought to be related to the early presentation of patients in the United Kingdom seeking medical attention as opposed to those living in Hong Kong. Intravenous urography and urography by CT reveal unilateral or bilateral ureteric narrowing. Bilateral hydronephrosis was reported in 44% to 50% of patients, and renal impairment is also described.<sup>146,152</sup> Biopsy of the ureter in a patient who underwent right nephrectomy with an ileal conduit anastomosis to the left renal pelvis demonstrated nephrogenic metaplasia throughout the ureter extending to the renal pelvis as well as ulceration with associated inflammatory changes as described by the bladder biopsies.<sup>101</sup> A murine model demonstrates the similarities between bladder and renal pathology induced by methoxetamine and ketamine.<sup>61</sup> The pathology of ketamine-induced urologic dysfunction is not confined to the lower urinary tract. Upper urinary tract involvement is variable.

Intense abdominal pain in frequent ketamine users is also suggestive of hepatobiliary dysfunction. Case series of patients who used ketamine illicitly or therapeutically report abnormal liver function test results and biliary tract abnormalities.<sup>134</sup> Computerized tomography revealed common bile duct dilation with a smooth, tapered end, a condition that mimics benign cystic dilation of the bile ducts. Endoscopic retrograde cholangiopancreatography and hepatobiliary iminodiacetic acid studies concur with these findings suggesting gallbladder wall dyskinesia. These biliary abnormalities are noted to subside with cessation of ketamine use.<sup>134</sup>

## Emergence Reaction

The acute psychosis observed during the recovery phase of PCP anesthesia limited its clinical use. This bizarre behavior, characterized by confusion, vivid dreaming, and hallucinations, is termed an “emergence reaction.” These reactions occur most frequently in middle-aged men, with a reported incidence of 17% and 30%.<sup>92,114</sup> The most violent emergence reactions follow an IV dose of approximately 0.25 mg/kg of PCP.<sup>65</sup> The mildest degrees of agitation produced by PCP resemble the effects of ethanol intoxication.

These same postanesthetic reactions also limit the clinical use of ketamine. The incidence of emergence reactions after ketamine administration is approximately 50% in adults and 10% in children.<sup>87</sup> Patients older than age 10 years; women; and persons who normally dream frequently or have a prior personality disorder, a prior history of psychosis, premonitory denial of presence of illness or anosognosia (denial presence of an illness), and paranoia incur the greatest risk.<sup>87,150</sup> Although the experience of vivid dreaming and visual illusions usually cease upon regaining consciousness, their recurrence weeks after ketamine administration in both children and adults is reported.<sup>78</sup> The origin of these altered visual experiences is thought to be ketamine's depressive action on auditory (inferior colliculus) and visual (medial geniculate) relay centers. Feelings of floating in space or body detachment and ataxia and dizziness occur because of a decreased perception to gravity. Added to this experience are feeling of ataxia and dizziness.<sup>222</sup> The incidence of the occurrence of emergence reactions appears to be exacerbated when

dissociative anesthetics are rapidly administered IV, as well as in patients exposed to excessive stimuli during recovery. Although not demonstrated in a controlled study, reducing external stimuli during the recovery phase might reduce emergence reactions.

Ironically, the very characteristics that were thought to make PCP ideal for anesthesia—the preservation of muscle tone and cardiopulmonary function—exacerbate the difficulties in managing an individual who manifests dysphoria associated with an overdose. The course of delirium, stupor, and coma associated with PCP and ketamine is extremely variable, although the manifestations are much milder and shorter acting after ketamine use.

## Tolerance and Withdrawal

Phencyclidine induces modest tolerance in rats and squirrel monkeys. The development of tolerance is mostly secondary to the pharmacologic effects of PCP rather than to biodispositional changes. Dependence was also observed in monkeys who self-administered PCP (10 mg/kg/d to serum concentrations of 100–300 ng/mL) over 1 month by the appearance of dramatic withdrawal signs when access was denied. Signs included vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, difficulty remaining awake, tremors, and in one case convulsions.<sup>19</sup> These signs appeared within 8 hours of abstinence and were most severe at about 24 hours. When either PCP or ketamine (2.5 mg/kg/h) was readministered to the animals, PCP withdrawal symptoms were ameliorated, indicating cross-dependence between PCP and ketamine.<sup>23,108,202</sup>

Physiologic dependence in humans is not formally studied. It is implied to occur by the observation that chronic PCP users developed depression, anxiety, irritability, lack of energy, sleep disturbance, and disturbed thoughts after 1 day of abstinence from drug use.<sup>179</sup> Additionally, neonates whose mothers used PCP developed jitteriness, vomiting, and hypertonicity that lasted for at least 2 weeks.<sup>208</sup> These symptoms represent PCP withdrawal or intrinsic teratogenic effects on neurologic development.<sup>84,103</sup> Although there are no controlled studies observing the physiologic symptoms of withdrawal in humans who chronically use PCP or ketamine, there is a definite psychological dependence on the sensations experienced during recreational use.<sup>198</sup> There are a few cases of ketamine tolerance in which patients report a need to use an increased quantity of drug to achieve the same effects.<sup>57,157,172</sup> In a study of ketamine abstinence, patients characterized their withdrawal symptoms as anxiety, shaking, sweating, and palpitations.<sup>159</sup> In addition, ketamine impairs response inhibition, which is related to increases in subjective ratings of desire for the drug.<sup>158</sup>

## DIAGNOSTIC TESTING

If it is necessary to confirm the suspicion of PCP usage, urine is most commonly used matrix for analysis, although serum, and possibly gastric contents, can also be used. Rarely is it essential to make this determination. Most hospital laboratories do not perform quantitative analysis of PCP, but many can perform a qualitative urine test for its presence. Qualitative testing is more important than a quantitative determination as serum concentrations do not correlate closely with the clinical effects. Phencyclidine is qualitatively detected by an enzyme immunoassay at a cutoff calibration of 25 ng/mL.<sup>176</sup> High-affinity antibodies were once studied as specific PCP antagonists to reverse PCP-induced toxicity.<sup>170,213</sup> The detection of PCP is thus dependent on the concentration of PCP in the body fluid tested and the affinity of the antibody for the PCP molecule. As such, the immunoassay antibody binding to a molecule similar to PCP can produce false-positive reactions. Metabolites of PCP, such as PCE, PHP, and TCP and its pyrrolizidine derivative TCPy, cross-react with the immunoassay at concentrations 30 times higher than those used to detect PCP. Because of its similar structure to PCP, dextromethorphan and its metabolite dextrorphan also cross-react with Syva enzyme-multiplied immunoassay and fluorescence polarization PCP assays (Chap. 7).<sup>219</sup>

Although nonspecific, laboratory findings associated with PCP use include leukocytosis, hypoglycemia, and elevated concentrations of muscle enzymes (CPK), myoglobin, blood urea nitrogen (BUN), and creatinine.<sup>148</sup> In

patients administered ketamine, the EEG reveals diffuse slowing with  $\theta$  and  $\delta$  waves, which return to normal before the patient improves clinically.<sup>36,53</sup>

There is no commercially available quantitative immunoassay for ketamine or methoxetamine. When necessary, they are detected by gas chromatography and mass spectroscopy. The increase in popularity in ketamine use in certain parts of the world has led to the development of rapid-detection urine assays that are sensitive, specific, and accurate.<sup>39,217</sup> There is anecdotal evidence that ketamine also cross-reacts with the urine PCP immunoassay because of their structural similarity.<sup>197</sup> Other authors, including the manufacturer that tests the reactivity of the commercially available PCP immunoassay with ketamine, do not find such results.<sup>34,220</sup>

## MANAGEMENT

### Agitation

Conservative management is indicated for patients with arylcyclohexylamine toxicity and includes maintaining adequate respiration, circulation, and thermoregulation. The psychobehavioral symptoms observed during acute dissociative reactions and during the emergence reaction are similar. To treat the symptoms of agitation and alteration of mental status, it is helpful to recognize that both pharmacologic<sup>2,42,46,72,87,89,141,145</sup> and behavioral<sup>44,46,87,124</sup> modalities are used to diminish agitation and emergence phenomena during conscious sedation with ketamine. To prevent self-injury, a common form of PCP-induced morbidity and mortality, the patient must be safely restrained, initially physically, and then medically sedated. An IV catheter should be inserted and blood drawn for electrolytes, glucose, BUN, and creatinine concentrations. The use of 0.5 to 1.0 g/kg of body weight of dextrose and 100 mg of IV thiamine HCl should be administered as clinically indicated.

Hyperthermia occurs secondary to psychomotor agitation and should be rapidly identified. Treatment should be accomplished immediately with adequate sedation to control motor activity. At presentation, placing the patient in a quiet room with low sensory stimuli will help achieve this goal. Physical restraint should only be used temporarily, if necessary, until medical sedation is achieved. Rapid immersion in an ice water bath is recommended when body temperatures greater than 106°F (41.1°C) place the patient at great risk for end-organ injury.<sup>129</sup> These patients will need volume repletion and electrolyte supplementation because hyperthermia increases fluid loss from sweat.

In the pharmacologic treatment of emergence reactions, benzodiazepines are recommended as the first-line sedatives. A benzodiazepine such as diazepam, administered in titrated doses of up to 10 mg intravenously every 5 to 10 minutes until agitation is controlled, is usually safe and effective. Numerous studies demonstrate the benefits of benzodiazepines, but under certain conditions,<sup>17,42</sup> they prolong recovery time.<sup>35,145</sup> Additionally, in a double-blind, placebo-controlled study, lorazepam reduced the anxiety associated with ketamine without reducing the cognitive or psychotomimetic effects of ketamine (Antidotes in Depth: A26).<sup>122</sup> By contrast, phenothiazines lower the seizure threshold, and both phenothiazines and butyrophenones cause acute dystonic reactions. Phenothiazines also cause significant hypotension because of their  $\alpha$ -adrenergic blocking effects on the vasculature, worsen hyperthermia, and exacerbate any anticholinergic effects and they should therefore be avoided.

Some behavioral modalities are implemented in the treatment. Early studies demonstrated that the psychotomimetic effects of PCP were diminished when external stimulation was reduced by environmental sensory deprivation.<sup>44</sup> When feasible, agitated patients should be placed in a single quiet room with minimal sensory stimulation to diminish potential harm to self, staff, or other patients. Conversely, it is observed in patients undergoing ketamine anesthesia that emergence reactions are less violent when patients are talked to or when music is played.<sup>124,201</sup>

Although it is always important to ask the patient the names, quantities, times, and route of all xenobiotics taken, the information obtained may be unreliable. Even when the patient is trying to cooperate and give an accurate history, many street psychoactive xenobiotics are mixtures, with the contents being unknown to the patient. Consequently, pharmacologic management is complex and often sign or symptom dependent. Although some

authors have attempted to define the appropriate therapy for specific PCP congeners and for ketamine-induced psychosis, no single approach is consistently efficacious.<sup>81,82,120,142</sup>

### Decontamination

Patients with a history of recent oral use of arylcyclohexylamines are candidates for GI decontamination. Although there is rarely, if ever, an indication for orogastric lavage, aggressive decontamination is indicated if potentially lethal coingestants are suspected. Activated charcoal (1 g/kg) is recommended as soon as possible and repeated in 4 hours for 2 doses as long as no contraindications exist. Activated charcoal effectively adsorbs PCP and increases its nonrenal clearance even without prior gastric evacuation. This approach is usually adequate.<sup>174</sup>

Theoretically, xenobiotics that are weak bases, such as PCP, can be eliminated more rapidly if the urine is acidified. Although urinary acidification with ammonium chloride was previously recommended,<sup>13</sup> we do not recommend this approach. The risks associated with acidifying the urine—simultaneously inducing an acidemia, thereby potentially increasing urinary myoglobin precipitation—outweigh any perceived benefits (Chap. 6).

As opposed to the problems in applying ion trapping to renal excretion, ion trapping results in the active mobilization of PCP into gastric secretions. Phencyclidine is in a substantially ionized (and therefore non-lipid-soluble) form in the acid of the stomach and is absorbed only when it reaches the more alkaline intestine. As a result, gastric suction can remove a significant amount of the xenobiotic and interrupt the gastroenteric circulation by which the xenobiotic is secreted into the acid environment of the stomach, only to be reabsorbed again in the small intestine.<sup>13</sup> However, continuous gastric suction is unnecessary and can be dangerous. Continuous suction results in trauma to the patient as well as in fluid and electrolyte loss, which further complicate management and possibly interfere with the efficacy of activated charcoal. For these reasons, the administration of single or multiple-dose activated charcoal rather than continuous nasogastric suction appears to be the safest and most effective way of removing ion trapped drug from the stomach in severely poisoned patients.

Most patients rapidly regain normal CNS function within 45 minutes to several hours after its use. However, those who have taken exceedingly high doses or who have an underlying psychiatric disorder may remain comatose or exhibit bizarre behavior for days or even weeks before returning to normal. Those who rapidly regain normal function should be monitored for several hours and then, after a psychiatric consultation, should receive drug counseling and additional social support as indicated. Patients whose recovery is delayed should be treated supportively and monitored carefully in an intensive care unit.

Many patients become depressed and anxious during the “post-high” period, and chronic users manifest a variety of psychiatric disturbances.<sup>231</sup> These individuals typically present with repeated drug use, hospitalizations, and poor psychosocial functioning in the long term.

The major toxicity of PCP appears to be behaviorally related: self-inflicted injuries, injuries resulting from exceptional physical exertion, and injuries sustained as a result of resisting the application of physical restraints are frequent. Patients appear to be unaware of their surroundings and sometimes even oblivious to pain because of the dissociative anesthetic effects. In addition to major trauma, rhabdomyolysis and resultant myoglobinuric acute kidney injury account in large measure for the high morbidity and mortality associated with PCP. If significant rhabdomyolysis<sup>43,173</sup> occurs, myoglobinuria will be present. Early fluid therapy should be used to avoid deposition of myoglobin to the kidneys. Urinary alkalization as part of the treatment regimen for rhabdomyolysis would theoretically increase PCP reabsorption and deposition in fat stores and is not recommended.

### Cystitis

The objectives of the management of ketamine-induced cystitis are establishing the diagnosis, decreasing symptoms, and maintaining kidney function. Urinalysis should be obtained on all symptomatic patients to exclude urinary tract infection, and a serum creatinine should be obtained to evaluate kidney

function. However, initial urinalyses are typically sterile. For patients whose symptoms are mild, abstinence from ketamine use will be enough to reverse symptoms and pathology. Several therapeutic regimens have been tried with little success. They include antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and anticholinergics. Urologic evaluation and follow-up are necessary.<sup>152</sup>

Moderate and severe symptoms of LUTS are defined as daytime frequency greater than 6, nighttime frequency of one or more, regular urgency on voiding, and moderate bladder or pelvic pain. For patients with these symptoms, urologic consultation and repeated kidney function monitoring are essential. Ultrasonography and CT urography assist in detecting lower and upper tract abnormalities. In consultation with a urologist, urodynamic studies further quantify bladder voiding capacity and detrusor activity. Invasive procedures need to be undertaken in patients with impaired kidney function and deterioration. Cystoscopy aids in visualizing the bladder and exclude other causes of hematuria and LUTS. During this procedure, a bladder biopsy will further delineate mucosal pathology. Injury to the upper urologic tract imaged with CT urography. Nephrostomy insertions are necessary in patients who present with impaired kidney function secondary to ureteric narrowing. Refractory cases need to undergo surgical interventions such as augmentation enterocystoplasty, ureteroplasty, urinary diversion, cystectomy, or ileal neobladder formation.<sup>41,101,146</sup>

Toxic manifestations of ketamine and methoxetamine appear to be similar yet milder and shorter lived compared with PCP. In a study of 20 patients who presented with acute ketamine toxicity, all were treated conservatively and successfully with IV hydration, and sedation with benzodiazepines.<sup>220</sup>

## SUMMARY

- Arylcyclohexylamines produce an “out-of-body experience” with seemingly hallucinatory effects.
- The action of these xenobiotics is largely mediated by the NMDA receptor.
- The neuropsychiatric toxicity is managed with supportive care and sedation.
- The popularity of ketamine is related to its lesser toxicity and milder distortion of the personality.
- A chronic effect of ketamine abuse toxicity not recognized after use of PCP is cystitis and bladder dysfunction.

## CASE STUDY 9

**History** A 45-year-old man presented to the hospital complaining of hand and foot pain so severe that he was unable to drive his car. The man had been well until several weeks earlier, when he began having gastrointestinal distress that he thought was “heartburn” and mild weight loss, which he attributed to his dyspepsia. He denied fever, chills, nausea, vomiting, or diarrhea. He also related that on the day prior to admission he was unable to eat a meal because he thought it was spoiled after taking a few bites. The next morning, while driving, he pulled off the road and phoned emergency medical services. He was taking no medications and had no allergies.

**Physical Examination** In the emergency department, the patient appeared well developed and well nourished, but was complaining of severe pain in his hands and feet. Vital signs were: blood pressure, 124/68 mm Hg; pulse, 92 beats/min; respiratory rate, 14 breaths/min; oral temperature, 98.6°F (37.0°C); oxygen saturation, 99% on room air; and a rapid reagent glucose of 128 mg/dL. Physical examination was notable for pupils that were equal, round (4 mm), and reactive to light; normal extraocular movements; and the absence of nuchal rigidity. His chest was clear to auscultation, and his heart sounds were normal. His abdomen was soft and nontender, with normal bowel sounds and no organomegaly. He was awake, alert, and oriented with normal symmetrical strength and brisk reflexes. Although he complained of pain in his hands and feet, his two-point discrimination, proprioception, and vibration sensation appeared normal. His gait was slightly wide based and slow, but this was thought to be secondary to pain. Cranial nerves II through XII appeared intact, and cerebellar testing was normal.

**Initial Management** Although the patient appeared uncomfortable, there was no perception of an immediate life-threatening illness. An intravenous line was inserted, and blood was obtained for a complete blood count, electrolytes, and liver

function testing. A urinalysis was requested as was an electrocardiogram and a chest radiograph. Acetaminophen was given for analgesia, without relief. The patient ultimately required parenteral opioids to diminish his pain, although he noted that the distribution had spread to include most of his legs and arms. He also became somnolent, and it was unclear if the ensuing somnolence was opioid related.

**What Is the Differential Diagnosis?** The major presenting symptom in this case is a painful sensory peripheral neuropathy (an uncommon clinical manifestation) associated with gastrointestinal symptoms (a common manifestation). Considerations include a variety of metabolic and endocrine disorders, infections, medications, and toxins. Severely painful symmetrical paresthesias are fairly uncommon and the differential diagnosis is limited. Considerations include freezing injury such as frostbite (Chap. 29), proximity to radioactive materials (Chap. 128), and dermal exposure to hydrofluoric acid (Chap. 104). A list of xenobiotics that can cause such findings following ingestion is found in [Table CS9-1](#).

**TABLE CS9-1** Differential Diagnosis of Sensory Peripheral Neuropathy With Gastrointestinal Complaints

<b>Endocrine</b>	Nitrous oxide
Diabetes mellitus	Organic phosphorus compounds
Hypothyroidism	
<b>Nutritional</b>	<b>Medications</b>
Alcoholism	Cisplatin
B <sub>12</sub> deficiency	Disulfiram
Thiamine deficiency	Isoniazid
<b>Xenobiotics</b>	Metronidazole
Alcohol	Phenytoin
Acrylamide	Pyridoxine
Hexane derivatives	Taxol
Metals (arsenic, gold, mercury, thallium)	Vinca alkaloids
	<b>Connective tissue diseases</b>

### What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of This Patient's Presentation?

In addition to the above evaluation, a diagnosis of encephalitis was considered when the patient became somnolent, and a computed tomographic (CT) scan of the head was obtained without intravenous contrast. A lumbar puncture was performed after the CT scan was interpreted as normal. The lumbar puncture showed 2 red blood cells/mm<sup>3</sup>; 0 white blood cells/mm<sup>3</sup>; glucose, 85 mg/dL; and protein, 45 mg/dL, all within normal limits.

Unfortunately, over the next 48 hours, the patient's condition deteriorated and was characterized by encephalopathy with cranial nerve dysfunction and weakness with loss of deep tendon reflexes. A repeat lumbar puncture demonstrated elevated protein without abnormal cells and a CSF Gram stain was negative.

**Further Diagnosis and Treatment** A diagnosis of poisoning was considered, and a medical toxicology consult was obtained. The combination of gastrointestinal symptoms without significant diarrhea, severely painful ascending peripheral neuropathy and progression to encephalopathy with motor and cranial nerve findings strongly suggested metal poisoning, specifically thallium (Chap. 99). Treatment with Prussian Blue (Antidotes in Depth: A31) was recommended, and the original blood urine and cerebrospinal fluid were sent for thallium concentrations. Unfortunately, the patient's illness progressed rapidly, and he suffered a cardiac arrest shortly after the diagnosis was considered. Ultimately, a spot urine thallium concentration was reported as 50,000 mcg/L (normal < 5 mcg/L), and his serum was 8700 mcg/L (normal < 2 mcg/L).

**Acknowledgment** Postmortem findings and cerebrospinal fluid results of this case were reported in Sharma AN, Nelson LS, Hoffman RS: Cerebrospinal fluid analysis in fatal thallium poisoning: evidence for delayed distribution into the central nervous system. *Am J Forensic Med Pathol.* 2004;25:156-158.

## I. Metals

# ALUMINUM

Stephen A. Harding and Brenna M. Farmer

<b>Aluminum (Al)</b>	
Atomic number	= 13
Atomic weight	= 26.98 Da
Normal concentrations	
Serum	< 2 mcg/L (0.074 μmol/L)
Whole blood concentration	< 12 mcg/L (0.445 μmol/L)
Urine (24-hour)	< 4–12 mcg/g creatinine (0.148–0.445 μmol/g creatinine)

### CHEMISTRY

Aluminum (Al) is the most abundant metal in the crust of the earth, where it is found in many types of ores: bauxite, gibbsite, boehmite, as alumina, and in gems such as ruby, sapphire, and turquoise. The most naturally occurring isotope is <sup>33</sup>Al. Aluminum is a nonessential element and a trace metal with a single oxidation state, Al<sup>3+</sup>.

The aluminum industry is one of the largest industries in the world. Aluminum ores are converted to alumina and then reduced to aluminum metal. The first step usually involves refining bauxite at high temperature and pressure in a caustic soda to form alumina (aluminum oxide, Al<sub>2</sub>O<sub>3</sub>). The second step occurs by the Hall–Heroult process in potrooms and uses electrolytic reduction to form aluminum. Aluminum is then used alone or is processed into alloys to build a variety of products that are anticorrosive.<sup>20</sup> Aluminum is found in cookware, infant formula,<sup>26</sup> foil, vaccines as an adjuvant to boost immune response,<sup>34</sup> antiperspirants, antacids, and previously, in phosphate binders. It also contaminates hemodialysis (HD) fluids, intravenous (IV) fluids, total parenteral nutrition (TPN),<sup>45</sup> pharmaceutical albumin,<sup>46</sup> and is one component of alum solution (potassium aluminum sulfate or ammonium aluminum sulfate), which is used as an astringent for bladder irrigation.<sup>112</sup> In this chapter, aluminum metal is discussed as an occupational toxin with mainly lung manifestations. Aluminum salts, the more common form discussed in human toxicity, primarily act as neurotoxins, with both acute and chronic toxicity.

### HISTORY AND EPIDEMIOLOGY

The first case of aluminum toxicity with neurologic findings was reported in 1921. This patient had memory loss, tremor, and impaired coordination.<sup>100</sup> Subsequently, a case series described occupational asthma in Norwegian aluminum (potroom) workers (“potroom asthma”).<sup>27</sup> A pot is a large vessel in which aluminum is produced, and the building in which these pots are housed is known as a “potroom.” In 1947, 26% of German potroom workers exposed to high concentrations of aluminum dust mixed with mineral oil-based lubricants developed pulmonary fibrosis or “aluminosis.”<sup>30</sup> Some potroom workers also developed neurologic findings described as a progressive encephalopathy and termed “potroom palsy,” with balance problems, intention tremors, decreased cognitive ability, and impaired memory, initially described in 1962.<sup>53,60,83</sup>

In the 1970s, encephalopathy in patients with chronic kidney disease (CKD) was attributed to using aluminum salt-containing phosphate binders or, more rarely, to aluminum-contaminated dialysis fluid. This clinical syndrome, known as “dialysis dementia,” develop after years of HD.<sup>90</sup> By 1976, elevated serum aluminum concentrations were reported in encephalopathic HD patients.<sup>77</sup> Both the relation between aluminum and microcytic anemia

and the connection between aluminum and osteomalacia in dialysis patients were recognized in 1978.<sup>21,103</sup>

In 1982, alum (potassium aluminum sulfate or ammonium aluminum sulfate) was first used in the treatment of hemorrhagic cystitis.<sup>75</sup> Neurotoxicity develops if patients absorb alum systemically, especially if chronic kidney disease is present.

Subsequently, aluminum was linked to the spongiform leukoencephalopathy that in rare cases developed in heroin users who were “chasing the dragon.” These patients inhaled the pyrolysate of heroin heated on aluminum or tin foil. A 2007 study showed elevated urinary aluminum concentrations in patients using heroin in this manner.<sup>22</sup> They developed bizarre behavior, slowed speech and movements, as well as cognitive abnormalities.<sup>52</sup>

There is also a concern over the relation between aluminum and Alzheimer disease. This linkage was studied because of the dialysis encephalopathy syndrome (dialysis dementia) and the association of aluminum with neuropsychiatric deficits and electroencephalographic (EEG) changes that occur in aluminum welders.<sup>84</sup> Although aluminum is a component of neurofibrillary tangles in senile plaques associated with Alzheimer disease, to date no studies have proven that aluminum is the cause of the disease.<sup>67,77</sup> Regardless, this association led several agencies in the United States and Canada, including the US Food and Drug Administration (FDA) and Health Canada, to decrease the amount of aluminum contamination allowable in food and water products.<sup>108</sup>

### ALUMINUM-CONTAINING XENOBIOTICS

#### Antacids

Aluminum-containing products are rarely prescribed. However, patients take antacids containing aluminum hydroxide for symptomatic control of dyspepsia and gastroesophageal reflux disease. Aluminum hydroxide is usually packaged with magnesium hydroxide to counteract the induced delay of gastric emptying and constipation caused by aluminum hydroxide. These antacids are poorly absorbed and exit the stomach in about 30 minutes. The neutralizing effects of antacids last for 2 to 3 hours, especially in the presence of food.

#### Sucralfate

Sucralfate, an aluminum-containing salt with sucrose sulfate, is used for symptomatic control of ulcer disease, to accelerate healing of peptic ulcer disease, and as a protectant against stress ulcer formation. This sucrose aluminum complex is poorly absorbed from the gastrointestinal (GI) tract, and the little that is absorbed is excreted by the kidney without undergoing any metabolic changes. Although not approved by the FDA as a phosphate binder, it does have phosphate-binding properties.<sup>12</sup>

#### Alum

Alum is usually a 1% solution of potassium aluminum sulfate salt {KAl(SO<sub>4</sub>)<sub>2</sub> \* 12H<sub>2</sub>O} or an ammonium aluminum sulfate salt {NH<sub>4</sub>Al(SO<sub>4</sub>)<sub>2</sub> \* 12H<sub>2</sub>O}, and is uncommonly used as an astringent for hemorrhagic cystitis and administered by bladder irrigation. It is poorly absorbed, although toxicity occurs.<sup>94</sup>

### TOXICOKINETICS

Aluminum toxicokinetics are difficult to comprehend as many mechanisms remain to be elucidated. It is known that daily intake occurs, that absorption is limited, but that the concentrations of aluminum in urine and feces do not equal 100% of the exposure.<sup>31</sup> More research is necessary to expand current knowledge of toxicokinetics.

## Absorption

Aluminum is ubiquitous in the food we eat and water we drink.<sup>76</sup> The daily intake of aluminum in the United States is estimated to be 2 to 25 mg from food and beverages, depending on the diet studied.<sup>31</sup> Gastrointestinal absorption mainly occurs in the proximal small bowel with uptake by the intestinal mucosal cells. Uptake occurs through both passive transport methods such as diffusion and active transport methods via transferrin as well as active methods shared by calcium.<sup>31</sup> Transferrin also mediates absorption into the blood from the mucosal cells.<sup>31</sup> The exact amount of aluminum absorption in humans is difficult to quantify because of the short half-lives of isotopes and lack of sensitive analysis techniques.<sup>31</sup> However, GI absorption and serum aluminum concentrations increase in the presence of citrate, other small organic acids, uremia, and iron deficiency anemia.<sup>23,31,35,73,97</sup> The GI absorption of aluminum is decreased in the presence of phosphorus and silicon.<sup>35</sup> There is negligible dermal absorption from the use of antiperspirants containing aluminum.<sup>24,31</sup> Pulmonary absorption of inhaled aluminum particulates is 1.5% to 2%, based on increased urinary aluminum excretion in workers exposed to aluminum-containing metal fumes.<sup>31,68,95</sup>

## Distribution

The initial volume of distribution of aluminum is 0.06 L/kg with an equal distribution between plasma and red blood cells.<sup>104</sup> Aluminum then becomes 90% bound to transferrin, with approximately 10% bound to citrate.<sup>101,107</sup> From the blood, it distributes to many tissues, including 50% to the bone, where it is concentrated at the mineralization front,<sup>111</sup> and approximately 1% to the brain, primarily in the gray matter.<sup>77</sup> The remainder of the aluminum distributes variably to the heart, liver, kidney, and other organ systems. Citrate is the primary carrier in the cerebrospinal fluid (CSF).<sup>107</sup> Intracellularly, aluminum localizes in the lysosomes of brain neurons, liver (not the Kupffer cells), spleen, kidney epithelial tubules and glomerular mesangium cells, cardiac myocytes,<sup>8,88</sup> and in the mitochondria of osteoblasts.<sup>19</sup>

## Metabolism/Excretion

Aluminum is not metabolized in the body and is considered to be greater than 95% excreted unchanged in the urine.<sup>31,29</sup> Citrate in the blood enhances the excretion of aluminum.<sup>31,56</sup> Less than 2% of aluminum is excreted by the bile.<sup>47,80,109</sup> Because aluminum is primarily excreted in the urine, patients with CKD have decreased aluminum excretion. The elimination half-life for aluminum is approximately 85 days in patients receiving dialysis.<sup>89</sup> Based on urinary excretion in workers (with preserved kidney function) with prolonged occupational exposure, the apparent half-life is extended to years.<sup>51</sup> This prolonged half-life may be related to deposits of aluminum metal dust in the lungs of workers with pulmonary fibrosis from exposure to aluminum dust. There is no normal reference point for elimination half-life.

## PATHOPHYSIOLOGY

Little is known about the pathophysiology of aluminum toxicity. The information that follows is based on a summary of limited research. Some animal studies provide insight into the mechanisms that are responsible for the toxicity of aluminum, mainly citing oxidative stress on various tissues, but the studies are limited and do not offer a comprehensive understanding.<sup>102</sup> There remain many gaps in our knowledge of aluminum toxicity on specific organ systems.

### Pulmonary System

In rats exposed to alumina and aluminum through intratracheal injection, fibrosis (aluminosis when secondary to aluminum) develops.<sup>42,43</sup> These animals develop epithelialization of alveoli, focal fibrosis occurring in the respiratory bronchioles and alveolar ducts, and alveolar proteinosis.<sup>33,79</sup>

### Central Nervous System

Aluminum exposure is associated with acute encephalopathy, dialysis encephalopathy, seizures, and Alzheimer disease. The primary site of

aluminum entry into the brain appears to be the cerebral microvasculature. Following IV administration in rats and rabbits, aluminum concentrations are higher in the frontal cortex than in the lateral ventricles. The cortex concentrations should result from blood supply, whereas the lateral ventricle concentration may be derived from the blood supply or the CSF, which bathes the lateral ventricles.<sup>110,111</sup> The mechanisms of entry are postulated to be transferrin mediated, endocytosis and other active processes.<sup>27</sup> Aluminum interacts with the acetylcholine pathways in the brain and decreases acetylcholine activity. High-affinity choline uptake in the brains of rats also decreases; the activity of choline acetyltransferase in rabbit brains is also decreased.<sup>36,50</sup> Rabbits treated with aluminum have significantly decreased acetylcholine outflow compared with controls, a finding that does not improve with potassium neuronal supplements. This finding suggests that aluminum attenuates the response of neurons to potassium-induced depolarization.<sup>110</sup> Adult rabbits exposed to aluminum also have a significant reduction in conditioned responses compared with rabbits exposed in utero or in the first or second month postpartum.<sup>106</sup>

### Hematologic System

Early toxicity of aluminum affects hematopoiesis resulting in a microcytic hypochromic anemia before affecting the CNS. In rats, aluminum inhibits cell growth, while in humans hematopoietic cells are inhibited. In mice, aluminum decreases cell proliferation and hemoglobin synthesis.<sup>5,64</sup> Aluminum inhibits  $\delta$ -aminolevulinic acid dehydrogenase in the heme synthesis pathway,<sup>3,61</sup> leading to the accumulation of erythrocyte protoporphyrins (Fig. 20-3). This effect is most noted in HD patients with aluminum overload.<sup>14</sup>

### Musculoskeletal System

Vitamin D-resistant osteomalacia and osteopathy occur in patients with aluminum toxicity. It is characterized by hyperosteoidosis, minimal osteoblastic activity, and decreased mineralization. The metabolism and kinetics of calcium, magnesium, and phosphate do not appear to be affected in these patients.<sup>17</sup> Aluminum concentrates in the mitochondria of the osteoblasts at the mineralization front.<sup>19</sup> It is theorized that aluminum competes and replaces other cations in the bone, leading to osteopathy.<sup>32</sup> The osteomalacia is not caused solely by CKD but develops in the presence of aluminum exposure.<sup>86</sup> In rat studies, exogenous parathyroid hormone enhanced aluminum deposition into bone, leading to osteopathy.<sup>57,58</sup>

## MANIFESTATIONS

### Acute Toxicity

Regardless of pathophysiology, patients with acute aluminum toxicity typically develop encephalopathy, myoclonus, and seizures. The encephalopathy manifests as disorientation, confusion, and coma. All symptoms appear to develop within days to a few weeks of receiving massive systemic aluminum exposure (usually to an aluminum salt). Serum concentrations range from barely elevated to extremely elevated. Most patients who manifest toxicity have systemically absorbed aluminum, usually in the presence of CKD. In several case reports of acute aluminum toxicity, the initial exposure to aluminum was associated with alum bladder irrigations for hemorrhagic cystitis.<sup>40,70,78</sup> In 2 patients, these symptoms developed after only weeks of exposure to aluminum-containing phosphate binders in the presence of citrate.<sup>44</sup> Two neonates with uremia developed neurotoxicity after exposure over a 1- to 2-month period to infant formula with high aluminum content.<sup>25</sup> Although recovery occurs in patients promptly treated with deferoxamine and/or HD,<sup>40,69,70</sup> patients with unrecognized signs and/or a delay to treatment usually die (supportive care typically never able to restore a normal mental status).<sup>44,90,94</sup>

### Chronic Toxicity

Two distinct types of chronic aluminum toxicity are reported: occupationally related lung disease, such as asthma and pulmonary fibrosis, and a multisystem syndrome most often noted in HD patients, which was initially described as dialysis encephalopathy syndrome or "dialysis dementia." These terms are not descriptive of the full effects of aluminum toxicity. Animal

studies also report changes in cognitive development and memory following chronic exposure to aluminum salts.<sup>6</sup>

### Pulmonary

Potroom asthma consists of dyspnea, cough, wheezing, bronchitis, and chest tightness.<sup>62</sup> These symptoms develop after only a few months of exposure to the metal fumes of aluminum and aluminum dust. The asthma often improves on cessation of exposure, although some workers never fully recover.<sup>74</sup> These manifestations cause for the high turnover among potroom workers, which, in turn, limits the quality of long-term follow-up.<sup>38,99</sup>

Pulmonary fibrosis from aluminum, termed aluminosis, is very similar to the other pneumoconiosis, like silicosis, and morbidity and mortality are consequential. This pathologic finding develops in workers exposed to aluminum dust. Patients experience cough, shortness of breath, and dyspnea on exertion, and they eventually develop restrictive lung disease.<sup>48,63</sup> Abnormal chest radiographic findings include increased pulmonary markings, distortion of pleura and diaphragms, and irregular opacities.<sup>28,36,92</sup> Recovery of lung function does not occur, and patients die from complications of pulmonary disease such as pneumonia.

### Multisystem Toxicity

The other form of chronic aluminum toxicity has multisystem manifestations. It primarily affects 3 organ systems: hematopoietic, nervous, and musculoskeletal. In patients with CKD, the toxicity occurs after months to years of exposure to aluminum salt–contaminated dialysate and or aluminum salt–containing phosphate binders such as aluminum hydroxide and sucralfate. However, one review of 755 chronic dialysis patients in Australia found only 7 patients with significantly elevated aluminum concentrations, stating that modern techniques of reverse osmosis of water is substantially aluminum-free (nearly always <0.1 μmol/L).<sup>91</sup>

A similar clinical presentation developed over 3 months in a patient having used aluminum-coated cookware for 4 years to boil methadone for IV use.<sup>26,112</sup> Three industrial workers exposed to aluminum metal powder were reported to develop encephalopathy. One of these workers had a brain aluminum concentration 20 times normal.<sup>53</sup> Normal brain aluminum concentrations are reported as approximately 1.5 mcg/g dry weight, with a tendency to increase with age.<sup>49,59</sup> An infant with kidney insufficiency had 10 months of exposure to aluminum salt–containing phosphate binders and developed focal seizures, which eventually progressed to generalized seizures, hypotonia, poor head control, ataxia, and developmental delay in the presence of elevated serum aluminum concentration.<sup>82</sup>

The microcytic hypochromic anemia of aluminum poisoning is unresponsive to iron replacement therapy.<sup>37</sup> This clinical finding usually precedes encephalopathy and osteomalacia.<sup>93</sup> The encephalopathy is characterized by speech disturbances, EEG abnormalities, myoclonic jerks, and dementia.<sup>98</sup> The typical speech disturbances include dyspraxia, dysphasia, stuttering, and possibly mutism.<sup>54,87,98</sup> Electroencephalographic abnormalities include slowing of the normal rhythm and high-voltage biphasic or triphasic spikes.<sup>55,98</sup> The myoclonic activity includes uncontrolled twitching movements, myoclonus, or seizures.<sup>98</sup> The osteopathy and osteomalacia can lead to bone pain and fractures.<sup>18,108</sup> Death is common in these patients when aluminum toxicity is not recognized and treated.

### DIAGNOSTIC TESTS

A normal serum aluminum concentration should be less than or equal to 2 mcg/L,<sup>31</sup> whereas a whole blood aluminum concentration should be less than 12 mcg/L.<sup>96</sup> Daily urinary excretion less than 4 to 12 mcg aluminum is considered normal.<sup>31,72</sup> Toxicity has occurred in patients with a wide range of serum and urine concentrations, with some dying of severe clinical manifestations with concentrations only slightly above normal.

Pulmonary function testing can be performed to evaluate for restrictive lung function, as occurs with aluminosis. A Finnish occupational study recommended spot urine aluminum measurements, proposing a maximum of 2.3 μmol/g creatinine after 2 exposure-free days as an actionable limit that prompts closer monitoring of aluminum exposure.<sup>85</sup>

### MANAGEMENT

Patients with symptoms or with elevated aluminum concentrations should be removed from any aluminum exposure if identified. Exposure to aluminum in industry and exposure to antacids containing aluminum salts should also be limited. Patients with occupational asthma from aluminum exposure should be symptomatically treated with bronchodilators and steroids.

The only chelator with proven benefit is deferoxamine (DFO). Chelation therapy is recommended for both acute and chronic toxicity from aluminum salts. Chelation not only limits but also improves manifestations of neurotoxicity, anemia, and osteomalacia (Antidotes in Depth: A7). Other chelators such as D-penicillamine and 2,3-dimercapto-1-propanol (BAL) were tried in chronic HD patients without any improvement in their manifestations or aluminum concentrations and therefore we recommend that they not be used.<sup>16</sup> A review of numerous chelator studies revealed that no other chelator was an acceptable alternative to DFO.<sup>105</sup>

### Acute Toxicity

A DFO dose of 15 mg/kg/d intravenously is recommended. Adults have received doses ranging from 1 to 2 g for aluminum toxicity. Deferoxamine chelates the aluminum to form aluminoxamine, which is excreted in the urine or removed by HD.<sup>107</sup> Chelation mobilizes aluminum from its storage sites in blood and increases its renal elimination. In dialysis-dependent patients, DFO is reported to precipitate aluminum encephalopathy and death, either from DFO redistribution of aluminum to brain tissue or aluminum oxide redistribution across the blood–brain barrier.

It is recommended that in patients with stage 5 chronic kidney disease that, 3 to 4 hours of HD is performed 6 to 8 hours after chelation in order to clear the aluminoxamine (the aluminum-DFO product) and prevent redistribution to vital tissues.<sup>69</sup> Patients with normal kidney function and urine output do not require HD, as the aluminoxamine is excreted in the urine (Antidotes in Depth: A7, “Deferoxamine”).

### Chronic Toxicity

Chelation therapy with DFO reverses encephalopathy, osteomalacia, and anemia. Numerous case reports demonstrate the reversal of the neurotoxicity, vitamin D–resistant bone disease, and iron-resistant anemia.<sup>7,11,15</sup> The National Kidney Foundation provides guidelines for the treatment of dialysis encephalopathy. These guidelines of nephrologists recommend 4 months of once weekly DFO at 5 mg/kg over 1 hour given 5 hours before a regularly scheduled HD session in patients with serum aluminum concentrations greater than 300 mcg/L. In patients with serum aluminum concentrations between 50 and 300 mcg/L, DFO 5 mg/kg is given during the last hour of HD, once a week for 2 months. Serum aluminum concentrations are then monitored, and this therapy is repeated as needed based on renal function and neurologic symptoms.<sup>71</sup> A small study evaluated the effect of lower doses of DFO (2.5 mg/kg/week) for treatment of chronic toxicity in dialysis patients, and found similar therapeutic benefit compared to 5 mg/kg/week dosing, but stressed the need for further studies.<sup>39</sup>

### Other Treatments

A myriad of other treatments were proposed and tested in animal models, though they were mainly small samples sizes and none have been tested in humans. Nearly all of the xenobiotics used reported benefit due to antioxidant properties and an overall decrease in oxidative stress. Substances with reported benefit have included, among others, zinc, copper, pomegranate peel, vitamin E, selenium, taurine, melatonin, coenzyme Q10, and fish oil, although there is not enough evidence to recommend the routine use of any of these substances at this time.<sup>1,2,13,41,65,66,81</sup>

### SUMMARY

- Inhalational exposure to aluminum metal causes pulmonary toxicity, primarily manifested as bronchospasm, but progresses to restrictive lung disease.
- Acutely, aluminum salts are neurotoxins with manifestations of encephalopathy and seizures.

- Chronically, aluminum salts affect at least 3 organ systems with manifestations of anemia, encephalopathy, dementia, and osteomalacia.
- Treatment involves limiting or terminating exposure, chelation with DFO, and HD in patients with CKD.

# 85

## ANTIMONY

Asim F. Tarabar

### Antimony (Sb)

Atomic number	=	51
Atomic weight	=	121.75 Da
Normal concentrations		
Serum	<	3 mcg/L (24.6 nmol/L)
Urine (24-hour)	<	6.2 mcg/L (50.1 nmol/L)
	<	3.5 mcg/g creatinine (28.7 nmol/g creatinine)

### HISTORY AND EPIDEMIOLOGY

Antimony (Sb) and its compounds are among the oldest known remedies in the practice of medicine.<sup>115,169</sup> Because of a strong chemical similarity to arsenic, the features of antimony poisoning closely resemble arsenic poisoning (Chap. 86). Antimony poisoning also shares features common with other metal poisonings, described in the chapters that follow. Although relatively uncommon, antimony toxicity occurs, usually as a complication of the treatment of visceral leishmaniasis.<sup>101</sup> Acute overdose represents an even rarer, but potentially lethal event, most often recently as a result of an unconventional alcohol aversion treatment.<sup>109,154</sup>

Objects discovered during exploration of ancient Mesopotamian life (third and fourth millennium B.C.) suggest that both the Sumerians and the Chaldeans were able to produce pure antimony.<sup>115,169</sup> The reference to eye paint in the Old Testament suggested the use of antimony.<sup>115</sup> For several thousand years, Asian and Middle Eastern countries used antimony sulfide in the production of cosmetics, including rouge and black paint for eyebrows, also known as kohl or surma.<sup>106,114</sup> Because of the scarcity of antimony sulfide, lead replaced antimony as a main component in antiquated cosmetic preparations.

One of the first monographs on metals, written in the 16th century, included a description of antimony.<sup>160</sup> The medicinal use of antimony for the treatment of syphilis, whooping cough, and gout dates to the medieval period. Paracelsus was credited with establishing the therapeutic efficacy of antimony compounds and increasing their popularity. In spite of being aware of its toxic potential, many of the disciples of Paracelsus enthusiastically continued the use of antimony.<sup>115</sup> Various antimony compounds were also used as topical preparations for the treatment of herpes, leprosy, mania, and epilepsy.<sup>169</sup> Orally administered tartar emetic (antimony potassium tartrate) was used for treatment of fever, pneumonia, inflammatory conditions, and as a decongestant, emetic, and sedative, but it was abandoned because of its significant toxicity.<sup>26,53,76,88</sup> The use of antimony as a homicidal agent<sup>155</sup> continued well into the 20th century (Chap. 1).

The current medical use of antimony is limited to the treatments of leishmaniasis and schistosomiasis, and to sporadic use as aversive therapy for substance abuse.<sup>109,154</sup> Pentavalent compounds are used as antiparasitics because they are better tolerated. In the endemic regions of the world, generic pentavalent antimonials remain the mainstay of therapy because of their efficacy and low cost. The growing incidence of resistance is affecting their use,<sup>119</sup> forcing a shift toward the use of novel cost-effective delivery systems for antimonials and second-line agents as amphotericin B, miltefosine, and paromomycin (aminosidine).<sup>75</sup>

Some contemporary homeopathic<sup>67</sup> and anthroposophical<sup>148</sup> practices recommend the use of antimonial compounds as home remedies in rare cases.<sup>115,169</sup> In spite of its anticancer effects *in vitro*<sup>53</sup> and remarkable therapeutic efficacy in patients with acute promyelocytic leukemia,<sup>143</sup> there is no current accepted oncologic use of antimony. When compared with suramin, a well-known chemotherapeutic, sodium stibogluconate appears to be a

better inhibitor, giving a foundation for future research of antimony-based chemotherapeutics.<sup>143</sup>

The elemental form of antimony has very few industrial uses because of its physical limitations, in particular the fact that it is not malleable. By contrast, its alloys with copper, lead, and tin have important applications. Various antimony compounds are used in the production of textiles, enamels, ceramics, fireworks, and pigments, and as catalysts in chemical reactions. Industrial and occupational exposure to antimony occurs mainly through the inhalation of dust or fumes during the processing or packaging of antimony compounds.<sup>16,69</sup> Workers involved in electronic waste recycling without adequate personal protective equipment develop elevated antimony concentrations in their hair, suggestive of significant exposure.<sup>90</sup> Smelters are at risk of occupational exposure to antimony as it is often present in arsenic-containing ore.<sup>66</sup> A time-weighted average over an 8-hour shift of the permissible exposure limit for antimony and its compounds is established by the Occupational Safety and Health Administration at 0.5 mg per cubic meter of air ( $\text{mg}/\text{m}^3$ ).<sup>34</sup> Antimony concentrations in cigarette smoke range from 10 to 60 mg/kg,<sup>66,123</sup> which is likely responsible for a substantial percentage of the antimony found in the lungs of smokers (Table 85-1).<sup>66</sup>

In developed countries, antimony poisoning rarely occurs following intentional ingestion of antimonials.<sup>109,169</sup> Most recent descriptions of antimony toxicity result from parenteral exposures during the treatment of schistosomiasis and leishmaniasis. Because of the infrequent use of therapeutic antimonials, health care providers in the United States are often not familiar with the standard dosing and administration procedures, placing their patients at risk for therapeutic misadventures.<sup>95</sup> An expected increase in the number of cases of domestically treated leishmaniasis resulted from the deployment of US troops to the Middle East.<sup>170</sup> Cutaneous leishmaniasis affected as many as 2% of troops deployed to Afghanistan and Iraq.<sup>14</sup>

Oral exposures usually occur following the use of antimonials containing potassium tartrate compounds.<sup>109,154</sup> Several cases were described after the use of old porcelain houseware or after the use of antimonials as home remedies.<sup>4,99,118,154</sup>

### CHEMISTRY

Antimony is found in the same group on the periodic table as arsenic (As), and as such it has many similar chemical, physical, and toxicologic properties. Because it can react as both a metal and a nonmetal, antimony is classified as a metalloid (Chap. 10).<sup>16,150</sup> Pure antimony is a lustrous, silver-white, brittle, hard metal that is easily pulverized.<sup>54,169</sup> It is extremely rare to find elemental antimony in nature because of its ability to rapidly convert to either antimony oxide or antimony trioxide.<sup>16</sup> It is suggested that even its name originates from *anti monon* (enmity to solitude) because antimony is almost always found with some other metal.<sup>115</sup> Thus, for the purposes of this chapter, the term *antimony* refers to antimony ions.

In nature, antimony is found in more than 100 different minerals,<sup>91,115</sup> including stibnite, cervantite, valentine, and kermesite.<sup>60</sup> The sulfide ore (stibnite) is the most abundant form,<sup>115</sup> and Bolivia and South Africa are among the leading producers.<sup>169</sup> Like arsenic, antimony forms both organic and inorganic compounds with trivalent ( $3^+$ ) and pentavalent ( $5^+$ ) oxidation states. Common inorganic trivalent antimony compounds include antimony potassium tartrate ( $\text{C}_8\text{H}_4\text{K}_2\text{O}_{12}\text{Sb}_2$ ), antimony trichloride ( $\text{SbCl}_3$ ), antimony trioxide ( $\text{Sb}_2\text{O}_3$ ), antimony trisulfide ( $\text{Sb}_2\text{S}_3$ ), and stibine ( $\text{SbH}_3$ ). Antimony pentasulfide ( $\text{Sb}_2\text{S}_5$ ) and pentoxide ( $\text{Sb}_2\text{O}_5$ ) are inorganic compounds that can act as oxidizing agents.<sup>23</sup> Antimony pentachloride ( $\text{SbCl}_5$ )

TABLE 85–1 Antimony Regulations and Advisories

Agency	Guidelines Description	Concentration
<b>Air</b>		
ACGIH (2004)	TLV (TWA) for antimony and inorganic antimony compounds	0.5 mg/m <sup>3</sup>
EPA IRIS (1999)	Inhalation Reference Concentration (RfC) Antimony Antimony trioxide	Not established 2 X 10 <sup>-4</sup> mg/m <sup>3</sup>
NIOSH (1994)	REL (15-minute ceiling limit) for antimony and its compounds IDLH for antimony (as Sb)	0.5 mg/m <sup>3</sup> 50 mg/m <sup>3</sup>
OSHA (2012) 29 CFR 1910.1000 Table Z-1	PEL (8-hour TWA) for antimony and compounds (General/Construction Industry/Shipyard Employment)	0.5 mg/m <sup>3</sup>
<b>Water</b>		
EPA (2009)	National primary drinking water standards for antimony MCL MCLG	0.006 mg/L (6 ppb) 0.006 mg/L (6 ppb)
FDA	Bottled drinking water	0.006 mg/L
WHO (2011)	Drinking water quality guidelines for antimony	0.02 mg/L (20 mcg/L)
ACGIH		
<b>Human Carcinogenic Effect</b>		
EPA/NTP	Not listed	
IARC (1999)	Group 2B (possibly carcinogenic to humans {antimony trioxide})	

ACGIH = American Conference of Governmental Industrial Hygienists; CFR = Code of Federal Regulations; DWEL = drinking water equivalent level; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; IARC = International Agency for Research on Cancer; IDHL = immediately dangerous to life or health; IRIS = Integrated Risk Information System; MCL = maximum contaminant level; MCLG = maximum contaminant level goal; MW = molecular weight; NIOSH = National Institute for Occupational Safety and Health; NTP = National Toxicology Program; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average; WHO = World Health Organization.

is used as a chemical reagent with acidic properties. It reacts with water, forming hydrochloric acid, which has a direct corrosive effect on the skin and mucous membranes.<sup>43</sup>

Besides amphotericin and paromomycin,<sup>171</sup> the standard treatment of cutaneous leishmaniasis, recommended by the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC), is a 20-day course of 20 mg/kg/day of sodium stibogluconate.<sup>170</sup> The use of higher doses is associated with increased side effects.<sup>170</sup> One analytical approach measured a higher presence of trivalent antimony than previously reported with a pentavalent antimonial drug. It is postulated that trivalent antimony is released specifically in the acidic intracellular compartment targeting the *Leishmania* parasites. Released trivalent antimony could be responsible for the toxic effects of antiparasitic treatment.<sup>141</sup> The proposed mechanism of antimonial activity against the *Leishmania* parasites is the inhibition of trypanothione reductase that is essential for the parasite survival and virulence.<sup>9</sup>

From an industrial perspective, the most important application of antimony is the use of antimony oxychloride (Sb<sub>2</sub>O<sub>3</sub>Cl<sub>4</sub>) as a flame retardant.<sup>115</sup> An investigation by the CDC of possible antimony toxicity in US firefighters who wear uniforms made from fabric containing antimony demonstrated no toxic link.<sup>33</sup>

Analysis of soil around firing ranges<sup>104</sup> and environmental examination around mines revealed elevated concentrations of antimony that can pose a significant health risk.<sup>79,174</sup> A public health concern was raised after reports of elevated antimony concentrations in water containers and commercial juices due to leaching from the packaging material or a flawed manufacturing process.<sup>77,144</sup>

Tartar emetic (antimony potassium tartrate) is an odorless trivalent antimony compound with a sweet metallic taste<sup>78</sup> and a potent emetic effect.<sup>23</sup> Antimony potassium tartrate is considered to be one of the most toxic antimony compounds, with minimal lethal doses reported between 200 mg<sup>118</sup> and 1,200 mg.<sup>115</sup> There are large species variations of the LD<sub>50</sub> in experimental animals, with a reported range of 115 mg/kg in rabbits and rats to 600 mg/kg in mice. In comparison, because of low water solubility, antimony trioxide is considered to be nontoxic, with an LD<sub>50</sub> greater than 20,000 mg/kg.<sup>64</sup>

## PHARMACOLOGY

One proposed mechanism for the antiparasitic mechanisms of action of antimony is the inhibition of phosphofructokinase, which is the rate-limiting step in the glycolytic pathway of *Schistosoma* spp.<sup>36</sup> Trivalent antimony compounds inhibit phosphofructokinase, leading to energy failure from impaired adenosine triphosphate (ATP) synthesis.<sup>31,169</sup> It is also speculated that antimonial preparations exert their antiparasitic effect through selective targeting of guanosine diphosphate–mannose pyrophosphorylase, which interferes with nucleoside and mannose metabolism.<sup>61</sup> The result is that the parasites cannot synthesize purines and cannot survive without these mannose-containing glycoconjugates. A more recently proposed mechanism involves the inhibition of trypanothione reductase.<sup>9</sup> Even less is known about the effects of antimony on humans. It is proposed that, like other metals, antimony inactivates thiol-containing proteins and enzymes by binding to sulfhydryl groups.<sup>48</sup> Pentavalent antimony may act as a prodrug that is converted in acidic intracellular compartments into active and more toxic trivalent antimony.<sup>141</sup>

## TOXICOKINETICS

### Absorption

Antimony is absorbed by inhalation, ingestion, or transdermally. Absorption from the gastrointestinal tract begins immediately following ingestion, and the oral bioavailability of antimony ranges from 15% to 50%.<sup>65,163</sup> It is suggested that antimony absorption is a saturable process, given that several studies failed to demonstrate a dose–response relationship for absorption.<sup>2,151</sup> In fact, after a lethal ingestion of antimony tartrate, the total body antimony burden was only 5% of the ingested dose.<sup>105</sup> This poor gastrointestinal absorption in humans, in addition to the concomitant emesis, necessitates parenteral administration of many antimony-based pharmaceuticals.

Pulmonary absorption of many inorganic antimony compounds is very slow and limited by low water solubility.<sup>115</sup> By contrast, animal data suggest that inhaled trivalent antimony is well absorbed from the lungs, distributed to various organs, and subsequently excreted in the feces and urine.<sup>52</sup>

Transdermal absorption of antimony trioxide and pentoxide was documented in studies with rabbits;<sup>122</sup> however, dermal absorption in humans of antimony trioxide is considered negligible.<sup>138</sup> In an investigation of a possible outbreak of antimony exposure in firefighters, no significant transdermal absorption occurred from the antimony containing firefighter uniforms.<sup>33</sup>

### Distribution

Distribution depends on the oxidation state of antimony. In animals, more than 95% of trivalent antimony is incorporated into the red blood cells within 2 hours of exposure, whereas 90% of pentavalent antimony remains in the serum in a similar time frame.<sup>55</sup>

When administered intravenously or orally, antimony is predominantly distributed among highly vascular organs, including the liver, kidneys, thyroid, and adrenals.<sup>128,169</sup> The antimony that is detected in the liver and spleen is predominantly in the pentavalent form, whereas the thyroid accumulates trivalent forms.<sup>15</sup> Uptake by the liver occurs through the mechanisms of diffusion and saturable binding.<sup>147</sup> In a hamster model, following a single injection of organic antimonials, the greatest concentration of antimony was found in the liver.<sup>65</sup> After inhalation, antimony accumulates predominantly in red blood cells and to a significantly lesser extent in the liver and spleen.<sup>52,55</sup> It is possible that inhaled antimony is retained in the lungs for a prolonged period of time without significant systemic absorption and distribution.<sup>66</sup> Animal data also demonstrated the accumulation of antimony in the skeletal system and in fur.<sup>57,58</sup>

After intramuscular (IM) administration of sodium stibogluconate, the antimony concentration versus time profile suggested a 2-compartment open model, with the rapid distribution phase and slower elimination half-life in the range of 10 hours.<sup>175</sup>

### Metabolism

Although antimony and arsenic share many toxicokinetic properties, inorganic trivalent antimony, unlike arsenic, is not methylated in vivo.<sup>8</sup> Some microorganisms, however, are capable of biomethylation of antimony.<sup>19</sup> In humans, metabolic transformations of antimony are limited. Antimony is converted by binding to macromolecules, incorporation into lipids,<sup>18</sup> and covalent interactions with sulfhydryl groups and phosphates. Pentavalent antimony is either converted to trivalent compounds in the liver<sup>169</sup> or in the acidic intracellular environment of *Leishmania*-infected cells.<sup>141</sup>

### Excretion

Trivalent antimony is excreted in the bile after conjugation with glutathione. A significant proportion of excreted antimony undergoes enterohepatic recirculation.<sup>8</sup> The remainder is excreted in urine. The overall elimination is very slow, with only 10% of a given dose cleared in the first 24 hours and 30% in the first week<sup>12</sup> although antimony is still detected in the urine 100 days after administration.<sup>108,169</sup> Pentavalent antimony is much more rapidly excreted by the kidneys than trivalent antimony (50%–60% vs 10% over the first 24 hours).<sup>169</sup> Renal excretion of sodium stibogluconate is as high as 90% within 6 hours of an IM administration.<sup>135</sup> However, urine and serum antimony concentrations remain elevated for several years following therapeutic use.<sup>111</sup> In workers, urine concentrations of pentavalent antimony correlate well with the extent of exposure.<sup>8</sup>

The clearance of tartar emetic has a biphasic pattern, with 90% being excreted within 24 hours after acute exposure, followed by a second slower phase with an estimated half-life of approximately 16 days.<sup>57</sup>

The renal elimination half-life of inhaled stibine was estimated at approximately 4 days following occupational exposure.<sup>100</sup>

## PATHOPHYSIOLOGY

Antimony has no known biological functions and is considered to be toxic even at very low concentrations.<sup>145</sup> Like other toxic metals, antimony binds to sulfhydryl groups to inhibit a variety of metabolic functions.<sup>37,48</sup> Trivalent antimony compounds are more toxic than the pentavalent compounds because of their higher affinity for erythrocytes and sulfhydryl groups.<sup>102</sup> Tartar emetic and other antimony salts are gastrointestinal irritants. One proposed

mechanism for this local effect is the activation of enterochromaffin cells, which produce and secrete serotonin (5-HT). Released serotonin acts on the 5-HT<sub>3</sub> receptors, stimulating vagal sensory fibers and activating the vomiting center.<sup>74,165</sup> In addition, there is an apparent direct central medullary action, particularly after the administration of higher doses of antimony.<sup>169</sup>

## CLINICAL MANIFESTATIONS

Data on human toxicity of antimony are very limited. They are largely extrapolated from occupationally exposed patients, adverse effects that have occurred during treatment of leishmaniasis and schistosomiasis, and very few case reports of intentional antimony exposures.<sup>118</sup> Serious adverse events and deaths resulting from treatment with sodium stibogluconate are very rare, and include cardiac dysrhythmias or pancreatitis.<sup>170</sup> Patients older than 50 years are at an increased risk for more serious reactions to meglumine antimonate used for the treatment of visceral leishmaniasis (Table 85–2).<sup>51,125</sup>

Workers with occupational exposures usually present with subtle delayed clinical manifestations as chronic toxicity develops. It is important to recognize that antimony ore contains a small concentration of arsenic, making it difficult to determine whether the effects on workers are caused by contaminants such as arsenic or by the antimony. Patients have side effects at therapeutic doses of prolonged treatment regimens with very large cumulative doses that result in acute and subacute clinical manifestations.<sup>158</sup> Therapeutic misadventures are possible, particularly in a setting in which antimony preparations are rarely used and health care providers are not familiar with the dosing regimen.<sup>94</sup>

Patients with acute ingestions usually present with signs and symptoms mimicking the toxicity of arsenic and other metal and metalloid salts.

### Local Irritation

The most common manifestations of antimony toxicity involve local irritation. In sufficient concentration, antimony acts as an irritant to the eyes, skin, and mucosa. Ophthalmic exposure causes conjunctivitis.<sup>21,60,136</sup> Irritation of the upper respiratory tract leads to pharyngitis and frequent epistaxis.<sup>168</sup>

Antimony pentachloride is very irritating and causes local dermal and mucosal burns, as it reacts with water, releasing hydrochloric acid, heat, and antimony pentoxide (Sb<sub>2</sub>O<sub>5</sub>). Following ingestion, contact with the water in saliva produces sufficient hydrochloric acid to result in consequential gastrointestinal burns.

Ophthalmic exposure to Sb<sub>2</sub>O<sub>5</sub> causes a typical caustic injury, resulting in blepharospasm, lacrimation, photophobia, and corneal burns. Exposure to antimony trichloride fumes causes similar ocular findings.<sup>68</sup>

Following systemic exposure, ophthalmic toxicity manifests in optic atrophy, uveitis, and retinal hemorrhage with exudates resulting in diminished visual acuity.<sup>40,97</sup> Some of these changes are permanent.<sup>97</sup> Interestingly, a metallic intraocular foreign body composed of antimony was removed 60 years after the initial injury with no evidence of metallosis. A postprocedural electroretinogram was normal.<sup>146</sup>

Thrombophlebitis is common after the intravenous (IV) use of antimony but it also occurs following oral exposure.<sup>105</sup>

### Gastrointestinal

Following acute exposures, antimony rapidly produces anorexia, nausea, vomiting, abdominal pain, and diarrhea.<sup>105,109,166</sup> Some patients report a metallic taste in the mouth.<sup>8,46</sup> A garlic odor on the breath is often recognized but this may be due to concomitant arsenic exposure. In severe overdose, gastrointestinal irritation progresses to hemorrhagic gastritis.<sup>105</sup> Workers chronically exposed to antimony dusts have a much higher incidence of gastrointestinal ulcers in comparison to controls (63 per 1,000 vs 15 per 1,000).<sup>27</sup> Many patients develop pancreatitis following treatment with pentavalent antimonial salts.<sup>47,63,116</sup> Because most cases improved despite continuation of treatment, a mechanism other than direct pancreatic toxicity is presumed. In another series, several patients with human immunodeficiency virus (HIV) who were treated with high doses of meglumine antimonate developed severe pancreatitis and died.<sup>49</sup>

TABLE 85–2 Clinical Manifestations of Antimony Compounds Poisoning\* (Continued)

Antimony Compound	Stibine	Antimony Potassium Tartrate	Antimony Trioxide	Antimony Pentachloride/Pentoxide	Meglumine Antimoniate	Sodium Stibogluconate
<b>Neurologic</b>						
Vestibular-Cochlear toxicity					+	
Tinnitus					+	
Rotatory dizziness					+	
Peripheral sensory neuropathy						+
Cerebellar ataxia						+

Muscle and joint pain					+	+
Rhabdomyolysis						
<b>Genotoxicity</b>	+					
<b>Carcinogenicity</b>			+			

\*The absence of a + indicates the absence of reported or recognized clinical manifestation.

### Cardiovascular

In animals, antimony decreases myocardial contraction; lowers coronary vasomotor tone, producing decreased systolic pressure; and causes bradycardia.<sup>45,169</sup> The majority of reported human cardiac effects are related to the electrocardiographic (ECG) changes. Prolongation of the QT interval, inversion or flattening of T waves, and ST segment changes are frequently described during treatment of visceral leishmaniasis with pentavalent antimonial compounds (sodium stibogluconate and meglumine antimonate).<sup>39,139,172</sup> Torsade de pointes was described in patients treated with pentavalent antimonial preparations.<sup>127,157</sup> Prolongation of the cardiac action potential may be due to an increase in cardiac calcium currents.<sup>103</sup>

In some patients with underlying myocardial disease such as a cardiomyopathy, ECG changes occur even at subtherapeutic antimony doses.<sup>73</sup> These changes are not necessarily associated with deterioration in cardiac function.<sup>80,82</sup> However, it is important to recognize that pentavalent antimonial drugs used for the treatment of leishmaniasis are associated with sudden death, probably as a result of the development of ventricular dysrhythmias.<sup>35,153</sup> Cardiomyopathy followed by congestive heart failure and death is rare but is a reported adverse effect attributed to antimony.<sup>125,152</sup> Pericarditis, presenting with chest pain and typical ECG changes, is reported during the treatment with meglumine antimoniate.<sup>56</sup>

Chronic antimony exposure resulting in elevated concentrations of antimony in urine are associated with an increase in composite cardiovascular and cerebrovascular disease.<sup>1</sup>

### Respiratory

Local irritation from antimony trioxide produces laryngitis, tracheitis, and pneumonitis.<sup>66,136,156</sup> Pneumonitis is usually reversible after exposure ceases and can be followed radiologically.<sup>136</sup> Acute respiratory distress syndrome was reported after acute inhalation of antimony pentachloride.<sup>43,44</sup>

Although antimony oxides are capable of causing metal fume fever,<sup>6,59</sup> this is much less common in comparison to exposure to zinc oxide (Chaps. 100 and 121).<sup>6,59</sup> Antimony metal fume fever is reported to occur even with air concentrations below 5 mg/m<sup>3</sup>.<sup>42</sup>

Workers chronically exposed to antimony compounds are at risk for developing “antimony pneumoconiosis.”<sup>41,114</sup> Patients present with cough, wheezing, and exertional dyspnea, which can progress to obstructive lung disease. Radiologically, antimony pneumoconiosis appears as diffuse, dense, punctate nonconfluent opacities with a predominant distribution in the middle and lower lung lobes with or without pleural adhesions.<sup>132</sup> In the general population, increased urinary antimony concentrations are associated with higher odds of experiencing obstructive sleep apnea.<sup>142</sup>

### Renal

Patients treated with sodium stibogluconate develop varied manifestations of nephrotoxicity ranging from renal cell casts, proteinuria, and increased blood urea nitrogen concentration<sup>40</sup> due to acute kidney injury (AKI).<sup>10,133</sup> Some patients also develop renal tubular acidosis<sup>87</sup> and acute tubular necrosis.<sup>134</sup> Older age and underlying chronic kidney disease are risk factors for the development of AKI that can progress to death.<sup>112,125</sup> Hemodialysis is reportedly helpful during the oliguric phase in acute overdose.<sup>109</sup>

Antimonials are also suggested as a possible cause of drug-induced acute interstitial nephritis responsive to treatment with steroids.<sup>162</sup>

### Hepatic

Acute exposure to antimony results in severe acute liver injury.<sup>109</sup> Long-term therapeutic use of antimony compounds for the treatment of leishmaniasis causes hepatotoxicity that ranges from reversible elevations of aminotransferase concentrations to hepatic necrosis.<sup>83,85,140,169</sup> Elderly patients are at an increased risk for the development of significant hepatic failure.<sup>125</sup> Some pediatric patients treated for leishmaniasis develop fulminant hepatic failure after an initial positive response to antimony. The mechanism is unknown, but the condition may be due to a direct antimony effect in combination with immunologically mediated liver injury.<sup>11,50</sup>

Interestingly, in an animal study, concurrent administration of ascorbic acid (15 mg/kg/day) appeared to be hepatoprotective. Its activity reduced the extent of histologic changes, the apoptotic index, and the peroxidase activity.<sup>98</sup>

### Hematologic

Severe anemia was reported in HIV-positive patients during treatment with sodium stibogluconate. Bone marrow biopsy documented transient severe marrow dyserythropoiesis, followed by complete recovery on discontinuation of the therapy.<sup>84,110</sup>

Patients treated with sodium stibogluconate for visceral leishmaniasis occasionally develop thrombocytopenia.<sup>22,81,94</sup> Rare cases of epistaxis are described during the treatment.<sup>96</sup> Visceral leishmaniasis is associated with pancytopenia, probably as a result of an increased destruction of peripheral blood cells.<sup>131</sup> It is difficult to determine whether this phenomenon is caused by the disease itself or is secondary to the treatment, although some authors suggested a drug-induced immune thrombocytopenia.<sup>131</sup>

Leukopenia is frequently observed in patients treated with antimonial compounds.<sup>49,169,173</sup> Some authors speculate that antimony-induced lymphopenia is associated with an increased frequency of herpes zoster in HIV-infected patients.<sup>173</sup> It is suggested that pentavalent antimony precipitates sickle cell crisis via a common glutathione pathway.<sup>62</sup> A homeopathic study

suggested a procoagulant effect, leading some homeopathic practitioners to include antimony as a treatment for bleeding disorders.<sup>86</sup>

### Dermatologic

Antimony spots<sup>149</sup> are papules and pustules that develop around sweat and sebaceous glands and resemble varicella. Chronically exposed patients typically develop eczema and lichenification of the arms, legs, and in the joint creases with sparing of the face, hands, and feet that typically occur in the summer.<sup>114,136</sup> A similar skin rash was described in the 18th century after the external application of antimony tartrate for medicinal use.<sup>115</sup> Curiously, these eruptions were usually interpreted as a sign of cure.<sup>76</sup> It is also suggested that antimony trioxide causes contact dermatitis.<sup>120</sup> A very high incidence of severe cutaneous reactions (37%) was reported in patients who were treated with meglumine antimonate at 20 mg/kg/day.<sup>126</sup> This high incidence was associated with high concentrations of other metals in the one particular drug lot. Herpes zoster was reported as a complication of antileishmaniasis treatment with associated leukopenia.<sup>126,173</sup> An isolated case of an infant who developed acute urticaria after her mother's parenteral use of meglumine antimonate increases the possibility of antimony exposure via breast milk.<sup>121</sup>

### Neurologic

Patients treated with sodium stibogluconate developed a reversible, peripheral sensory neuropathy,<sup>29</sup> and cerebellar ataxia in temporal association with exposure.<sup>101</sup> Reversible vestibular-cochlear toxicity was reported in a patient who presented with a significant increase in auditory threshold during the treatment with meglumine antimonate. In addition, the patient experienced tinnitus and severe rotatory dizziness.<sup>161</sup>

### Musculoskeletal

The therapeutic use of parenteral antimonials is associated with diffuse muscle and joint pain.<sup>32,46,140,169</sup> One of the most frequently reported clinical adverse effects of pentavalent antimonials was musculoskeletal pain.<sup>126</sup> The symptoms are sometimes so severe that they will require treatment interruption in about one third of patients. Patients who are not candidates for nonsteroidal antiinflammatory drug treatment are usually managed with glucocorticoids.<sup>28</sup>

### Metabolic

Antimony is a recognized metalloestrogen,<sup>38</sup> and chronic exposure increases the risk of diabetes<sup>117</sup> through this hormonal disruption.

### Immunologic

A case-control study of 100 patients and 300 controls showed a marked association between systemic sclerosis and antimony exposure in both male and female patients.<sup>112</sup> It is still unclear what the pathogenic mechanisms of antimony in development of systemic sclerosis are, although basic science research implied that antimony is capable of altering the epigenome, resulting in chromosomal aberration in cultured mammalian cells,<sup>113</sup> as well as in the excess production of reactive oxygen species and interference with the DNA repair system.<sup>7</sup> The use of meglumine antimonate was reported to cause 2 different subsets of cutaneous hypersensitivity reactions: immunoglobulin E (IgE)-mediated allergic reactions (type-I) that presents immediately and can range from localized and generalized urticaria to anaphylaxis and delayed (type-IV) allergic reactions, including eczematous lesions and persistent subcutaneous nodules.<sup>24</sup>

### Reproductive

In animal studies, antimony causes ovarian atrophy, uterine metaplasia, and impaired conception.<sup>17</sup> An association was found with spontaneous abortion and premature births reported in women who were occupationally exposed to antimony salts. Antimony was found in the blood, urine, placenta, amniotic fluid, and breast milk of these women.<sup>17</sup>

### Carcinogenicity

Female rats developed lung tumors after the inhalation of antimony trioxide and antimony trisulfide.<sup>20,72,164</sup> A survey among antimony smelters suggested an excess of lung cancer, with a latency of 20 years, in comparison to

a nonexposed population. However, concomitant exposure to arsenic and its effects could not be excluded, and the data were inadequately controlled for smoking habits.<sup>93</sup> In one group of workers who were exposed to antimony oxide over 9 to 31 years, there was no increased incidence of lung cancer.<sup>132</sup> Patients with schistosomiasis have an increased incidence of bladder tumors, and antimony compounds are considered to be one potential cause.<sup>169</sup> The International Agency for Research on Cancer classified antimony trioxide as possibly carcinogenic to humans (group 2B).<sup>71</sup>

### Genotoxicity

Both stibine and trimethylstibine are capable of damaging DNA, presumably by the generation of reactive oxygen species. Other forms of antimony tested, including potassium antimony tartrate, potassium hexahydroxyantimonate, and trimethylantimony dichloride, were found to not be genotoxic.<sup>5</sup> Trivalent antimony interferes with proteins involved in nucleotide excision repair and partly impairs this pathway, pointing to an indirect mechanism in the genotoxicity of trivalent antimony.<sup>71</sup>

### STIBINE

Antimony compounds react with nascent hydrogen, forming an extremely toxic gas, stibine (SbH<sub>3</sub>), which resembles arsine (AsH<sub>3</sub>) (Chap. 86). Stibine is probably the most toxic antimony compound. It is a colorless gas with a very unpleasant smell that rapidly decomposes at temperatures above 302°F (150°C).<sup>70,169</sup> Historically, stibine release was reported during the charging of lead storage batteries.<sup>169</sup> In addition to gastrointestinal effects that include nausea, vomiting, and abdominal pain, stibine has strong oxidative properties that results in massive hemolysis (Chap. 20). Similar to arsine,<sup>137</sup> severe stibine exposure results in hematuria, rhabdomyolysis, and death. Maintenance workers are advised to avoid use of drain cleaners containing sodium hydroxide, which is capable of releasing hydrogen in situations where antimony is present.<sup>129</sup>

### DIAGNOSTIC TESTING

Standard laboratory testing to assess volume depletion and AKI is indicated for patients with acute antimony toxicity. A complete blood count, electrolytes, renal function studies, and a urinalysis should be obtained. When there is a known or suspected exposure to stibine, additional studies should include tests for hemolysis, such as determinations of bilirubin and haptoglobin. Blood should also be obtained for a blood type and cross-match, as transfusions are likely to be required.

An ECG should be obtained to evaluate for QT interval prolongation and dysrhythmias. Patients with known myocardial disease should have frequent evaluations of cardiac function,<sup>73</sup> and continuous ECG monitoring is recommended for all patients with significant toxicity or abnormal cardiovascular status. A chest radiograph should be performed in patients with respiratory symptoms and findings and evidence of hypoxia after significant inhalation exposure. In addition, an abdominal radiograph is reasonable in patients with ingestion to evaluate gastrointestinal antimony load and help guide decontamination.<sup>30</sup>

An antimony concentration in a 24-hour urine collection is used for the assessment of the intensity of exposure to either trivalent or pentavalent antimony.<sup>8</sup> A normal urinary antimony concentration in unexposed patients is reported as less than 6.2 mcg/L.<sup>130,167</sup> A serum antimony concentration cannot be determined in a timely fashion. The normal serum concentration of antimony is in the range of less than 3 mcg/L,<sup>111</sup> although some laboratories use higher values.<sup>124</sup>

### TREATMENT

#### Decontamination

Following a significant acute ingestion, the majority of patients develop vomiting. Induction of emesis is unlikely to offer any additional benefit. By contrast, gastric lavage is reasonable, especially if performed before the onset of spontaneous emesis. Although it is unknown whether antimony is adsorbed to activated charcoal, based on experience with salts of arsenic, thallium, and

mercury, administration of activated charcoal is recommended. Additionally, because antimony has a documented enterohepatic circulation, multiple-dose activated charcoal is reasonable if the patient can tolerate it.<sup>8</sup> Limited data on arsenic decontamination suggests the effectiveness of this method.<sup>92</sup> Based on experience with arsenic poisoning, whole-bowel irrigation (WBI) is also recommended with severe ingestions in patients who are able to tolerate it, especially if radiographs confirm radiopaque material.<sup>3,30</sup> It is suggested that WBI has no effectiveness after 48 hours from arsenic exposure,<sup>92</sup> but it is unclear whether this is applicable to antimony.

For patients exposed to stibine, removal from the exposure should be followed by the administration of high-flow oxygen. While theoretically patients with severe stibine exposures may benefit from exchange transfusion for the removal of the stibine-hemoglobin complex,<sup>137</sup> data are insufficient to routinely recommend this practice. Patients with dermal exposures, particularly to antimony tri- or pentachloride, should be decontaminated with soap and water. Prompt removal from the contaminated area is important for patients exposed to stibine. Rescuers need to take appropriate precautions to ensure their own safety (Chap. 132).

### Supportive Care

The mainstay of treatment for antimony poisoning is good supportive care. Clinicians should anticipate massive volume depletion and begin rehydration with isotonic crystalloid solutions. Electrolytes, urine output, and renal and liver function<sup>109</sup> should be followed closely. A central venous pressure monitor is reasonable in patients with cardiovascular instability. Antiemetics are recommended both for patient comfort and to facilitate the administration of activated charcoal. Following stibine exposure, the hemoglobin concentration should be followed closely and blood should be transfused based on standard criteria.

### Chelation

Human experience with regard to chelation of antimony is rather limited because of the scarcity of serious toxicity and the rarity of instances in which patients have received chelation. Most of the available data are based on animal experimentation. Dimercaprol, succimer, and dimercaptopropane-sulfonic acid (DMPS) all improve the survival of experimental animals.<sup>13,25,89,159</sup> A group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the murine LD<sub>50</sub> of tartar emetic 16-fold.<sup>107</sup> One animal study that compared survival after treatment with multiple chelators concluded that the most effective antidotes were DMPS and succimer.<sup>13</sup>

A single case series documented survival in 3 of 5 patients exposed to tartar emetic who were treated with intramuscular dimercaprol at a dose of 200 to 600 mg/day. All 5 patients had increased urinary excretion of antimony.<sup>105</sup> In another case report, a patient survived after chelation with dimercaprol but without evidence of enhanced urinary excretion of antimony.<sup>8</sup> Although specific recommendations are difficult to make, it is reasonable to begin therapy with IM dimercaprol until it is certain that antimony is removed from the gastrointestinal tract, at which time the patient can be switched to oral succimer. If the patient experiences cardiac or respiratory effects with associated ECG changes during administration of dimercaprol, treatment should be stopped.<sup>109</sup> Because chelation doses for antimony poisoning are not established, chelators should be administered in doses and regimens that are determined to be safe and effective for other metals such as arsenic given the similarities of these metals (Antidotes in Depth: A28 and A29).

### SUMMARY

- Antimony toxicity should be suspected in patients with unexplained profuse nausea, vomiting, diarrhea, and abdominal pain, particularly in the setting of alcohol aversion treatment and acute kidney injury.
- Most patients will require only supportive therapy with decontamination.
- Multiple doses of activated charcoal are reasonable.

- Whole-bowel irrigation is recommended and likely most beneficial in the first 48 hours following oral exposure.
- Symptomatic patients should be admitted to telemetry for monitoring for cardiac dysrhythmias.
- Chelation with dimercaprol is reasonable in severe cases of acute overdose.
- Serious complications from treatment of leishmaniasis antimonial preparations are rare, related to the heart and pancreas, with age and underlying diseases constituting known risk factors.

## ARSENIC

Stephen W. Munday

### Arsenic (As)

Atomic number	=	33
Atomic weight	=	74.92 Da
Normal concentrations		
Whole blood	<	5 mcg/L (0.067 μmol/L)
Urine (24-hour)	<	50 mcg/L (0.67 μmol/L)
	<	100 mcg/g creatinine (1.33 μmol/g creatinine)

### HISTORY AND EPIDEMIOLOGY

Arsenic poisoning can be unintentional, suicidal, homicidal, occupational, environmental, or iatrogenic.<sup>114,115,150,177</sup> Mass poisonings have occurred. Nearly 400 residents of Hong Kong fell ill after eating contaminated bread from the Esing Bakery in 1857, when 2 bakery foremen had tampered with the recipe.<sup>94</sup> In the 1900 Staffordshire beer epidemic in England, 6,000 beer drinkers fell ill and 70 died from beer brewed with sugar made with arsenic-contaminated sulfuric acid.<sup>114</sup> In Wakayama, Japan, 67 people were poisoned by eating intentionally contaminated curry at a festival in 1998.<sup>235</sup> In 2003, the largest recent outbreak of arsenic poisoning in the United States, occurred in New Sweden, Maine, when intentionally adulterated church coffee resulted in the death of one parishioner and the hospitalization of an additional 15 victims.<sup>19</sup> Arsenic trioxide (As<sub>2</sub>O<sub>3</sub>) reemerged as a treatment for acute promyelocytic leukemia (APML) in the 1990s after physicians in Harbin, China, found a high remission rate in patients given a crude As<sub>2</sub>O<sub>3</sub> infusion.<sup>135,251</sup>

Contaminated soil, water, and food are the primary sources of arsenic for the general population. Pentavalent arsenic (As<sup>5+</sup>) is the most common inorganic form in the environment.<sup>61</sup> Inorganic arsenic exposure from food is generally low and usually occurs from soil-derived foods such as rice and produce.<sup>32,211,265,273</sup>; however, there is evidence that rice contamination is a significant source of arsenic exposure beyond drinking water.<sup>113,125</sup> Exposure to organic arsenic compounds of low toxicity occurs from consumption of algae, fish, and shellfish. In the past few decades, consumption of contaminated water has emerged as the primary cause of large-scale outbreaks of chronic arsenic toxicity. Arsenic leaches from certain minerals and ores, as well as from industrial waste.<sup>157</sup> In Bangladesh, millions of people have been poisoned by drinking water from wells contaminated with arsenic leached from ground minerals.<sup>182</sup> Ironically, the wells were dug to obtain safer groundwater. Hydroarsenicism is also reported in Chile, Taiwan, Brazil, India, Mexico, and Argentina.<sup>35,54,61,107,157,182,251</sup> In 2001, the US Environmental Protection Agency decreased the maximum contaminant concentration of arsenic in drinking water to 10 parts per billion (ppb), or 10 mcg/L, after statistical modeling indicated an increased risk of lung and bladder cancer from water contaminated with arsenic at the formerly acceptable concentration of 50 ppb.<sup>70</sup> The World Health Organization also recommends a maximum concentration of 10 ppb.

### CHEMISTRY

Arsenic is a metalloid that exists in multiple forms: elemental, gaseous (arsine), organic, and inorganic (As<sup>3+</sup> {trivalent, or arsenite} and As<sup>5+</sup> {pentavalent, or arsenate}). Tables 86-1 and 86-2 list sources of arsenic and regulatory standards about arsenic, respectively. Arsenic metal is considered nonpoisonous because of its insolubility in water and, therefore, bodily fluids.<sup>210</sup> Arsine, which is highly toxic, is discussed in Chap. 121. Trivalent arsenicals include arsenic trioxide (As<sub>2</sub>O<sub>3</sub>), tetra-arsenic tetrasulfide (realgar; As<sub>4</sub>S<sub>4</sub>), and diarsenic trisulfide (orpiment; As<sub>2</sub>S<sub>3</sub>). Realgar and orpiment were used by the Chinese to treat malignancies, diarrhea, and infections of the chest and liver.<sup>148</sup> Organic arsenicals vary in toxicity. Arsenobetaine, which

is synthesized from inorganic arsenic by fish and crustaceans, and arsenosugars, which are synthesized by fish, crustaceans, and algae, have very low toxicity.<sup>12,67,140</sup> By contrast, the organoarsenical medication melarsoprol, used to treat the meningoencephalitic stage of African trypanosomiasis, is highly toxic and similar to inorganic arsenite.<sup>27,199</sup>

### PHARMACOLOGY/PHYSIOLOGY

Arsenic trioxide is used to treat APML. The role of arsenic in our pharmacopeia is expanding. Its efficacy in treating various other leukemias, lymphomas, and multiple myeloma, as well as a variety of solid tumors such as breast cancer, colon cancer, lung cancer, hepatocellular carcinoma, colorectal cancer, renal cell carcinoma, and osteosarcoma is under study.<sup>38,130,171</sup>

Arsenic trioxide is administered therapeutically for treating APML in doses of 0.15 to 0.16 mg/kg/day by either the intravenous or oral route.<sup>132,135,213,214,217</sup> At this dose, its beneficial effects occur predominantly by initiating cellular apoptosis when arsenic concentrations reach 0.5 to 2.0 μmol/L. Apoptosis is triggered by several mechanisms. The trivalent arsenic (As<sup>3+</sup>) ion binds to mitochondrial membrane sulfhydryl (SH) groups, damaging mitochondrial membranes and collapsing membrane potentials. Cytochrome C is released from the damaged mitochondria, with subsequent activation of

TABLE 86-1 Sources of Exposure to Arsenic

<b>Inorganic</b>
Occupational/manufacturing
Animal feed (additive)
Brass/bronze
Ceramics/glass
Computer chips (same as semiconductors)
Dyes/paints
Electron microscopy
Fireworks (Chinese)
Fossil fuel combustion—coal
Herbicides
Insecticides/pesticides
Metallurgy
Mining
Rodenticides
Semiconductors (gallium arsenide)
Smelting—copper, lead, zinc, sulfide minerals
Soldering
Wood preservatives
Medications/contaminated xenobiotics
Chemotherapeutics (acute promyelocytic leukemia)
Depilatory
Herbals/alternative medicines
Homeopathic remedies
Kelp
“Moonshine” ethanol
Opium
Other
Well water (contaminated)
Candies/foods, eg, licorice (contaminated)
<b>Organic</b>
Melarsoprol (trypanocidal)
Thiacetarsamide (heartworm therapy in dogs)
Seafood (arsenobetaine)

TABLE 86–2 Regulations and Guidelines Applicable to Arsenic and Arsenic Compounds

Agency	Guideline Description	Concentration	Source
<b>Air</b>			
ACGIH	TLV (TWA) for arsenic and inorganic arsenic compounds	0.01 mg/m <sup>3</sup>	ACGIH 2004
NIOSH	REL (15-min ceiling limit) for arsenic and inorganic compounds	0.002 mg/m <sup>3</sup>	NIOSH 2005
	IDLH for arsenic and inorganic compounds	5 mg/m <sup>3</sup>	NIOSH 2005
OSHA	PEL (8-hour TWA) for organic arsenic compounds (general industry, construction, and shipyard)	0.5 mg/m <sup>3</sup>	OSHA 2005 29 CFR 1910.1000; 1926.55; 1915.1000
	PEL (8-hour TWA) for general industry for inorganic arsenic compounds	10 mcg/m <sup>3</sup>	OSHA 2005 29 CFR 1910.1018

IARC			IARC 2007

ACGIH = American Conference of Governmental Industrial Hygienists; CFR = Code of Federal Regulations; DWEL = drinking water equivalent level; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; IARC = International Agency for Research on Cancer; IDLH = immediately dangerous to life or health; IRIS = Integrated Risk Information System; MCL = maximum contaminant level; MCLG = maximum contaminant level goal; MW = molecular weight; NIOSH = National Institute for Occupational Safety and Health; NTP = National Toxicology Program; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average; WHO = World Health Organization.

caspses 3, 8, and 9 and initiation of apoptosis. Cells are more susceptible if the intracellular concentrations of catalase and glutathione peroxidase (H<sub>2</sub>O<sub>2</sub> scavenging enzymes) and glutathione-S-transferase (responsible for conjugating glutathione to xenobiotics) are reduced.<sup>47,69,84,117,203</sup> Arsenic trioxide also facilitates apoptosis by down-regulating gene expression of BCL2, a prosurvival protein that protects against apoptosis.<sup>36</sup> Finally, As<sub>2</sub>O<sub>3</sub> arrests cells early in mitosis, subsequently leading to apoptosis.<sup>97</sup>

Low-dose As<sub>2</sub>O<sub>3</sub> treatment (0.08 mg/kg/day) promotes cell differentiation of APL cells when arsenic concentrations reach 0.1 to 2.0 μmol/L. This differentiation is impaired by the promyelocytic leukemia-retinoic acid receptor α (PML-RARα) oncoprotein. This oncoprotein results from the APLM-defining translocation of chromosomes 15 and 17. The PML portion of this oncoprotein plays a key role in leukemogenesis by interfering with RARα activity that is essential for normal myeloid cellular development. Trivalent arsenic degrades this PML portion, freeing RARα to facilitate cell differentiation.<sup>47,164,173</sup>

Melarsoprol is a trivalent organic arsenical compound used in Africa and parts of Europe to treat the meningoencephalitic stages of both species of African trypanosomes. It is ineffective against American trypanosomiasis and is available in the United States only directly from the Centers for Disease Control and Prevention (CDC), as it is not approved by the US Food and Drug Administration (FDA). The mechanism of action is still poorly understood but is related to inhibition of glycolysis and oxidation-reduction reactions. The pharmaceutical compound also contains dimercaprol (BAL), which seems to reduce toxicity without diminishing effectiveness. The therapeutic use of melarsoprol produces many of the toxic effects that occur with inorganic arsenic, including fever, encephalopathy, and acute cerebral edema with seizures and coma. Whether these effects are caused by drug toxicity or by an immune reaction elicited by trypanosomal antigens is unknown.<sup>27,183,199</sup> Other adverse effects include vomiting, abdominal pain, peripheral neuropathy with hypersensitivity reactions, hypertension, myocardial damage, and albuminuria. Hemolysis occurs in patients with glucose-6-phosphate dehydrogenase deficiency, and erythema nodosum occurs in patients with leprosy.<sup>27,183</sup> In a study of the usefulness of melarsoprol as a treatment for refractory or advanced leukemia, efficacy was very limited, and reported adverse effects included fatigue, vomiting, diarrhea, vertigo, fever, seizures, headache, back pain, and injection site pain.<sup>218</sup>

## TOXICOLOGY/PATHOPHYSIOLOGY

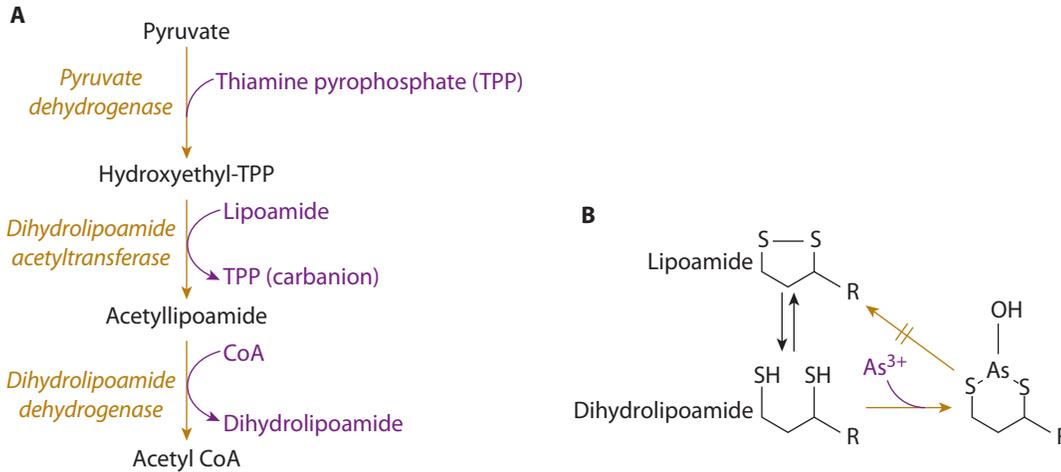

Investigations of the pathophysiologic effects induced by toxic doses of arsenic are discussed below. The apoptotic mechanisms<sup>30</sup> thought to be responsible for some therapeutic effects of As<sub>2</sub>O<sub>3</sub> are not well studied in toxicity models, but limited evidence suggests that cell necrosis may be more important.

### Trivalent Arsenic

The primary biochemical effect of As<sup>3+</sup> is inhibition of the pyruvate dehydrogenase (PDH) complex (Fig. 86–1). Normally, dihydrolipoamide is recycled to lipoamide, a necessary cofactor in the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). Trivalent arsenic (As<sup>3+</sup>) binds the sulfhydryl groups of dihydrolipoamide, blocking lipoamide regeneration.<sup>198</sup> Acetyl-CoA is a central molecule in metabolism, and the resulting decrease leads to several deleterious effects:

- Decreased citric acid cycle activity and thus decreased adenosine triphosphate (ATP) production.
- Disruption of oxidative phosphorylation, which leads to production of hydrogen peroxide and oxygen radicals.
- Decreased gluconeogenesis that worsens hypoglycemia. Pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate (initial step in gluconeogenesis), and this reaction requires the carboxylation of biotin, a CO<sub>2</sub> carrier attached to pyruvate carboxylase. Biotin cannot be carboxylated unless acetyl-CoA is attached to the enzyme.<sup>199,223</sup>

In the citric acid cycle, oxidation of α-ketoglutarate to succinyl-CoA uses an α-ketoglutarate dehydrogenase complex that contains the same cofactors as the PDH complex, including lipoamide. Succinyl-CoA is necessary for production of porphyrins and amino acids, and deficiency contributes to the anemia and wasting that occurs with chronic arsenic poisoning. Arsenic inhibition of thiolase, the catalyst for the final step in fatty acid oxidation, also impairs ATP production. Diminished fatty acid oxidation results in decreased acetyl-CoA, in the loss of the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide (FADH<sub>2</sub>) (electron carriers reduced during fatty acid breakdown whose subsequent oxidation yields ATP). Trivalent arsenic also inhibits glutathione synthetase, glucose-6-phosphate dehydrogenase (required to produce nicotinamide adenine dinucleotide phosphate {NADPH}), and glutathione reductase.<sup>8</sup> These inhibitions result in decreased concentrations of reduced

**FIGURE 86-1.** Effect of trivalent arsenicals ( $\text{As}^{3+}$ ) on pyruvate dehydrogenase (PDH) complex. **(A)** The PDH complex is composed of the 3 enzymes, which use thiamine pyrophosphate (TPP) and lipoamide as cofactors to decarboxylate pyruvate and form acetyl CoA. **(B)** Arsenic interferes with the regeneration of lipoamide from dihydroliipoamide, thereby altering the function of the PDH complex.

glutathione, which is required to facilitate arsenic metabolism, protect red blood cells (RBCs) from oxidative damage, maintain hemoglobin in the ferrous state, and scavenge hydrogen peroxide and other organic peroxides.

Arsenic affects cardiac repolarization currents. When toxicity occurs, the result is ventricular dysrhythmias, including torsade de pointes. An in vitro study of cells exposed to  $\text{As}^{3+}$  demonstrated blockade of the delayed rectifier channels  $I_{\text{Ks}}$  and  $I_{\text{Kr}}$ . Interestingly, activation of  $I_{\text{K-ATP}}$ , a weak inward rectifier channel, also occurred; this activation potentially counteracts some of the effects of  $\text{As}^{3+}$  on the  $I_{\text{Ks}}$  and  $I_{\text{Kr}}$  channels.<sup>64</sup> Recent epidemiologic evidence demonstrates a relationship between well water and urine arsenic concentrations and QT interval prolongation in women.<sup>46</sup>

Animal experiments with phenylarsine oxide, a trivalent arsenical, demonstrate inhibition of insulin-induced glucose transport involving vicinal (adjacent) sulfhydryl groups, as well as  $\beta$  cell damage in pancreatic islets attributed to inhibition of the  $\alpha$ -ketoglutarate dehydrogenase complex.<sup>25</sup> The impaired glucose transport, plus the inhibited gluconeogenesis, leads to glycogen depletion and hypoglycemia.<sup>200</sup> Several animal experiments indicate improved central nervous system (CNS) glucose content<sup>199</sup> and increased survival time with glucose treatment.<sup>199</sup>

Effects on RBCs include decreased membrane fluidity and ATP depletion.<sup>258</sup> Chronic arsenic exposure is associated with vascular disease; in vitro studies demonstrate inhibition of endothelial cell proliferation and glycoprotein synthesis in addition to lipid peroxidation.<sup>37</sup> Evaluations of genetic polymorphisms showed an association between genetic variants and endothelial dysfunction.<sup>261</sup> A study on rodent and human platelets demonstrates increased platelet aggregation and arterial thrombosis.<sup>142</sup> Noncirrhotic hepatic portal fibrosis sometimes develops. In a controlled study where mice chronically ingested water containing equal parts  $\text{As}^{3+}$  and  $\text{As}^{5+}$  for up to 15 months, the development of portal fibrosis was preceded by decreased hepatic glutathione (GSH) concentration, increased lipid peroxidation, and diminished concentrations or activities of numerous enzymes involved in regenerating GSH or scavenging free radicals.<sup>208</sup> Proposed mechanisms by which arsenic induces cancer include DNA damage induced by a dimethyl sulfide (DMS)-derived peroxy radical, gene amplification, replacing phosphate in DNA during replication, increased cell proliferation, and decreased DNA repair efficiency.<sup>17,122,264</sup> Experimental evidence and human studies support a number of etiologic or contributing factors for skin keratosis and cancer,<sup>1</sup> including chronic stimulation of keratinocyte-derived growth factors such as transforming growth factor- $\alpha$  (TGF- $\alpha$ ), impaired methylation, mutation in the p53 tumor-suppressor gene, inhibition of poly(adenosine diphosphate {ADP}-ribose) polymerase vital for DNA repair, and interference with mitotic spindle and microtubular function.<sup>7,86,111,146,260</sup> Pigmentary changes also occur, and hyperpigmentation is attributed to increased melanin.

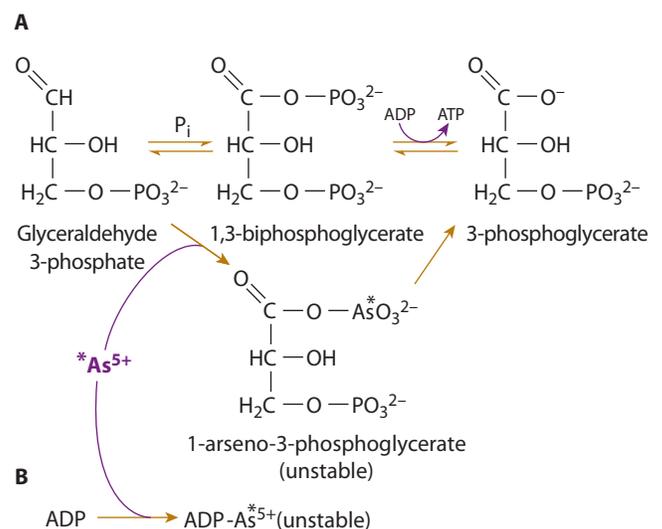

### Pentavalent Arsenic

Several mechanisms contribute to the toxicity of  $\text{As}^{5+}$ . Pentavalent arsenic is readily reduced to  $\text{As}^{3+}$ .<sup>112,243</sup> Pentavalent arsenic also resembles phosphate chemically and structurally, may share a common transport system for cellular uptake with phosphate,<sup>112</sup> and inhibits oxidative phosphorylation by substituting for inorganic phosphate ( $\text{P}_i$ ) in the glycolysis reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (Fig. 86-2).<sup>34,201</sup> The resulting unstable product, 1-arseno-3-phosphoglycerate, spontaneously hydrolyzes to 3-phosphoglycerate, so glycolysis continues but the ATP normally produced during conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate is lost. Uncoupling also occurs if ADP forms ADP-arsenate, instead of ATP, in the presence of  $\text{As}^{5+}$ . The ADP-arsenate rapidly hydrolyzes, thus uncoupling oxidative phosphorylation.

### PHARMACOKINETICS AND TOXICOKINETICS

#### Absorption

Inorganic arsenic is tasteless and odorless and is absorbed by the gastrointestinal (GI), respiratory, intravenous, and mucosal routes. Gastrointestinal

**FIGURE 86-2.** Pathophysiologic effects of  $\text{As}^{5+}$  (arsenate). **(A)** Arsenate (chemical formula  $\text{AsO}_4^{3-}$ ) substitutes for inorganic phosphate ( $\text{P}_i$ ; the asterisk indicates substitutions), bypassing the formation of 1,3-bisphosphoglycerate (1,3-BPG), and thus losing the ATP formation that occurs when 1,3-BPG is metabolized to 3-phosphoglycerate. **(B)** Energy loss also occurs if arsenate substitutes for  $\text{P}_i$  and blocks the formation of ATP from ADP. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

absorption is facilitated by increased solubility and smaller particle size, and it occurs predominantly in the small intestine, followed by the colon. Poorly soluble trivalent compounds such as  $\text{As}_2\text{O}_3$  are less well absorbed than more soluble trivalent and pentavalent compounds that, in aqueous solution, have an oral bioavailability greater than 90%. Therefore, when placed in an aqueous solution,  $\text{As}_2\text{O}_3$  is more toxic than an identical dose of undissolved  $\text{As}_2\text{O}_3$  eaten in food because of its failure to dissolve, thereby limiting absorption.<sup>240</sup> Organic arsenicals tend to be well absorbed; for example, a rodent study demonstrated that approximately 70% GI absorption of the commonly used organic arsenical herbicide, dimethylarsinic acid (cacodylic acid).<sup>220</sup> Systemic absorption via the respiratory tract depends on the particulate size, as well as the arsenic compound and its solubility. Large, nonrespirable particles are cleared from the airways by ciliary action and swallowed, allowing GI absorption to occur. Respirable particles lodging in the lungs can be absorbed over days to weeks or remain unabsorbed for years.<sup>28,255</sup> Dermal penetration of arsenic through intact skin does not pose a risk for acute toxicity but potentially is problematic with chronic application. Arsenic acid ( $\text{H}_3\text{AsO}_4$ ) applied to intact skin in rhesus monkeys resulted in absorption of a mean of 2.0% to 6.4% of the applied dose.<sup>253</sup> Skin irritation and damage increases systemic absorption.<sup>83,202</sup>

### Pharmacokinetics of Arsenic Trioxide

Intravenous administration of a single 10-mg dose of  $\text{As}_2\text{O}_3$  to 8 patients showed mean pharmacokinetic values as follows: maximum plasma concentration ( $\text{Cp}_{\text{max}}$ ) of 6.85  $\mu\text{mol/L}$ ,  $\alpha$  elimination half-life ( $t_{1/2\ \alpha}$ ) of  $0.89 \pm 0.29$  hours, and  $\beta$  elimination half-life ( $t_{1/2\ \beta}$ ) of  $12.13 \pm 3.31$  hours.<sup>214</sup> In 6 patients, only 1% to 8% of the daily dose was eliminated in a 24-hour urine test. Repeat pharmacokinetic studies on day 30 of treatment were not statistically different.<sup>214</sup> Another study of patients receiving a single dose of 5 mg of  $\text{As}_2\text{O}_3$  intravenously demonstrated mean pharmacokinetic values as follows:  $\text{Cp}_{\text{max}}$  of 2.6  $\mu\text{mol/L}$ ,  $t_{1/2\ \alpha}$  of 1.41 hours,  $t_{1/2\ \beta}$  of 9.41 hours, serum clearance of 1.98 L/h, and area under the plasma drug concentration versus time curve (AUC) of 12.7  $\mu\text{mol/L}\cdot\text{h}$ . A single dose of 10 mg intravenously showed a  $\text{Cp}_{\text{max}}$  of  $6.7 \pm 0.3$   $\mu\text{mol/L}$ .<sup>213</sup> Arsenic trioxide 10 mg given orally for APLM demonstrated total plasma and blood AUC values that were 99% and 87%, respectively, of the corresponding values reported for a 10-mg intravenous dose administered in the same 9 patients.<sup>132</sup>

A study in humans receiving intravenous radioarsenic isotope ( $^{74}\text{As}$ ) showed arsenic clearing from the blood in 3 phases:

- Phase 1 (2–3 hours)—Arsenic is rapidly cleared from the plasma with a  $t_{1/2}$  of 1 to 2 hours; more than 90% is cleared during this phase because of redistribution to tissue and renal elimination.
- Phase 2 (3 hours–7 days)—A more gradual plasma decline occurs, with an estimated  $t_{1/2}$  of 30 hours.
- Phase 3 (10 or more days)—Clearance continues from the plasma slowly with an estimated  $t_{1/2}$  of 300 hours.<sup>159</sup>

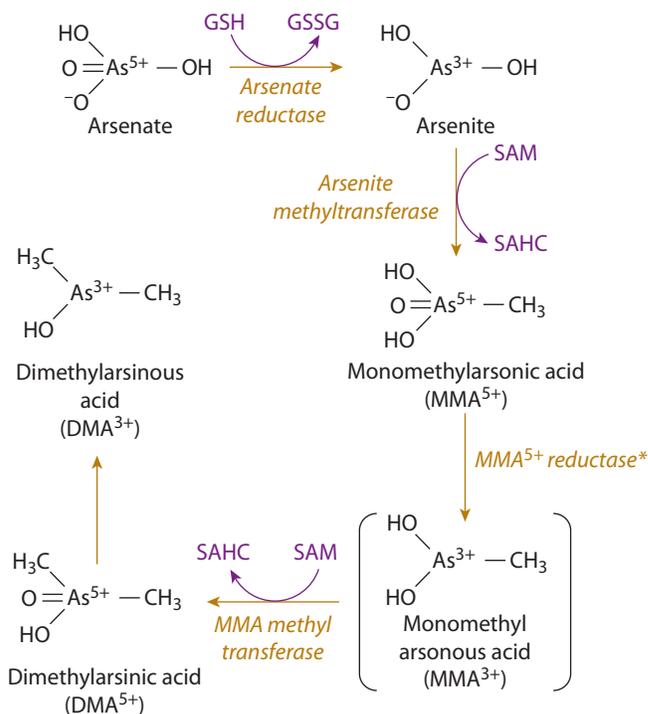

The rapid clearance in phases 1 and 2 explains why blood testing for arsenic is unreliable, except early in acute poisoning.

Initial distribution is predominantly to liver, kidney, muscle, and skin. The skin is rich in sulfhydryl groups; the elimination  $t_{1/2}$  of arsenic by the skin was estimated to be one month in a rabbit study.<sup>65</sup> Distribution to brain also occurs quickly.<sup>79</sup> In the  $\text{As}$  ( $^{74}\text{As}$ ) study, 0.3% of the administered dose was found in brain biopsy samples in the first hour postinfusion. This peak declined to 0.16% by day 7.<sup>159</sup> Ultimately, arsenic distributes to all tissues. In the single patient in this study who was followed for 18 days, 96.6% of the total injected arsenic dose was recovered in the urine. Fecal arsenic recovery was less than 1% of the total dose.<sup>159</sup> Other studies in humans demonstrate renal arsenic elimination of 46% to 68.9% within the first 5 days postingestion.<sup>29,32,118,191</sup> Approximately 30% is eliminated with a half-life of greater than one week, while the remainder is slowly excreted with a half-life of greater than one month.<sup>29,158</sup> Fecal elimination is considerably less, with reported amounts as much as 6.1% in humans.<sup>225</sup> Canine studies revealed that the mechanisms of urinary elimination of unchanged arsenic and its methylated metabolites are via glomerular filtration and tubular secretion; active reabsorption also occurs.<sup>233</sup>

Arsenic crosses the placenta and accumulates in the fetus,<sup>149</sup> but 3 studies of breast milk excretion from women exposed to drinking water with arsenic concentrations of approximately 200 mcg/L came to disparate conclusions. Breast milk arsenic concentrations were low in these studies, and only one of them demonstrated a correlation between maternal arsenic concentrations and concentrations in breast milk.<sup>55,71,207</sup> A single study suggests that breast feeding actually protects the infant from arsenic exposure.<sup>71</sup>

Metabolism, by adding methyl groups, occurs primarily in the liver, as well as in the kidneys, testes, and lungs (Fig. 86–3). If the arsenic is pentavalent, approximately 50% to 70% of  $\text{As}^{5+}$  will first be reduced to  $\text{As}^{3+}$ .<sup>54,221,241</sup> This bioactivation step requires the oxidation of glutathione<sup>62</sup> and can begin within 15 minutes of exposure.<sup>241</sup> *S*-Adenosylmethionine (SAM) is the primary methyl donor. Nonenzymatic methylation is also demonstrated in an in vitro study using human liver cytosol; here, methylcobalamin (methyl  $\text{B}_{12}$ ) was the methyl donor.<sup>270</sup> Dietary and vitamin deficiencies, as well as high doses of inorganic arsenic, may diminish the ability to methylate arsenic, and folate supplementation lowers blood arsenic concentrations in a folate-deficient population.<sup>15,80–82,98,102,103,188,190,242</sup> However, a study in pregnant Bangladeshi women showed efficient arsenic methylation despite nutritional deficiencies.<sup>145</sup> Addition of one methyl group produces monomethylarsonic acid ( $\text{DMA}^{5+}$ ); adding a second methyl group produces dimethylarsinic acid ( $\text{DMA}^{3+}$ ). Production of a trivalent intermediate in this reaction, monomethylarsonous acid ( $\text{MMA}^{3+}$ ), is catalyzed by  $\text{MMA}^{5+}$  reductase. In rabbits, this is the rate-limiting enzyme in the biotransformation pathway; however, no data exist to confirm a similar role in human metabolism.<sup>239,271</sup> Conversion of  $\text{MMA}^{5+}$  to  $\text{DMA}^{5+}$  is catalyzed by a methyltransferase. Genomic studies have begun to identify gene polymorphisms in these pathways that are associated with variations in arsenic metabolism and toxicity.<sup>3,187</sup>

These monomethylation and dimethylation steps were previously thought to detoxify arsenic, but is now questioned because of the generation of these trivalent intermediates, which are more toxic than the parent compounds.<sup>237</sup> Estimated human  $\text{LD}_{50}$  (median lethal dose for 50% of test subjects) doses were reported to be  $\text{As}_2\text{O}_3$ , 1.43 mg/kg;  $\text{MMA}^{5+}$ , 50 mg/kg;

**FIGURE 86–3.** Metabolism of arsenate [ $\text{As}^{5+}$ ] and arsenite [ $\text{As}^{3+}$ ]. DMA = dimethylarsinic acid; GSH = glutathione; GSSG = oxidized glutathione; MMA = monomethylarsonic acid; SAHC = *S*-adenosylhomocysteine; SAM = *S*-adenosylmethionine. The asterisk (\*) denotes  $\text{MMA}^{5+}$  reductase, the rate-limiting enzyme in rabbit studies of arsenic metabolism; the analogy to humans is unknown.

and DMA<sup>5+</sup>, 500 mg/kg. However, it is important to note that the doses cited for MMA and DMA apply to arsenic existing in the pentavalent form (As<sup>5+</sup>). Studies in animals and cell cultures indicate that MMA<sup>3+</sup> is more toxic than As<sup>3+</sup>.<sup>153,185,186</sup> Cytotoxicity studies in human hepatocytes revealed descending toxicity of arsenic and its metabolites as follows: MMA<sup>3+</sup> > arsenite > arsenate > MMA<sup>5+</sup> = DMA<sup>5+</sup>.<sup>185</sup> Thus, toxicity increases with the formation of MMA<sup>3+</sup>.

There is some evidence that these findings have clinical relevance. In a study from a blackfoot disease hyperendemic area of Taiwan, lower capacity to methylate inorganic arsenic to DMA<sup>5+</sup> is associated with increased risk of blackfoot disease. The capacity to methylate arsenic to DMA<sup>5+</sup> was measured as the ratio of DMA<sup>5+</sup> to MMA<sup>5+</sup> and the ratio of MMA<sup>5+</sup> to the sum of As<sup>3+</sup> and As<sup>5+</sup>.<sup>231</sup> Another study demonstrated an association between incomplete methylation capacity and carotid intima-media thickness.<sup>44</sup> Moreover a prospective study demonstrated an association between methylation capacity and heart disease risk.<sup>45</sup> In addition, a cohort study found that the odds of premalignant skin lesions increased with increasing urinary MMA<sup>5+</sup> and decreasing urinary DMA<sup>5+</sup>.<sup>3</sup> They also found that there was an increased risk of skin lesions associated with genetic polymorphisms of glutathione *S*-transferase and borderline increased risk with polymorphisms of methylenetetrahydrofolate reductase. The authors suggested that the conversion of MMA<sup>5+</sup> to DMA<sup>5+</sup> is saturable and that arsenic metabolism and toxicity are affected by genetics.<sup>3</sup> An additional nested case-controlled study of this cohort confirmed that folate deficiency and DNA hypomethylation were risk factors for skin lesions.<sup>189</sup>

Arsenobetaine (AsB) is also well absorbed orally and is excreted unchanged in the urine.<sup>240</sup> Elimination occurs more rapidly than with inorganic arsenic. In a study involving human volunteers, 25% was excreted within 2 to 4 hours, 50% by 20 hours, and 70% to 83.7% after 166 hours. A 2-compartment exponential model shows nearly 50% of the arsenobetaine eliminated, with a first compartment  $t_{1/2}$  of 6.9 to 11.0 hours and a second compartment  $t_{1/2}$  of 75.7 hours.<sup>118</sup>

## CLINICAL MANIFESTATIONS

### Inorganic Arsenicals

Toxic manifestations vary, depending on the amount and form, route, and chronicity of arsenic exposure. Other influencing factors include individual variations in methylation and excretion. Larger doses of a potent compound, such as As<sub>2</sub>O<sub>3</sub>, will rapidly produce manifestations of acute toxicity, whereas chronic ingestion of substantially lower amounts of As<sup>5+</sup> in groundwater will result in different clinical findings over time. Manifestations of subacute toxicity can develop in patients who survive acute poisoning, as well as in patients who are slowly poisoned environmentally.

### Acute Toxicity

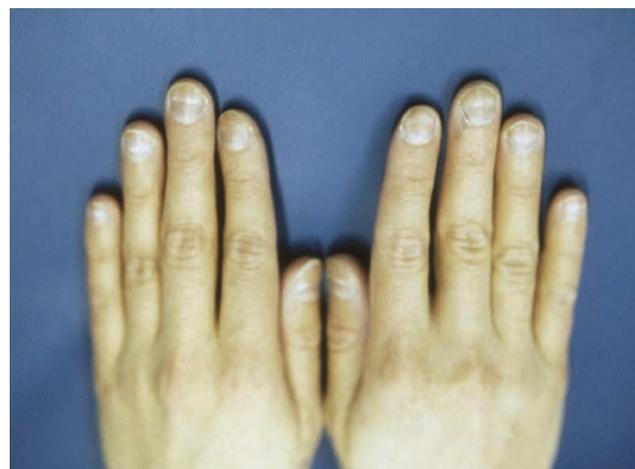

Gastrointestinal signs and symptoms of nausea, vomiting, abdominal pain, and diarrhea, which occur 10 minutes to several hours following ingestion, are the earliest manifestations of acute poisoning by the oral route. The diarrhea is compared to cholera in that it resembles “rice water.” Severe multisystem illness ensues with extensive exposure. Cardiovascular signs, ranging from sinus tachycardia and orthostatic hypotension to shock, can develop. Reported cases often mimic myocardial infarction or systemic inflammatory response syndrome, with intravascular volume depletion, capillary leak, myocardial dysfunction, and diminished systemic vascular resistance.<sup>16,22,24,90,119,212</sup> Acute encephalopathy develops and progress over several days, with delirium, coma, and seizures attributed to cerebral edema and microhemorrhages.<sup>76,212</sup> Seizures may be secondary to dysrhythmias, and the underlying cardiac rhythm should be assessed. Seizures apparently secondary to torsade de pointes associated with a prolonged QT interval developed 4 days to 5 weeks after acute arsenic ingestion.<sup>22,88,219</sup> Acute respiratory distress syndrome (ARDS) and respiratory failure, hepatitis, hemolytic anemia, acute kidney injury (AKI), rhabdomyolysis, ventricular dysrhythmias, and death are all reported.<sup>24,74,93,167,234</sup> Death occurs after suddenly developing bradycardia, followed by asystole.<sup>24,119,150</sup> Fever sometimes develops, misleading the practitioner to diagnose sepsis.<sup>66,119</sup> Hepatitis occurs and as a result of altered intrahepatic heme metabolism causing an increased synthesis of bilirubin or a result of altered protein transport between hepatocytes.<sup>6</sup> Acute kidney

injury occurs secondary to ischemia caused by hypotension, tubular deposition of myoglobin or hemoglobin, renal cortical necrosis, and direct renal tubular toxicity.<sup>26,85,209,234</sup> Glutathione depletion is contributory.<sup>108</sup> Unusual complications include phrenic nerve paralysis, unilateral facial nerve palsy, pancreatitis, pericarditis, and pleuritis.<sup>18,271</sup> Fetal demise is reported, with toxic arsenic concentrations found in the fetal organs.<sup>24,149</sup>

Acutely poisoned patients with less severe illness experience gastroenteritis and mild hypotension that persist despite antiemetic and intravenous crystalloid therapies. Hospitalization and continued intravenous fluids often are required for several days.<sup>141</sup> The prolonged character of the GI effects is atypical for most viral and bacterial enteric illnesses and should alert the physician to the possibility of arsenic poisoning, especially if there is a history of repetitive GI illnesses. A metallic taste or oropharyngeal irritation, mimicking pharyngitis, occurs.<sup>24,105</sup> Gastrointestinal ulcerative lesions and hemorrhage are reported.<sup>76,90</sup> Toxic erythroderma and exfoliative dermatitis result from a hypersensitivity reaction to arsenic.<sup>226</sup>

In the days and weeks following an acute exposure, prolonged or additional signs and symptoms in the nervous, GI, hematologic, dermatologic, pulmonary, and cardiovascular systems occur. Encephalopathic findings of headache, confusion, decreased memory, personality change, irritability, hallucinations, delirium, and seizures develop and persist.<sup>66,79,204</sup> Sixth cranial nerve palsy and bilateral sensorineural hearing loss are reported.<sup>53,88</sup> Peripheral neuropathy typically develops 1 to 3 weeks after acute poisoning, although in one series 9 patients developed maximal neuropathy within 24 hours of exposure.<sup>53,105,141,253</sup> Sensory symptoms develop first, with diminished to absent vibratory sense. Progressive signs and symptoms include numbness, tingling, and formication with physical findings of diminished to absent pain, touch, temperature, and deep-tendon reflexes in a stocking-glove distribution. Superficial touch of the extremities sometimes elicits severe or deep aching pains, a finding that also occurs with thallium poisoning (Chap. 99). Motor weakness often develops. The most severely affected patients manifest an ascending flaccid paralysis that mimics Guillain-Barré syndrome.<sup>53,105,141</sup> Respiratory findings include dry cough, crackles, hemoptysis, chest pain, and patchy interstitial infiltrates.<sup>105,184</sup> These findings are often misinterpreted as viral or bronchitic disease. Leukopenia, and less commonly anemia and thrombocytopenia, occur from days to 3 weeks after an acute exposure, but resolve as bone marrow function returns.<sup>114,144</sup>

Dermatologic lesions include patchy alopecia, oral herpetic lesions, a diffuse pruritic macular rash, and a brawny nonpruritic desquamation (Chap. 17). Diaphoresis and edema of the face and extremities are reported.<sup>1</sup> Mees lines (transverse striate leuconychia of the nails) are 1- to 2-mm-wide horizontal nail bands that represent disturbed nail matrix keratinization (Fig. 86-4). They are uncommon in arsenic poisoning. A minimum of

**FIGURE 86-4.** Mees lines, parallel white bands across the nails, result from exposures to metals, radiation, and chemotherapeutics, among others. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

**FIGURE 86-5.** Characteristic hemorrhagic vesicles of arsenical dermatitis is shown. (Used with permission from the New York University Department of Dermatology.)

30 days after exposure is required for the lines to extend visibly beyond the nail lunulae.<sup>105,260</sup> Contact dermatitis is reported from topical exposure in an occupational setting. Other possible toxic manifestations of subacute inorganic arsenic toxicity include nephropathy, fatigue, anorexia with weight loss, torsade de pointes, and persistence of GI effects.<sup>16,154</sup>

### Chronic Toxicity

Malignant and nonmalignant skin changes, hypertension, diabetes mellitus (DM), and peripheral cardiovascular and cerebral vascular disease, as well as lung, bladder, renal and hepatic malignancies are associated with drinking water containing arsenic that is consumed by study populations.<sup>50,58,72,116,133,161,166,168,182,192,267</sup> The skin is very susceptible to the toxic effects of arsenic; multiple dermatologic lesions are reported in populations suffering from hydroarsenicism.<sup>157,267</sup> Alterations in pigmentation occur first, with hyperpigmentation being the most common. Hypopigmentation (“raindrop” pattern) also occurs (Fig. 86-5). Hyperkeratoses typically develop on the palms and soles, but can be diffuse (Fig. 86-6). Squamous and basal cell carcinomas and Bowen’s disease (intraepidermal squamous cell carcinoma) occur. Bowen’s disease usually proliferates in multiple sites, especially on the trunk, and is noted for developing on sun-protected areas. Latency periods for developing keratoses, Bowen’s disease, and squamous cell carcinoma were 28, 39, and 41 years, respectively, in 17 patients chronically exposed to environmental or medicinal arsenic.<sup>60,259</sup> Gastrointestinal signs and effects of nausea, vomiting, and diarrhea are less likely but do occur. Hepatomegaly was present in 120 of 156 patients with hydroarsenicism; liver biopsy in 45 cases revealed a noncirrhotic portal fibrosis in 91.1%.<sup>157</sup> Rodent

**FIGURE 86-6.** Characteristic vesicular xerotic arsenical dermatitis is shown. (Used with permission from the New York University Department of Dermatology.)

studies also demonstrate hepatic fibrosis from inorganic arsenic exposure.<sup>208</sup> Portal hypertension and hypersplenism occur.<sup>157,208</sup> Hepatic angiosarcomas are linked to arsenic exposure.<sup>51,121,139</sup>

Some, but not all, population studies in areas of Bangladesh, Taiwan, and the United States with arsenic-contaminated water show an increased prevalence of DM, pulmonary fibrosis, and other organ system effects.<sup>39,124,194,195,232</sup> A cross-sectional drinking water study from the United States revealed an odds ratio of 3.58 for prevalence of type 2 DM among those at the 80th percentile, as compared to those at the 20th percentile, despite a median total arsenic concentration of only 7.1 ppb.<sup>138,172</sup> However, a cross-sectional study in Bangladesh did not find a relationship between arsenic exposure and DM.<sup>39</sup> Animal studies demonstrate that arsenic decreases insulin-mediated uptake of glucose by cells and also disrupts insulin transcription factor signal transduction.<sup>181,248</sup> In a study from West Bengal, India, restrictive lung disease was reported in 9 of 17 patients, and a restrictive plus obstructive pattern occurred in another 7 cases.<sup>157</sup> Lung disease is also noted in other populations.<sup>58,95</sup> Proposed mechanisms include arsenic-induced inflammation and oxidative stress and endothelial dysfunction.<sup>178,263</sup> Aplastic anemia and agranulocytosis are documented in patients exposed to arsenic.<sup>66</sup> A dose–response relationship between arsenic exposure and vascular disease is reported in several populations.<sup>250</sup> After adjusting for age, sex, hypertension, DM, cigarette smoking, and ethanol consumption, a significant relationship was observed with cerebrovascular disease in a region of Taiwan.<sup>50</sup> Blackfoot disease, an obliterative arterial disease of the lower extremities, occurring in Taiwan, is linked to chronic arsenic exposure,<sup>35,230</sup> as is ischemic heart disease.<sup>33,166</sup> There is accumulating evidence that the vascular effects are related to endothelial dysfunction and that genetic polymorphisms moderate these effects.<sup>261-263</sup> The incidence of Raynaud phenomenon and vasospasm<sup>35,230</sup> was reported to be increased in smelter workers exposed to arsenic, compared with a control group.<sup>137</sup> Encephalopathy and peripheral neuropathy are the neurologic manifestations most commonly reported.<sup>21,99</sup> Electromyographic studies of 33 patients with chronic ingestion of arsenic-contaminated water<sup>21</sup> revealed 10 patients with findings consistent with sensory neuropathy. The minimum duration of exposure was 2 years. Interestingly, 3 of these patients consumed water with an arsenic concentration that only slightly exceeded the contaminant concentration of 50 ppb previously permissible in the United States.<sup>107</sup>

Arsenic is classified as a definite carcinogen by the International Agency for Research on Cancer (IARC, Group 1) and the National Toxicology Program (NTP). Cancers known to develop include lung, skin, and bladder.<sup>12,52,113,207,216</sup> Transitional cell bladder carcinoma was the most common type in one large epidemiologic study.<sup>49</sup> However, the exposure threshold of concern remains controversial.<sup>160</sup> A critical literature review of animal and human studies found that exposure to environmental arsenic was unlikely to cause reproductive or developmental toxicity.<sup>63</sup> However, a rodent study revealed fetal growth retardation and neurotoxicity at doses relevant to human exposure and in the absence of maternal toxicity.<sup>249</sup> More concerning, 2 drinking water cohort studies from Bangladesh showed small but statistically significant increases in birth defects and fetal loss.<sup>134,194,238</sup> In addition to possibly increasing the risk of birth defects, there is also cohort and cross-sectional evidence that in utero or early childhood exposure is associated with persistent neurocognitive effects in children.<sup>31,39,57,99,100,124,229,246,251,252</sup> Finally, there is evidence that in utero or early childhood exposure to arsenic in drinking water increases the risk of malignant and nonmalignant lung diseases in young adults.<sup>216</sup> In summary, there is accumulating evidence of persistent adverse effects from in utero or early childhood exposure, but additional prospective studies are needed to confirm these findings by decreasing the effects of confounding and bias that may explain the results.

Many of the questions regarding the chronic health effects of exposure to arsenic in drinking water are currently being investigated in the Health Effects of Arsenic Longitudinal Study (HEALS). This study is designed to evaluate the health effects of a full range of drinking water arsenic exposures,

including mortality, premalignant and malignant skin tumors, pregnancy outcomes, and children's cognitive development.<sup>5</sup>

The HEALS study is a prospective cohort study in Arahazar, Bangladesh. Participants are between the ages of 18 and 75 years and married, although both members of a couple are not required to enroll. A total of 11,764 subjects enrolled, 6,704 women and 5,042 men. The participation rate in the initial enrollment was 97.5% of those approached.<sup>5</sup> Ninety-eight percent of those who agreed to participate completed an extensive questionnaire that included demographic and lifestyle components and a validated food-frequency questionnaire. They also participated in a clinical examination with an extensive skin evaluation. More than 90% of this group also provided blood and spot urine arsenic samples.<sup>5</sup>

Approximately one-third of the participants consumed water in each of 3 groups: greater than 100 mcg/L, 25 to 100 mcg/L, and less than 25 mcg/L. Average urinary concentrations of arsenic were approximately 140 mcg/L.

Many studies from this cohort are already published. Studies of persons with arsenic-induced skin lesions show increasing risk of disease as exposure increases.<sup>4,13</sup> Modification of risk was noted in relationship to nutritional status, sunlight exposure, smoking, and some occupational exposures such as fertilizers and pesticides.<sup>41,42,162</sup> A dose–response relationship was also found for other health effects, including total mortality,<sup>14</sup> cardiovascular disease,<sup>40</sup> respiratory symptoms,<sup>179</sup> proteinuria,<sup>43</sup> oral cavity lesions,<sup>222</sup> and neurologic effects.<sup>96,180</sup> Skin lesions are linked to lung cancer risk, and this risk is shown to be synergistic with cigarette smoking.<sup>110</sup> Biannual follow-up of this cohort continues.

### Adverse Drug Effects: Arsenic Trioxide

The most common adverse effects are dermatologic (skin dryness, pigmentary changes, maculopapular eruptions with or without pruritus); GI (nausea, vomiting, anorexia, diarrhea, and dyspepsia); hematologic (leukemoid reactions); hepatic (elevation of aminotransferase concentrations typically less than or equal to 10 times the upper limit of normal values, with a reported incidence of 20% with low-dose and 31.9% with conventional-dose therapy<sup>213</sup>); cardiac (prolonged QT interval in 40%–63% of patients, first-degree atrioventricular block, ventricular ectopy, monomorphic nonsustained ventricular tachycardia, torsade de pointes, asystole, and death);<sup>206,213,217,236,257</sup> facial edema; and neurologic (paresthesias, peripheral neuropathy, and headache). All of these effects occurred more commonly in one case series with conventional-dose therapy (0.16 mg/kg/day) when compared to low-dose therapy. The majority of patients are treated symptomatically without discontinuing As<sub>2</sub>O<sub>3</sub> treatment. Leukemoid reactions, defined as white blood cell counts greater than  $50 \times 10^9/L$ , develop in nearly 50% of patients between 14 and 42 days of beginning treatment. Such patients are at risk for intracerebral hemorrhage or infarction and for the APML syndrome. This syndrome is similar to the differentiation syndrome (DS), which was formerly known as the retinoic acid syndrome.<sup>165</sup> The remission-induction treatment phase is the period of greatest risk.<sup>214</sup> Common clinical findings in this syndrome include pulmonary interstitial infiltrates and/or pleural effusions, dyspnea, tachypnea, fluid retention, myalgias, arthralgias, fever, and weight gain; approximately 20% to 25% of patients treated with arsenic trioxide will develop one or more signs or symptoms of this syndrome.<sup>155,171,206,213,214</sup>

Although a theoretical concern, there is currently no evidence of increased risk of secondary malignancies in treated patients. Continued close follow-up will be necessary to evaluate whether secondary malignancy risk will increase over time.<sup>69</sup>

### DIAGNOSTIC TESTING

Timing of testing for arsenic must be correlated with the clinical course of the patient and whether the poisoning is acute, subacute, chronic, or remote with residual clinical effects. To properly interpret laboratory measurements, confounding factors, such as food-derived organic arsenicals or accumulated arsenic (DMA and arsenobetaine) in patients with chronic kidney disease, must be evaluated.<sup>59,275,276</sup> Failure to understand potential confounders, as well as the time course of arsenic metabolism, clearance, and effect on

laboratory parameters, can cause erroneous assessment of possible arsenic poisoning.

### Urine and Blood

Diagnosis ultimately depends on finding an elevated urinary arsenic concentration. In an emergency, a spot urine sample for arsenic should be sent prior to beginning chelation therapy. A markedly elevated arsenic concentration verifies the diagnosis in a patient with characteristic history and clinical findings, but a low concentration does not exclude arsenic toxicity.<sup>247</sup> In 9 acutely symptomatic patients, initial spot urine arsenic concentrations ranged from 192 to 198,450 mcg/L.<sup>123</sup> Definitive diagnosis of arsenic exposure hinges on finding a 24-hour urinary concentration equal to or greater than 50 mcg/L, 100 mcg/g creatinine, or 100 mcg total arsenic. A study on arsenic exposure from drinking water showed excellent correlations between spot and 24-hour urine arsenic concentrations. There are not enough data to determine if this relationship holds true in acutely poisoned patients, so a 24-hour collection is still preferred.<sup>32</sup> Challenge testing with dimercaptopropane sulfonate (DMPS) has been performed in individuals exposed to arsenic in drinking water and clearly increases arsenic excretion; however, it also alters the percentages of the arsenic species recovered compared with controls and is not correlated with clinical effects.<sup>11</sup> All urine should be collected in metal-free polyethylene containers; acid-rinsed containers are not recommended since the acid alters the arsenic species.<sup>73</sup> If testing is performed by an outside reference laboratory, specimens from acutely ill patients should be sent via express transportation with a request for a rapid result.

When interpreting slightly elevated urinary arsenic concentrations, laboratory findings must also be correlated with the history and clinical findings, because seafood ingestion is reported to transiently elevate urinary total arsenic excretion up to 1700 mcg/L.<sup>12</sup> When seafood arsenic is a consideration, speciation of arsenic can be accomplished by high-performance liquid chromatography (HPLC) separation, followed by inductively coupled plasma–mass spectrometry (ICPMS), HPLC via ion-pair chromatography coupled with hydride-generation atomic fluorescence spectrometry (HGAFS), or by hydride generation coupled with cold-trap gas chromatography–atomic absorption spectrometry. These techniques separate arsenobetaine, As<sup>3+</sup>, As<sup>5+</sup>, MMA, and DMA.<sup>73</sup> Arsenobetaine can also be directly measured by silica-based cation-exchange separation, followed by atomic absorption spectrometry.<sup>174</sup> Two other methods, selective hydride-generation atomic absorption spectrometry (HGAAS) and resin-based ion exchange chromatography, do not directly measure arsenobetaine; instead, they indirectly derive this value by subtracting the sum of all measured arsenic species from the total arsenic concentration.<sup>174</sup> If arsenic speciation cannot be done, the patient should be retested after a one-week abstinence from fish, shellfish, and algae food products.

Conditions under which urine is stored affect total arsenic recovery, as well as proportionality of the species. The various arsenic species—arsenate (As<sup>5+</sup>), arsenite (As<sup>3+</sup>), MMA, DMA, and arsenobetaine—remain stable for 2 months in urine stored without preservatives at either  $-4^{\circ}F$  ( $-20^{\circ}C$ ; freezer) or  $39.2^{\circ}F$  ( $4^{\circ}C$ ; refrigerator); AsB is stable for 8 months under these conditions. Storage for longer than 2 months can alter the recovery of various species. Addition of 0.1% hydrochloric acid (HCl) facilitates reduction of arsenate to arsenite and also decreases MMA and DMA concentrations. Acid-washed collection containers should not be used if measurement of the various arsenic species is planned. Total arsenic recovery is diminished by any of the following: specimen storage for greater than 2 months, acidification, or testing using HPLC-ICPMS and HPLC-HGAFS, because all these methods usually require that the samples be filtered prior to undergoing HPLC separation.<sup>73</sup>

Diagnostic evaluation of chronic toxicity should include laboratory parameters that typically become abnormal within days to weeks following an acute exposure. Tests should include a complete blood count, kidney and liver function tests, urinalysis, and 24-hour urinary arsenic determinations. Complete blood count findings can include a normocytic, normochromic, or megaloblastic anemia; an initial leukocytosis followed by development of

leukopenia, with neutrophils depressed more than lymphocytes, and a relative eosinophilia; thrombocytopenia; and a rapidly declining hemoglobin, indicative of hemolysis or a GI hemorrhage.<sup>136</sup> Basophilic stippling of RBCs occurs, but this is reported in other toxic and clinical disorders. Karyorrhexis, a rupture of the RBC cell nucleus with chromatin disintegration into granules that are extruded from the cell, and dyserythropoiesis are reported in both lead- and arsenic-toxic patients. Both findings are caused by arsenic-induced inhibition of DNA synthesis and damage to the nuclear envelope.<sup>68</sup> The karyorrhexis occurs within 4 days and resolve by 2 weeks after poisoning, and is an early indication of arsenic toxicity.<sup>136</sup> Elevated serum creatinine, aminotransferases, and bilirubin, as well as depressed haptoglobin concentrations, develop. Urinalysis reveals proteinuria, hematuria, and pyuria. Cerebrospinal fluid examination in patients with CNS findings are often normal or exhibit mild protein concentration elevation, measured at 26.5 mg/dL in one case.<sup>105</sup> Urinary arsenic excretion in subacute and chronic cases varies inversely with the postexposure time period, but low concentration excretion for months after exposure is reported. In a study of 41 cases of arsenic-induced peripheral neuropathy, most patients with a neuropathy of 4 to 8 weeks' duration had total 24-hour urinary arsenic measurements of 100 to 400 mcg.<sup>105</sup>

### Hair and Nail Testing

In cases of suspected arsenic toxicity, in which the urinary arsenic measurements fall to less than toxic concentrations, analysis of hair and nails may yield the diagnosis. Arsenic is detected in the proximal portions of hair within 30 hours of ingestion.<sup>268</sup> Inorganic arsenic is the form best absorbed by these tissues and the form most commonly found in human poisoning cases; small amounts of methylated metabolites are also detected.<sup>193</sup> Arsenobetaine is not found in hair and tissues in human and animal studies.<sup>265,266</sup> Hair grows at rates varying from 0.7 to 3.6 cm per month, with a mean rate of 1 cm per month.<sup>254</sup> The Society of Hair Testing has made the following recommendations for collection of hair specimens: (1) collect approximately 200 mg of hair from the posterior vertex region of the scalp using scissors to cut as close to the scalp as possible, and (2) tie the hairs together, wrap in aluminum foil to protect from environmental contamination, and store at room temperature.<sup>254</sup> Although these recommendations are only validated for testing drugs of abuse, it is reasonable to follow them for hair testing of arsenic. Nails grow approximately 0.1 mm per day. Total replacement of a fingernail requires 3 to 4 months, whereas toenails require 6 to 9 months of growth. These facts, plus the frequency of hair cutting, should be evaluated when estimating the usefulness of measuring arsenic concentrations in these tissues. The normal concentration of the testing laboratory should be used to determine whether arsenic concentrations are elevated. In cases of remote toxicity, hair and nail arsenic concentrations are not always elevated, depending on the time elapsed since exposure. Sequential hair analysis to assess the time(s) of exposure can be performed by solid sampling graphite furnace atomic absorption spectrophotometry or by x-ray fluorescence spectrometry.<sup>126,227,228</sup>

### Other Tests

Abdominal radiographs demonstrate radiopaque material in the GI tract soon after an ingestion.<sup>2,45,90,91,106</sup> However, even after an acute ingestion, the presence of radiopaque materials on abdominal radiographs may not be recognized.<sup>56</sup> Although it is reasonable to obtain radiographs, the incidence of positive radiographs after an ingestion is unknown, and a negative radiograph should not eliminate arsenic as a diagnostic consideration. Electrocardiographic changes reported include QRS complex widening, QT interval prolongation, ST segment depression, T-wave flattening, ventricular premature contractions, nonsustained monomorphic ventricular tachycardia, and torsade de pointes.<sup>20,176,217,236</sup> Nerve conduction studies (NCS) will confirm or diagnose clinical or subclinical axonopathy. Both the sensory nerve action potential (SNAP) and the motor compound muscle action potential (CMAP) measure the number of axons that are available to conduct impulses. Because the sensory studies are more sensitive than motor studies in detecting axonal degeneration and demyelination, decreased SNAP measurements better indicate subclinical neuropathy. In motor nerve studies, the amplitude (height

of the CMAP) is a more sensitive measure of the number of axons that are able to conduct impulses than is the conduction velocity; this is explained by the pattern of axonal destruction as opposed to myelin injury (which mainly affects conduction velocity). Nerve biopsies demonstrate disintegration of both axons and myelin in patients with arsenic-induced peripheral neuropathy; the axonal loss begins distally in the lower extremities and is initially scattered. Thus, conduction along the remaining functional axons can be sufficient to produce normal or only slightly decreased conduction measurements on NCS.<sup>87,105,127,141,170,175</sup>

## MANAGEMENT

### General

Acute arsenical toxicity is life threatening and mandates aggressive treatment. Advanced life support monitoring and therapies should be initiated when necessary, but with a few caveats. Careful attention to fluid balance is important because cerebral and pulmonary edema occur. Xenobiotics that prolong the QT interval, such as the class IA, class IC, and class III antidysrhythmics, should be avoided whenever possible (Chaps. 15 and 57). Potassium, magnesium, and calcium concentrations should be maintained within normal range to avoid exacerbating a prolonged QT interval. Glucose concentrations and glycogen stores should be maintained parenterally with dextrose and hyperalimentation solutions or with enteral feedings, in view of their beneficial effects in experimental models of arsenic poisoning.<sup>147,199,200,223</sup>

Gastrointestinal decontamination of patients acutely poisoned with arsenic is controversial. Arsenic is poorly adsorbed to activated charcoal, cholestyramine, and bentonite.<sup>197</sup> Moreover, significantly poisoned patients usually have nausea and vomiting and altered mental status, which make activated charcoal administration difficult. Despite these concerns, activated charcoal, in conjunction with airway protection if necessary, is recommended because of the relatively low likelihood of harming the patient and the hope that preventing even a small amount of absorption might prevent or lessen the potentially disastrous consequences of arsenic poisoning. If radiopaque material is visualized in the GI tract, whole-bowel irrigation is reasonable until the radiopaque material is no longer visualized on repeat abdominal radiograph. Continuing nasogastric suction removes arsenic resecreted in the gastric or biliary tract and is reasonable. Arsenite was still detectable in the gastric aspirate in 3 patients 5 to 7 days following an ingestion.<sup>152</sup> There is no clinical experience with the use of *N*-acetylcysteine to increase glutathione concentrations. Although an animal model suggested a protective effect, there are not enough data to recommend *N*-acetylcysteine for arsenic poisoning and treatment.<sup>196</sup>

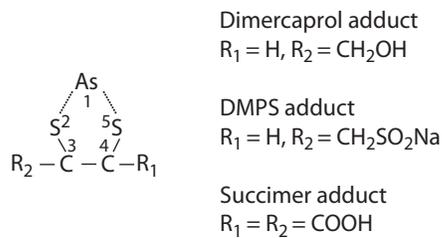

In cases of chronic toxicity, patients should be removed from the arsenic source. It is reasonable to perform GI decontamination if there is evidence of arsenic in the GI tract. Arsenic can be readily removed from skin with soap, water, and vigorous scrubbing. In this situation, when homicidal intent is suspected, all hospital visitors should be closely monitored, and outside nutritional products should be forbidden.

### Chelation Therapy

#### Chelators

Dimercaprol (BAL) and 2,3-dimercaptosuccinic acid (succimer) are the 2 chelators available to treat arsenic poisoning in the United States. A third drug, DMPS, is distributed by Heyl, a German pharmaceutical company, as Dimaval, but it is not approved or marketed in the United States (Antidotes in Depth: A28 and A29). All contain vicinal dithiol moieties that bind arsenic to form stable 1,2,5-arsadithiolanes (Fig. 86–7), and all are most effective when administered in doses equimolar to the arsenic burden.<sup>169</sup> Dosing regimens and adverse effects are listed in Table 86–3.

The decision to initiate chelation therapy should depend on the clinical condition of the patient as well as the laboratory results for arsenic in urine, hair, or nails. A severely ill patient with known or suspected acute arsenic poisoning should be chelated immediately, prior to laboratory confirmation. In the United States, dimercaprol remains the initial chelator for acute arsenical toxicity.<sup>169</sup> In a series of 33 patients who had coma, seizures, or both,

**FIGURE 86-7.** 1,2,5-Arsadithiolane adducts with dimercaprol (BAL), dimercaptopropane sulfonate (DMPS), and dimercaptosuccinic acid (DMSA).

24 patients were treated with dimercaprol within 6 hours (mean, 1 hour) and 75% survived, compared with a survival rate of 45% of 9 patients who were treated later (range, 9–72 hours; mean, 30 hours).<sup>66</sup> In cases of subacute and chronic toxicity, it is reasonable to await laboratory confirmation prior to beginning chelation, unless the clinical condition deteriorates.

In a cellular study of glucose uptake impaired by a lipophilic arsenical, dimercaprol was superior to succimer and DMPS in restoring cellular equilibrium.<sup>169</sup> A human case series found increased survival with early use of dimercaprol and improvement in encephalopathy within 24 hours of initiating therapy.<sup>66</sup> However, other acute cases treated promptly with dimercaprol developed peripheral neuropathy.<sup>141</sup> In a study of subacute cases with peripheral neuropathy, dimercaprol accelerated neurologic recovery but did not affect the overall recovery rate.<sup>53</sup> Despite starting dimercaprol therapy 8 hours postexposure, a man who had ingested 2.15 g of arsenic developed severe toxicity and neurologic deficits.<sup>75</sup> Most concerning are the animal experiments indicating that dimercaprol shifts arsenic into the brain and testes, 2 organs that have blood–organ barriers susceptible to this lipophilic drug.<sup>10,109,129</sup> It is clear that dimercaprol has limitations, and that a safer, more effective intracellular/extracellular parenteral chelator is needed.

Succimer is an oral hydrophilic analog of dimercaprol and is the chelator of choice for subacute and chronic toxicity. It has proven effective in animal studies and in reported human cases.<sup>10,128,143,151,215</sup> In mice exposed to sodium arsenite, succimer was more effective than either DMPS or dimercaprol in decreasing lethality and more potent than dimercaprol in restoring activity

in the pyruvate dehydrogenase complex.<sup>10</sup> It is equal or superior to dimercaprol in speeding arsenic elimination.<sup>157</sup> Liver function tests and essential metal concentrations should be monitored in patients requiring prolonged therapy.<sup>78,92</sup>

2,3-Dimercapto-1-propanesulfonic acid (DMPS) is also a water-soluble analog of dimercaprol. It is not approved for use in the United States. It is administered by the oral, intravenous, or intramuscular route. It is eliminated from the body more slowly than succimer and has the advantage of intracellular as well as extracellular distribution.<sup>7</sup> It predominantly binds  $MMA^{3+}$  and possibly removes the  $MMA^{3+}$  from endogenous ligands. The DMPS– $MMA^{3+}$  complex is eliminated in the urine.<sup>9,11,84</sup> It also works by synergistically increasing the nonenzymatic methylation of  $As^{3+}$ .<sup>270</sup> Two brothers ingested nearly pure arsenic trioxide (1 and 4 g each) and were treated with intravenous and oral DMPS. The brother who ingested 4 g developed hypotension, AKI, respiratory insufficiency, and asystolic cardiac arrest. 2,3-Dimercapto-1-propanesulfonic acid was started 32 hours postingestion, and the patient survived with normal kidney function and no neurologic dysfunction. His sibling had a milder course; DMPS was started 48 hours postingestion, and there were no neurologic sequelae on follow-up examination.<sup>167</sup> 2,3-Dimercapto-1-propanesulfonic acid significantly increased biliary excretion of arsenic in a guinea pig model but did not increase fecal excretion. The latter is most likely a result of enterohepatic recirculation of the DMPS–As complex.<sup>197</sup> However, in another guinea pig model, the addition of oral cholestyramine to either DMPS or DMSA but not to dimercaprol increased fecal arsenic excretion.<sup>169</sup>

D-Penicillamine has not demonstrated efficacy in chelating or reversing the biochemical lesions of arsenic and should not be used. Its previous advantage of oral administration is no longer relevant with the availability of succimer.

Because of the limitations of currently available chelators, research is ongoing to find better chelators to treat arsenic toxicity. For example, some analogs of succimer, especially its monoisoamyl ester, have increased intracellular penetration relative to the parent compound and increase survival in arsenic-poisoned rats.<sup>77,120</sup> In addition to improved chelators, other treatments for arsenic toxicity are being investigated. Some rodent studies suggest that certain micronutrients, such as zinc or selenium, decrease arsenic toxicity.<sup>77</sup> However, early findings from the HEALS cohort are mixed. A cross-sectional substudy from this group revealed an inverse relationship between the severity of skin lesions and dietary intake of folate, pyridoxine, riboflavin, and vitamins A, C, and E.<sup>269</sup> By contrast, another study from the same cohort did not find a statistically significant relationship between the severity of skin lesions and supplementation with vitamin E, selenium, or both.<sup>245</sup> Until more data are available, nutritional supplementation, in the absence of dietary deficiency, remains controversial.

### Hemodialysis

Hemodialysis removes negligible amounts of arsenic, with or without concomitant dimercaprol therapy, and is not indicated in patients with normal kidney function.<sup>23,101,156</sup> In patients with AKI, hemodialysis clearance rates have ranged from 76 to 87.5 mL/min, with or without concomitant dimercaprol therapy.<sup>244</sup> In 2 acutely toxic patients with AKI, total arsenic removed during a 4-hour dialysis measured 4.68 mg in one and 3.36 mg in the other. Concomitant 24-hour urinary arsenic excretions were 3.12 mg and 2.03 mg, respectively. When kidney function returned, however, the 24-hour urinary excretion of arsenic far exceeded that recovered with dialysis, with reported amounts of 18.99 mg in the first patient and 75 mg in the second patient.<sup>244</sup> There are no published rigorous data regarding hemodialysis removal of a water-soluble complex such as DMPS–As.<sup>131</sup>

### SUMMARY

- Environmental contamination of water sources is the major source of arsenic in many countries, including the United States.
- Arsenicals produce multisystem toxicity by a variety of pathophysiologic mechanisms.

**TABLE 86-3** Chelators for Arsenic Poisoning

Dosage	Adverse Effects
<b>Dimercaprol</b> 3–5 mg/kg IM every 4–6 hours	Hypertension, febrile reaction, diaphoresis, nausea, vomiting, salivation, lacrimation, rhinorrhea, throat or chest pain, headache, painful injection, injection site sterile abscess, hemolysis in G6PD-deficient patients, chelation of essential metals (prolonged course)
<b>Succimer</b> 10 mg/kg/dose orally every 8 hours for 5 days, then 10 mg/kg/dose every 12 hours	Nausea, vomiting, diarrhea, abdominal gas and pain, transient elevations of hepatic aminotransferases and alkaline phosphatase concentrations, rash, pruritus, sore throat, rhinorrhea, drowsiness, paresthesias, thrombocytosis, eosinophilia
<b>DMPS (not FDA approved)</b> Dose: 5 mg/kg/dose IM, administered as a 5% solution Day 1: every 6–8 hours Day 2: every 8–12 hours Day 3 and thereafter: every 12–24 hours Regardless of the chelator used, the end point of chelation is a 24-hour urinary arsenic concentration of <50 mcg/L	Allergic reactions, increased copper and zinc excretion, nausea, pruritus, vertigo, weakness, toxic epidermal necrolysis

G6PD = glucose-6-phosphate dehydrogenase; IM = intramuscularly. DMPS = 2,3-dimercapto-1-propanesulfonic acid

- A thorough understanding of inorganic arsenic metabolism and excretion as well as the different clinical manifestations of acute, subacute, and chronic toxicity are necessary to avoid misdiagnosis.
- Chelation therapy with dimercaprol in the United States, or with DMPS elsewhere, if available, should be started immediately in the severely ill patient.
- For patients with subacute or chronic toxicity, it is reasonable to await laboratory results unless clinical deterioration occurs.

# DIMERCAPROL (BRITISH ANTI-LEWISITE OR BAL)

Mary Ann Howland

## INTRODUCTION

British anti-Lewisite (BAL) (2,3-dimercaptopropanol; dimercaprol) is a metal chelator used clinically in conjunction with edetate calcium disodium (CaNa<sub>2</sub>EDTA) for lead encephalopathy and severe lead poisoning as well as other metals and metalloids.<sup>26,34</sup> In severe lead poisoning, dimercaprol should precede the first dose of CaNa<sub>2</sub>EDTA by 4 hours to prevent redistribution of lead to the central nervous system (CNS).<sup>17,18</sup> Dimercaprol has a narrow therapeutic index and is only administered intramuscularly (IM) because it is formulated in peanut oil. Oral succimer is used for patients with less severe lead toxicity. The roles for dimercaprol in arsenic and mercury poisoning have diminished since the development of succimer and the investigational chelator 2,3-dimercaptopropane sulfonate (DMPS). Dimercaprol remains indicated when the gastrointestinal tract is compromised.

## HISTORY

Investigation into the use of sulfur donors as antidotes was precipitated by the World War II threat of chemical warfare with Lewisite (dichloro[2-chlorovinyl]arsine) and mustard gas (dichlorodiethyl sulfide {ClCH<sub>2</sub>CH<sub>2</sub>}<sub>2</sub>S).<sup>1,35,36</sup> Both are vesicants that cause tissue damage when combined with protein sulphydryl groups (Chap. 126).<sup>39</sup> The investigations of Stocken and Thompson at Oxford led to the discovery of the dithiol 2,3-dimercaptopropanol (or BAL) that combines with Lewisite to form a stable 5-membered ring.<sup>44,47</sup>

## PHARMACOLOGY

### Chemistry

Dimercaprol has a molecular weight of 124.2 Da and a specific gravity of 1.21.<sup>37</sup> It is an oily liquid with only 6% weight/volume water solubility, 5% weight/volume peanut oil solubility, and a disagreeable odor. Aqueous solutions are easily oxidized and therefore unstable. Peanut oil stabilizes dimercaprol and benzyl benzoate (in the ratio of one part dimercaprol to 2 parts of benzyl benzoate), which renders the dimercaprol miscible in peanut oil.<sup>40</sup>

### Mechanism of Action

The sulphydryl groups of dimercaprol form chelates with certain metals, which are then excreted in the urine. Lead, arsenic, and inorganic mercury salts are the metals most amenable to chelation with dimercaprol.

### Pharmacokinetics

The limited information available about the pharmacokinetics of dimercaprol was determined in the 1940s.<sup>1,28</sup> Serum concentrations of dimercaprol peak about 30 minutes after IM administration, and distribution occurs rapidly.<sup>40,43</sup> Within 2 hours after IM administration to rabbits, serum concentrations rapidly fall. Urinary excretion of dimercaprol metabolites, perhaps partially as glucuronic acid conjugates, accounted for nearly 45% of the dose within 6 hours and 81% of the dose within 24 hours.<sup>40,42</sup> Very little is excreted unchanged in the urine.<sup>40</sup> Dimercaprol is concentrated in the kidney, liver,

and small intestine.<sup>38</sup> Dimercaprol is also found in the feces, suggesting that an enterohepatic circulation exists. Hemodialysis is useful in removing the dimercaprol-metal chelate in cases of kidney failure.<sup>26,33,46</sup>

## ROLE OF DIMERCAPROL IN ARSENIC POISONING

### Animal Studies

The fear of Lewisite attack causing skin lesions led researchers to investigate the potential for cutaneous application of dimercaprol.<sup>44</sup> This was based on the limited water solubility and high lipid solubility of dimercaprol. In a rodent model, low concentrations of topical dimercaprol were very effective both in preventing Lewisite-induced toxicity and in reversing toxicity when administered within one hour of skin exposure.<sup>37,39</sup> In rabbits, ophthalmic application of dimercaprol proved effective in preventing corneal destruction if applied within 20 minutes of exposure.<sup>26</sup> Additionally, urinary arsenic concentrations were significantly increased after the application of dimercaprol.<sup>39</sup>

The effectiveness of both parenteral single-dose and multiple-dose dimercaprol against lewisite and other arsenicals was studied in rabbits. When begun within 2 hours of lewisite exposure, dimercaprol injections of 4 mg/kg every 4 hours led to a 50% survival of exposed rabbits. This dosing regimen was demonstrated to be one-seventh of the maximum tolerated dose of dimercaprol.<sup>20</sup>

The most recent animal studies demonstrate that although dimercaprol increases the LD<sub>50</sub> (median lethal dose for 50% of test subjects) of sodium arsenite, the therapeutic index of dimercaprol is low and arsenic redistribution to the brain occurs.<sup>4,6,7,23,41</sup> In these same animal models, succimer and DMPS also increased the LD<sub>50</sub> but with better therapeutic indices and without causing redistribution to the brain.<sup>3,4</sup>

Ophthalmic damage caused by Lewisite is partly a result of the liberation of hydrochloric acid, which results in an acid injury causing localized superficial opacities of the cornea and deep penetration of lewisite into the cornea and aqueous humor with resultant rapid necrosis. In an experimental model, a 5% dimercaprol ointment or solution applied within 2 minutes of exposure prevented the development of a significant reaction; application at 30 minutes limited the reaction, but did not prevent permanent damage.<sup>24</sup>

### Human Studies

Experiments in human volunteers who were given minute amounts of arsenic demonstrated that dimercaprol increased urinary arsenic concentration by approximately 40%, with maximum excretion occurring 2 to 4 hours after dimercaprol administration.<sup>49</sup> Dimercaprol was subsequently used in the treatment of arsenical dermatitis resulting from organic arsenicals used to treat syphilis. When applied to affected skin, topical dimercaprol produced erythema, pruritus, and dysesthesias, without adverse effects on unaffected skin. Dimercaprol (IM) produced both subjective and objective improvement, limited the duration of the arsenical dermatitis, and increased urinary arsenic elimination.<sup>15,31,32</sup>

In a study of 227 patients with inorganic arsenic poisoning, maximal efficacy and minimal toxicity were achieved when 3 mg/kg of dimercaprol was administered IM every 4 hours for 48 hours and then twice daily for 7 to 10 days. This regimen resulted in complete recovery in 6 of 7 patients with severe arsenical encephalopathy and demonstrated the importance of administering dimercaprol as soon as possible after an exposure. Of 33 patients with

severe arsenical encephalopathy, 18 of 24 (75%) treated within 6 hours survived, whereas only 4 of 9 (44%) treated after a delay of greater than 72 hours survived.<sup>19</sup> Furthermore, the effectiveness of dimercaprol was demonstrated in 3 patients who were treated successfully after mistakenly receiving 10 to 20 times the therapeutic dose of oxophenarsine hydrochloride an arsenical primarily used for the treatment of syphilis. A fourth patient, treated with inadequate doses of dimercaprol, died.<sup>19</sup> These cases support the effectiveness of dimercaprol in treating arsenic-induced agranulocytosis, encephalopathy, dermatitis, and probably arsenical fever.<sup>18</sup>

When dimercaprol first became more widely available, 42 children were treated following arsenic ingestions, and their results were compared with a historical group of 111 untreated children who had also ingested arsenic.<sup>50</sup> The percentage of children exhibiting symptoms on presentation were similar between groups (46%), but in the group of children treated with dimercaprol there were fewer deaths (zero vs 3), a shorter average hospital stay (1.6 vs 4.2 days), and fewer cases of persistent symptoms at 12 hours (0% vs 29.3%).

### ROLE OF DIMERCAPROL IN MERCURY POISONING

Because mercury also reacts with sulfhydryl groups, animal studies were performed to assess the affinity and ability of thiols to competitively chelate inorganic mercury and prevent toxicity. As in the case of arsenic, the dithiol dimercaprol was more effective than the monothiol 1-thiosorbitol in preventing mercury-induced death and uremia.<sup>22</sup> The clinical efficacy of dimercaprol in treating inorganic mercury poisoning was substantiated in patients who ingested mercuric chloride.<sup>29,30</sup> Thirty-eight patients ingesting more than 1 g of mercuric chloride who were treated with dimercaprol within 4 hours of exposure were compared with historical controls.<sup>29</sup> There were no deaths in the 38 patients treated with dimercaprol as compared to 27 deaths in the 86 untreated patients. Death typically resulted from hemorrhagic gastritis and kidney failure.<sup>29</sup> Dimercaprol is particularly useful for patients who ingested a mercuric salt, as the associated gastrointestinal toxicity of the mercuric salt limits the potential of an orally administered antidote such as succimer.<sup>48</sup>

Animal models demonstrate that when dimercaprol is administered following poisoning from elemental mercury vapor or short-chain organic mercury compounds, brain concentrations of mercury increase.<sup>10,14</sup> As a result, dimercaprol therapy is not recommended in these circumstances (Chap. 95).<sup>2,5,26</sup>

### ROLE OF DIMERCAPROL IN LEAD POISONING

Dimercaprol is used in combination with  $\text{CaNa}_2\text{EDTA}$  to treat patients with severe lead poisoning. In all other cases, succimer is the chelator of choice. When treating patients with lead encephalopathy, it is essential to administer the dimercaprol first, followed 4 hours later by  $\text{CaNa}_2\text{EDTA}$  with a second dose of dimercaprol. This regimen prevents the  $\text{CaNa}_2\text{EDTA}$  from redistributing lead into the brain.<sup>17,18</sup> Providing 2 different chelators also reduces the blood lead concentration significantly faster than either one alone, and maintains a better molar ratio of chelator to lead.<sup>17</sup> Once the mobilization of lead is initiated, it is essential to provide uninterrupted therapy to prevent redistribution of lead to the brain (Chap. 93).<sup>17</sup> In the event that  $\text{CaNa}_2\text{EDTA}$  is not available, succimer has been used successfully with and without dimercaprol.<sup>8,45</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Dimercaprol has an  $\text{LD}_{50}$  in mice via intraperitoneal administration of 90 to 180 mg/kg, which is significantly lower than that of  $\text{CaNa}_2\text{EDTA}$  at 4,000 to 6,000 mg/kg, succimer at 2,480 mg/kg, and DMPS at 1,100 to 1,400 mg/kg.<sup>2</sup>

Among 700 patients who received 2.5 mg/kg of BAL IM every 4 to 6 hours for 4 doses, less than 1% developed minor reactions, such as pain at the injection site.<sup>15</sup> When doses of 4 and 5 mg/kg were given, the incidence of adverse effects rose to 14% and 65%, respectively.<sup>19</sup> At these higher doses, the following symptoms were reported in decreasing order of frequency: nausea; vomiting; headache; burning sensation of lips, mouth, throat, and eyes; lacrimation; rhinorrhea; salivation; muscle aches; burning and tingling of extremities; tooth pain; diaphoresis; chest pain; anxiety; and agitation.<sup>31</sup> These effects were maximal within 10 to 30 minutes of dosing and usually

subsided within 30 to 50 minutes.<sup>19</sup> Elevations in systolic and diastolic blood pressure and tachycardia were common and correlated with increasing doses.<sup>26,34</sup> Thirty percent of children given dimercaprol developed a fever that persisted throughout the therapeutic period.<sup>26</sup> In addition, in children, a transient reduction in the percentage of polymorphonuclear leukocytes also occurred.<sup>26</sup> We recommend not to administer doses above 5 mg/kg because of the high risk of adverse reactions. Doses above 25 mg/kg often resulted in a hypertensive encephalopathy with convulsions and coma.<sup>50</sup>

Dimercaprol is not very effective in the presence of arsenic-induced hepatotoxicity.<sup>32</sup> Moreover, in rats, preexistent hepatotoxicity was exacerbated when dimercaprol was used for treatment of arsenic poisoning. Therefore, unless the hepatotoxicity is considered to be arsenic induced, hepatic dysfunction is a contraindication to dimercaprol use.<sup>39</sup> Dimercaprol should not be used for patients poisoned by methylmercury because animal studies demonstrate a redistribution of mercury to the brain.<sup>5,26</sup> In a rabbit model of sodium arsenite poisoning, dimercaprol increased the concentration of arsenic in the brain whereas succimer did not alter the concentration and DMPS reduced the concentration.<sup>4,27</sup>

Because dissociation of the dimercaprol-metal chelate will occur in acidic urine, we recommend that the urine of patients receiving dimercaprol be alkalinized with hypertonic sodium bicarbonate to a pH of 7.5 to 8.0 to prevent liberation of the metal (Antidotes in Depth: A5).<sup>9,26</sup> Dimercaprol causes hemolysis in 2 children with glucose-6-phosphate dehydrogenase (G6PD) deficiency.<sup>25</sup> Because G6PD deficiency syndromes are variably expressed, patients at risk should be carefully monitored for hemolysis. In addition, chelators are relatively nonspecific and bind metals other than those desired, thus causing essential metal deficiencies. For example, dimercaprol given to mice increased copper elimination to 3 times normal.<sup>13</sup> Dimercaprol is formulated in peanut oil; therefore, the patient should be questioned regarding any known peanut allergy and a risk-benefit analysis undertaken. Limited evidence suggests that iron supplements should not be given to patients while receiving dimercaprol because the dimercaprol-iron complex causes severe vomiting and decreases metal chelation.<sup>17,18,21</sup>

Unintentional intravenous (IV) infusion of dimercaprol could theoretically produce fat embolism (peanut oil), lipid pneumonia, chylothorax, and associated hypoxia.<sup>42</sup>

### Pregnancy and Lactation

Dimercaprol is pregnancy category C.<sup>9</sup> There are no animal studies evaluating the effects of dimercaprol on reproduction. It is unknown whether dimercaprol is harmful to a fetus or is capable of affecting reproduction capability.<sup>9</sup> There are no data in human poisoning in pregnancy, and dimercaprol should only be administered to a pregnant woman after addressing a risk-benefit analysis with the patient.<sup>9</sup>

No data address whether dimercaprol or its chelates are excreted in human breast milk. It is not known whether succimer is excreted in human milk, but breast feeding is a contraindication<sup>11</sup> in some sources and is a caution in the package insert.<sup>28</sup> However in the 2010 CDC Guidelines for the identification and management of lead exposure in pregnant and breast-feeding women, the CDC suggests allowing breastfeeding for mothers with BLLs of less than or equal to 40 mcg/dL.<sup>16</sup> Mothers with BLLs of greater than 40 mcg/dL are encouraged to pump and discard their breast milk until their BLLs drop to less than 40 mcg/dL. Because dimercaprol is only indicated for BLLs greater than 40, we encourage the latter.

### DOSING AND ADMINISTRATION

No clinical trial has been performed to identify the appropriate dose of dimercaprol. The dosing for dimercaprol is expressed in both milligrams per square meter body surface area ( $\text{mg}/\text{m}^2$ ) and milligrams per kilogram body weight ( $\text{mg}/\text{kg}$ ) (Table A28-1). Dimercaprol should be administered only by deep IM injection. The dose of dimercaprol for lead encephalopathy is 75  $\text{mg}/\text{m}^2$  IM every 4 hours for 5 days in children (Table 93-8).<sup>17,18</sup> As noted earlier, we recommend that the first dose of dimercaprol precede the first dose of  $\text{CaNa}_2\text{EDTA}$  by 4 hours. Thereafter, IV  $\text{CaNa}_2\text{EDTA}$ , in a dose of 1500  $\text{mg}/\text{m}^2/\text{day}$  (up to a

**TABLE A28-1** Calculations for Average Deep Intramuscular (IM) Dimercaprol Use When Using Body Surface Area (m<sup>2</sup>)

Child	Average Height (in.)	Average Weight (lb)	m <sup>2</sup>	75 mg/m <sup>2</sup> Every 4 hours IM <sup>a</sup>	50 mg/m <sup>2</sup> Every 4 hours IM <sup>b</sup>
2-year-old boy	36	30.5	0.593	44.5 mg	30 mg
2-year-old girl	35	29	0.57	43 mg	28.5 mg
4-year-old boy	42	39.75	0.73	55 mg	36.5 mg
4-year-old girl	41.75	38.75	0.72	54 mg	36 mg

<sup>a</sup>Approximately 4 mg/kg. <sup>b</sup>Approximately 3 mg/kg.

maximum of 2–3 g) as a continuous infusion, or divided into 2 to 4 doses, is recommended. A continuous infusion is reasonable because the half-life of CaNa<sub>2</sub>EDTA is short. For adults, the dose of dimercaprol is 4 mg/kg every 4 hours (Table 93–8).<sup>9</sup> We recommend shortening the duration of dimercaprol to 3 days if there is prompt resolution of the encephalopathy and the blood lead concentration decreases to below 50 mcg/dL while the CaNa<sub>2</sub>EDTA continues for the remainder of the 5 days.

The dose of dimercaprol for arsenic poisoning is not established. One regimen for severe arsenic poisoning suggests the use of 3 mg/kg IM every 4 hours for 48 hours and then every 12 hours for 10 days or until complete recovery for severe poisoning.<sup>19</sup> In this large case series in adults, arsenic poisoning was a result of the treatment of syphilis with arsenic (oxophenarsine) and severe was defined as encephalopathy, exfoliative dermatitis, blood dyscrasia, or massive injection of the arsenical. In this same series, 2.5 mg/kg IM for each of 4 daily doses spaced every 4 hours for the first 2 days and then reduced to one or 2 injections daily for 10 days or until complete recovery was suggested for mild arsenic toxicity defined as fever, rash, and mild arsenical dermatitis. Another regimen uses 3 to 5 mg/kg IM every 4 to 6 hours on the first day and then tapers the dose and frequency, depending on the patient's symptomatology. A third regimen reduces the number of injections by day 2 from 6 to 4 and then from 3 to 2 to 1 and terminates therapy within 5 to 7 days.<sup>50</sup> Based on this limited data, we recommend the first regimen cited in this paragraph.

The dose of dimercaprol for patients exposed to inorganic mercuric salts is 5 mg/kg IM initially, followed by 2.5 mg/kg every 12 to 24 hours until the patient appears clinically improved, up to a total of 10 days.<sup>9</sup> Dimercaprol is for deep IM use only.

As noted above, we recommend that the urine be alkalized to avoid dissociation of the dimercaprol–metal chelate.<sup>12,26</sup>

## FORMULATION AND ACQUISITION

Commercially available dimercaprol is a yellow, viscous liquid with a sulfur odor. It is available in 3-mL ampules containing 100 mg/mL of dimercaprol, 200 mg/mL of benzyl benzoate, and 700 mg/mL of peanut oil.<sup>9</sup>

## SUMMARY

- Dimercaprol is a metal chelator used clinically in conjunction with CaNa<sub>2</sub>EDTA for lead encephalopathy and severe lead toxicity.<sup>26,34</sup>
- In patients with severe lead poisoning, we recommend that dimercaprol precede the first dose of CaNa<sub>2</sub>EDTA by 4 hours.
- When dimercaprol is not available, succimer with CaNa<sub>2</sub>EDTA or even succimer alone in resource-poor areas appears adequate.
- The roles of dimercaprol in arsenic and mercury poisonings are being supplanted by oral succimer and the investigational chelator DMPS, which are reasonable unless the gastrointestinal tract is compromised.

# BISMUTH

Rama B. Rao

<b>Bismuth (Bi)</b>	
Atomic number	= 83
Atomic weight	= 208.98 Da
Normal concentrations	
Blood	< 5 mcg/dL (239.5 nmol/L)
Serum	< 1 mcg/dL (<47.9 nmol/L)
Urine	< 20 mcg/L (<95.7 nmol/L)

## HISTORY AND EPIDEMIOLOGY

Elemental bismuth is nontoxic. Bismuth salts have therapeutic uses and are responsible for the toxicities described in this chapter. Thus, the term *bismuth* in this chapter refers to bismuth salts. Nearly 300 years ago, bismuth was recognized as medicinally valuable. It was included in topical salves and oral preparations for various gastrointestinal (GI) disorders. Nephrotoxicity was first described as early as 1802. In the early 20th century, acute kidney injury was reported in children administered intramuscular bismuth salts for the treatment of gingivostomatitis.<sup>8,28,51,52</sup> Administration of bismuth thioglycollate and its related water-soluble compounds, triglycollamate and trithioglycollamate, were responsible for the kidney failure, which occurred with as little as one or 2 doses.<sup>9,13,32,37,41,59</sup> Children with kidney failure would typically present with abdominal pain, oliguria, anuria, malaise, depressed mental status, and vomiting. Alterations in consciousness usually abated with chelation or resolution of the uremia. After the use of intramuscular injections was abandoned, this form of bismuth-induced kidney failure became rare. Syphilis was previously treated with intramuscular bismuth. A rash known as “erythema of the 9th day,” consisting of a diffuse macular rash of the trunk and extremities, occasionally occurred and resolved without intervention.<sup>17</sup>

In patients administered “Analbis” antipyretic rectal suppositories, hepatic failure was described histopathologically as yellow atrophy with vacuolization.<sup>4,25</sup> An investigation of the suppositories suggested that diallylacetic acid, a xenobiotic that is no longer marketed in the United States, and not bismuth, was the hepatotoxin.

Today, bismuth is one of many xenobiotics commonly used in prescription and nonprescription oral preparations for treatment of traveler’s diarrhea, nausea, and vomiting. In addition, bismuth-impregnated surgical packing paste is used for the treatment of the flatus and odor associated with ileostomies and colostomies,<sup>10,61</sup> and as an adjunct in the treatment of oral and gastrointestinal ulcers.<sup>15,18</sup> In the GI tract, bismuth binds to sulfhydryl groups and decreases fecal odor through formation of bismuth sulfide.<sup>54</sup> Sulfhydryl binding is also the proposed mechanism for the antimicrobial effect of bismuth, causing lysis of *Helicobacter pylori*, the causative bacteria in peptic ulcer formation. Bismuth also inhibits bacterial enzyme function, as well as prevent adhesion of *H. pylori* to the gastric mucosa.<sup>60</sup>

Epidemics of bismuth-induced encephalopathy, particularly among patients with ileostomies or colostomies, were reported from France, Britain, and Australia.<sup>7,11,29,31,35</sup> As a result, some countries banned or restricted bismuth preparations to prescription only. Bismuth subsalicylate, which is currently available in the United States as a nonprescription remedy, is still periodically responsible for cases of encephalopathy.<sup>16,19,33</sup> Other reported causes of bismuth-induced encephalopathy include systemic absorption from bismuth-impregnated surgical packing paste and transdermal absorption from long-term application of a bismuth-containing skin cream.<sup>27</sup>

In 2006, the United States Food and Drug Administration (FDA) issued a warning on an alternative health product known as “bismacine” or

“chromacine.” This alternative medicine product was not FDA approved, but was used by some practitioners as an injectable treatment for Lyme disease, for which efficacy data are lacking. The product contains bismuth citrate and was associated with at least one death and other adverse events.<sup>2</sup>

## CHEMISTRY AND TOXICOLOGY

Bismuth is present in nature in both the trivalent and pentavalent forms. The trivalent form of bismuth is used for all medicinal purposes, usually as the bismuthyl (BiO) moiety generated by hydrolysis of trivalent bismuth compounds to yield a low-solubility alkaline salt. Bismuth salts are divided into 4 groups based on their water or lipid solubility; or whether they are organic or inorganic (Table 87-1). Most orally administered bismuth remains in the GI tract, and is subsequently excreted in the feces, and with only 0.2% is systemically absorbed.<sup>22</sup> Absorption of some bismuth preparations such as colloidal bismuth subcitrate increases as gastric pH increases.<sup>39</sup> The time to peak absorption ranges between 15 and 60 minutes with high intra- and interindividual variation.<sup>26,28</sup> The serum-to-blood ratio of bismuth is 1.55.<sup>5</sup> The distribution and elimination of orally administered bismuth follows a complex, multicompartmental model. The volume of distribution in humans is unknown.<sup>6,46,47</sup>

Novel research of bismuth uptake in human cells indicates that up to 90% of bismuth is passively absorbed and binds to glutathione and is transported by a multidrug-resistant protein into vesicles. In the same in vitro model, human cells depleted of glutathione and exposed to bismuth had reduced cell survival.<sup>20</sup>

Once in the circulation, bismuth binds to  $\alpha_2$ -macroglobulin, IgM,  $\beta$ -lipoprotein, and haptoglobin. Bismuth rapidly enters liver, kidney, lungs, and bone.<sup>55</sup> It crosses the placenta and enters the amniotic fluid and fetal circulation.<sup>57</sup> It also readily crosses the blood-brain barrier.<sup>38</sup> Evidence in a rat model suggests that, when administered intramuscularly, bismuth enters the central nervous system (CNS) via retrograde axonal transport.<sup>53</sup> In both animal models and human reports, bismuth is identified in the fenestrated membranes of synaptosomes,<sup>41,44</sup> localizing in the thalamus and cerebellum with diffuse cortical uptake as well.<sup>28,38</sup> Ninety percent of absorbed bismuth is eliminated through the kidneys, where it induces the production of its own metal-binding protein.<sup>55</sup>

Three different half-lives describe the pharmacokinetics of orally administered therapeutic doses of bismuth.<sup>6,46</sup> The first, the distribution half-life, is approximately 1 to 4 hours. The second, the apparent plasma half-life, lasts 5 to 11 days. The third is the apparent half-life of urinary excretion lasting between 21 and 72 days<sup>5</sup> with urinary bismuth detected as late as 5 months after the last oral dose.<sup>26</sup>

## PATHOPHYSIOLOGY

Like other metals, bismuth toxicity involves multiple organ systems. The effect of different bismuth salts can be categorized into 4 groups based on solubility and GI absorption (Table 87-1).<sup>46,47</sup> The highly lipid-soluble compounds such as bismuth subsalicylate or bismuth subgallate are most commonly associated with neurotoxicity.

Bismuth-induced encephalopathy likely results from neuronal sulfhydryl binding. In patients who die of bismuth encephalopathy, the gray-matter concentration of bismuth is nearly twice that of white-matter.<sup>28</sup> In a patient with bismuth encephalopathy dying from concomitant sepsis, the autopsy revealed loss of cerebellar Purkinje cells, which would be unexpected from sepsis.<sup>29</sup> The factors predisposing some individuals to encephalopathy from lipid soluble bismuth salts, however, are not well defined. Age, gender, and duration of

TABLE 87-1 The Physicochemical Characteristics of Bismuth Salts

Group	Chemistry	Toxicity	Examples
I	Water insoluble	Minimal	Bismuth subnitrate

therapeutic use do not predict the likelihood of developing encephalopathy, but typically these patients were chronically treated (Table 87-1).

## CLINICAL MANIFESTATIONS

### Acute

Acute kidney injury is primarily due to exposure to the water-soluble bismuth salts (group III).<sup>37,42</sup> Massive overdoses of water-soluble bismuth salts result in abdominal pain and oliguria or anuria. In reported cases, overdoses of colloidal bismuth subsalicylate or tripotassium dicitratobismuthate (TDC) caused acute tubular necrosis.<sup>1,21,23,51,52,56</sup> Histopathologically, bismuth causes degeneration of the proximal tubule, similar to other metals. Although these xenobiotics are potentially neurotoxic, signs of encephalopathy are generally absent.<sup>12,19</sup> In one case, a patient with bismuth-induced kidney failure was described as having diminished deep tendon reflexes, muscle weakness, and myoclonus, without an alteration in consciousness.<sup>21</sup>

Neurotoxicity in the acute and subacute setting is less common, but also occurs. Bismuth subnitrate iodoform-impregnated surgical packs for oral surgery are implicated in neurotoxicity, occurring within as little as 9 days of exposure (Table 87-1).<sup>3</sup>

A young woman who reported ingesting 8 tablets of bismuth subsalicylate every 2 hours for up to 20 days developed hearing loss, tinnitus, and altered mental status within 5 days of her last dose. She subsequently developed chronic neurologic impairments.<sup>48</sup>

### Chronic

The most common toxicologic finding associated with repeated therapeutic doses of oral bismuth compounds is a diffuse, progressive myoclonic encephalopathy.<sup>12,19</sup> Affected patients exhibit neurobehavioral changes, such as apathy and irritability. With continued exposure, these patients develop difficulty concentrating, diminished short-term memory, and occasionally, visual hallucinations.<sup>30,31</sup> A movement disorder characterized by muscle twitching, myoclonus, ataxia, and tremors ensues.<sup>12</sup> Weakness and, rarely, seizures ultimately advance to immobility.<sup>33,35</sup> With continued bismuth administration, these patients develop coma and die.

Rarely, patients recovering from severe encephalopathy complain of scapular, humeral, or vertebral pain because of fractures caused by severe neuromuscular manifestations such as myoclonus.<sup>14</sup>

Like several other metals, bismuth often causes a generalized pigmentation of skin. Deposition of bismuth sulfide into the mucosa causes a blue-black discoloration of gums.<sup>62</sup> This occurs in the absence of toxic effects. Formation of the same compound in the GI tract causes blackening of the stool. Liver failure is rarely reported, except in patients with multisystem organ failure from fatal neurotoxicity.

## DIAGNOSIS

The clinician must have an index of suspicion based on the acute or chronic nature of the exposure. For oral exposures, the class of bismuth salt ingested will determine primary organ toxicity. Patients with acute massive overdoses

TABLE 87-2 Differential Diagnosis of Bismuth Encephalopathy

Akinetic status epilepticus
Creutzfeldt–Jacob disease
Delirium tremens
Hyperglycemic hyperosmolar syndrome

Paradichlorobenzene encephalopathy
Postanoxic and posthypoglycemic encephalopathies
Progressive multifocal ataxia
Tetanus/strychnine
Viral encephalopathies

NMDA = *N*-methyl-D-aspartate.

should be evaluated for acute kidney injury. Formation of nuclear inclusion bodies can be identified on renal biopsy or on postmortem examination.<sup>13,43</sup>

The diagnosis of bismuth-induced encephalopathy is based on a history of exposure coupled with diffuse neuropsychiatric and motor findings.<sup>31</sup> Other causes of encephalopathy should be entertained and excluded (Table 87-2). An abdominal radiograph will likely demonstrate radiopacities of bismuth in the intestines. Stool likely will be black and test negative for occult blood.

The presence of bismuth in the blood is confirmatory of exposure, but absolute concentrations correlate poorly with morbidity.<sup>6</sup> In a review of 310 patients with bismuth-induced encephalopathy, 288 (93%) had a blood concentration greater than 10 mcg/dL, with the majority of these blood concentrations between 10 and 100 mcg/dL.<sup>30</sup> Twenty-two patients had encephalopathy at blood concentrations lower than 10 mcg/dL.<sup>30</sup> In another report, 2 patients with encephalopathy had blood concentrations of 90 and 250 mcg/dL, both of whom recovered when their concentrations fell below 50 mcg/dL.<sup>7</sup> Just as blood concentrations do not reflect severity of illness, tissue concentrations also correlate poorly with severity of illness. This is demonstrated by a patient who recovered from a severe bismuth encephalopathy. On discharge, he had a low blood bismuth concentration and died 3 months later of unrelated trauma. At autopsy, he had an elevated CNS bismuth concentration but no reported symptoms at the time of the trauma.<sup>11</sup>

The electroencephalographic (EEG) findings of patients with bismuth encephalopathy generally demonstrate nonspecific slow-wave changes.<sup>16,21</sup> In one study, the EEG findings were described in association with blood concentrations. At less than 5 mcg/dL, the EEG was normal or demonstrated diffuse slowing. In patients with blood concentrations up to 150 mcg/dL, the findings of sharp-wave abnormalities were noted. At higher concentrations (>200 mcg/dL), some patients with neurologic events, such as myoclonic jerks, did not have corresponding EEG changes. The authors proposed that an elevated body burden might have an inhibitory effect on the cerebral cortex paradoxically affecting EEG findings.<sup>11</sup>

In encephalopathic patients with blood concentrations greater than 200 mcg/dL, diagnostic imaging such as computed tomography demonstrates a diffuse cortical hyperdensity of the gray matter.<sup>11</sup> These findings tend to resolve with recovery. Magnetic resonance image was normal in another encephalopathic patient.<sup>16</sup>

## TREATMENT

Typically, cessation of bismuth exposure and supportive care results in a complete recovery. For toxicity from bismuth-iodoform-impregnated surgical packing, removal is warranted.<sup>3</sup> For oral bismuth exposures, some authors suggest GI decontamination with activated charcoal and polyethylene glycol solution.<sup>49</sup> Administration of polyethylene glycol solution is recommended

until the rectal effluent is clear. Although evidence for activated charcoal is lacking, one dose, especially in patients with severe encephalopathy from oral exposure, is reasonable once the airway is protected. In patients with kidney failure, resolution is generally observed with supportive care. The use of chelators in patients with acute overdose without neurotoxicity is probably not indicated.

It is uncertain whether different chelators affect the clinical course of patients with bismuth encephalopathy (see Chelation below). Withdrawal of the source of bismuth results in complete reversal of effects within days to weeks, even in those patients who are severely ill. Prevention is the most effective means of avoiding neurotoxicity. Blood concentrations of bismuth are not routinely performed nor readily available, but a bismuth concentration above 10 mcg/dL or symptoms at lower concentrations warrant withdrawal of bismuth therapy.

Although novel data on the role of glutathione in bismuth uptake are described,<sup>20</sup> the clinical significance of this finding is unknown. The role of intravenous *N*-acetylcysteine to replete glutathione is not known at this time. In life-threatening cases of severe bismuth poisoning, it is reasonable to administer *N*-acetylcysteine at doses typically used for the treatment of acetaminophen toxicity.

## CHELATION

In general, the data regarding chelation are limited and in vitro, and animal models are not clearly predictive of human response. Chelation therapy with dimercaprol (BAL) is beneficial in experimental models,<sup>49,52</sup> reportedly beneficial in humans,<sup>34</sup> and often recommended by others, although clear evidence of efficacy is lacking. Dimercaprol undergoes biliary elimination, offering a major advantage over other chelators in patients who develop acute kidney injury. Based on the limited data available, it is reasonable to administer dimercaprol in encephalopathic patients with kidney failure in whom no neurologic improvement is noted within 48 hours of whole-bowel irrigation and bismuth withdrawal (Antidotes in Depth: A28).

One report of a patient with bismuth-induced kidney injury advocated the addition of dimercaptopropane sulfonate (DMPS), as BAL did not affect hemodialysis clearance, but the addition of DMPS to patients needing hemodialysis was effective in enhancing elimination.<sup>52</sup> It is uncertain whether the clinical course of the patients was improved. In human volunteers given colloidal bismuth subcitrate, succimer and DMPS, both at a dose of 30 mg/kg, increased urinary elimination of bismuth by 50-fold.<sup>50</sup> The availability of DMPS and indications for use are limited (Antidotes in Depth: A29). Although succimer can be added to severe cases, there is no current data that outcomes are changed once the offending source of bismuth is withheld or removed.

In an animal model, D-penicillamine was most efficacious in enhancing elimination of bismuth. In a human volunteer model using therapeutic doses of tripotassium-dicitrate-bismuthate, however, a single dose of D-penicillamine did not enhance urinary excretion.<sup>36</sup> Based on the above information, we recommend withdrawal of bismuth therapy and whole-bowel irrigation as a first intervention. Although data on chelation efficacy is lacking, BAL is reasonable in patients with life-threatening encephalopathy unresponsive to initial measures after 48 hours.

## BISMUTH DRUG INTERACTIONS AND REACTIONS

The coadministration of proton pump inhibitors (PPIs) increases the absorption of some bismuth preparations. In a prospective evaluation of patients receiving different treatment regimens for *H. pylori*-induced dyspepsia or peptic ulcer disease, individuals taking PPIs had a statistically significant elevation in their blood bismuth concentrations, with 3 patients exceeding 5,000 mcg/dL, compared with a similar group administered bismuth without PPIs. The authors suggest that the bismuth preparation used, colloidal bismuth subcitrate, is more soluble and absorbable at the higher gastric pH of patients on PPIs.<sup>22</sup> All these patients received short courses of therapy (2 weeks). Although the investigators did not attempt to follow neurobehavioral or neuropsychiatric changes, none of the patients had clinically evident bismuth toxicity.<sup>39</sup>

Based on this investigation, coadministration of PPIs with longer courses of colloidal bismuth subcitrate should be avoided or only offered with extreme caution. Ranitidine, which is frequently prescribed with a bismuth compound for dyspepsia or ulcer disease, does not affect the pharmacokinetics of bismuth absorption.<sup>26</sup>

In the United States, where bismuth subsalicylate is the most common oral bismuth-containing compound, up to 90% of the salicylate is absorbed.<sup>40,45</sup> Salicylate toxicity is rare but reported, and salicylate concentrations should be determined in both acute and chronic exposures.<sup>45,51</sup> Methemoglobinemia from subnitrate salt of bismuth is uncommonly described.<sup>24</sup>

## SUMMARY

- Bismuth toxicity manifests as nephrotoxicity following exposure to group III water soluble bismuth salts.
- Myoclonic encephalopathy, myoclonics, and coma occur following chronic exposure to Group II (lipophilic) bismuth salts.
- Supportive care, whole-bowel irrigation, and withdrawal of the bismuth-containing compound are the mainstays of treatment.
- Dimercaprol is reasonable in patients with life threatening encephalopathy unresponsive to initial measures after 48 hours.
- Salicylate concentrations are elevated in some cases of chronic bismuth subsalicylate poisoning.

## CADMIUM

Stephen J. Traub and Robert S. Hoffman

### Cadmium (Cd)

Atomic number	=	48
Atomic weight	=	112.4 Da
Normal concentrations		
Whole blood	<	5 mcg/L (44.5 nmol/L)
Urine	<	3 mcg/g creatinine
	<	26.7 nmol/g creatinine

### HISTORY AND EPIDEMIOLOGY

Cadmium, atomic number 48, is a transition metal in IUPAC group 12 of the modern periodic table. In its pure atomic form, it is a bluish solid at room temperature. It is readily oxidized to a divalent ion, Cd<sup>2+</sup>. Naturally occurring cadmium commonly exists as cadmium sulfide (CdS), a trace contaminant of zinc-containing ores.<sup>39</sup>

Cadmium sulfide, cadmium oxide, and other cadmium-containing compounds are refined to produce elemental cadmium, which is used for industrial purposes. When combined with other metals, cadmium forms alloys of relatively low melting points, which accounts for its extensive use in solders and brazing rods. Today, cadmium is primarily used as a reagent in electroplating and in the production of nickel-cadmium batteries. Other uses of cadmium include as a pigment in paint and as a neutron absorber in nuclear reactors. Cadmium salts were once also used as veterinary anthelmintics.<sup>14</sup>

As cadmium processing has increased, so has the incidence of cadmium toxicity. Cadmium toxicity usually occurs after environmental, occupational, or hobby work exposure.

### Environmental Exposure

Environmental exposure to cadmium generally occurs through the consumption of foods grown in cadmium-contaminated areas. Because cadmium is fairly common as an impurity in ores, areas where mining or refining of ores takes place are the most likely to contain cadmium-contaminated soil.

In the 1950s, a mine near the Jinzu River basin in Japan discharged large amounts of cadmium into the environment, contaminating the rice that was a staple of the local food supply. An epidemic of painful osteomalacia followed, affecting hundreds of people, particularly postmenopausal multiparous women.<sup>70</sup> The afflicted were prone to develop pathologic fractures, and were reported to call out “itai-itai” (“ouch-ouch”) as they walked because of the severity of their pain.<sup>30</sup> These symptoms were ultimately linked to cadmium, and the event came to be known as the Itai-Itai epidemic. Less consequential environmental cadmium exposures are also reported from Sweden,<sup>49</sup> Belgium,<sup>12</sup> and China.<sup>51</sup> Smokers have higher blood cadmium concentrations than nonsmokers,<sup>96</sup> probably as a result of contamination of soil where the tobacco is grown. This is noteworthy, in that cadmium and tobacco are reported to be synergistic causes of chronic pulmonary disease.<sup>66</sup>

### Occupational and Hobby Exposure

Welders, solderers, and jewelry workers who use cadmium-containing alloys are at risk for developing acute cadmium toxicity due to inhalation of cadmium oxide fumes. Other workers who do not work with metals per se are at risk for chronic cadmium toxicity through exposure to cadmium-containing dust.

Hobbyists who work with cadmium solders have exposures similar to occupational metalworkers. Significant cadmium toxicity in this population is usually the result of metalworking in a closed space with inadequate ventilation and/or improper respiratory precautions.

### TOXICOKINETICS

There is no known biologic role for cadmium. Ingested cadmium salts are poorly bioavailable (5%–20%), whereas inhaled cadmium fumes (cadmium oxide) are readily bioavailable (up to 90%).<sup>104</sup> As the only data on cadmium toxicokinetics are derived from work with cadmium salts and oxides, the term “cadmium” in the following discussions refers to these species unless otherwise noted.

After exposure, cadmium is absorbed into the bloodstream, where it is bound to  $\alpha_2$ -macroglobulin and albumin.<sup>105</sup> It is then quickly and preferentially redistributed to the liver and kidney, and to a lesser extent to other organs such as the pancreas, spleen, heart, lung, and testes.<sup>27</sup> Cadmium enters target organs via 3 possible mechanisms: zinc and calcium transporters; uptake of cadmium–glutathione or cadmium–cysteine complexes by transport proteins; and/or endocytosis of cadmium–protein complexes.<sup>111</sup>

After incorporation into the liver and kidney, cadmium forms a complex with metallothionein, an endogenous thiol-rich protein that is produced in both organs. Metallothionein binds and sequesters cadmium. Over time, hepatic stores of the cadmium–metallothionein complex (Cd-MT) are slowly released. Circulating Cd-MT is filtered by the glomerulus but reabsorbed and concentrated in proximal tubular cells,<sup>21,91,92</sup> explaining why the kidney is a principal target organ in cadmium toxicity.

There is no evidence that cadmium ions are oxidized, reduced, methylated, or otherwise biotransformed in vivo. The volume of distribution ( $V_d$ ) of cadmium is unknown, but is presumably quite large as a consequence of significant hepatic sequestration. Cadmium distribution and elimination are complex, and an 8-compartment kinetic model is proposed.<sup>57</sup> The slow release of cadmium from metallothionein-complexed hepatic stores accounts for its very long biologic half-life of 10 or more years.

### PATHOPHYSIOLOGY

#### Cellular Pathophysiology

Cadmium toxicity results from interactions of the free cations with target cells.<sup>27,38,64,69,92</sup> Complexation with metallothionein is cytoprotective,<sup>24,64</sup> and metallothionein functions as a natural chelator with a strong affinity for cadmium.<sup>20,58</sup> Although metallothionein plays a role in proximal tubular concentration of cadmium, kidney damage is attenuated by metallothionein, as metallothionein-deficient mice are more susceptible to cadmium toxicity than controls.<sup>64</sup>

There are several mechanisms by which cadmium interferes with cellular function. Cadmium binds to sulfhydryl groups, denaturing proteins and/or inactivating enzymes. The mitochondria are severely affected by this process,<sup>1</sup> which results in an increased susceptibility to oxidative stress.<sup>50</sup> Generally, cadmium affects processes involved in DNA repair, generation of reactive oxygen species, and induction of apoptosis.<sup>80</sup> Specifically, cadmium interferes with mediators of cell adhesion such as E-cadherin, N-cadherin, and  $\beta$ -catenin,<sup>76-78</sup> and interacts with other proteins such as kinesin<sup>10</sup> and amyloid beta protein 1-42.<sup>71</sup> Finally, the demonstrated interference of cadmium with calcium transport mechanisms<sup>101,102</sup> leads to intracellular hypercalcemia and, ultimately, apoptosis.

#### Specific Organ System Injury (Table 88–1)

##### Kidney

The kidney damage caused by cadmium develops over years. Proteinuria is the most common clinical finding and correlates with proximal tubular dysfunction, which manifests as urinary loss of low-molecular-weight proteins

**TABLE 88–1 Major Acute and Chronic Organ System Effects of Cadmium**

Organ	Acute	Chronic
Kidney		Proteinuria Nephrolithiasis
Bone		Osteomalacia
Lung	Pneumonitis	Cancer
Gastrointestinal system	Caustic injury	

such as  $\beta_2$ -microglobulin and retinol-binding protein. Cadmium also produces hypercalciuria,<sup>88</sup> possibly also via damage to the proximal tubule.

### Musculoskeletal

Cadmium-induced osteomalacia is a result of abnormalities in calcium and phosphate homeostasis, which, in turn, result from renal proximal tubular dysfunction. In one autopsy study, the severity of osteomalacia in cadmium exposed subjects correlated with a decline in the serum calcium-phosphate product.<sup>95</sup>

### Pulmonary

Acute cadmium pneumonitis is characterized by infiltrates on chest radiograph and hypoxia. Human autopsy studies<sup>35,75,89,106</sup> generally show degeneration and/or loss of bronchial and bronchiolar epithelial cells.

### Gastrointestinal Tract

Based on case reports,<sup>13,107</sup> ingested cadmium salts are caustic with the potential to induce significant nausea, vomiting, and abdominal pain, and result in GI hemorrhage, necrosis, and perforation. With respect to their effect on the GI mucosa, cadmium salts act similar to mercuric salts (Chap. 95).

## CLINICAL MANIFESTATIONS

### Acute Poisoning

#### Pulmonary/Cadmium Fumes

Cadmium pneumonitis results from inhalation of cadmium oxide fumes. The acute phase of cadmium pneumonitis mimics metal fume fever (Chap. 121), but the 2 entities are distinctly different. Whereas metal fume fever is benign and self-limited, acute cadmium pneumonitis progresses to hypoxia, respiratory insufficiency, and death.

Published case reports of patients who develop acute cadmium pneumonitis<sup>4,5,34,75,89,98,106,110</sup> are strikingly similar in their presentation. Within 6 to 12 hours of soldering or brazing with cadmium alloys in a closed space, patients typically develop constitutional symptoms, such as fever and chills, as well as a cough and respiratory distress.

On initial presentation, patients often have a normal physical examination, oxygenation, and chest radiograph. This relatively mild presentation potentially leads both to the misdiagnosis of metal fume fever and an underestimation of the severity of illness. As the pneumonitis progresses to acute respiratory distress syndrome (ARDS) (Chap. 121), crackles and rhonchi develop, oxygenation becomes impaired, and the chest radiograph develops a pattern consistent with alveolar filling. In fulminant cases, death usually occurs within 3 to 5 days.<sup>35,75,89,106</sup>

Patients who survive an episode of acute cadmium pneumonitis are at increased risk for developing chronic pulmonary disorders, including restrictive lung disease,<sup>4,5</sup> diffusion abnormalities,<sup>4</sup> and pulmonary fibrosis,<sup>98</sup> although recovery without sequelae is also reported.<sup>110</sup>

#### Oral/Cadmium Salts

Most acute cadmium exposures are inhalational, and acute ingestions are rare. Based on case report data, GI injury is likely to be the most significant clinical finding after acute ingestion, although other presentations are possible.

In one case,<sup>13</sup> a 17-year-old student ingested approximately 150 g of cadmium chloride that she obtained from her school science stockroom. She presented to the emergency department with hypotension and edema of the face,

pharynx, and neck. Her condition quickly deteriorated, and she suffered a respiratory arrest. She was intubated and underwent orogastric lavage, chelation with an unspecified chelator, and charcoal hemoperfusion. Multisystem organ failure ensued, and she died within 30 hours of presentation. At autopsy, the most significant finding was hemorrhagic necrosis of the upper GI tract. Her blood cadmium concentration was more than 2,000 times normal.

In a second reported case, a 23-year-old man ingested approximately 5 g of cadmium iodide in a suicide attempt and presented with acute hemorrhagic gastroenteritis.<sup>107</sup> His condition deteriorated, and despite treatment with calcium disodium ethylenediaminetetraacetic acid (CaNa<sub>2</sub>EDTA) and supportive measures, he died on hospital day 7. Autopsy did not reveal a specific cause of death.

A 51-year-old man taking multiple nutritional supplements who had no history to suggest cadmium exposure presented with a one-month history of fatigue, with laboratory findings suggestive of autoimmune hemolytic anemia. He was treated aggressively for that condition, but developed progressive multisystem organ failure and expired one week after presentation. His blood cadmium concentrations were extraordinarily high, suggesting an acute ingestion, although the source of cadmium was never determined.<sup>81</sup>

### Chronic Poisoning

#### Nephrotoxicity

The most common finding in chronic cadmium poisoning is proteinuria. Low-molecular-weight proteinuria is usually more significant than, and generally precedes, glomerular dysfunction, although some cadmium-exposed workers manifest predominantly glomerular proteinuria.<sup>7</sup> There is a dose–response relationship between total body cadmium burden and kidney dysfunction,<sup>12,47,49,70,100</sup> although this relationship weakens at low doses.<sup>42</sup> Patients with diabetes mellitus are reported to be particularly susceptible to the nephrotoxic effects of cadmium.<sup>40</sup> In most cases, proteinuria is considered to be irreversible even after removal from exposure,<sup>41,55,84</sup> but improvement is sometimes reported.<sup>63,99</sup> Less clear is the question of whether kidney dysfunction progresses after removal from exposure, with studies showing both stable<sup>41</sup> and deteriorating<sup>45,83,84</sup> function in cadmium-exposed workers who are removed from exposure. The routes and duration of exposure, as well as blood and urine cadmium concentrations, differ markedly among these studies, limiting wider applicability of any analysis. Occupational cadmium exposure is also associated with nephrolithiasis,<sup>48,87</sup> likely as a result of hypercalciuria.<sup>88</sup>

#### Pulmonary Toxicity

Large studies of workers chronically exposed to relatively low concentrations of cadmium fail to demonstrate consistent effects on the lung. In one study of 57 workers with sufficient exposure to cadmium oxide to produce kidney dysfunction, there was no evidence of pulmonary dysfunction, even in those with the greatest cumulative cadmium exposure.<sup>29</sup> By contrast, other studies report both restrictive<sup>19</sup> and obstructive<sup>23,86</sup> changes on pulmonary function tests. Interestingly, a follow-up study of the group with restrictive lung disease showed improvements after cadmium exposure was reduced.<sup>18</sup> The discrepancies in these results are due in part to markedly different doses and durations of exposure among the various groups. Cadmium is also associated with pulmonary neoplasia; the carcinogenicity of cadmium is discussed separately (see Cancer below).

#### Musculoskeletal Toxicity

Cadmium-induced osteomalacia usually occurs in the setting of environmental exposure;<sup>46</sup> although mentioned in case reports,<sup>8,56</sup> osteomalacia is generally not a prominent feature of occupational exposure to cadmium. Gender and age differences explain part of this apparent difference: victims of the original Itai-Itai epidemic were mostly older women, whereas occupational cadmium exposures typically occur in younger men. In addition, differences in cumulative dosing and in route of exposure (oral vs pulmonary) partly account for the unique prominence of osteomalacia in patients with environmental exposures. Cadmium exposure is associated with osteopenia and osteoporosis even in areas (such as the United States) where widespread environmental exposure is unlikely.<sup>108</sup>

### Hepatotoxicity

Although the liver stores as much cadmium as any other organ, hepatotoxicity is not a prominent feature in humans with cadmium exposure, probably because hepatic cadmium is usually complexed to metallothionein.<sup>40</sup> The liver is a potential target organ, however, as hepatotoxicity is easily inducible in animals.<sup>1,25,26,77</sup>

### Neurologic Toxicity

Cadmium exposure is linked to olfactory disturbances,<sup>67,85,94</sup> impaired higher cortical function,<sup>103</sup> and parkinsonism.<sup>72,103</sup>

### Cardiovascular

Cadmium induces hypertension in rats,<sup>62</sup> but human studies have only yielded unconvincing and conflicting results.<sup>33,61,73,97</sup> Cadmium is associated with the development of atherosclerotic plaques<sup>34</sup> as well as heart failure.<sup>11</sup>

### Other Organ Systems

Although there is evidence that cadmium causes immunosuppression affecting both humoral and cell-mediated immunity in animals,<sup>26</sup> a single human study showed no overt immunopathology in an occupationally exposed cohort.<sup>54</sup> The testes are clearly a target organ in animal exposures,<sup>60</sup> but they are not considered a major target organ in humans.

### Cancer

Cadmium induces tumors in multiple animal organs, an effect that is exacerbated by zinc deficiency.<sup>104</sup> In humans, cadmium exposure is principally associated with lung cancer.<sup>74</sup> The strength of this association is questioned, as most studies have methodologic problems such as coexposure to arsenic, a known pulmonary carcinogen.<sup>9,56</sup> Despite these confounding coexposures, cadmium is designated as a human carcinogen by the International Agency for Research on Cancer.<sup>44</sup>

## DIAGNOSTIC TESTING

Other than to confirm exposure, cadmium concentrations have limited usefulness in the management of the acutely exposed patient. Diagnosis and treatment are based on the history, physical examination, and symptoms, and in acute exposures ancillary tests (such as pulse oximetry and chest radiography) are more useful than actual cadmium concentrations.

In the patient chronically exposed to cadmium, both cadmium concentrations and ancillary testing are recommended. Urinary cadmium concentrations, which reflect the slow, steady-state turnover and release of metallothionein-bound cadmium from the liver, are a better reflection of the total body cadmium burden than are whole blood concentrations. In a 22-year follow-up study, mortality was higher in those with elevated urine cadmium concentrations, although it was impossible to determine if the cadmium was causative or served as a marker for another process.<sup>79</sup>

Cadmium is a significant workplace toxin. In the United States, the Permissible Exposure Limit (PEL), expressed as the concentration of cadmium in air as an 8-hour time-weighted average exposure (TWA), is 5 mcg/m<sup>3</sup>. Workers must also be provided with lunchroom facilities in which the concentration of cadmium in air must be below 2.5 mcg/m<sup>3</sup>.

Yearly biologic monitoring plays an important role in the surveillance of workplace cadmium toxicity, and involves testing not only for urinary and blood levels of cadmium but for indices of renal function as well. Abnormalities in monitoring data require 90-day follow-up testing; if subsequent testing meets action levels, the worker must be medically removed from exposure to cadmium. Workers with higher cadmium indices on initial evaluation have lower thresholds for removal based on 90-day follow-up testing. Testing and removal thresholds for workplace cadmium testing are noted in Table 88–2.

The values noted for industrial hygiene are reasonable in light of the fact that kidney dysfunction is reported to occur at cadmium concentrations as low as 5 mcg/g urinary creatinine,<sup>22,47</sup> a concentration significantly higher than that of the general US population (95% of whom have concentrations that are less than 3 mcg/g urinary creatinine).<sup>17</sup>

TABLE 88–2 Workplace Cadmium Exposure Risk Assessment Values

Biologic Index	Initial Low Risk Level	Initial High Risk Level	90-Day Medical Removal Level
Urine Cadmium (mcg/g Cr)	3	7	15
Beta <sub>2</sub> -Microglobulin (mcg/g Cr)	300	750	1,500
Whole Blood Cadmium (mcg/L)	5	10	15

## MANAGEMENT

### Acute Exposure

#### Oral Exposure/Cadmium Salts

After the patient's airway, breathing, and circulation are secured, attention should be given to GI decontamination. Although large ingestions of soluble cadmium salts are rare, they are potentially fatal,<sup>13,107</sup> with the lowest reported human lethal dose being 5 g. In light of this, if a significant ingestion occurs but emesis has not occurred, gastric lavage is recommended. In this situation, a small nasogastric tube should suffice, as inorganic cadmium salts are powders, not pills.

Given the relative lack of experience with acute oral cadmium poisoning, all patients with known exposures and/or abnormal findings consistent with cadmium toxicity or exposure should be admitted to the hospital for supportive care, monitoring of renal and hepatic function, and possibly evaluation of the GI tract for injury.

Although it seems logical to use chelation therapy in any patient with an acute life-threatening ingestion of a metal compound, the benefit of chelation in acute cadmium exposure is unproven. Multiple chelators have been studied, all in animal models, with inconsistent results.

The ideal chelator for treatment of oral cadmium toxicity would be well tolerated, and would decrease GI absorption of cadmium and decrease the concentration of cadmium in organs such as the kidney and liver, while not increasing cadmium concentrations in other critical organs such as the brain. Of the chelators studied for cadmium toxicity, succimer comes closest to fulfilling these criteria. In models of acute oral cadmium toxicity, succimer decreases the GI absorption of cadmium,<sup>3,6</sup> without increasing cadmium burdens in target organs, and improves survival.<sup>2,6,53</sup>

In a patient thought to have acutely ingested potentially lethal amounts of cadmium, treatment with succimer is reasonable but unproven. Succimer should be given as soon as possible after the ingestion, as the effectiveness of chelators decreases dramatically over time in experimental models of cadmium poisoning.<sup>16</sup>

It must be stressed, however, that supporting data for chelation are solely derived from animal models. Succimer dosing in human cadmium poisoning is unstudied. Doses that are well tolerated (10 mg/kg/dose 3 times a day) are reasonable.

Other chelators with potential benefits include diethylenetriaminepentaacetic acid (DTPA)<sup>6,15</sup> and 2,3-dimercaptopropane sulfonate (DMPS),<sup>13,53</sup> both of which reduce tissue burdens and increase survival but for which further investigation is needed.

Most other chelators are either ineffective or detrimental, including dimercaprol (British anti-Lewisite {BAL}),<sup>15,21,52</sup> penicillamine,<sup>15,65</sup> cyclic tetramines (such as cyclam and tACPD),<sup>93</sup> detergent formula chelators (such as sodium tripolyphosphate {STPP} and nitrilotriacetic acid {NTA}),<sup>31,32</sup> CaNa<sub>2</sub>EDTA,<sup>68</sup> and dithiocarbamates.<sup>3,35</sup>

#### Pulmonary/Cadmium Fumes

The patient who is ill after exposure to cadmium fumes (generally cadmium oxide) presents with predominantly respiratory complaints and constitutional symptoms. The patient's airway should be assessed and appropriate oxygenation ensured, although hypoxia is commonly delayed.

Corticosteroids are used in most reported cases (although there are no studies to support their efficacy), and a standard dose of methylprednisolone (1 mg/kg up to 60 mg) is reasonable. Because cadmium inhalation injuries are neither benign nor self-limited, all patients with acute inhalational exposures to cadmium should be admitted to the hospital for observation and supportive care until respiratory symptoms have resolved. All such patients should have long-term follow-up arranged with a pulmonologist to assess the possibility of chronic lung injury, even following a single exposure.

Chelation is not recommended as an option for patients with single acute exposures to cadmium fumes, as these patients do not appear to develop extrapulmonary injury.<sup>4,5,98,110</sup>

### Chronic Exposure

Patients chronically exposed to cadmium frequently come to attention during routine screening, as those who work with cadmium are under close medical surveillance (Chap. 131). These patients may have developed proteinuria or, less commonly, chronic pulmonary complaints.

Management is challenging. Cessation of cadmium exposure is the first intervention. However, as mentioned earlier, chronic cadmium-induced kidney and lung changes are largely irreversible.

We recommend again chelation for chronic cadmium toxicity. There is no evidence that chelation of chronically poisoned animals improves long-term outcomes, and one study in humans found no improvement in cadmium-induced kidney dysfunction with periodic  $\text{CaNa}_2\text{EDTA}$  chelation.<sup>109</sup> Furthermore, in a chronically exposed patient, the majority of cadmium is bound to intracellular metallothionein, which greatly reduces its toxicity. Any attempt to remove cadmium from these deposits risks redistributing cadmium to other organs, possibly exacerbating toxicity, as is known to occur with BAL therapy.<sup>25</sup>

Of all the chelators tested thus far in animal models of chronic cadmium toxicity, the dithiocarbamates have shown the most success in reducing total body cadmium burdens. Unfortunately, these chelators tend to cause redistribution of cadmium to the brain; the lipophilicity that allows them to cross cell membranes into hepatocytes (to access stored cadmium) also promotes their uptake into the lipid-rich central nervous system (CNS).<sup>37</sup> Numerous dithiocarbamates have been synthesized and studied with regard to cadmium decorporation, however, and several species effectively reduce whole-body, kidney, and liver cadmium concentrations without an increase in CNS cadmium.<sup>59,90</sup> Thus, at present, there is insufficient evidence to justify the use of any chelator in the treatment of patients with chronic cadmium toxicity.

### SUMMARY

- Cadmium toxicity is largely dependent on the route of and chronicity of exposure.
- After acute oral exposure, GI injury predominates.
- After acute inhalation, a severe chemical pneumonitis can ensue.
- With chronic environmental or occupational exposure, nephrotoxicity (usually manifested by proteinuria) is the most significant finding, although other organ systems, such as the lungs, can be affected.
- Treatment for all patients with suspected cadmium poisoning consists of removal from the source, decontamination if possible, and supportive care.
- In the rare instance of a potentially life-threatening acute cadmium salt ingestion, treatment with succimer is reasonable.
- At this time, we recommend against chelation in the patient with chronic cadmium poisoning.

## CESIUM

Zhanna Livshits

### Cesium (Cs)

Atomic number	=	55
Atomic weight	=	132.91 Da
Normal concentrations		
Whole blood	=	<10 mcg/L (75.42 nmol/L)
Urine	=	<20 mcg/L (150.48 nmol/L)

### HISTORY AND EPIDEMIOLOGY

The name “cesium” derives from the Latin word for “sky,” *caelum*. Cesium (Cs) is among the most rare and reactive alkali metals. Elemental cesium (Cs<sup>0</sup>) is silvery white, soft, and malleable. It has a relatively low melting point of 82.4°F (28°C) and thus exists as both solid and liquid at room temperature. Elemental cesium (Cs<sup>0</sup>) ignites violently when exposed to moist air or water but forms stable salt complexes. The greatest concentration of naturally occurring cesium (32%), the compound cesium oxide (Cs<sub>2</sub>O), is found in the ore pollucite.<sup>1,81,83</sup> Since Cs<sup>0</sup> is so highly reactive and short-lived, the name “cesium” will refer to cesium salts in the following discussion, unless specifically noted otherwise.

Radionuclides of cesium were identified in the 1940s by the American scientist and Nobel Prize winner Glenn Seaborg and his student Margaret Melhase.<sup>63</sup> Radioactive cesium isotopes are products of nuclear fission of uranium and plutonium.<sup>85</sup> Both <sup>134</sup>Cs and <sup>137</sup>Cs decay via β particle emission; however, <sup>137</sup>Cs also emits γ rays.<sup>81</sup> Because <sup>137</sup>Cs has a long half-life of 30 years, it serves not only as an “atomic clock” but also poses potential radiological hazard as it deposits and complexes in earth and water. Of the numerous cesium radioisotopes that are identified to date, only <sup>133</sup>Cs is stable.<sup>9</sup>

Several releases of radioactive cesium have occurred in the past century, resulting in large-scale contamination and human exposure. Examples include the nuclear weapons use in Hiroshima and Nagasaki; nuclear weapons testing in Bikini Atoll<sup>11</sup> and Republic of Georgia;<sup>26</sup> poor nuclear waste management in Goiânia,<sup>36,60,68</sup> Tammiku,<sup>37</sup> and Camp Lilo in the Republic of Georgia;<sup>26</sup> as well as critical nuclear power plant malfunctions in Chernobyl<sup>71</sup> and Fukushima Daiichi.<sup>42</sup>

Occupational exposure to radiocesium occurs routinely in nuclear power plant employees and people who live and work in close proximity to a nuclear facility. Both <sup>137</sup>Cs and <sup>133</sup>Cs are used as sources of external and internal radiation for treatment of numerous malignancies. Internal radiotherapy with <sup>131</sup>Cs seed implantation, called brachytherapy, is approved by the US Food and Drug Administration (FDA).<sup>23</sup> Physicians and staff working with these isotopes are at risk of occupational exposure.<sup>24,61</sup>

Cesium compounds are employed in scintillation counters, photoelectric cells, vacuum tubes, optical instruments, semiconductors and extensively in alternative medicine.<sup>1</sup> They serve as catalysts for organic synthesis and are utilized for laboratory experiments in animal models of ventricular dysrhythmias. Nonradioactive cesium chloride is promoted as a supplement or an alternative treatment for cancer, despite no scientific support for this claim. Its increasing popularity in cancer treatment stems from a theory that cesium chloride increases the intracellular pH of tumor cells, resulting in cell death.<sup>7,73</sup> This theory was first proposed in a paper describing the effects of cesium, rubidium, and potassium in cancer cells and its effects in mice.<sup>7</sup> Although the extent of its popularity is unknown, cesium chloride is promoted as a treatment for cancers on various websites and can be easily found for sale on the Internet. There is no scientific evidence that cesium chloride is effective for cancer treatment in humans, and it has the potential for grave toxicity. Cesium chloride is also suggested for treatment of depression on some internet websites, however dosing

and mechanism of action are unclear. Cesium chloride was also proposed, but not implemented, as a preventive therapy for potential radiocesium exposure.<sup>6</sup>

### PHARMACOLOGY

Like thallium (Chap. 99), cesium has a molecular structure that resembles potassium, and similarly, it either mimics or antagonizes potassium in cellular processes.<sup>44</sup> Because cesium blocks the delayed rectifier (I<sub>Kr</sub>) channel in the cardiac myocyte and prolongs repolarization (Chap. 15), it is used in animal models to induce QT interval prolongation and subsequent ventricular ectopy and ventricular dysrhythmias.<sup>57,74</sup>

Although radiocesium is indistinguishable from nonradioactive cesium in biological and chemical reactions, radiocesium damages tissues via emission of β particles and γ rays during its decay (Chap. 128). <sup>134</sup>Cesium decays to a stable isotope by emission of β particles. <sup>137</sup>Cesium initially emits β particles to form the unstable intermediate barium isotope <sup>137m</sup>Ba, which then further emits γ rays to form stable <sup>137</sup>Ba. Radiocesium is such a potent emitter that lethal doses of radiation are delivered following exposures that are too small to cause cardiac effects.

Oral and intravenous cesium chloride preparations are used as an alternative cancer therapy. There is a significant risk for cardiac toxicity and no proven therapeutic benefit. Dysrhythmias and death are reported following intravenous, oral, and subcutaneous administration.

### PHARMACOKINETICS AND TOXICOKINETICS

Pharmacokinetic data following radiocesium injection and ingestion are limited and derived from radiotracer studies in animals and a few reports in human volunteers.

Exposure to cesium occurs through ingestion, inhalation,<sup>55</sup> injection, and dermal contact. Animal studies with a guinea pig model demonstrate rapid absorption via inhalation, intraperitoneal injection, and ingestion.<sup>77</sup> Human volunteer studies demonstrate 98% to 99% absorption of ingested cesium salts.<sup>69,70</sup> Absorption through intact skin is minimal. One case estimated 20% dermal absorption of radiocesium through burned skin.<sup>85</sup>

Once absorbed, cesium is rapidly distributed to the blood compartment, followed by subsequent distribution to various organs. Animal studies with rat, dog, and guinea pig models demonstrate that cesium is initially distributed to the myocardial, renal, pulmonary, and hepatic tissue followed by subsequent accumulation in the skeletal muscle.<sup>43,51,77,80</sup>

Data from human volunteers suggest that once ingested, cesium is absorbed from the small intestine,<sup>32,44</sup> distributes to the blood compartment and various organs. Initial accumulation occurs in the salivary glands following ingestion, and in the liver both following ingestion and injection of radiocesium; subsequent distribution to the myocardium, spleen, adrenals, gastrointestinal (GI) tract, bone, and lungs, with elevated concentration in the skeletal muscle approximately 10 days postexposure.<sup>35,69</sup>

Cesium undergoes enterohepatic circulation limiting fecal elimination. As such, urinary excretion accounts for 80% to 90% and fecal excretion for 2% to 10% of elimination of an ingested dose.<sup>47,49,65</sup> Some elimination occurs in the feces independent of whether cesium is injected or ingested, likely due to hepatic elimination.<sup>69</sup> Only a small amount of cesium is eliminated through sweat or respiratory secretions.<sup>22,49,86</sup>

The biological elimination half-life ranges from 50 to 150 days,<sup>9,31,34,35,49,52,67,70,82</sup> with a few cases up to 200 days<sup>35</sup> following ingestion. The biological half-life increases with age<sup>48</sup> and male sex<sup>4</sup> and decreases with pregnancy.<sup>94</sup> The half-life in children and infants is significantly shorter than that of adults.<sup>52</sup>

<sup>137</sup>Cesium elimination follows first-order kinetics.<sup>45,47</sup> Pharmacokinetic analysis in a woman who developed cardiac toxicity from nonradioactive cesium suggested first-order elimination using a 2-compartment model.<sup>91</sup>

Radiocesium transfers to placenta and maternal breast milk.<sup>3,25,30,53,89</sup> Modeling based on estimates and human studies demonstrates approximately 0.5%, 10%, and 24% transfer of <sup>137</sup>Cs through maternal milk during the stages of early pregnancy, late pregnancy, and lactation respectively.<sup>30</sup>

## PATHOPHYSIOLOGY

<sup>137</sup>Cesium undergoes radioactive decay. Beta particles have very limited dermal penetration and effects from external exposure are limited to dermal irritation and burns (Chap. 128). Release of  $\beta$  particles within the body, as typically occurs after inhalation, ingestion, or dermal absorption, harms internal organs. Gamma rays penetrate the skin with external exposure and cause organ toxicity.

As noted above, cardiotoxicity is the principal and most life-threatening clinical effect of nonradioactive cesium. QT interval prolongation occurs rapidly and predisposes individuals to torsade de pointes (TdP) and other ventricular dysrhythmias. In animal models, especially in canines, cesium is one of the more reliable methods to induce and study nonischemic ventricular dysrhythmias. Prolongation of the QT interval in the cardiac myocyte results from antagonism at the delayed rectifier  $I_{Kr}$  channel.<sup>93</sup> This delays the repolarization phase of the cardiac action potential, thus prolonging the action potential duration.<sup>29</sup> Additionally, it promotes early after-depolarizations (EADs), which are cellular depolarizations that occur during phases 2 and 3 of the cardiac action potential prior to completion of repolarization.<sup>19,29,46</sup> This generation of EADs leads to TdP,<sup>13,19,20,27,78</sup> as cesium chloride-induced EADs precede the development of dysrhythmias in a canine model.<sup>46,62</sup>

Cesium-induced ventricular dysrhythmias are potentiated by bradycardia.<sup>5,38,62</sup> This is explained by either potentiation of EAD formation<sup>38</sup> or increase in temporal variability of the refractory period throughout the cardiac muscle.<sup>28</sup> Overdrive pacing abolishes both EADs and ventricular dysrhythmias in an isolated canine cardiac tissue.<sup>17,46,62</sup> In addition to bradycardia, EADs are induced by hypokalemia<sup>21</sup> and metabolic acidosis<sup>12</sup> (Chaps. 15 and 16). These EADs are modulated by L-type calcium channel currents,<sup>2,38</sup> and calcium channel blockers, such as verapamil, suppress cesium-induced ventricular dysrhythmias in dogs.<sup>46,57</sup>

Sodium channel modulation also may be contributory in cesium-induced ventricular dysrhythmias. Low concentrations of tetrodotoxin, a sodium channel antagonist, terminate EADs induced by cesium chloride.<sup>5,40</sup> Lidocaine abolishes cesium-induced ventricular dysrhythmias in a canine model.<sup>57</sup>

## CLINICAL MANIFESTATIONS

Radiation injuries are discussed in detail in Chap. 128. The following discussion focuses on nonradioactive cesium toxicity observed with oral and intravenous CsCl preparation used by patients as an alternative form of cancer therapy. The case reports for cesium chloride use and toxicity are limited to cancer therapy.

### Cardiovascular Toxicity

Prolongation of the QT interval and subsequent ventricular dysrhythmias are the principal cardiac effects, described with cumulative oral ingested doses ranging from 3 g/day<sup>33,48,72,90</sup> to 10 g/day.<sup>15,92</sup> Time from daily oral cesium exposure to development of dysrhythmias ranged from 1 week to 3 months. Rapid onset of dysrhythmias is reported following injection of a 9 mL of oral preparation of cesium chloride into a breast mass.<sup>75</sup> The patient died within 1 week after failing to have a neurologic recovery.<sup>75</sup> Most patients with ventricular ectopy, TdP, or ventricular dysrhythmias developed syncope or “seizures.” A prolonged QT interval was present and either resistant to potassium repletion or was challenging to correct. Serum and urine cesium concentrations were markedly elevated in all case reports ranging from 2,400 mcg/dL<sup>59</sup> to 28,000 mcg/dL,<sup>33</sup> and 130,000 mcg/L<sup>33</sup> to 360,000 mcg/L<sup>59</sup> respectively.

Whole blood cesium concentration were reported in 2 cases; 100,000 mcg/L<sup>75</sup> and 160,000 mcg/L.<sup>15</sup> The QT interval normalized and dysrhythmias ceased after termination of cesium chloride exposure.<sup>10,14,15,48,59,64,72,90,91</sup>

Intravenous injection of cesium chloride in 2 patients with metastatic kidney and lung cancer resulted in death. Forensic records indicate that the first patient had chills and seizures during the first session and went into cardiac arrest during the second session. The second patient collapsed during the infusion.<sup>9</sup> Postmortem whole blood concentration of cesium was 84,000 mcg/L for first patient and 28,100 mcg/L for second patient. Another case report described an 8-year-old boy who developed bradycardia, premature ventricular depolarizations, and TdP that terminated without intervention.<sup>14</sup> Cesium concentrations were not obtained.

### Gastrointestinal Effects

Patients receiving alternative oral therapies of 3 to 10 g of cesium chloride per day for diverse neoplasms developed nausea, vomiting, diarrhea, and abdominal cramping.<sup>10,15,48,59,72,92</sup>

### Electrolyte Abnormalities

Some patients taking cesium chloride alternative cancer therapy develop hypokalemia and hypomagnesemia. Serum potassium concentrations ranged from 2.7 mEq/L<sup>75</sup> to 3.4 mEq/L/L<sup>92</sup> and serum magnesium concentrations were reported as low as 1.4 mEq/L/dL.<sup>90</sup> Both corrected with electrolyte repletion. Electrolyte imbalance likely reflects GI loss through vomiting and/or diarrhea.<sup>10,15,48,64,72,90</sup>

### Neurologic Effects

A heightened sense of perception as well as facial and acral tingling are described following self-administration of 6 g of cesium chloride daily for 36 consecutive days.<sup>58</sup> Reports of syncope<sup>10,48,59,64,90,91</sup> and “seizures”<sup>9,15</sup> should be interpreted with caution because a nonperfusing cardiac rhythm is the most likely etiology for both clinical presentations.

## DIAGNOSTIC TESTING

Radioactive cesium is detected by whole-body counters using  $\gamma$ -ray spectrometry and  $\beta$  counting.<sup>81</sup> Shielding of the room where testing is performed is sometimes necessary to reduce background radiation. Urine and feces are analyzed for <sup>137</sup>Cs and/or <sup>134</sup>Cs in a similar manner.

Analysis of nonradioactive cesium in blood, urine, feces, or tissue samples is performed by spectrometric methods such as flame atomic emission spectrometry, inductively coupled plasma-mass spectrometry (ICP-MS), or instrumental neutron activation analysis.<sup>1</sup>

Computed tomography (CT) imaging of the brain was obtained in a patient with metastatic breast cancer to the brain who presented to the hospital following a seizure following the receipt of intravenous cesium chloride as an alternative chemotherapeutic.<sup>41</sup> The CT findings showed diffusely increased attenuation of brain parenchyma. She died within 48 hours of hospitalization. Patient also had elevated post-mortem brain cesium concentration of 780 mg/kg.

## MANAGEMENT

### Radiocesium and Cesium

Patient management following radiation exposure is outlined in detail in Chap. 128 and Antidotes in Depth: A31. Although most data are obtained following cesium exposures in animals and humans, the treatment of patients with radiocesium-induced toxicity is similar. Recognition of radiocesium exposure and decontamination is critical in all cases of exposure and toxicity due to the potential radiation injuries.

Gastrointestinal decontamination is likely of limited value and is not recommended following cesium ingestion. Cesium is not well adsorbed to activated charcoal,<sup>88</sup> and patients who present with significant cesium toxicity often have vomiting or altered mental status. Administration of antiemetics and repletion of volume loss with intravenous fluids is central to supportive management of patients who present with nausea and vomiting. Caution is warranted with use of 5HT<sub>3</sub> antagonists such as ondansetron given their

potential for QT interval prolongation. Serum potassium and magnesium concentrations should be carefully monitored and supplemented as needed.

All patients with suspected cesium salt ingestion should have an electrocardiogram (ECG) and be attached to a continuous cardiac monitor. Their QT intervals should be monitored closely and documented often with serial ECGs. Intravenous magnesium and overdrive pacing should be used to prevent recurrent episodes torsade de pointes. It is recommended to use synchronous cardioversion in unstable rhythms. Lidocaine is also a reasonable choice. Amiodarone is not routinely recommended given its propensity to prolong the QT interval. Even though amiloride decreased the need for supplemental potassium supplementation in a case report,<sup>33</sup> it is not recommended at this time given paucity of data and potential for adverse effects.

Because isolated seizures are not reported, syncope and "seizurelike activity" should heighten concern for hypoperfusion or potential cardiac dysrhythmias.

The following therapies have been attempted after radiocesium exposure and have not been effective: activated charcoal, diuretics, enhanced sweating, and disodium ethylenediaminetetraacetate (EDTA).<sup>22,87</sup> The paucity of literature makes it impossible to conclusively recommend or reject hemodialysis as a modality for enhanced cesium elimination.<sup>39,87</sup>

### Prussian Blue

Prussian blue, ferric hexacyanoferrate(II), is a blue crystal lattice composed of iron and cyanide molecules. In 2003, the insoluble form of Prussian blue was approved by the FDA for oral treatment of radioactive cesium and/or radioactive or nonradioactive thallium (Antidotes in Depth: A31).<sup>66</sup> The insoluble crystal lattice adsorbs cesium<sup>18</sup> in the intestinal lumen, and enhances both elimination and gut dialysis.<sup>56</sup> A systematic analysis of published literature on the use of Prussian blue in the treatment of radiocesium poisoning suggests that it reduces the half-life of radiocesium by as much as 43%.<sup>79</sup>

Although the majority of Prussian blue literature focuses on radiocesium elimination,<sup>47,50,54,76,79</sup> it was also used for a patient with cesium chloride toxicity. Prussian blue was started on hospital day 7 in a patient with cardiac toxicity following cesium ingestion. She received 3 g 3 times per day for 4 weeks. Cesium half-life was decreased by 47.7% (from 61.7 days to 29.4 days).<sup>10</sup>

Because laboratory confirmation of cesium will be substantially delayed, Prussian blue is recommended on suspicion of cesium toxicity. Although the optimal dose and interval are unknown, the package insert for Prussian blue, which recommends 3 g orally 3 times per day, for a total daily dose of 9 g in adults and adolescents is reasonable. A dose of 1 g orally 3 times per day is recommended in children for a total daily dose of 3 g. Cesium concentration and clinical effects should guide the duration of therapy.

### SUMMARY

- Radioactive cesium is a strong  $\beta$ -particles and  $\gamma$ -ray emitter that is released following normal operation of power plants and/or nuclear incidents.
- Because of the availability of commercial and therapeutic sources of radioactive cesium, human exposure is also likely either through unintentional exposure to discarded equipment or through acts of terrorism.
- Exposure to nonradioactive cesium salts occurs through intentional use as an alternative therapy for cancer.
- The principal toxicity of nonradioactive cesium is ventricular dysrhythmias and TdP that result from blockade of cardiac potassium channels.
- In addition to supportive care, Prussian blue is used for both radioactive and nonradioactive cesium toxicity.

# CHROMIUM

Steven B. Bird

## Chromium (Cr)

Atomic number	= 24
Atomic weight	= 51.99 Da
Normal concentrations	
Whole blood	= 20–30 mcg/L (385–577 nmol/L)
Serum	= 0.05–2.86 mcg/L (1–54 nmol/L)
Urine	= <1 mcg/g creatinine (<0.22 nmol/mmol creatinine)

## INTRODUCTION

Chromium toxicity results from occupational exposure, environmental exposure, or a combination of both routes. Like many metals, the clinical manifestations of chromium toxicity depend upon whether the exposure is acute or chronic and on the chemical form of chromium. Acute toxicity is more likely to involve multiple-organ failure, whereas chronic exposure is more likely to lead to cancer.

## HISTORY AND EPIDEMIOLOGY

Chromium (from the Greek word for color, *chroma*) is a naturally occurring element that is found in oxidation states of  $-2$  to  $+6$ , but it primarily exists in the trivalent ( $\text{Cr}^{3+}$ ) and hexavalent ( $\text{Cr}^{6+}$ ) forms. It was first discovered in 1797 in the form of Siberian red lead (crocoite:  $\text{PbCrO}_4$ ), and occurs only in combination with other elements, primarily as halides, oxides, or sulfides (Table 90–1). Elemental chromium ( $\text{Cr}^0$ ) does not occur naturally but is extracted commercially from ore. Chromium is found most abundantly in chromite ore ( $\text{FeCr}_2\text{O}_4$ ).<sup>7</sup>

Elemental chromium is a blue-white metal that is hard and brittle. It is typically polished to a fine, shiny surface, affords significant protection against corrosion, and added to steel to form stainless steel (an alloy of chromium, nickel, and iron). One of the most important uses of chrome plating is to apply a hard, smooth, surface to machine parts such as crankshafts, printing rollers, ball bearings, and cutting tools. This is known as “hard” chrome plating. Elemental chromium is also used in armor plating safes, and is used

in forming brick molds because of its high melting point and moderate thermal expansion.

The carcinogenic potential of hexavalent chromium was first recognized as a cause of nasal tumors in Scottish chrome pigment workers in the late 1800s. In the 1930s, the pulmonary carcinogenicity of hexavalent chromium was first described in German chromate workers.<sup>10</sup>

## PHARMACOLOGY

Chromium is an essential element involved in glucose metabolism. The mechanism appears to be either facilitation of insulin binding to insulin receptors or by amplification of the effects of insulin on carbohydrate and lipid metabolism.<sup>19</sup>

The chemical properties and health risks of chromium depend mostly on its oxidative state, and on the solubility of the chromium compound. Chromium is found naturally in the hexavalent ( $\text{Cr}^{6+}$ ) or in the trivalent ( $\text{Cr}^{3+}$ ) valence states, the species most relevant to human exposures. However, chromium has very different properties in the  $\text{Cr}^{6+}$  and  $\text{Cr}^{3+}$  oxidation states. The relationship between these oxidative states is described by the following equation<sup>12</sup>:

This difference of 1.33 eV in electric potential between the  $\text{Cr}^{6+}$  (in  $\text{Cr}_2\text{O}_7^{2-}$ ) and  $\text{Cr}^{3+}$  states reflects both the significant oxidizing potential of  $\text{Cr}^{6+}$  and the high energy required for the oxidation of  $\text{Cr}^{3+}$  to  $\text{Cr}^{6+}$ . Reduction of  $\text{Cr}^{6+}$  to  $\text{Cr}^{3+}$  occurs in vivo by abstraction of electrons from cellular constituents such as proteins, lipids, DNA, RNA, and plasma transferrin and accounts for the toxicity of  $\text{Cr}^{6+}$ .<sup>37</sup>

The rapidity and completeness of the reduction of  $\text{Cr}^{6+}$  is the subject of considerable scientific debate. Hexavalent chromium is reduced to  $\text{Cr}^{3+}$  in saliva, the gastrointestinal tract, respiratory tract epithelium and pulmonary macrophages, and in blood.<sup>2,32</sup> During this reduction, several other oxidative states transiently occur (namely  $\text{Cr}^{4+}$  and  $\text{Cr}^{5+}$ ) and contribute to the cytotoxicity, genotoxicity, and carcinogenicity of  $\text{Cr}^{6+}$  chromium compounds.<sup>46</sup>

Although most  $\text{Cr}^{6+}$  is rapidly reduced on entering the gastrointestinal tract, ingestion of  $\text{Cr}^{6+}$  in drinking water leads to measurable chromium concentrations in plasma, red blood cells, and urine. Hexavalent chromium accumulates in most body tissues, raising concerns that chromium-induced toxicity and carcinogenesis are more widespread than was previously appreciated.<sup>10</sup>

## Environmental Exposure

The processing of chromium ores primarily releases  $\text{Cr}^{3+}$  into the environment. However, some hexavalent chromium is released from chromate manufacturing and coal-based power plants. The most significant environmental sources of  $\text{Cr}^{6+}$  are chromate production, ferrochrome pigment manufacturing, chrome plating, and certain types of welding.

The general population is exposed to chromium via drinking water, food and food supplements (eg, chromium picolinate), joint arthroplasty, coronary artery stents, and cigarettes. Chromium is used extensively to prevent equipment and piping corrosion in industrial cooling towers and air conditioning (trivalent chromium). Dermal exposure occurs from use of tanned leather products or wood treated with CCA (copper, chromate, and arsenate), which contains hexavalent chromium that is reduced to trivalent chromium by organic compounds once incorporated in wood. Lumber treated with CCA was voluntarily removed from the US consumer market in 2003, because of possible health concerns resulting from exposure to the arsenic and chromium. No specific adverse health effects related to

TABLE 90–1 Common Forms of Chromium

Name	Chemical Formula	Oxidation State	Uses
Barium chromate	$\text{BaCrO}_4$	$6^+$	Safety matches, anticorrosive, paint pigment
Calcium chromate	$\text{CaCrO}_4$	$6^+$	Batteries, metallurgy
Chromic acid	$\text{H}_2\text{CrO}_4$	$6^+$	Electroplating, oxidizer
Chromic chloride	$\text{CrCl}_3$	$3^+$	Supplement in total parenteral nutrition
Chromic fluoride	$\text{CrF}_3$	$3^+$	Mordant in dye industry, mothproofing for wool
Chromic oxide	$\text{Cr}_2\text{O}_3$	$3^+$	Metal plating, wood treatment
Chromite ore	$\text{FeCr}_2\text{O}_4$	$3^+$	Water tower treatment
Chromium picolinate	$\text{C}_{18}\text{H}_{12}\text{CrN}_3\text{O}_6$	$3^+$	Nutritional supplement
Lead chromate	$\text{PbCrO}_4$	$6^+$	Yellow pigment for paints and dye
Potassium dichromate	$\text{K}_2\text{Cr}_2\text{O}_7$	$6^+$	Oxidizer of organic compounds, leather tanning, porcelain painting

CCA-treated lumber were reported by the Environmental Protection Agency before the voluntary withdrawal. A reanalysis of cancer mortality and hexavalent chromium-contaminated drinking water from Liaoning Province, China, demonstrated an increase in stomach cancer rate in communities with chromium-contaminated drinking water.<sup>5</sup> Significant exposure from more than 160 chromate production waste sites within Hudson County, New Jersey, was discovered in the late 1980s.<sup>17</sup> A final report published by the Agency for Toxic Substances and Disease Registry in 2008 found an increased risk of lung cancer in populations living in proximity to historic chromium ore-processing residue sites, although the increases were not statistically significant.<sup>33</sup>

### Occupational Exposure

Workers in industries that use chromium are exposed to 100 times greater concentrations of chromium than the general population. Chromium pigmentation production and leather tanning use significantly more Cr<sup>6+</sup> compounds, whereas metal finishing, wood preservation, and cooling towers use Cr<sup>3+</sup> compounds (Table 90–2).

Several studies focus on the risk of chromium exposure in welders.<sup>41,42</sup> Stainless steel welding liberates significantly more hexavalent chromium than do other types of welding. Although the lung cancer rate of stainless steel (containing chromium) welders was not found to be different from that in regular steel welders, in 2006 the Occupational Safety and Health Administration (OSHA) lowered the permissive exposure limit of hexavalent chromium by 10-fold for welders. More recently, a meta-analysis of occupational exposures demonstrated a statistically significant increase in both lung and stomach cancer in workers with exposure to hexavalent chromium.<sup>50</sup>

### Medical Device Exposure

Recent concerns and media attention are directed to the use of metal on metal (MoM) implants for total hip arthroplasty and surface refinishing. Unlike non-MoM implants in which the articular surfaces are made of ceramic or polyethylene, these metal implants have metal rubbing on metal. For more than 20 years, it has been known that blood concentrations of metal ions increase in patients with MoM hip arthroplasty. One-year postoperative blood chromium concentrations increased by 21 times over the preoperative concentrations.<sup>21</sup> Metal release will cause some tiny metal particles to wear off of the device around the implant, which causes damage to bone and/or soft tissue surrounding the implant and joint. Although some patients with failed MoM hip implants report memory difficulties, chronic pain, and pain in the implanted hip, the true incidence and nature of adverse health outcomes due to release of chromium ions and particles from these implants is not yet established. Currently, there is insufficient evidence to conclusively demonstrate that with regard to chromium, MoM hip implants produce side effects beyond those that may occur at the site of implantation. There is no consensus on what might be the significance of elevated blood chromium concentrations,

**TABLE 90–2** Occupations at Risk for Chromium Exposure

nor are there data to specify the concentration of chromium necessary to produce adverse systemic effects. Further discussion of orthoprosthesis cobaltism is found in the chapter on cobalt effects in MoM Hip implants. (Chap. 91).<sup>16</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

Because they possess significantly different properties, Cr<sup>3+</sup> and Cr<sup>6+</sup> must be evaluated separately.

### Absorption

#### Trivalent Chromium Compounds

Oral absorption of Cr<sup>3+</sup> salts is limited. Approximately 98% is recovered in the feces, just 0.1% is excreted in the bile, and 0.5% to 2.0% is excreted in the urine.<sup>14,16</sup> Human case reports and animal studies also corroborate the generally poor absorption of Cr<sup>3+</sup> salts by the oral, inhalational, and dermal routes, except through burns and other disrupted mucosal or epithelial surfaces.<sup>27</sup>

#### Hexavalent Chromium Compounds

Cr<sup>6+</sup> is modestly absorbed after ingestion partly as a result of the structural similarity between hexavalent chromium compounds and phosphate and sulfate.<sup>11</sup> These 3 chemicals undergo facilitated diffusion through non-specific anion channels as well as active transport. In human volunteers, approximately 10% of an ingested dose of sodium chromate was absorbed; duodenal administration increased this to roughly 50%.<sup>14</sup> This difference likely relates to the reduction of the hexavalent chromium to trivalent chromium in the acidic environment of the stomach. Similarly, 3 hours after the ingestion of a lethal amount of potassium dichromate (hexavalent), greater than 80% of the chromium was reduced to the trivalent state in the blood.<sup>20</sup> Hexavalent chromium compounds are generally not well absorbed after dermal exposure. Whatever the route of exposure, Cr<sup>6+</sup> is absorbed much more readily than Cr<sup>3+</sup>, but the Cr<sup>6+</sup> is then rapidly reduced to Cr<sup>3+</sup> after absorption.

Epidemiologically, inhalation of Cr<sup>6+</sup> is the most consequential route of exposure. Furthermore, the greatest health consequences from Cr<sup>6+</sup> exposure are due to inhalation. The exact rate of absorption is unknown, but is dependent on the solubility of the specific Cr<sup>6+</sup> compound, the size of the particles, the phagocytic activity of the pulmonary macrophages, and the general health of the lungs. In animal studies roughly 50% to 85% of small (<5 μm) inhaled Cr<sup>6+</sup> potassium dichromate particles are absorbed.<sup>34</sup>

### Distribution

Because most of the Cr<sup>6+</sup> is rapidly reduced on absorption by the gastrointestinal tract and by red blood cells (RBCs), Cr<sup>3+</sup> accounts for virtually the entire body burden of chromium. Trivalent chromium accumulates to the greatest extent in the kidneys, bone marrow, lungs, lymph nodes, liver, spleen, and testes. The kidneys and liver alone account for approximately 50% of the total body burden.<sup>11</sup>

### Elimination

Urinary excretion of trivalent chromium occurs rapidly. Roughly 80% of parenterally administered Cr<sup>6+</sup> is excreted as Cr<sup>3+</sup> in the urine and 2% to 20% in the feces.<sup>31</sup> The urinary excretion half-life of Cr<sup>6+</sup> ranges from 15 to 41 hours.<sup>22</sup> Because Cr<sup>6+</sup> undergoes reduction to Cr<sup>3+</sup> following uptake by RBCs, an apparent slow compartment is created, with the elimination half-life dependent on the life span of erythrocytes. Small amounts of chromium are detectable in sweat, breast milk, nails, and hair.

## PATHOPHYSIOLOGY

### Trivalent Chromium

Trivalent chromium is an essential trace metal required for the metabolism of glucose and fats. The complex nutritional interactions of trivalent chromium with numerous metabolic pathways are not understood, and remain the subject of much debate among researchers. However, it is clear that dietary chromium deficiency leads to insulin resistance with elevated insulin concentrations, hypercholesterolemia, hyperglycemia, increased body fat, and the attendant risks of these metabolic derangements. Trivalent

chromium enhances insulin sensitivity and glucose disappearance concomitantly with lower insulin concentrations in an obese rat model, with no difference in lean controls.<sup>9</sup>

Chromium picolinate is a popular Cr<sup>3+</sup> dietary supplement. There is a dearth of rigorous science concerning the efficacy or safety of chromium picolinate. However, organ deposition of Cr<sup>3+</sup> occurs.<sup>40</sup> There is no strong evidence of any significant end-organ toxicity due to exposure to Cr<sup>3+</sup>, perhaps because Cr<sup>3+</sup> is so poorly absorbed. There is little or no rigorous evidence that exposure to Cr<sup>3+</sup> compounds increases cancer risk. Animal work and epidemiologic studies of workers exposed to Cr<sup>3+</sup> compounds fail to demonstrate a statistically significant increased incidence of cancer.<sup>3</sup>

### Hexavalent Chromium

Hexavalent chromium is a powerful oxidizing agent that has corrosive and irritant effects. The greatest toxicity from Cr<sup>6+</sup> lies in its ability to produce oxidative DNA damage. Strand breaks with DNA, DNA–DNA and DNA–protein crosslinks, and nucleotide modifications all occur.<sup>12</sup> Although the exact mechanisms of how Cr<sup>6+</sup> is genotoxic are unknown, transient toxic chromium intermediates such as Cr<sup>4+</sup> and Cr<sup>5+</sup> are probably responsible.<sup>39</sup>

Inconsistent data suggest that either immunostimulation or immunosuppression result from chronic chromium exposure. At least one study suggests that chromium induced immunosuppression is responsible for implant associated infections in patients after hip or knee arthroplasty.<sup>39</sup> Although human data are incomplete, adverse developmental effects, including cleft palate, hydrocephalus, and neural tube defects, are demonstrated in animals.<sup>13</sup>

### CLINICAL MANIFESTATIONS

The clinical manifestations of chromium poisoning depend on the valence of chromium, the source and route of exposure, and the duration of exposure. The clinical manifestations of chromium exposure are best divided into acute and chronic (low-level exposure) effects.

#### Acute

Manifestations of acute, massive Cr<sup>6+</sup> ingestions are similar to other caustic metal ingestions. Gastrointestinal hemorrhage, with or without bowel perforation, occurs acutely.<sup>51</sup> Because of the strong oxidative properties of Cr<sup>6+</sup>, intravascular hemolysis with disseminated intravascular coagulation is also observed. Renal effects include acute tubular necrosis leading to acute kidney injury.<sup>49</sup> Metabolic abnormalities after acute, massive, exposure include metabolic acidosis with elevated lactate concentration, hyperkalemia, and uremia. Acute respiratory distress syndrome (ARDS) develops up to 3 days after exposure. Although Cr<sup>6+</sup> is generally not well absorbed after dermal exposure, it is a caustic that causes skin inflammation and ulceration, which ultimately increases dermal absorption. Dermal chromic acid (H<sub>2</sub>CrO<sub>4</sub>) burns lead to severe systemic toxicity with as little as 10% body surface area involvement.

#### Chronic

Because most chronic exposures are inhalational, the respiratory tract is the organ most affected after chronic chromium exposure. When inhaled, Cr<sup>6+</sup> is a respiratory tract irritant that causes inflammation and, with continued exposure, ulceration including nasal septum perforation.<sup>23</sup> Furthermore, the sensitizing effects of Cr<sup>6+</sup> leads to chronic cough, shortness of breath, occupational asthma, bronchospasm, and anaphylactoid reactions. Chronic deposition of chromium dust is also associated with pneumoconiosis.<sup>38</sup>

Epidemiologic studies of chromate workers in the 1980s indicated a significantly increased risk of lung cancer in those individuals exposed to Cr<sup>6+</sup> compounds.<sup>24,35</sup> Small cell and poorly differentiated carcinomas are the most common types, although nearly all pathologic types of lung cancer are associated with inhalational Cr<sup>6+</sup> exposure.<sup>1</sup> The latency between exposure and development of lung cancer ranges from 13 to 30 years, although cases are reported after as few as 2 years.<sup>6</sup>

Although conclusive evidence is lacking, it appears that chronic exposure to Cr<sup>6+</sup> via all routes causes mild to moderate elevation in hepatic aminotransferases and abnormal liver architecture, visible on histologic

specimens.<sup>51</sup> Unlike acute exposures, low-dose chronic chromium exposure occasionally causes transiently elevated urinary β<sub>2</sub>-microglobulin concentrations, with no obvious lasting effects.<sup>49</sup>

Type IV (delayed-type) hypersensitivity reactions occur after acute exposure to hexavalent chromium compounds. Chronic hexavalent chromium exposures also occur via dermal contact. Up to 24% of cement workers who have frequent contact with wet cement (which contains Cr<sup>6+</sup>), automobile part handlers, and locksmiths develop skin sensitivity to chromium compounds.<sup>26,28</sup>

Occupational chromium exposure leads to contact dermatitis in as many as 10% to 20% of chromium workers.<sup>44</sup> There remains considerable debate over the relative sensitization abilities of Cr<sup>3+</sup> and Cr<sup>6+</sup>. Furthermore, what was initially thought to be sensitization to Cr<sup>3+</sup> exposure was more likely exposure to Cr<sup>6+</sup> with subsequent in vivo reduction to Cr<sup>3+</sup>. It is likely, however, the Cr<sup>6+</sup> is a more potent sensitizer than Cr<sup>3+</sup>, and that there is limited cross-reactivity between the 2 forms of chromium.<sup>15</sup> Similarly, exposure to chromium-containing gaming table felt has led to hand dermatitis referred to as “blackjack disease,” and virtually all occupations that involve exposure to inhaled chromium can lead to painless, scarring skin and nasal septum ulcerations, referred to as “chrome holes”.<sup>25</sup>

### DIAGNOSTIC TESTING

Chromium is detected in blood, urine, and hair of exposed individuals. Because of the great difficulty in speciation, differentiation between Cr<sup>3+</sup> and Cr<sup>6+</sup> is generally not performed; instead, the total chromium concentration is usually reported. Needles used for phlebotomy and plastic containers used for sample storage generally contain significant amounts of chromium. Unfortunately, there are no commercially available chromium-free needles. Modern, highly sensitive assay equipment, such as graphite furnace atomic absorption spectrometry, neutron activation analysis, and graphite spark atomic emission spectrometry, require diligence in sample handling to ensure that biological samples are not contaminated.

Because of the inherent difficulties in quantifying trace elements such as chromium, and the lack of standard chromium reference materials, the reported normal serum and urine chromium concentrations in unexposed people have varied by more than 5,000-fold over the last 50 years.<sup>34</sup> Consequently, older reference ranges should be interpreted with caution. Lastly, although cigarette smoke contains chromium, no studies have quantified the effect of smoking on serum, blood, or urinary chromium concentrations.

#### Blood or Serum

Chromium is distributed evenly between the serum and erythrocytes. Serum chromium concentrations are reflective of recent exposure to both Cr<sup>3+</sup> and Cr<sup>6+</sup>. Serum concentrations in people without occupational exposure to chromium are reported to be from 0.05 mcg/L (1 nmol/L)<sup>8</sup> up to more than 2.8 mcg/L (54 nmol/L).<sup>34</sup> It is not certain whether concentrations above these values should be considered potentially toxic, as no clear correlation has been found between serum or blood concentrations and physiologic effects.

#### Urine

Although urine chromium concentrations reflect the acute absorption of chromium over the previous 1 to 2 days, wide individual variation in metabolism and total body burden limit the value of urinary chromium monitoring. Urine should be collected over a 24-hour period because of diurnal variation in excretion. Data from the third National Health and Nutrition Examination Survey (NHANES III) demonstrated mean and median urinary chromium concentrations in approximately 500 individuals without known exposure to chromium of 0.22 mcg/L (4.2 nmol/L) and 0.13 mcg/L (2.5 nmol/L). When corrected for creatinine, the values were 0.21 and 0.12 mcg/g creatinine, respectively.<sup>30</sup>

#### Hair and Nails

Hair and nail samples are not reliable indicators of exposure to chromium because of the difficulty distinguishing between chromium contamination of the hair sample from chromium incorporated into the hair during normal

hair protein synthesis. Chromium found in hair is not due to contamination or exposure to shampoo or tap water.<sup>18</sup> Chromium concentrations in hair are up to 1,000 times higher than those found in serum.

### Ancillary Tests

After confirmed or suspected acute chromium exposure, complete blood count, serum electrolytes, blood urea nitrogen, creatinine, urinalysis, and liver enzymes testing should be performed. If signs of systemic toxicity are evident, serial determination of coagulation function and disseminated intravascular coagulation may be useful to guide therapy.

### MANAGEMENT

Acute chromium ingestions are infrequent, but often severe, with significant morbidity and mortality. Consequently, after adequate airway, breathing, and circulatory support are addressed, attention should be given to decontamination.

### Decontamination

Because of its serious but very limited toxicity, Cr<sup>3+</sup> compounds require limited decontamination measures. Decontamination with soap and water is recommended after skin contact. No specific pulmonary decontamination is required.

Hexavalent chromium is caustic and profuse vomiting and hematemesis usually follow acute ingestions. Nasogastric lavage is reasonable after Cr<sup>6+</sup> ingestions if the patient presents to the emergency department within several hours of exposure and no vomiting has occurred. There are no data regarding the use of activated charcoal in acute chromium ingestions and endoscopic visualization will be more difficult after administration of activated charcoal. Therefore, we recommend using activated charcoal in order to obtain adequate endoscopic visualization.

Oral *N*-acetylcysteine increases the renal excretion of chromium in rats,<sup>4</sup> but there are no human data to support this therapy. Years of clinical experience using *N*-acetylcysteine for other indications and the very low incidence of adverse effects, however, makes the administration of oral *N*-acetylcysteine in the setting of acute chromium toxicity reasonable.

Although ascorbic acid facilitates reduction of Cr<sup>6+</sup> to Cr<sup>3+</sup> in vitro, there are no data to substantiate decreased absorption.<sup>44</sup> There is some evidence that topical ascorbic acid reduces dermal Cr<sup>6+</sup> exposure, but this was not demonstrated in controlled trials.<sup>39</sup> Therefore, the routine use of ascorbic acid cannot be recommended at this time.

### Chelation Therapy

Currently available chelators do not appear efficacious at either lowering serum or blood chromium concentrations or ameliorating chromium toxicity in experimental models. Specifically, calcium ethylenediaminetetraacetic acid (CaEDTA) had no effect on urinary chromium excretion in experimental animals<sup>48</sup> and dimercaprol (British anti-Lewisite {BAL}) was not beneficial in an animal model of chromium poisoning.<sup>29</sup>

In a single study, dimercaptopropane sulfonate (DMPS) had no effect on urinary chromium excretion in humans.<sup>35</sup> D-Penicillamine also failed to increase urinary excretion of chromium.<sup>29</sup> There are no studies of chromium chelation with 2,3-dimercaptosuccinic acid (succimer). Therefore, at this time, there is no evidence to support the use of any chelation therapy after acute Cr<sup>6+</sup> or Cr<sup>3+</sup> poisoning.

### Extracorporeal Elimination

Hemodialysis, hemofiltration, and peritoneal dialysis do not efficiently remove chromium. Studies in animals and human case reports indicate that as little as 1% of chromium is removed by hemodialysis or hemofiltration after acute dichromate (a hexavalent compound) exposure.<sup>20,43</sup> Limited data in dialysis patients demonstrate some ability of peritoneal dialysis and hemodialysis to remove intravenously administered chromium.<sup>36</sup> Therefore, in the setting of normal renal function, extracorporeal means of eliminated chromium are not likely to be of benefit. In the setting of acute

kidney injury or chronic kidney disease, peritoneal dialysis or hemodialysis is a reasonable therapeutic choice to attempt to reduce serum chromium concentrations, although there are no data that clinical outcomes are affected.

### SUMMARY

- Hexavalent chromium remains an uncommon, but serious, cause of acute metal poisoning, whereas trivalent chromium is minimally toxic.
- Acute ingestion of Cr<sup>6+</sup> chromium salts causes gastrointestinal hemorrhage, hepatic necrosis, and acute kidney injury.
- Toxicity after chronic Cr<sup>6+</sup> chromium exposure includes ulcerations of the skin and nasopharynx (“chrome holes”), and more significantly, lung and stomach cancer. Definitive data regarding other types of cancer resulting from chronic Cr<sup>6+</sup> exposure are unavailable.
- Regardless of the time course of the poisoning, treatment for chromium exposure includes removal of the patient from the source of exposure, gastrointestinal decontamination, and supportive care.
- There is insufficient evidence to support the use of chelators in either acute or chronic chromium poisoning.

# COBALT

Gar Ming Chan

## Cobalt (Co)

Atomic number	=	27
Atomic weight	=	58.9 Da
Normal concentrations		
Serum	=	0.1–1.2 mcg/L (1.7–20.4 nmol/L)
Urine	=	0.1–2.2 mcg/L (1.7–37.3 nmol/L)

## HISTORY AND EPIDEMIOLOGY

The name cobalt (Co) originates from, “kobold” (German for “goblin”), and was given to the cobalt-containing ore cobaltite (CoAsS), because it made exposed miners ill. However, the miners’ illness had more likely resulted from the arsenic exposure than that of the cobalt. Georg Brandt discovered cobalt in 1753 during an attempt to prove that an element other than bismuth gave glass a blue hue.

With an atomic number of 27 and a molecular weight of 58.93 Da, cobalt is a light metal that has a melting point of 1,768.2° K and a boiling point of 3,373° K. These attributes make elemental Co (Co<sup>0</sup>) very useful in industry, in which it is primarily incorporated into hard, high-speed, high-temperature cutting tools. When aluminum and nickel are blended with cobalt, an alloy (Alnico) with magnetic properties is formed. Other uses for cobalt include electroplating because of its resistance to oxidation and as an artist’s pigment owing to its bright blue color.

A Co<sup>3+</sup> ion is at the center of cyanocobalamin (vitamin B<sub>12</sub>), which is synthesized only by microorganisms and is not found in plants. Common dietary sources are fish, eggs, chicken, pork, and seafood. A diet deficient in cyanocobalamin results in pernicious anemia. Hydroxocobalamin, a Co<sup>3+</sup>-containing precursor to cyanocobalamin, is used as an antidote for cyanide poisoning (Antidotes in Depth: A41).

Medicinally, cobalt chloride was combined with iron salts and marketed in the 1950s as Roncovite, for the treatment of anemia because of its ability to stimulate erythropoiesis. As recently as 1976, physicians still used cobalt salts to reduce transfusion requirements in anemic patients in spite of concomitant adverse effects.<sup>47</sup> The other common medical use of cobalt is as a radioactive isotope, cobalt-60 (<sup>60</sup>Co). This gamma emitter was formerly used in the radiotherapy of cancers but was largely replaced by linear accelerators in the Western world. Radiotherapy devices are a source of radioactive material that could be used by terrorist groups.

Epidemics of cardiomyopathy and goiter termed “beer drinker’s cardiomyopathy”<sup>18</sup> and “cobalt-induced goiter”<sup>33,104</sup> occurred between the 1950s and the 1970s. During that period, cobalt sulfate was added to beer as a foam stabilizer. In the 1970s, these epidemics were halted with the discontinued use of cobalt sulfate for this purely aesthetic purpose.<sup>119</sup>

Current sources of cobalt exposure include chemistry sets,<sup>80</sup> weather indicators,<sup>80</sup> antiquated anemia therapies,<sup>80</sup> cement,<sup>88</sup> fly ash,<sup>88</sup> dyes,<sup>56</sup> mineral wool,<sup>88</sup> asbestos,<sup>88</sup> molds for ceramic tiles,<sup>52</sup> the production of Widia-steel (utilized in the wood industry),<sup>159</sup> mining,<sup>81</sup> porcelain paint,<sup>140</sup> orthopedic implants,<sup>79</sup> dental hardware,<sup>9</sup> and as a nutritional supplement.<sup>177</sup> The most recent area of concern is “arthroprosthetic cobaltism,”<sup>109,128,145,175,176</sup> which results from cobalt-containing orthopedic implants.<sup>2</sup> The prevalence of arthroprosthetic cobaltism is largely unknown, and likely underreported. The usage of metal-on-metal implants began in the 1990s and since has been voluntarily recalled as a result of the high rate of implant failure in 2010.<sup>97</sup> Determining the at-risk population is both difficult and dynamic due to the associated reporting practices and potential litigation activity. Metal-on-metal implants are considered the highest-risk prostheses; however, there are cases

that include exposure to other types of metal-containing implants.<sup>30</sup> A proposed risk stratification algorithm uses patient factors, such as female sex and high levels of activity, and implant factors such as diameter of femoral heads ( $\geq 36$  mm).<sup>96</sup>

The largest source, however, arises through the formation of cemented tungsten carbide, a “hard metal.” In tungsten carbide factories, powdered cobalt and tungsten are combined through an intense sintering process that exposes these metals to hydrogen heated to 1,000°C. The first published investigation of these factories reported a 10-fold increase in workspace cobalt concentrations compared to atmospheric concentrations.<sup>49</sup> These respiratory exposures produced pulmonary toxicity, known as “hard-metal disease.” As a result of this report, occupational studies and preventive measures have greatly reduced the acceptable cobalt exposure concentration in the workplace.

## CHEMISTRY

Like other metals, cobalt occurs in elemental, inorganic, and organic forms. The clinical effects of each form are less well defined than the more common transition metals such as lead, mercury, or arsenic. Elemental cobalt (Co<sup>0</sup>) toxicity is reported through both inhalational<sup>173</sup> and oral exposures.<sup>74</sup> Inorganic cobalt salts typically occur in one of 2 oxidation states: cobaltous (Co<sup>2+</sup>) or cobaltic (Co<sup>3+</sup>). Inorganic cobalt salts, such as cobaltous chloride (CoCl<sub>2</sub>) and cobaltous sulfate (CoSO<sub>4</sub>), were historically used for the treatment of anemias<sup>19,62,70,139,186</sup> and were implicated in the “beer drinker’s cardiomyopathy” epidemics, respectively.<sup>4,113,121</sup>

Organic cobalt exposure results from cyanocobalamin (vitamin B<sub>12</sub>) ingestion, but as a result of its limited oral absorption and its rapid renal elimination it is considered of low toxicity.<sup>136</sup> Comparing organic and inorganic forms of cobalt in animal models, inorganic cobalt salts are more toxic than the organic forms such as cobalt stearate.<sup>25</sup>

## TOXICOKINETICS

Based on animal studies, oral absorption of cobalt oxides, salts, and metal is highly variable, with a reported bioavailability of 5% to 45%.<sup>89,103</sup> In human studies, both iron deficiency and iron overload (hemochromatosis) enhance radio-labeled <sup>57</sup>CoCl<sub>2</sub> absorption in the small bowel.<sup>127</sup> Similarly, inhaled cobalt oxide is about 30% bioavailable,<sup>103</sup> but the volume of distribution and elimination half-life are not well defined.

The distribution of cobalt is influenced by plasma proteins, mainly albumin,<sup>26,27</sup> and is the basis of the U.S. Food and Drug Administration (FDA) approved the Albumin Cobalt Binding test (ACB test) for myocardial ischemia. Transferrin, another plasma protein, which normally binds iron, also binds cobalt, explaining its erythropoietic effect.<sup>82</sup> Following distribution, cellular uptake is mediated by the P2X7 transporter<sup>179</sup> and the active divalent metal transporter 1 (DMT1).<sup>27</sup>

Most (50%–88%) absorbed cobalt (organic and inorganic) is eliminated renally, and the remainder is eliminated in the feces.<sup>157</sup> Acutely, an increase in inorganic cobalt concentrations will result in an increased renal elimination.<sup>86</sup> However, this initial increased elimination decreases rapidly in spite of a large body burden.<sup>5,127</sup>

The elimination of cobalt correlates with the patterns of occupational exposure.<sup>173</sup> For example, a worker with a standard (Monday to Friday) work week will have much higher urine cobalt concentrations on Friday morning compared to Monday morning.<sup>173</sup> However, this finding that Monday afternoon urine cobalt concentrations are higher than Friday morning concentrations is due to the rapid elimination that occurs following an

initial exposure.<sup>5,173</sup> Based on these findings, the exposure over time must be considered when interpreting urinary cobalt concentrations in occupationally exposed individuals.<sup>14</sup>

## PATHOPHYSIOLOGY

Like other transition metals, cobalt is a multiorgan toxin. Divalent cobalt inhibits several key enzyme systems and interferes with the initiation of protein synthesis.<sup>15</sup> Polynucleotide phosphorylase, an essential enzyme in RNA synthesis, requires  $Mg^{2+}$  to function normally. In vitro, this enzyme only functions at 50% that of normal in the presence of  $Co^{2+}$ .<sup>15</sup> It is hypothesized that  $Co^{2+}$  is capable of displacing  $Mg^{2+}$  from the cofactor site of this enzyme.<sup>15</sup>

Cobalt salts interfere with the citric acid cycle mitochondrial enzyme,  $\alpha$ -ketoglutarate dehydrogenase. Because of this inhibition,  $Co^{2+}$  increases the rate of anaerobic glycolysis and at the same time decreases oxygen consumption,<sup>36</sup> and thus inhibits aerobic metabolism. In vitro studies demonstrate that other divalent cations,  $Zn^{2+}$ ,  $Cd^{2+}$ ,  $Cu^{2+}$ , and  $Ni^{2+}$ , also inhibit  $\alpha$ -ketoglutarate dehydrogenase (Chap. 11).<sup>183</sup> When compared with these divalent cations,  $Co^{2+}$  is not considered a potent inhibitor.<sup>183</sup> However, this in vitro model demonstrates that  $Co^{2+}$  is capable of almost entirely inhibiting the reaction when nicotinamide adenine dinucleotide (NADH) is added.<sup>183</sup> This study suggests that NADH abundance, such as occurs with chronic ethanol use, potentiates the inhibition of  $\alpha$ -ketoglutarate dehydrogenase.<sup>184</sup>

Moreover, cobalt salts are capable of inhibiting  $\alpha$  lipoic acid and dihydrolipoic acid by complexing with its sulfhydryl groups.<sup>38,183</sup> These reactions result in the inability to convert both pyruvate into acetyl-CoA and  $\alpha$ -ketoglutarate into succinyl-CoA (Chap. 11 and Antidotes in Depth: A27). These combined interactions offer explanations as to why chronic ethanol use and cobalt exposure result in cardiomyopathy (Chap. 53).<sup>183</sup>

In addition to enzyme inhibition,  $CoCl_2$  induces oxidant-mediated pulmonary toxicity (see below)<sup>124</sup> and neurotoxicity.<sup>27</sup> Xenobiotics implicated in free radical-mediated pulmonary injury are capable of accepting an electron from a reductant and subsequently transferring the electron to oxygen, forming a superoxide free radical (Chap. 10). Cobalt is then capable of accepting another electron, which starts the cycle over again—a process known as redox cycling. This leads to an accumulation of free radicals in the lung due to the abundance of oxygen ready to receive electrons and results in injury.

Within the endocrine system,  $CoCl_2$  inhibits tyrosine iodinase.<sup>92</sup> This enzyme is responsible for combining iodine ( $I_2$ ) with tyrosine to form monoiodotyrosine and serves as the first step in the synthesis of thyroid hormone (Chap. 53). This inhibition decreases circulating  $T_3$  and  $T_4$ , which results in hypothyroidism (see below).

The hematopoietic system is also affected by Co salts. Multiple animal models demonstrate that  $CoCl_2$  administration results in reticulocytosis, polycythemia, and erythropoiesis.<sup>55,90,118,129,130,186</sup> These events occur in both the bone marrow and extramedullary locations.<sup>19,59</sup> Although the pathogenesis remains largely unknown,<sup>38</sup> one theory is that cobalt ion binds to iron-binding sites such as transferrin,<sup>82</sup> resulting in impaired oxygen transport to renal cells, which in turn induces erythropoietin production. A second theory in which cobalt is thought to stimulate erythropoiesis is through improving iron availability. In an animal model of anemia, a greater degree of gastrointestinal iron uptake occurs in cobalt-treated rats compared to rats with either hypoxia or nephrectomy.<sup>59</sup> A similar study of injected cobalt chloride in mice suggested that the increase in iron uptake exceeded that following exogenous erythropoietin.<sup>6</sup> Moreover, human data demonstrate  $CoCl_2$  in vivo induce hypoxia inducible factor-1 alpha (HIF-1 $\alpha$ ) protein expression, transcription factors responsible for hypoxia-linked effects.<sup>152</sup>

Finally, within the nervous system,  $CoCl_2$  inhibits neuromuscular transmission by competing with  $Ca^{2+}$ , another divalent ion.  $Co^{2+}$  is 20 times more potent than magnesium with regard to its ability to compete with calcium for a site on the motor nerve terminal.<sup>182</sup> Additionally, the formation of free radicals is theorized as a cause of cobalt associated neurotoxicity.<sup>27</sup>

## TOXICITY

The single acute minimal toxic dose of cobalt salts is not well defined, and comparable doses have variable effects in different patients. Patients with “beer drinker’s cardiomyopathy” received an average daily dose of 6 to 8 mg of  $CoSO_4$  (over weeks to months) and developed toxic effects of acidemia, cardiomyopathy, shock, and death,<sup>87,121</sup> whereas infants being treated for anemia who received much higher daily cobalt doses of an iron-cobalt preparation (40 mg of  $CoCl_2$  and 75 mg of  $FeSO_4$ ) for 3 months did not develop toxicity.<sup>147</sup> The inconsistency of these findings suggests that multiple factors are responsible for the development of the clinical manifestations; in this case the role of ethanol metabolism and/or nutritional status is an important variable.<sup>26,80</sup>

## CLINICAL MANIFESTATIONS

Organ systems affected by acute cobalt poisoning include endocrine,<sup>74</sup> gastrointestinal,<sup>47,62</sup> central<sup>62,156</sup> and peripheral nervous system,<sup>156</sup> hematologic,<sup>55,90,118,186</sup> cardiovascular,<sup>74</sup> ophthalmic,<sup>12,13,83,126</sup> and metabolic.<sup>74</sup> Chronic inhalational exposures affect the pulmonary system<sup>31,37,49,94,95,143,165</sup> and dermatologic system.<sup>53,150,185</sup> In the past, the following section was divided into acute and chronic clinical manifestations; however, there is substantial temporal cross-over and these presentations have systemic diversity. These distinctions suggest a deterministic outcome whereas stochastic processes are just as probable. The clinical manifestations will be described by organ system and chronic occupational manifestations. The 2 major organ systems cardiovascular and soft tissue will be illustrated by “beer drinker’s cardiomyopathy” and arthroprosthetic cobaltism respectively despite these special populations having a myriad of shared manifestations.

### Cardiovascular

“Beer drinker’s cardiomyopathy.” In 1966, a Veterans Affairs (VA) Hospital in Nebraska cared for 28 white men with a history of beer drinking who presented with tachycardia, dyspnea, and metabolic acidosis with elevated lactate concentrations, and congestive heart failure.<sup>113</sup> The mortality rate for these cases was 38% and death occurred rapidly within 72 hours of presentation, because of severe metabolic acidosis and cardiac failure.<sup>113</sup> Of the survivors, most responded immediately to supportive care and thiamine supplementation, and a lack of response was found to be secondary to complications; most commonly, symptomatic pericardial effusions or embolic events.<sup>113</sup> Epidemiologic evaluation of this case series revealed that these men habitually drank large quantities of beer.

Ultimately, 64 cases and 30 fatalities were reported from Nebraska.<sup>172</sup> Twenty-six of the 30 deaths received autopsies. Common post-mortem findings were dilated cardiomyopathy and cellular degeneration with vacuolization and edema with a lack of inflammation or fibrosis.<sup>113</sup> When cobalt was implicated in the pathogenesis of these deaths, preserved cardiac tissue of 8 decedents revealed cobalt concentrations 10 times greater than that of controls.<sup>172</sup>

Within a year of the Nebraska cases, reports began to emerge from Quebec.<sup>121</sup> Forty-eight beer drinkers (only 2 of whom were women) developed unexplained cardiomyopathy, with a mortality rate of 46%.<sup>121</sup> The only association between these patients was the common consumption of Dow Beer, originally anonymized as “XXX” beer.<sup>121</sup> The producers of this beer had factories in Quebec City and Montreal. The only difference between the Nebraska brewery and the one in Quebec was that the latter added 10 times the amount of  $CoSO_4$  to the beer as a foam stabilizer.<sup>119</sup> Clinical findings in these cases included tachycardia, tachypnea, polycythemia, and low-voltage electrocardiograms (ECGs).<sup>120</sup> Cases began to appear 1 month after beer with the higher amount  $CoSO_4$  was released onto the market, and no new cases were reported in Quebec after this beer with more  $CoSO_4$  was removed from the market.<sup>119</sup>

Between the years 1964 and 1967, 20 additional cases occurred in Minneapolis with similar findings of tachycardia, dyspnea, pericardial effusion, polycythemia, and metabolic acidosis with elevated lactate concentrations, and there was a mortality rate of 18% acutely and 43% over a 3-year period.<sup>4</sup>

Similar to the previous cases, all were associated with the addition of  $\text{CoSO}_4$  as a foam stabilizer in beer.

Because the clinical findings resemble the cardiomyopathy associated with chronic alcoholism<sup>51</sup> and infantile malnutrition,<sup>137</sup> a debate persists as to whether cobalt is the sole cause of this syndrome. Cardiomyopathies due to poor protein intake, vitamin deficiency, and cobalt toxicity have similar histologic findings. For example, myocardial biopsy of dogs with cobalt-induced cardiac failure revealed diffuse cytosolic vacuolization, loss of cross-striations, and interstitial edema,<sup>154</sup> all of which are similar to findings of malnutrition.<sup>51,137</sup> However, some other findings are more specific to cobalt-associated cardiomyopathy. For example, a small retrospective analysis revealed myocyte atrophy and myofibril loss to be present in people with cobalt-associated cardiomyopathy significantly more often than in those with idiopathic dilated cardiomyopathy.<sup>28</sup>

Some animal models of cobalt cardiomyopathy were only able to reproduce pathologic and ECG findings if cobalt and ethanol<sup>10</sup> were coadministered whereas others required protein deficiency.<sup>148</sup> Contrary to these studies, several murine and canine models of cobalt poisoning demonstrated cardiac lesions,<sup>68,153,154</sup> cardiac failure,<sup>71,153,154</sup> and ECG abnormalities while receiving nutritional supplementation.<sup>69,153</sup>

Despite the implication that cobalt-induced cardiomyopathy requires malnutrition or alcoholism, a case of cardiac toxicity following acute cobalt poisoning is reported.<sup>74</sup> However, it is difficult to identify other cases reported outside of the aforementioned small epidemics in beer drinkers. In a controlled study of occupationally exposed subjects evaluated with echocardiograms, significantly more cobalt exposed workers had diastolic dysfunction when compared to controls.<sup>101</sup> However, none of these subjects under study developed congestive heart failure.<sup>101</sup> Of the few reported cases of cardiomyopathy associated with arthroprosthetic cobaltism, patients are typically older than those with the “beer drinker’s cardiomyopathy” cohort, and their nutritional status and ethanol use are unreported.<sup>128,135</sup> There are rare reports of cardiomyopathy in chronically exposed workers,<sup>17,35,85</sup> which suggests that the cardiomyopathy reported in the “beer drinkers” cohort is multifactorial and not solely due to cobalt.

Another source of criticism of the role of cobalt in the development of cardiomyopathy is the relatively low dose of cobalt needed to induce heart failure in these patients.<sup>87</sup> In patients receiving 20 to 75 mg/day of  $\text{CoCl}_2$  for various red cell dysplasias, there were no reports of heart failure<sup>87</sup> whereas the “beer drinker’s cardiomyopathy” group reportedly consumed only 6 to 8 mg/day of  $\text{CoSO}_4$  while drinking 24 pints of cobalt-containing beer.<sup>87,119</sup> All patients who developed cardiomyopathies were malnourished, which supports the theory that a multifactorial nutritional deficiency in the presence of excessive cobalt is necessary for the development of cardiomyopathy.<sup>87</sup>

Within the cases of arthroprosthetic cobaltism reported so far, few have detailed cardiac manifestations reported despite the presence of cardiomyopathy; this is most likely due to cardiomyopathy being common in the age group receiving hip arthroplasties. Of the 3 cases<sup>7,65,122</sup> within this cohort reporting histopathology, the common features are myocyte hypertrophy,<sup>7,122</sup> dilated atrial and ventricular chambers,<sup>57</sup> deposits of electron-dense material,<sup>65</sup> interstitial fibrosis,<sup>7,122</sup> cytoplasmic vacuoles,<sup>7,122</sup> and without evidence of infiltrative or infective cardiomyopathy.<sup>7,65,122</sup> Interestingly, heart failure was so profound that 2 of these cases went on to receive cardiac transplants.<sup>7,122</sup>

## Endocrine

Both acute and chronic cobalt exposures are associated with thyroid hyperplasia and goiter. A series of patients with severe sickle cell anemia treated with cobalt salts developed goiters with varying degrees of thyroid dysfunction<sup>70,91</sup> including clinical hypothyroidism.<sup>92</sup> In 1 patient, the goiter was so severe that airway obstruction developed.<sup>91</sup>

Older occupational data suggest that inhalational exposure to cobalt metals, salts, and oxides results in abnormalities in thyroid function studies.<sup>173</sup> When 82 workers in a cobalt refinery were compared to age- and sex-matched controls, exposed workers had significantly lower  $T_3$  concentrations.<sup>173</sup> Studies of cobalt-exposed workers in environments that

limit exposure do not demonstrate any changes in serum thyroid markers,<sup>99</sup> supporting occupationally imposed limits.

Within the previously mentioned beer drinker’s cardiomyopathy cohort, 11 of 14 decedents had abnormal thyroid histology.<sup>149</sup> Among them, the most common findings were follicular cell abnormalities and colloid depletion, which did not exist on thyroid analysis from 11 randomly selected autopsies that served as controls.<sup>149</sup> Of the patients with arthroprosthetic cobaltism, many had abnormal thyroid function studies with or without clinical symptoms of hypothyroidism<sup>128,135,189</sup>

## Hematologic

Anemias of the newborn,<sup>32,84,139</sup> erythrocyte hypoplasia,<sup>158</sup> red cell aplasia,<sup>180</sup> and kidney failure–associated anemia<sup>62</sup> were all successfully treated with cobalt salts. Patients undergoing  $\text{CoCl}_2$  therapy for these diseases had increased hemoglobin,<sup>62,139</sup> hematocrit,<sup>62,139</sup> and red cell counts.<sup>62,139</sup>

A published series of Peruvian cobalt miners working in an open pit at 4,300 m (2.7 miles) elevation developed clinical effects including headache, dizziness, weakness, mental fatigue, dyspnea, insomnia, tinnitus, anorexia, cyanosis, polycythemia, and conjunctival hyperemia consistent with acute mountain sickness.<sup>81</sup> When the study group was compared to age-, height-, and weight-matched high-altitude controls, the study group had higher chronic mountain sickness scores.<sup>81</sup> The only difference detected was elevated serum cobalt concentrations in the study group.<sup>81</sup>

In addition to effects on red cells, mice develop transient hemolysis, methemoglobinemia, and methemoglobinuria from subcutaneous  $\text{CoCl}_2$  exposure.<sup>75</sup> These findings explain reports of dark urine following cobalt exposure in other animal models.<sup>66,167</sup> However, similar human cases are not reported.

## Other

Gastrointestinal distress is reported following the ingestion of “therapeutic” doses of cobalt salts<sup>156</sup> and elemental cobalt.<sup>80</sup> Decreased proprioception, impaired cranial nerve VIII function, and nonspecific peripheral nerve findings are reported with acute oral  $\text{CoCl}_2$  exposures.<sup>156</sup> Patients with arthroprosthetic cobaltism have seizures, cerebellar deficits, retinopathy,<sup>12,126</sup> hearing loss, cognitive deficits, and peripheral neuropathy, and some of whom had concomitant elevations of cerebrospinal fluid cobalt concentrations.<sup>27,109,128,175,176</sup> Retinal effects were noted in at least 2 case reports of patients with cobalt-containing arthroplasties.<sup>10,11</sup> The pathophysiology of these cases is poorly understood and confounded by comorbidities typical in this cohort of patients. Radioactive  $^{60}\text{Co}$  used for radiation therapy is associated with radiation burns (Chap. 128). Unlike acute toxicity, chronic cobalt exposure is not associated with an increased mortality; a cohort study evaluating more than 1,100 persons with pulmonary exposures to cobalt salts and oxides over a 30-year period was unable to demonstrate an increased mortality rate.<sup>110</sup>

## Arthroprosthetic Cobaltism

### Soft Tissue

It has been known for some time that metal-on-metal alloy orthopedic implants result in elevations of the associated metal concentration in blood, urine, and hair.<sup>27</sup> Serum cobalt concentrations become elevated 3 weeks after surgery and remain elevated through a 5-year study period, which contradicts earlier theories of elevated concentrations being related to the life of the implant.<sup>20</sup> Despite the elevation of both chromium and cobalt in measured samples, it appears that the constellation of clinical findings is more consistent with cobalt rather than chromium toxicity.<sup>1</sup> Additionally, the toxicity of chromium develops more slowly than that of cobalt.<sup>1</sup>

Reported cases of toxicity follow revisions, dislocations, or first-time arthroplasties of cobalt-containing prosthetics.<sup>97,156,157</sup> The association of having a cobalt-containing prosthetic, an elevated marker of cobalt burden, and findings of end-organ toxicity has been coined “arthroprosthetic cobaltism.” Before these clinical manifestations occur, cobalt ions are deposited in the soft tissue. Gross deposition of metal in surrounding soft tissue is termed metallosis. Metallosis is accompanied by other clinical

findings such as discoloration of synovial fluid<sup>65</sup> and pseudotumor<sup>7,60,122</sup> formation. Pseudotumor is also described as an aseptic lymphocyte-dominated vasculitis-associated lesion (ALVAL). The specific findings on histopathology show an invasion of lymphocytes and plasma cells forming a perivascular lymphocytic infiltrate.<sup>181</sup> It is hypothesized that these findings are a type IV mediated immune response to metal ions, which correlates highly for these patients having a positive patch clamp skin test.<sup>174</sup> A newer entity is trunnionosis,<sup>117,164</sup> the erosion of metal at the level of the trunnion—the location of where the neck of the arthroplasty inserts into the femoral head implant. Trunnionosis occurs at a higher rate of metal-on-metal implants, but is also reported with metal-on-polyethylene implants. Both metallosis and trunnionosis are findings suggestive of implant failure and thought to place the patient at risk for systemic toxicity if left to progress.

Some of the common presentations of local soft tissue reactions are pain, swelling, and painful gait not attributed to recent surgery. These symptoms are a common presentation leading the clinician to suspect a local reaction to the metal-containing prosthesis. The presence of the above findings leads the clinician to suspect implant failure and, more consequentially, risk of developing cobalt toxicity.

Cases of implant failure and local tissue reactions are common but arthroprosthetic cobaltism remains a rarely reported entity, considering the hundreds of thousands of implants performed annually. Because of the concern of implant failure and systemic absorption of metal ions, government agencies from the United States, Canada, United Kingdom, European Union, and Australia have made recommendations regarding investigation of problematic implants.<sup>1-3,142</sup> However, these guidelines are not uniform, vary regionally, and subject to dated information.

Of the reported cases, some arthroplasties had excessive wear<sup>115</sup> or were placed following a ceramic arthroplasty, resulting in metallosis.<sup>100</sup> Lumbar metal-on-metal total disk replacements are associated with smaller elevations in serum cobalt concentrations when compared with hip resurfacing or total hip arthroplasties,<sup>19</sup> there are no reported cases of clinical cobaltism with lumbar implants.

### Renal

A single report associates reversible acute kidney injury with the chronic administration of  $\text{CoCl}_2$  as treatment for anemia.<sup>156</sup> Some animal models of cobalt cardiomyopathy demonstrate cellular changes in renal tissue.<sup>67</sup> However, when 26 exposed hard-metal workers were evaluated for urinary albumin, retinol binding protein, beta<sub>2</sub>-microglobulin, and tubular brush border antigens, no detectable differences could be found between the study group and controls.<sup>58</sup> Additionally, patients with cobalt-containing total hip arthroplasties were followed over 2 years with elevated serum cobalt concentrations without any significant effect on serum creatinine over this study period.<sup>16</sup> Based on these few reports, it appears that acute and chronic exposure to cobalt has little effect on the kidneys.

### Reproduction

In pregnant rats,  $\text{CoCl}_2$  exposure neither results in teratogenicity nor fetal toxicity.<sup>132</sup> In a case report of a pregnant woman with hard-metal disease, the woman was able to bring the pregnancy to term and deliver without complication.<sup>141</sup> In another case report, a woman with a cobalt-containing hip arthroplasty had repeated joint aspirations, dislocations, and revisions before and during her pregnancy.<sup>60</sup> Cobalt concentrations of this mother were 138 to 143 mcg/L throughout the pregnancy; cord blood concentration was 75 mcg/L; and infant blood concentration at 8 weeks was 13 mcg/L. Despite these elevated concentrations, there was no clinical evidence of toxicity.<sup>60</sup> It is hypothesized that only exposures that are toxic to the mother result in fetal toxicity.<sup>46</sup>

In mice, chronic exposure to cobalt results in impaired spermatogenesis and decreased fertility without affecting follicular stimulating hormone or luteinizing hormone, whereas acute exposures did not demonstrate similar reproductive effects.<sup>134</sup> Additional murine studies discuss the possible interactions between cobalt with iron and zinc, which are both essential elements

for spermatogenesis.<sup>8</sup> Despite these findings, there are no reported human cases that associate cobalt exposure with teratogenicity or impaired fertility.

### Carcinogenesis

Animal experiments with injection of  $\text{CoCl}_2$  into soft tissue resulted in soft tissue sarcomas, leading the International Agency for Research on Cancer (IARC) to consider cobalt metal without tungsten carbide, cobalt sulfate, and other soluble cobalt(II) salts possibly carcinogenic to humans (group 2B).<sup>18,33,44,152,167</sup> Cobalt metal associated with tungsten carbide is probably carcinogenic to humans (group 2A).<sup>167</sup> There are case reports and cohort studies that suggest that pulmonary exposure to  $\text{Co}^{2+}$  increases the risk of lung cancer. However, these studies were unable to control for other known carcinogens such as arsenic.<sup>33</sup> In the largest occupational cohort study to date, which followed more than 1,100 workers for more than 38 years, there was no increase in the prevalence of lung cancer.<sup>109</sup> Finally, in 2 of the largest population studies to date, researchers were unable to demonstrate a higher cancer rate for individuals with metal-on-metal implants when compared to the general population;<sup>22,108</sup> however, because of the relatively recent nature of the implants, these studies suffer from length-time bias and do not capture the needed time between exposure to carcinogenesis.

## Chronic Occupational Exposure

### Pulmonary

Both asthma and “hard-metal disease” are associated with cobalt exposure. Occupational asthma is reported in hard-metal workers with a prevalence of 2% to 5%<sup>31,94,95</sup> at exposure concentrations as low as 50 mcg/m<sup>3</sup>.<sup>95</sup> As is the case with most causes of occupational asthma, cobalt hypersensitivity-induced asthma is most likely immune mediated rather than toxicologic.<sup>34,94,165</sup> Most hard-metal workers are exposed to other metals, such as tungsten (W) and nickel (Ni), in addition to cobalt, and these other metals account for some of the occupational asthma that is attributed to cobalt.<sup>162,163</sup> However, in a small but well-performed study in patients with cobalt-associated asthma, intradermal cobalt chloride resulted in a positive wheal response in all subjects and 50% of patients had a positive radioallergosorbent test (RAST) scores, which correlated to the wheal size<sup>161</sup> and suggests cobalt salts elicit an immune response independent of the other metals.

Cobalt-associated pulmonary toxicity was first noted in tungsten carbide workers,<sup>49,72</sup> and was subsequently referred to as “hard-metal disease.” Exposures result from the process by which tungsten-carbide is sintered with cobalt. Signs and symptoms of hard-metal disease include upper respiratory tract irritation, exertional dyspnea, severe dry cough, wheezing, and interstitial lung disease ranging from alveolitis to progressive fibrosis. The prevalence of hard-metal disease is largely unknown. In one study, 11 of 290 (3.8%) exposed workers were diagnosed with interstitial infiltrates on chest radiographs but only 2 (0.7%) had a decrease in predicted total lung capacity.<sup>168</sup>

Certain individuals who are exposed to large doses of hard metal for prolonged periods never develop disease; which suggests that a susceptible population exists. A glutamate substitution for lysine in position 69 of the beta unit HLA-DP has a strong association with hard-metal disease, similar to chronic beryllium disease.<sup>138</sup> Clinically, hard-metal disease is difficult to distinguish from berylliosis, although an occupational history is helpful.

Histopathologic findings of hard-metal disease include multinucleated giant cells and interstitial pneumonitis with bronchiolitis.<sup>11</sup> Elevated concentrations of cobalt in lung tissue are detected,<sup>144,166</sup> even as long as 4 years after exposure.<sup>144</sup> In patients with interstitial lung disease, bronchoalveolar lavage commonly reveals multinucleated giant cells, type II alveolar cells, and alveolar macrophages.<sup>37</sup> The finding of multinucleated giant cells from bronchoalveolar lavage washing is characteristic of hard-metal disease.<sup>34,39,40,114,178</sup>

A cross-sectional study of more than a 1,000 tungsten carbide-exposed workers found an increased odds ratio of 2.1 for having a work-related wheeze, when exposed to greater than 50 mcg/m<sup>3</sup> of Co.<sup>169</sup> In the same study, workers with exposures recorded at greater than 100 mcg/m<sup>3</sup> had higher odds (OR 5.0) of having a chest radiograph perfusion score of greater than

or equal to 1/0.<sup>169</sup> This perfusion score, established by the United Nations agency, the International Labor Organization (ILO), is a grading system for pneumoconioses. When used to grade radiographs of asbestosis, this score correlates strongly with mortality risk,<sup>111</sup> reduced diffusing capacity, and decreased ventilatory capacity.<sup>73,123</sup> Additional studies have similarly concluded that pulmonary disease occurs when individuals are exposed to concentrations of cobalt that approach 100 mcg/m<sup>3</sup>.<sup>93</sup> Thus, with a margin of safety, the current threshold limit value (TLV) is less than 50 mcg/m<sup>3</sup>.

Until 1984, all reported cases of hard-metal disease were associated with the combination of cobalt and other metals, such as nickel, cadmium, and tungsten.<sup>11,72,95,169</sup> When diamond polishers initiated the use of high-speed grinding disks coated with abrasive microdiamonds embedded in a matrix of cobalt powder,<sup>96</sup> case reports ensued demonstrating similar clinical<sup>98</sup> and pathologic findings to hard-metal disease, strengthening the association with cobalt.<sup>34,39,125</sup> Some authors still contend that the presence of other metals<sup>11,72,95,169</sup> and diamond dust<sup>39,63,125</sup> are confounding factors.<sup>173</sup> Like hard-metal disease, most reported cases show resolution of symptoms following removal from the exposure,<sup>39</sup> although this is not always sufficient.<sup>125</sup>

There are very few reports of isolated cobalt exposures. In an age-matched and sex-matched study of 82 workers with respiratory exposures to cobalt oxides, cobalt salts, cobalt metal, and no other metal, researchers were unable to detect a difference between exposed (mean of 8 years, time-weighted average 125 mcg/m<sup>3</sup>, 25% >500 mcg/m<sup>3</sup>) and unexposed workers with any objective measured pulmonary tests.<sup>173</sup> Neither group had any abnormality in chest radiography that would suggest pulmonary fibrosis.<sup>173</sup> The only significant pulmonary differences detected were a higher reported rate of dyspnea both on exertion and at rest and the presence of wheezing in the exposed group.<sup>173</sup> These authors concluded that cobalt contributes to the development of pulmonary disease but is not independently responsible for the development of pulmonary fibrosis.<sup>173</sup>

Despite the progressive and debilitating nature of hard-metal disease, most signs and symptoms improve with cessation of exposure.<sup>110,115,188</sup> Moreover, the length and dose of exposure do not appear to correlate with the presence or severity of illness, suggesting that individual susceptibility is the key determinant for developing illness.<sup>110,151</sup>

### Dermatology

In a study of 1,782 construction workers, 23.6% developed dermatitis and 11.2% developed oil acne while using cobalt-containing cement, fly ash, or asbestos.<sup>88</sup> As in hard-metal disease, it is difficult to isolate cobalt as the sole contributor to the development of dermatitis. Nickel (Chap. 96) is the classic xenobiotic causing dermatitis. Commonly found in some of these construction occupations, nickel is implicated in the development of cutaneous manifestations.<sup>53,150</sup> However, consumer products such as piercings, tattoo ink, plastics, clothing dye, makeup, and dental treatments are implicated in cobalt-induced allergic contact dermatitis.<sup>56</sup> Additionally, within the arthroprosthetic cobaltism cohort, dermatitis is found to present both in proximity and remotely from the cobalt reservoir, and diffusely.<sup>187</sup> Furthermore, *in vitro* studies demonstrate that cobalt induces production of both Th1- and Th2-type cytokines in peripheral blood mononuclear cells—the same pathway implicated in nickel contact dermatitis.<sup>116</sup> Thus, it appears that cobalt induces a hypersensitivity reaction independent of the presence of nickel. Within the arthroprosthetic cobaltism group, cases of both local and remote dermatitis are reported, but because of poor reporting details of its nature, the pathophysiology of these particular cases is unclear.<sup>170,176</sup>

## DIAGNOSTIC TESTING

Currently, body fluid cobalt concentrations are not readily available and therefore cannot be used to direct emergent clinical care. Some adjunctive testing that supports a clinical diagnosis of cobalt toxicity should include complete blood count (CBC), reticulocyte count, erythropoietin (EPO) concentration, and thyroid-stimulating hormone (TSH) concentration. The results of these tests reflect the level of exposure or potential toxic manifestations.

### Cardiac Studies

Electrocardiogram, echocardiogram, and radionuclide angiography with <sup>99</sup>Tc(RNA) are useful screening tests for detecting abnormalities associated with cobalt cardiomyopathy and/or pulmonary hypertension due to hard-metal disease.<sup>35</sup> Magnetic resonance imaging is used to exclude other causes of cardiomyopathy.<sup>7,122</sup> In a single case report, a cardiac MRI demonstrated extensive hyperenhancement, diffuse edema, and was instrumental in excluding other causes of heart failure.<sup>122</sup> The true sensitivity and specificity of these cardiac tests for cobalt-induced cardiomyopathy is unknown.

### Pulmonary Testing

Patients with hard-metal lung disease demonstrate bilateral upper lobe interstitial lung disease on chest radiograph. However, patients have signs and symptoms of disease without specific radiographic findings.<sup>141</sup> Pulmonary function testing in occupationally exposed workers shows decreased vital capacity<sup>141</sup> and a decrease in transfer factor for carbon monoxide, both of which are useful in identifying patients at risk for developing pulmonary fibrosis.<sup>171</sup> An inversion of CD4/CD8 ratio in bronchoalveolar lavage washings is a useful tool for diagnosis and evaluation of progression of illness and that normalization is a marker for improvement.<sup>143</sup> Despite these available tests, a definitive diagnosis of hard-metal disease requires a tissue sample with findings of multinucleated giant cells in the setting of interstitial pulmonary fibrosis.

### Soft Tissue Imaging

Specifically with regard to failed cobalt-containing implants, some groups recommend plain radiographs for the assessment of metallosis, osteolysis, and other subtle findings of implant failure.<sup>96</sup> However, ultrasonography combined with metal artifact reduction sequence MRI has come to the forefront as the more sensitive and specific radiologic study for cobalt-containing implants, revealing soft tissue reactions, metallosis, and pseudotumor, and assist in revision planning.<sup>96</sup> These tests, however, do not assist in the diagnosis of cobalt toxicity, but merely reveal the presence of local reactions that would place the patient at risk of systemic toxicity. Various governing bodies made recommendations/guidelines for physicians caring for patients with hip arthroplasties in which cobalt poisoning is a risk. The American Association of Hip and Knee Surgeons, the American Academy of Orthopaedic Surgeons, and the Hip Society endorse a stratifying schema placing patients into low-, medium-, and high-risk groups based on characteristics that are not prospectively validated.<sup>96</sup> In addition to these guidelines, government oversight bodies for medical devices all over the world have varying recommendations from biologic testing to treatment. It is advised that the reader refer to their regional medical device oversight body (eg, FDA, Medicines and Healthcare products Regulatory Agency)<sup>1-3,24</sup> for current recommendations.

### Cobalt Testing

Cobalt, as stated above, is primarily eliminated in the urine and to a lesser extent in the feces, making urine cobalt evaluation most appropriate.<sup>103</sup> The difficulty lies in the interpretation of the result. Cobalt is detectable in the urine after inhalational exposure and reflects elimination kinetics that are rapid during an initial exposure but which slow after prolonged exposure.<sup>103,155</sup> Because of this variable elimination pattern, it is difficult to interpret both urine and blood concentrations unless the dose and length of exposure are precisely known. Furthermore, the defined patterns are applicable to shift workers exposed to soluble forms of cobalt.<sup>103</sup>

Further complicating the interpretation of urinary cobalt concentrations is the abundance of organic cobalt in the form of vitamin B<sub>12</sub>. A detailed vitamin supplementation history is needed before the interpretation of a urine or blood cobalt concentration, as a diet regimen high in vitamin B<sub>12</sub> increases urine cobalt concentrations. For this reason, speciation of cobalt should be investigated. The ratio of inorganic to organic cobalt is higher in occupationally exposed workers (2.3) when compared to controls (1.01) independent of the wide variations of urinary cobalt concentrations.<sup>61</sup> This is a promising area of study for the evaluation of cobalt-exposed workers.

Further complicating the meaning of a cobalt concentration is the availability of plasma, serum, and whole blood cobalt testing.<sup>133</sup> Evidence suggests whole blood cobalt reflects total body metal burden more accurately because it takes albumin into consideration.<sup>26</sup> Toxic concentrations of cobalt in serum and urine are poorly defined. Published literature on “normal values” is fraught with variability, which reflects differences in the population under study and the techniques and fluids used for measurement. Normal serum concentrations of cobalt are frequently reported as 0.1 to 1.2 mcg/L.<sup>5,18,74,78,160</sup> In a cohort of patients with asymptomatic cobalt-containing hip implants, the peak serum cobalt concentration did not exceed 11.5 mcg/L, barring 1 outlier of 35 mcg/L at 1 year postprocedure.<sup>16,21,23</sup> Based on this data, some recommend suspecting arthroprosthetic cobaltism when a blood concentration exceeds 10 mcg/L.<sup>3,175</sup> In comparison, a single acutely poisoned patient had a reported serum concentration of 41 mcg/L.<sup>74</sup> In the arthroprosthetic cobaltism group, serum cobalt concentrations ranged from 23 to 1,085 mcg/L.<sup>7,60,65,77,109,122,128,135,146,170,176</sup> Interestingly, a cobalt concentration of more than 7 mcg/L in whole blood “indicates potential for soft tissue reaction” according to the Medicines and Healthcare products Regulatory Agency in the United Kingdom,<sup>3</sup> whereas the FDA has no threshold concentration of concern, but allows the clinician to interpret these findings and take appropriate actions.<sup>2</sup> Despite the lack of uniformity in recommendations, most agencies currently recommend whole blood cobalt concentrations as the preferred form of testing.<sup>2,3</sup>

Normal reference urine cobalt concentrations are between 0.1 and 2.2 mcg/L.<sup>5,18,74,78,131,160</sup> In contrast, a patient with an acute elemental cobalt ingestion had a concentration of 1,700 mcg/L on a spot urinalysis several days after the exposure.<sup>74</sup> In the arthroprosthetic cobaltism group, 1 patient had a urine cobalt concentration of 16,500 mcg/L.<sup>128</sup>

Chronic exposures should be evaluated differently as discussed above (see Toxicokinetics). Exposed workers, without clinical disease, have reported spot urine concentrations that range from ten to several hundred micrograms per liter.<sup>76</sup>

## TREATMENT

### Acute Management

Patients with acute cobalt poisoning require aggressive therapy. It is reasonable to conclude that the same decontamination principles used for other metals apply to cobalt. There are no studies examining the benefit of gastric emptying, activated charcoal, or whole-bowel irrigation (WBI) following acute ingestion. It is reasonable to attempt WBI for radiopaque solid forms of cobalt prior to endoscopic or surgical removal.<sup>74</sup> Regardless of the decontamination procedure used, we recommend against chelation therapy until the gastrointestinal cobalt source is removed. If there is a large stomach burden of a solid, endoscopic or surgical removal is reasonable, keeping in mind that the administration of activated charcoal prior to surgical removal will obscure visualization of the surgical field (Chap. 5). After decontamination, reduction of tissue burden and prevention of end organ toxicity is the next crucial step.

The data on chelation therapy is unfortunately limited to animal models<sup>41-46,105-107</sup> and human case reports.<sup>74,135</sup> The basis of chelation therapy originates from the mid-1900s when oral protein intake was found to result in a reduction of cobalt toxicity in calves<sup>48</sup> and rats.<sup>68</sup> Certain sulfur-containing proteins serve as good chelators for some transition metals.

In a series of animal models of acute cobalt toxicity, several potential chelators, *N*-acetylcysteine (NAC), succimer, calcium disodium ethylenediaminetetraacetic acid  $\text{CaNa}_2(\text{EDTA})$ , glutathione, and diethylenetriaminepentaacetic acid (DTPA) were evaluated for their ability to enhance urinary and fecal elimination of cobalt.<sup>105</sup> Succimer and EDTA were able to enhance fecal elimination.<sup>105</sup> Glutathione and DTPA were able to enhance urinary elimination, and NAC was able to enhance elimination by both routes.<sup>105</sup>

In 2 separate animal studies, NAC reduced the tissue burden and injury due to cobalt in the liver and spleen.<sup>45,105</sup> Glutathione, another sulfur-containing protein, also reduced tissue concentrations of cobalt, but only in the spleen.<sup>105</sup>

The sulfur-containing proteins, NAC,<sup>42,45</sup> L-cysteine,<sup>41,42</sup> L-methionine,<sup>42</sup> and L-histidine,<sup>46</sup> were studied for their ability to reduce mortality in

rats that were administered an  $\text{LD}_{50}$  of  $\text{CoCl}_2$  orally and intraperitoneally. *N*-acetylcysteine, L-cysteine and L-histidine<sup>46</sup> therapy were more effective than L-methionine in protecting against mortality, offering almost 100% protection. In a similar fashion,  $\text{CaNa}_2\text{EDTA}$  was effective in reducing mortality.<sup>44</sup> In all of these therapies, the successful reduction in mortality from these therapies is predicated on its early administration.<sup>41,42,44-46</sup>

In a murine model, L-cysteine, NAC, glutathione, L-histidine, sodium salicylate, D,L-penicillamine, succimer, *N*-acetylpenicillamine (NAPA), diethyldithiocarbamate (DDC), dimercaprol, 4,5-dihydroxy-1,3-benzene disulfonic acid,  $\text{Na}_3\text{CaDTPA}$ ,  $\text{CaNa}_2\text{EDTA}$ , and deferoxamine were each evaluated for exposures to an  $\text{LD}_{50}$  and an  $\text{LD}_{99}$  of  $\text{CoCl}_2$ .<sup>107</sup> Potential chelators that were ineffective at improving survival following an  $\text{LD}_{50}$  were sodium salicylate, NAPA, DOC, dimercaprol, 4,5-dihydroxy-1,3-benzene disulfonic acid and deferoxamine.<sup>107</sup> Chelators that were seemingly effective at  $\text{LD}_{50}$  and not at  $\text{LD}_{99}$  were L-histidine and D,L-penicillamine.<sup>106</sup> *N*-acetylcysteine, L-cysteine, and succimer were able to improve survival by 40% to 50%.<sup>107</sup> The most effective chelators at  $\text{LD}_{99}$  were  $\text{CaNa}_2\text{EDTA}$  and DTPA.<sup>106,107</sup> An expanded analysis of these data revealed that  $\text{CaNa}_2\text{EDTA}$  and DTPA had better therapeutic indices when compared with succimer.<sup>107</sup> In another in vitro study, dimercaprol was unable to chelate  $\text{Co}^{2+}$  that was already bound to  $\alpha$ -ketoglutarate.<sup>183</sup>

Data on chelation in humans is available from 6 case reports.<sup>57,64,65,74,135,146</sup> In 1 case, a child ingested multiple elemental cobalt-containing magnets, resulting in a serum cobalt concentration of 41 mcg/L.<sup>74</sup> Five days of 50 mg/kg/day of intravenous  $\text{CaNa}_2\text{EDTA}$  enhanced renal elimination of cobalt, and the patient's metabolic acidosis and the cardiac dysfunction resolved simultaneously.<sup>74</sup> All other cases studied are as a result of arthroprosthetic cobaltism.

Clinical symptoms and serum cobalt reduction respond well to arthroplasty revision<sup>100,128,135,176</sup> and potentially chelation therapy.<sup>64,135</sup> A 56-year-old man developed arthroprosthetic cobaltism with elevated serum (506 mcg/L), cerebrospinal fluid concentrations (8.5 mcg/L) of cobalt, hypothyroidism, cardiomyopathy with pericardial effusion, polycythemia, and both central and peripheral neuropathy.<sup>135</sup> Unlike the previous case report, this patient was treated with 2,3-dimercaptopropane-1-sulfonate (DMPS) at a dose of 14 mg/kg for 6 days and followed by 4 mg/kg for 5 days for a total of 10 gm of antidote. Serum cobalt concentrations were reduced 26% in 1 month following treatment.<sup>135</sup> However, despite removal of the prosthesis and chelation therapy, the patient had permanent hearing loss and a persistently elevated serum concentration,<sup>135</sup> most likely because of a delay of 7 months from onset of symptoms and metallosis of tissue.

Another human case receiving chelation therapy was a 58-year-old woman with a hip prosthesis, symptoms of cobaltism, and cobalt blood concentrations of 549 mcg/L, cerebrospinal fluid concentrations of 11.4 mcg/L, and urine concentrations of 11.4 mcg/L.<sup>146</sup> Initial chelation with  $\text{CaNa}_2\text{EDTA}$  resulted in a decrease in cobalt concentrations, but without a significant change in her symptoms.<sup>146</sup> After several months, she had resection of the arthroplasty and only then did she have gradual improvements in her symptoms.<sup>146</sup> Quantitative concentrations were not reported subsequent to chelation, and it is unclear whether she had continued chelation following the initial dosing before, during, or after revision surgery.<sup>146</sup>

Contrasting the previous cases, there is a single human case report describing the use of dimercaprol in a patient with evidence of arthroprosthetic cobaltism and elevated blood cobalt concentrations.<sup>65</sup> This is a curious choice of chelators because evidence demonstrates its ineffectiveness at reducing cobalt burden in animal models.<sup>107</sup> However, cobalt concentration reduced by 33% and the patient went on to have the arthroplasty resected, resulting in a further 40% reduction of cobalt.<sup>65</sup> Unfortunately, despite the resection and chelation, the patient was unable to be weaned from balloon pump and care was withdrawn.<sup>65</sup>

There is one case report of arthroprosthetic cobaltism with ventricular dysfunction and rapid clinical deterioration following relocation of a dislocated hip.<sup>57</sup> The patient had progressive elevations of her cobalt concentrations and worsening left ventricular function and a metabolic acidosis with elevated lactate concentration. Treatment was initiated with NAC and she

was due to receive a revision, but subsequently died with worsening acidemia and heart failure prior to revision.<sup>57</sup> Because of insufficient data, it is unclear if the NAC had assisted in the reduction of cobalt concentrations.<sup>57</sup> In contrast to this aforementioned case, a 75-year-old patient with arthroprosthetic cobaltism had resolution of both ventricular dysfunction and a pericardial effusion, and reduction of blood cobalt concentrations with intravenous and oral NAC as the sole chelator without concomitant hip revision.<sup>64</sup> There is such variability in the human case reports and chelation approaches that it is difficult to draw any evidence-based recommendations at this point.

In conclusion, based on human case reports, several animal studies, and safety profiles: CaNa<sub>2</sub>EDTA and NAC are reasonable chelating choices. Despite a paucity of data, reasonable indications for chelation include patients who demonstrate end organ manifestations of toxicity. This includes acidemia and cardiac failure. Other manifestations of severe cobalt toxicity such as pericardial effusion, clinically significant goiter, and hyper-viscosity syndrome should be treated as aggressively as are patients from other etiologies—pericardiocentesis, airway protection, and phlebotomy, respectively. Based on years of experience with lead, we recommend the regimen for CaNa<sub>2</sub>EDTA at doses of 1,000 mg/m<sup>2</sup>/day by continuous infusion for 5 days. If the diagnosis is confirmed and signs of cardiac failure and acidemia persist after 5 days, an alternate chelator (succimer or DTPA) can be started. Similarly, we recommend NAC dosing based on the acetaminophen (APAP) experience. The 20-hour intravenous NAC protocol should be initiated, and continued as in the case of fulminant hepatic failure (Antidotes in Depth: A3) for as long as the patient can tolerate therapy, or continued if cardiac failure or acidemia persists. If there are contraindications to intravenous NAC, oral NAC should be administered using one of the APAP treatment regimens. Thiamine hydrochloride should be administered to all patients presenting independent of whether the patient is an alcoholic, had heart failure, or is malnourished. The dose of thiamine is not well defined but should be based on its safety and clinical experience with the treatment of Wernicke encephalopathy. We recommend the administration of 500 mg intravenously of thiamine 3 times daily for 2 to 3 days and 250 mg intravenously daily for the next 3 to 5 days for life-threatening manifestations (cardiac failure and acidemia) (Antidotes in Depth: A27).

### Arthroprosthetic Cobaltism

The key to treatment of this entity is early clinical suspicion with the constellation of findings of cardiomyopathy, hypothyroidism, polycythemia, and peripheral and central nervous system impairment. Early arthroprosthetic revision supports the decontamination tenets within this text and published in case reports,<sup>20,112,128,135,176</sup> however emergent revisions may not be practical in a patient who is acutely ill. Therefore, the only modality of treatment other than a supportive one is chelation. However, based on the limited literature, it is unclear if chelation eliminates significant quantities of cobalt in the presence of a large reservoir of metal.

### Occupational/Chronic Exposure

As is always the case of occupational poisonings, prevention is of paramount importance. The use of skin and respiratory protection and improvement of personal hygiene reduces exposure and subsequently the amount of urinary cobalt in occupationally exposed workers.<sup>102</sup> Barrier and emollient creams cannot prevent the dermatitis associated with cobalt metal exposures.<sup>54</sup>

Large statistically significant reductions in urinary cobalt concentrations were demonstrated after the implementation of aspirator systems over machines in the production of Widia-steel.<sup>29</sup> These aspirators were found to reduce ambient cobalt concentrations by as much as a factor of 6.<sup>50</sup>

### SUMMARY

- Acute cobalt toxicity results in multiorgan toxicity, including the cardiac, endocrine, hematopoietic, gastrointestinal, and neurologic systems.
- The literature regarding metal-containing hip prostheses is focused on preventing, detecting, and treating implant failures and does not address toxicity.

- Arthroprosthetic cobaltism is unique in that there is a large reservoir of metal, and the clinical presentation is subacute and often mistaken for other disease processes.
- The evaluation and treatment of all patients will be determined by the cobalt source and type (elemental, inorganic, or organic), route of poisoning, and time and duration of exposure.
- Treatment of patients with chronic occupational exposures is mainly symptomatic and is often dependent on improving industrial hygiene and removal from the source.
- Acute poisoning with end-organ manifestations requires aggressive decontamination and chelation therapy utilizing CaNa<sub>2</sub>EDTA and NAC and at times succimer is reasonable.

# COPPER

Lewis S. Nelson

## Copper (Cu)

Atomic number	=	29
Atomic weight	=	63.5 Da
Normal concentrations		
Whole blood	=	70–140 mcg/dL (11–22 mmol/L)
Total serum	=	120–145 mcg/dL (18.8–22.8 mmol/L)
Free serum	=	0.1–7 mcg/dL (0.02–1.1 mmol/L)
Ceruloplasmin	=	20–50 mg/dL (1–4 mmol/L)
Urine	=	25–50 mcg/d (0.4–0.8 mmol/24 d)

## HISTORY AND EPIDEMIOLOGY

Copper is available in nature as elemental copper or as one of its sulfide or oxide ores. Important ores include malachite ( $\text{CuCO}_3 \cdot (\text{OH})_2$ ), chalcocite ( $\text{Cu}_2\text{S}$ ), cuprite ( $\text{Cu}_2\text{O}$ ), and chalcopyrite ( $\text{CuFeS}_2$  or  $\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$ ). Chalcopyrite, a yellow sulfide ore, is the source of 80% of the world's copper production. The smelting, or separation, of copper ores began about 7,000 years ago; copper gradually assumed its current level of importance at the start of the Bronze Age, around 3000 B.C. Smelting begins with roasting to dry the ore concentrate, which, in more modern times, is further purified by electrolysis to a 99.5% level of purity. The sulfide ores have naturally high arsenic content, which is released during the extraction process, posing a risk to those who smelt copper.

Although acute copper poisoning is uncommon in the United States, the historical role of copper as a therapeutic remains noteworthy. Copper sulfate was used in burn wound debridement until cases of systemic copper poisoning including hemolysis were reported.<sup>50</sup> In one report, each wound debridement procedure was associated with an 8% to 10% fall in the hematocrit. In the 1960s, copper sulfate (250-mg dose, containing 100 mg copper ion) ironically was recommended as an emetic, typically for use in children following potentially toxic exposures.<sup>59</sup> It was recognized for its speed of onset and effectiveness, and it compared favorably with syrup of ipecac. However, copper-induced emesis was rapidly identified to be extremely dangerous, and this practice was generally discontinued,<sup>67</sup> although fatal cases still occur. Copper salts are administered in religious rituals as a blue-green-colored “spiritual water,” containing 100–150 g/L of copper sulfate as an emetic to “expel one’s sins.”<sup>109</sup>

Copper sulfate is used as a fungicide and algicide, and to eradicate tree roots that invade septic, sewage, and drinking water systems. Copper oxide, in combination with salts of chromium and arsenic (chromated cupric arsenate {CCA}), was used as an outdoor wood preservative, despite concerns over environmental arsenic contamination and has since been removed from the market.<sup>20</sup> Copper sulfate is the most readily available compound and is the form involved in the majority of nonindustrial copper exposures. Copper sulfate was a favorite ingredient in many home chemistry sets because of its brilliant blue color when dissolved in water. Although serious poisoning, particularly in children, led regulatory agencies in the United States to restrict its use, it accounts for the most consequential chemistry set–related toxic exposures reported in other countries.<sup>78</sup> Similarly, homegrown copper sulfate crystals from kits are occasionally responsible for fatal poisonings.<sup>42</sup>

Acute or chronic copper poisoning occurs when the metal is leached from copper pipes or copper containers. This occurs when carbon dioxide gas, used for postmix soft drink carbonation, backflows into the tubing transporting water to the soda dispensers, creating an acidic solution of carbonic acid that leaches copper from the equipment pipes.<sup>121</sup> Similarly,

storage of acidic potable substances, such as orange or lemon juice, in copper vessels causes copper poisoning. A particularly dangerous situation occurs when acidic water is inadvertently used for hemodialysis.<sup>33,73</sup> In this circumstance, the leached copper avoids the normal gastrointestinal barrier and is delivered parenterally to the patient’s circulation. In one case series, the copper concentration in the dialysis water was 650 mcg/L, causing several poisonings and the death of a patient with a whole blood copper concentration of 2,095 mcg/L.<sup>34</sup> Similarly, stagnant water or hot water, even if not highly acidic, can accumulate copper ions from pipes and cause poisoning.<sup>8,34</sup>

Although most natural water contains a small quantity of copper (4–10 mcg/L), it is tightly bound to organic matter and therefore not orally bioavailable. Copper pipes typically add about 1 mg of copper to the daily intake of an adult. The Environmental Protection Agency guidelines permit up to 1.3 mg/L of copper in drinking water.<sup>28,89</sup>

Metallic copper is ideal for electrical wiring because it is highly malleable. Its electrical conductivity is only exceeded by silver. Similarly, copper’s excellent heat conductivity accounts for its widespread use in cookware. Although the metal is reactive with air, it forms a resistant surface of insoluble copper carbonate on its surface. This water- and air-resistant compound accounts for the green coloration of ornamental roofing and statues. Because copper is a soft metal, it must be strengthened prior to use in structural applications or as a coinage metal. This is most commonly done by the creation of copper alloys. Brass is an alloy of copper that is compounded with as much as 35% zinc. Similarly, bronze contains copper combined with up to 14% tin. Gun metal is an alloy that contains 88% copper, 10% tin, and 2% zinc. Sterling silver and white gold also contain copper.

There is a growing body of knowledge linking copper to the promotion of both physiologic and malignant angiogenesis.<sup>46</sup> In this latter case, copper may enable tumor expansion, invasion, and metastasis. Additionally, copper binding to amyloid fibers in the brain of patients with Alzheimer disease may lead to local oxidative damage and cause the characteristic neurodegeneration.<sup>21</sup> Copper is similarly implicated in the pathogenesis of both Parkinson disease and autism.<sup>23,125</sup>

## CHEMICAL PRINCIPLES

Elemental copper ( $\text{Cu}^0$ ) is a metal although not in itself poisonous, reacts in acidic environments to release copper ions to form either cuprous (I) or cupric (II) compounds. The elemental copper contraceptive intrauterine device (IUD) derives its efficacy from the local release of copper ions.<sup>14</sup> Elemental copper bracelets worn by patients with rheumatoid arthritis and other ailments purportedly derive their far-reaching “antiinflammatory effect” through dermal copper ion absorption and distribution to affected tissues.<sup>118</sup> Empiric support for this effect is lacking.<sup>97</sup> Local copper ion release is responsible for the occasional case of dermatitis that occurs following skin exposure to copper metal.<sup>51</sup> Ingestion of large amounts of metallic copper, for example as coins, rarely produces acute copper poisoning.<sup>96,124</sup> Poisoning under these circumstances is a result of the release of large amounts of copper ion from copper alloy by acidic gastric contents. Also, inhalation of finely divided metallic copper dust or bronze powder, used in industry and for gilding, produces life-threatening bronchopulmonary irritation, presumably as a consequence of the local release of ions.<sup>44</sup>

The majority of patients suffering from acute copper poisoning are exposed to ionic copper. In copper sulfate, also known as cupric sulfate, the copper atom is in the +2 oxidation state. Cuprous salts, containing copper in the +1 oxidation state, are unstable in water and readily oxidize to the cupric

TABLE 92–1 Important Copper Compounds

Chemical Name	Chemical Structure	Common Name	Notes
Chalcopyrite	CuFeS <sub>2</sub>	Copper iron sulfide	Copper ore; source of 80% of world's copper
Chromated cupric arsenate	35% CuO 20% CrO <sub>3</sub> 45% As <sub>2</sub> O <sub>3</sub>	CCA	Wood preservative <sup>a</sup>
Copper octanoate	Cu(CH <sub>3</sub> (CH <sub>2</sub> ) <sub>6</sub> COO) <sub>2</sub>	Copper soap	Fungicide in home garden products, paint, rot-proof rope, and roofing
Copper triethanolamine complex	Cu{(HOCH <sub>2</sub> CH <sub>2</sub> ) <sub>3</sub> N} <sub>2</sub>	Chelated copper	Algicide
Cupric acetoarsenite	Cu(C <sub>2</sub> H <sub>3</sub> O <sub>2</sub> ) <sub>2</sub> · 3Cu(AsO <sub>2</sub> ) <sub>2</sub>	Paris or Vienna green	Insecticide, wood preservative, pigment <sup>a</sup>
Cupric arsenite	CuHAsO <sub>3</sub>	Swedish or Scheele green	Wood preservative, insecticide <sup>a</sup>
Cupric chloride	CuCl <sub>2</sub>		Catalyst in petrochemical industry
Cupric chloride, basic	CuCl <sub>2</sub> · 3Cu(OH) <sub>2</sub>	Basic copper chloride; copper oxychloride	Fungicide
Cupric hydroxide	Cu(OH) <sub>2</sub>	Copper hydroxide	Fungicide
Cupric oxide	CuO	Black copper oxide; tenorite	Glass pigment, flux, polishing agent
Cupric sulfate	CuSO <sub>4</sub>	Roman vitriol, blue vitriol, bluestone, hydrocyanite	Fungicide, plant growth regulator, white wash, homegrown crystals
Cupric sulfate, basic	CuSO <sub>4</sub> · 3Ca(OH) <sub>2</sub> · 3CaSO <sub>4</sub>	Bordeaux solution	Fungicide
Cuprous cyanide	CuCN	Cupricin	Electroplating solutions
Cuprous oxide	Cu <sub>2</sub> O	Red copper oxide, cuprite	Antifouling paint

<sup>a</sup>No longer used in the United States.

form. There are numerous copper salts with varying oxidation states used in industry and agriculture (Table 92–1), many of which are not poisonous. Because those salts that are water soluble are more likely to be toxic, it is important to determine the nature of the copper compound implicated in an exposure. Analogously, when interpreting the literature, it is critical to discern which form of copper is involved in the study or case report before applying the results to clinical practice.

## PHARMACOLOGY AND PHYSIOLOGY

Copper is an essential metal with total body stores of 100–150 mg. Daily requirements for copper are approximately 50 mcg/kg in infants and 30 mcg/kg in adults. The average daily intake of copper in the United States noted in NHANES III is about 1.2 mg.<sup>35</sup>

The daily nutritional requirement is satisfied by eating nuts, fish, and green vegetables such as legumes, although our largest source is generally from drinking water. Copper deficiency is exceedingly rare even in the poorest communities, and most frequently results from excessive zinc intake.<sup>82</sup> A Genetic disorder, Menkes “kinky-hair” syndrome, results in impaired intestinal copper absorption. Menkes syndrome is characterized by mental retardation, thermoregulatory dysfunction, hypopigmentation, connective tissue abnormalities, and pili torti (kinky hair). Interestingly, with the increased focus on the role of copper in neurodegenerative disorders and cancer, some authors suggest intentionally depleting patients of their copper stores with tetrathiomolybdate, an experimental copper chelator.<sup>39</sup> There is currently inadequate evidence to support this approach.

Copper is absorbed by an active process involving a copper adenosine triphosphatase (CuATPase) in the small intestinal mucosal cell membrane, also known as the Menkes ATPase (see below). The gastrointestinal absorption varies with the copper intake and the food source and is as low as 12% in patients with high copper intake.<sup>47</sup> In the presence of damaged mucosa, such as following acute overdose, the fractional absorption is likely to be significantly higher.<sup>68</sup> Once absorbed, copper is rapidly bound to high-affinity

carriers such as ceruloplasmin, and low-affinity carriers such as albumin, for transport to the liver and other tissues.<sup>119</sup> The amount of unbound ionized copper in the blood under normal circumstances is well below 1%. After being released locally in the reduced form from its carrier, copper uptake by the hepatic cells occurs via a specific uptake pump.<sup>99</sup> This process, which is facilitated by the reducing agent ascorbic acid, provides a potential window, however brief, for elimination of the ion by chelators. In acute overdose, a high fraction of the plasma copper remains bound to low-affinity proteins, such as albumin, and thus is biologically active. The volume of distribution of copper is 2 L/kg.

In the hepatocyte, complex trafficking systems exist (involving ceruloplasmin, metallothionein, and other metallochaperones {carrier proteins} within the cytoplasm) to prevent copper toxicity and to aid delivery to the appropriate enzymes.<sup>94</sup> A distinct CuATPase, located on certain subcellular organelles such as the *trans*-Golgi network or pericanalicular lysosomes, assists in the appropriate localization and elimination, respectively, of the metal ion.<sup>120</sup> By this mechanism, copper is either incorporated into enzymes or released, as a metallothionein–copper complex, directly into the biliary system for fecal elimination.

Some copper released from the liver is bound primarily to ceruloplasmin, an  $\alpha_2$ -sialoglycoprotein with a molecular weight of 132,000 Da. Ceruloplasmin-bound copper accounts for approximately 90% to 95% of serum copper. Ceruloplasmin is a multifunctional protein that binds 6 copper ions per molecule. Copper bound to this carrier has a plasma half-life of approximately 24 hours. Ceruloplasmin is also involved in the mobilization of iron from its storage sites, and it serves an analogous role as a ferroxidase during the ferrous–ferric conversion. Copper in the Cu<sup>+</sup> form is oxidized directly by ceruloplasmin, thereby bypassing the generation of reactive oxygen species.

There are several important copper-containing enzymes in humans (Table 92–2). The common link among these enzymes is their participation in redox (reduction–oxidation) reactions in which a molecule, typically

**TABLE 92–2** Important Copper-Containing Enzymes and Proteins and Their Functions

Enzyme or Protein	Function
Alcohol dehydrogenase	Alcohol metabolism
Catalase	Peroxide detoxification
Ceruloplasmin enzymes	Copper transport, ferroxidase
Cytochrome C oxidase	Complex IV of electron transport chain
Dopamine β-hydroxylase	Dopamine conversion to norepinephrine
Factor V	Coagulation system cofactor
Lysyl oxidase	Cross-linkage of collagen and elastin precursors
Monoamine oxidase	Primary amine deamination
Superoxide dismutase	Free radical detoxification
Tyrosinase	Melanin production (rate-limiting step)

oxygen, donates or shares its electrons with another compound. In this respect, the physiology, chemistry, and toxicology of copper are most similar to that of iron. In fact, “blue-blooded” animals, such as octopi and spiders, use copper in hemocyanin, a blue pigment, in an analogous manner that “red-blooded” animals use iron in hemoglobin.

The elimination of copper occurs predominantly through biliary excretion following complexation with ceruloplasmin. Biliary excretion approximates gastrointestinal absorption, and averages 2 mg/24 h.<sup>94</sup> Renal elimination under normal conditions is trivial, accounting for approximately 5 to 25 mcg/24 h. The elimination  $t_{1/2}$  of erythrocyte copper is 26 days.

Copper in water is tasted at concentrations of 1 to 5 mg/L, and a blue-green discoloration is imparted when the concentrations are greater than 5 mg/L.<sup>32</sup> Acute gastrointestinal symptoms occur when drinking water contains more than 25 mg/L,<sup>52</sup> although concentrations as low as 3 mg/L are associated with abdominal pain and vomiting in many, without a rise in the serum copper concentrations.<sup>93</sup> In one blinded, randomized study comparing copper-adulterated water to pure water, women appeared more sensitive than men to copper, but both groups were symptomatic when the copper concentration in the water was 6 mg/L.<sup>7</sup>

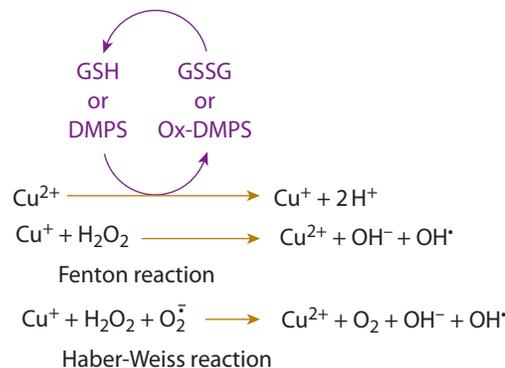

## TOXICOLOGY AND PATHOPHYSIOLOGY

### Redox Chemistry

Because copper is a transition metal, it is capable of assuming one of several different oxidation (or valence) states, and it is an active participant in redox reactions. In particular, participation in the Fenton reaction and the Haber–Weiss reaction explains the toxicologic effects of copper as a generator of oxidative stress and inhibitor of several key metabolic enzymes (Table 10–2).<sup>56</sup> In the presence of sulfhydryl-rich cell membranes, such as those on erythrocytes, cupric ions are reduced to cuprous ions, which are capable of generating superoxide radicals in the presence of oxygen.<sup>63</sup> This one-electron reduction of oxygen regenerates the cupric ion, allowing redox cycling and continuous generation of reactive oxygen species (Fig. 92–1). In particular, the mitochondrial electron transport chain and lipid membranes serve as ready sources of electrons for copper reduction, establishing a chain of events that ultimately leads to mitochondrial or membrane dysfunction, respectively.<sup>81</sup>

### Erythrocytes

Cupric ion inhibits sulfhydryl groups on enzymes in important antioxidant systems, including glucose-6-phosphate dehydrogenase and glutathione reductase.<sup>102</sup> However, although support for these effects is only indirect, intraerythrocytic concentrations of reduced glutathione fall demonstrably following copper exposure. This effect is presumably part of the

**FIGURE 92–1.** In the cupric or  $\text{Cu}^{2+}$  state, copper is reduced by sulfhydryl-containing compounds such as glutathione (GSH) or the chelator 2,3-dimercapto-1-propanesulfonic acid (DMPS) to its cuprous form ( $\text{Cu}^+$ ), forming disulfide links in the process. Oxidized glutathione (GSSG) is subsequently enzymatically reduced by glutathione reductase to regenerate GSH. Superoxide anions  $\text{O}_2^-$ , formed when molecular oxygen ( $\text{O}_2$ ) acquires an additional electron, are continually generated by mitochondria. Both the Fenton and the Haber–Weiss reactions use the cuprous form of copper as a catalyst to convert hydrogen peroxide or superoxide radical into the more biologically consequential hydroxyl radical ( $\text{OH}^\cdot$ ).

protective role that glutathione, a nucleophile or reducing agent, normally has on oxidants, such as either cupric ions or the reactive oxygen species they generate.<sup>75,76</sup> Thus, in the setting of copper poisoning, in which excessive quantities of oxidants are produced, the depletion of glutathione presumably augments peroxidative membrane damage.

The importance of hemoglobin-derived reactive oxygen species is demonstrated by the lack of hemolysis in the presence of copper under anaerobic conditions or in an environment saturated with carbon monoxide.<sup>11</sup> The *in vitro* hemolytic activity of copper sulfate is reduced by albumin and several sulfhydryl containing compounds, including D-penicillamine and succimer.<sup>1</sup> Interestingly, 2,3-dimercapto-1-propanesulfonic acid (DMPS), another sulfhydryl containing compound often used as a chelator, exacerbates copper-induced hemolysis. This paradoxical effect is variably attributed to concomitant inhibition of superoxide dismutase, an important antioxidant enzyme, or to the ability of DMPS to efficiently reduce either membrane dithiols or cupric ions, in either case increasing the generation of superoxide.<sup>2</sup>

Hemolysis frequently occurs within 24 hours following acute copper salt poisoning.<sup>109</sup> This rapidity of hemolysis differs markedly from most other oxidant stressors, which usually take several days, and is likely a result of the differing nature of the erythrocyte insult. That is, the hemolysis following most oxidant exposures is caused by precipitation of hemoglobin as Heinz bodies and subsequent erythrocyte destruction by the reticuloendothelial system. Hemoglobin precipitation can also occur in the setting of acute copper poisoning, particularly following less substantial exposure. Additionally, and accounting for the early hemolysis, copper also directly oxidizes the erythrocyte membrane, thereby initiating red cell lysis independently of the reticuloendothelial system.<sup>101</sup> Oxidant-induced disulfide cross-links in the erythrocyte membrane reduce its stability and flexibility, thereby predisposing to early cell rupture.<sup>3</sup>

Copper-induced oxidation of the heme iron within the erythrocyte produces methemoglobinemia.<sup>79</sup> Given the high incidence of hemolysis, the methemoglobin is commonly released within the plasma. In this situation, methylene blue does not reliably reduce the ferric iron.<sup>115,123</sup>

### Liver

Although most of the accumulated copper ions in hepatocytes are rapidly complexed with metallothionein, unsequestered copper ions participate in redox reactions. Hepatic cells are protected from copper toxicity *in vitro* after induction of metallothionein with zinc or cadmium salts or by the infusion of metallothionein prior to exposure. These interventions demonstrate the toxicologic significance of free intracellular ionic copper. These findings also

explain the therapeutic use of zinc acetate in patients suffering from Wilson disease. This benefit derives from the fact that reliably zinc induces the synthesis of hepatic metallothionein whereas ionic copper itself does not.

Copper ions also generate hydroxyl radicals, which are potent inducers of both lipid peroxidation and other reactive oxygen species. The peroxidative effect on biologic membranes is more significant in animals deficient in vitamin E and is prevented by vitamin E replacement, presumably because of the role of vitamin E as a free radical scavenger.<sup>107</sup> These effects are most pronounced in mitochondria, perhaps as a consequence of the reduction of cupric to cuprous ion in these organelles.<sup>41,108</sup> Ionic copper also accumulates in the cellular nuclei, where localized production of hydroxyl radicals forms DNA adducts and causes apoptosis.<sup>100</sup> Histologically, liver damage follows a centrilobular pattern of necrosis (Chap. 21).

The sequelae of the potent hepatotoxic effects of copper are not isolated to the liver. Once liver necrosis occurs, massive release of ionic copper into the blood occurs, which at times is of sufficient magnitude to cause hemolysis. This sequence of events is common during the crises of Wilson disease, and allows for an understanding of the delayed secondary episode of hemolysis that occurs in some ionic copper-poisoned patients.

### Kidney

The kidneys bioaccumulate ionic copper although it is primarily bound to metallothionein. Reactive oxygen species are probably also responsible for the nephrotoxic effects of unbound copper. Pathologic analyses of the kidneys of oliguric or anuric copper poisoned patients typically reveal acute tubular necrosis and demonstrate hemoglobin casts. These findings suggest that kidney failure results indirectly from the hemoglobinuria induced by the massive release of free extracellular hemoglobin. The urinary hemoglobin, like myoglobin, will undergo conversion to ferriheme or release its iron, both of which result in oxidative stress on the renal tubular epithelial cells. Additionally, free extracellular hemoglobin causes renal vasoconstriction through the local scavenging of nitric oxide within the renal arterioles.

### Central Nervous System

Charged entities such as copper ions do not readily cross the blood-brain barrier, whereas elevated cerebrospinal fluid ionic copper concentrations are characteristic of chronic copper overload conditions such as Wilson disease.<sup>110</sup> This accumulation is accomplished through carrier-mediated transport of albumin-bound, not ceruloplasmin-bound, ionized copper into the central nervous system. Once in the central nervous system, oxidative damage, as occurs in other tissues, results in cellular dysfunction and destruction.<sup>95</sup>

## CLINICAL MANIFESTATIONS

### Acute Copper Poisoning

The acute lethal dose following a single ingestion of copper sulfate is estimated to be 0.15 to 0.3 g/kg, but this is unverified.<sup>6</sup> Gastrointestinal irritation is the most common initial manifestation of copper salt poisoning. This syndrome includes the rapid onset of emesis and abdominal pain, possibly followed by gastroduodenal hemorrhage, ulceration, or perforation. Blue coloration of the vomitus does occur following the ingestion of certain copper salts, particularly copper sulfate.<sup>80</sup> Blue vomitus is not, however, pathognomonic for copper poisoning and also occurs in patients who ingest boric acid, methylene blue, paraquat (due to an additive), or food dyes. Other common symptoms include retrosternal chest pain and a metallic taste.

Given its location within the gastrointestinal tract, the liver receives the most substantial systemic exposure to ingested ionized copper. In patients with more severe acute copper sulfate poisoning, hepatotoxicity is a frequent, although rarely an isolated, manifestation. Jaundice, while among the most common clinical and biochemical findings following overdose, can be hepatocellular necrosis or hemolytic in origin.<sup>9</sup>

Hemolysis is more common than hepatotoxicity, and occurs invariably in those patients with liver damage.<sup>106</sup> As noted, copper-induced hemolysis often occurs rapidly following exposure (see Pathophysiology above

and Chap. 20). In most reported cases, significant methemoglobinemia occurs early in the patient's clinical course and is rapidly followed by hemolysis. Because free methemoglobin is filterable, methemoglobinuria occurs, although it cannot be differentiated from other heme forms in the urine without specialized testing.

Kidney and lung toxicities occur occasionally and represent extra-erythrocytic manifestations of the oxidative effects of the copper ions. In spite of massive intravascular hemolysis, hemoglobinuric acute kidney injury is uncommon in patients who receive adequate volume-replacement therapy.<sup>26</sup>

Hypotension and cardiovascular collapse occur in patients with the most severe poisoning and is likely multifactorial in origin.<sup>105</sup> Undoubtedly, intravascular volume depletion from vomiting and diarrhea is involved. However, the severity and poor patient outcome despite appropriate volume repletion suggest that direct effects of ionized copper on vascular and myocardial cells are also involved. Sepsis, as a result of transmucosal bacterial invasion from the gastrointestinal tract, can also be partially responsible.<sup>68</sup>

Depressed mental status, which ranges from lethargy to coma, or seizures following acute poisoning, is likely an epiphenomenon related to damage to other organ systems. These findings are particularly common in patients with hepatic failure and are comparable to those of hepatic encephalopathy from other causes. In patients with chronic copper poisoning, such as Wilson disease, neurologic manifestations are prominent, and typically involve movement disorders (see Chronic Copper Poisoning below).

Intravenous injection of copper sulfate produces a clinical syndrome identical to that which occurs following ingestion, although the gastrointestinal findings are less pronounced.<sup>13</sup> Subcutaneous administration of a veterinary copper glycinate solution in a patient with a suicide attempt produced localized skin necrosis.<sup>87</sup>

Inhalation of copper oxide fumes, generated during welding or other industrial processes, can produce metal fume fever, a syndrome historically called "brass chills" or "foundry workers' ague." Patients with this syndrome present with cough, chills, chest pain, or fever that are most likely immunologic, and not toxicologic, in origin (Chap. 121). However, copper oxide formation, unlike zinc oxide, only occurs at extremely high temperatures, accounting for the relative infrequency of the copper-induced metal fume fever.

### Chronic Copper Poisoning

Although hepatolenticular degeneration, known as Wilson disease, is a condition of chronic copper overload, there are qualitative similarities to acute copper salt poisoning. Wilson disease is an inherited, autosomal recessive disorder of copper metabolism affecting approximately 1 in 40,000 persons. The gene implicated in this disease (*ATP7B*, copper-transporting ATPase 2) codes for a hepatocyte membrane-bound copper-binding protein that is required for the maturation of ceruloplasmin and the biliary excretion of copper. Transgenic replacement models, in which human *ATP7B* is expressed in deficient animals, demonstrate normalization of copper excretion.<sup>74</sup> The absence of this gene and the resultant increase in hepatic copper concentrations produce continuing oxidative stress on the hepatocyte and cellular necrosis with the inevitable development of cirrhosis. Patients undergo periodic fluctuations in the extent of their copper-induced hepatotoxicity, and episodes of severe hepatotoxicity are frequently associated with hemolysis as stored copper is released from dying hepatocytes.

The adverse effects of ionized copper deposition in the lenticular nucleus in the basal ganglia cause movement disorders such as ataxia, tremor, parkinsonism, dysphagia, and dystonia.<sup>69,85</sup> No other forms of copper salt poisoning are associated with substantial or direct neurotoxicity. Psychiatric manifestations, such as behavioral changes or mood disorders, also occur. Accumulation of copper within the cornea accounts for the characteristic green-brown Kayser-Fleischer rings. Although the patient's serum copper concentrations are decreased, the individuals typically have a reduced ceruloplasmin concentration and an elevated urinary copper concentration. Treatment involves lifelong therapy with chelators such as D-penicillamine, trientine (triethylene tetramine), or molybdenum salts if the patient is

D-penicillamine sensitive. Zinc acetate, U.S. Food and Drug Administration (FDA) approved as a maintenance therapy, induces the formation of intestinal metallothionein and thereby blocks copper absorption by enhancing intestinal mucosal cell sequestration. Orthotopic liver transplantation results in improvement in nearly all aspects of the disease, including the central nervous system and ophthalmic manifestations.<sup>98</sup>

Chronic exogenous copper poisoning is uncommon in adults, but is reported following the use of copper-containing dietary supplements.<sup>84</sup> However, subacute or chronic exposure is common in children in some parts of the world. This condition, commonly called childhood cirrhosis in India or idiopathic copper toxicosis elsewhere, generally occurs in the setting of excessive dietary intake of copper because of copper-contaminated water from brass vessels used to store milk. These children have a genetic predisposition to copper accumulation, as signs of chronic liver disease develop by several months of age and progress rapidly.<sup>55,83</sup> Both serum copper and ceruloplasmin concentrations are markedly elevated, which differentiates this disease from Wilson disease. The incidence of the disease has fallen dramatically, probably as a result of improved nutrition and replacement of copper utensils and storage containers with those made of steel. One family of four developed abdominal pain, malaise, tachycardia, and anemia after approximately one month of eating home-grown vegetables treated with copper oxychloride pesticide.<sup>43</sup> Each patient had anemia and a slightly elevated (or upper limit of normal) serum copper concentration.

“Vineyard sprayer’s lung,” first described in 1969, refers to the occupational pulmonary disease that occurred among Portuguese vineyard workers applying Bordeaux solution, a 1% to 2% copper sulfate solution containing both hydrated lime {Ca(OH)<sub>2</sub>} and calcium sulfate.<sup>90</sup> The patients developed interstitial pulmonary fibrosis and histiocytic granulomas containing copper. Many of these workers also developed pulmonary adenocarcinoma, hepatic angiosarcoma, and micro-nodular cirrhosis, raising the possibility of a carcinogenic effect of long-term copper exposure.<sup>91</sup> There is also a suggestion of an increased incidence of pulmonary adenocarcinoma among smelters, who are, however, exposed to many other xenobiotics, including arsenic, a known carcinogen.<sup>70</sup> No forms of copper are on the list of suspected carcinogens compiled by the International Agency of Research on Cancer.

Ophthalmic effects of copper salts, primarily following occupational exposure, include irritation of the corneal, conjunctival, or adnexal structures. Chronic ophthalmic exposure to particulate elemental copper or one of its alloys results in chalcosis lenticis, from the Greek word *chalkos*, or copper. This chronic exposure manifests as a green-brown discoloration of the lens or cornea, similar to Kayser–Fleischer rings.

## DIAGNOSTIC TESTING

Real-time testing for copper is impractical, and almost all management decisions must be based on clinical criteria. Copper concentrations are often obtained for confirmatory or investigative purposes. Although never adequately studied, whole-blood copper concentrations appear to correlate better with clinical findings than do serum copper concentrations.<sup>4</sup> The rapid movement of copper from serum into the erythrocyte presumably explains this finding. However, although there is a statistical relationship between the whole-blood copper concentrations and the severity of poisoning,<sup>4,117</sup> there is little correlation between clinical findings at any given copper concentration, regardless of which biologic tissue is measured. Similarly, other than at extremely high or low concentrations, there is no concentration at which the prognosis is definitively established. Reported serum copper concentrations in patients with hemolysis range from 96 to 747 mcg/dL, and those following severe poisoning have values of 6,600 mcg/dL<sup>42</sup> and 8,267 mcg/dL.<sup>27</sup> Serum copper concentrations in 11 patients with copper-induced acute kidney injury ranged from 115 to 390 mcg/dL.<sup>25</sup> The normal urinary copper excretion per 24 hours is up to approximately 25 mcg, and is reportedly as high as 628 mcg/24 h in patients with copper poisoning.

Occasionally serum copper concentrations reveal a secondary rise, which likely results from release during hepatocellular necrosis. This secondary

rise typically occurs only in patients with life-threatening poisoning, and clinical evaluation is far more important and relevant than serial copper concentrations.<sup>106</sup>

Elevated copper concentrations are also noted in patients with inflammatory conditions, biliary cirrhosis, pregnancy, and estrogenic oral contraceptive use.<sup>22</sup> These conditions are associated with an elevated ceruloplasmin, and while the serum copper concentrations rise, the fraction of bound copper in the serum remains normal. Copper concentrations in the erythrocyte remain normal. Patients with Wilson disease have elevated hepatocyte copper content, but their serum copper concentrations are generally below normal unless hepatic necrosis is occurring.<sup>71</sup>

Although serum ceruloplasmin concentrations rise in patients with acute copper poisoning,<sup>117</sup> presumably reflecting increased hepatic synthesis, the ceruloplasmin concentration cannot be used to define the patient’s prognosis. Tissue metallothionein concentrations also commonly rise after copper poisoning, but the implication of this finding, which is limited by the inability to rapidly obtain tissue samples, is unknown.<sup>65</sup> Ceruloplasmin concentrations are low in patients with Wilson disease, reflecting aberrant enzymatic activity.

Routine laboratory testing following acute copper salt poisoning should include an assessment for both hemolysis and hepatotoxicity. Differentiation of these etiologies as a cause for jaundice is made by standard methodology, such as comparison of the bilirubin fractions and an assessment of the hepatic enzymes and hemoglobin; that is, indirect bilirubin is proportionally elevated in patients with hemolysis, whereas the direct fraction rises in patients with hepatocellular necrosis. An assessment of the patient’s electrolyte and hydration status is warranted. The prothrombin time can be prolonged in the absence of liver injury or disseminated intravascular coagulopathy and is likely the result of a direct effect of copper ions on the coagulation cascade.<sup>79</sup> In addition, many reports document an abnormal glucose 6-phosphate dehydrogenase (G6PD) activity, suggesting causation for hemolysis. However, interpretation of this test result is difficult, as copper poisoning interferes with the measurement of G6PD.<sup>36</sup>

Although copper metal embedded in the skin is clearly visible, topically applied copper salts are not visualized.<sup>15</sup> The clinical usefulness of radiographs to identify ingested copper salt solutions is unstudied. Obtaining an abdominal radiograph, while probably of limited benefit, is justified because it occasionally demonstrates the presence of radiopaque material in the gastrointestinal tract. Early efforts to use magnetic resonance imaging to identify Wilson disease are under way.<sup>95</sup>

## MANAGEMENT

Supportive care is the cornerstone to the effective management of patients with acute copper salt poisoning, emphasizing antiemetic therapy, fluid and electrolyte correction, and normalization of vital signs prior to the evaluation for chelation therapy. Gastrointestinal decontamination is of limited concern because the onset of emesis generally occurs within minutes of ingestion and is often protracted. In patients who present for health care prior to vomiting following ingestion of a liquid copper solution, aspiration with a nasogastric tube to remove copper ion is a reasonable option. In one case, even after extensive vomiting, nasogastric aspiration still removed blue solution, but removing this remaining volume is unlikely to provide significant clinical benefit and should not be done.<sup>17</sup> Although oral activated charcoal is unlikely to be harmful, it is of unproved benefit, and it will hinder the ability to perform gastrointestinal endoscopy to evaluate the corrosive effects of a copper salt on the mucosal surface.<sup>17</sup> For this reason, even though activated charcoal may adsorb the remaining copper in the proximal gastrointestinal tract, we recommend against administering it to patients with isolated copper salt exposures. The potential benefit of *N*-acetylcysteine has not been studied, although its usefulness in many forms of fulminant hepatic failure support its empiric use. Advanced therapy for patients with acute kidney injury includes hemodialysis, using the usual criteria. For patients with life-threatening hepatic failure, liver transplantation is a reasonable option,

but specific criteria for transfer to a specialized liver unit or for transplant, other than those that are applicable for Wilson disease or other more common, noncopper etiologies, are undefined.

### Chelation Therapy

Chelation therapy is recommended when hepatic or hematologic compromise or other concerning or severe manifestations of poisoning are present. Studies on the efficacy of chelation therapy following acute copper salt poisoning are limited. Even when chelation is initiated early and appropriately, organ damage and death still occur. Application of the data from the existing literature is difficult because of the lack of controlled therapeutic studies of human copper salt poisoning. Although experimental animal models and uncontrolled human data exist, the results are frequently contradictory. Fortunately, exhaustive research into diseases of copper metabolism, particularly Wilson disease, which has periodic exacerbations similar to acute copper poisoning, has provided insight into managing patients with acute copper salt poisoning. However, direct applicability remains uncertain.

Three chelators are clinically available, and most data regarding dosing and efficacy are derived either from their use in the treatment of patients with Wilson disease or from their effects on copper elimination during chelation of patients manifesting toxicity from other metals.

D-Penicillamine, a structurally distinct metabolite of penicillin, is an orally bioavailable monothiol chelator. It is used in the treatment of lead, mercury, and copper poisoning, as well as in the management of rheumatoid arthritis and scleroderma. It has also been investigated for its antiangiogenesis effects in cancer therapy, which occur by chelation of copper that serves as a cofactor for certain growth factors, such as fibroblast growth factor.<sup>113</sup> D-Penicillamine is effective in preventing copper-induced hemolysis in patients with Wilson disease. Its protective mechanism is primarily mediated through chelation of unbound ionized copper, rendering them inaccessible to participate in redox reactions,<sup>61</sup> and dramatically increasing their urinary elimination.<sup>116</sup> The D-penicillamine-copper complex undergoes rapid renal clearance in patients with competent kidneys.

The use of D-penicillamine is not formally studied in the patients with acute copper salt poisoning, but case studies and animal models suggest that copper elimination is enhanced.<sup>19,40,50</sup> For this reason, D-penicillamine is the drug of choice for acute copper salt poisoning. The recommended dose is 1 to 1.5 g/d given orally in 4 divided doses. D-Penicillamine is also indicated for the treatment of chronic copper salt poisoning, such as Indian childhood cirrhosis. Initiation early in the course of disease and discontinuation of the exposure are associated with hepatic recovery and dramatically improved survival rates.<sup>12</sup>

Although D-penicillamine is effective, it is associated with several significant complications. In nearly 50% of patients treated with D-penicillamine for Wilson disease, there is worsening of the neurologic manifestations.<sup>16</sup> Subacute toxicities of D-penicillamine include aplastic anemia, agranulocytosis, renal and pulmonary disease, and loss of trace metals.<sup>53</sup> Long-term use of D-penicillamine is also associated with the development of cutaneous lesions and immunologic dysfunction. However, in the brief treatment necessary for acutely poisoned patients, the major risk is the potential for hypersensitivity reactions that occur in 25% of patients who are penicillin allergic. This hypersensitivity reaction is likely related to contamination of the pharmaceutical preparation with penicillin, rather than immunologic cross-reactivity.<sup>49,58</sup> The use of D-penicillamine during pregnancy is associated with congenital abnormalities, although all of the data are derived from women with Wilson disease who were receiving long-term therapy.<sup>92</sup>

Trientine (triethylenetetramine), another orally bioavailable chelator, is the second-line agent for patients with Wilson disease, but it is generally better tolerated.<sup>54</sup> However, unlike D-penicillamine, its use in patients with acute copper salt poisoning is unstudied. It was studied for its role as a copper chelator in patients with Alzheimer disease.<sup>30</sup> Trientine is generally safe, although colitis is reported.<sup>18</sup> One concern with trientine, as with penicillamine, is an initial neurologic worsening in about 25% of the patients who receive it for Wilson disease.<sup>48</sup>

Although intramuscular British anti-Lewisite (BAL) is likely to be less effective than other chelators described above, its use is appropriate in patients in whom vomiting or gastrointestinal injury prevents oral D-penicillamine administration.<sup>111</sup> Furthermore, because the dimercaprol-copper complex primarily undergoes biliary elimination, whereas D-penicillamine undergoes renal elimination, dimercaprol should be used in patients with acute kidney injury. When tolerated, D-penicillamine therapy should be started simultaneously or shortly after the initiation of therapy with dimercaprol (Antidotes in Depth: A28).

Calcium disodium ethylenediaminetetraacetate (CaNa<sub>2</sub>EDTA) reduces the oxidative damage induced by ionized copper in experimental models.<sup>122</sup> However, it does not greatly enhance the elimination of copper ions when used for the chelation of other metals.<sup>112</sup> In addition, short-term use of CaNa<sub>2</sub>EDTA inactivates dopamine β-hydroxylase in humans, presumably by chelating the copper moiety from its active site.<sup>31</sup> However, because the *in vivo* activity of this enzyme is restored on the addition of copper salt supplement, the potential for inhibition of the formation of neuronal norepinephrine during the treatment of acute poisoning is unknown. Successful clinical use of CaNa<sub>2</sub>EDTA is reported making its use appropriate if other options are not available.<sup>37,86</sup> Interestingly, CuCaEDTA is used as a copper supplement in animals, and overdose of this formulation results in copper poisoning, suggesting that its chelating ability is limited (Antidotes in Depth: A30).<sup>38</sup>

Succimer is sometimes described as an ineffective copper chelator, although it is able to triple the baseline copper elimination in a murine model. Given its ease of use, ready availability, relative safety, and benefit in experimental models,<sup>1</sup> succimer can often be used in lieu of D-penicillamine or trientine in patients with less consequential poisoning, particularly when there is difficulty in obtaining penicillamine. Under these circumstances, it is reasonable to utilize standard lead poisoning succimer dosing regimens. (Chap. 93 and Antidotes in Depth: A29).

Dimercaptopropane sulfonate, an experimental chelator that is gaining popularity for the treatment of arsenic poisoning, prevents acute tubular necrosis in copper-poisoned mice.<sup>77</sup> 2,3-Dimercapto-L-propanesulfonic acid also proved to be the most effective of a panel of chelators in a murine model of copper sulfate poisoning,<sup>57</sup> and it substantially increased urinary copper elimination in nonpoisoned individuals.<sup>114</sup> However, DMPS, unlike D-penicillamine, forms intramolecular disulfide bridges, which, in so doing, liberates an electron. Although this accounts for its potency as a reducing agent, it also probably explains its propensity to worsen copper-induced hemolysis *in vitro*.<sup>2</sup> Because an adequate analysis of risk versus benefit is unavailable we recommend against using DMPS to chelate copper-poisoned patients.

Administration of zinc to induce metallothionein synthesis, which is also of proven, but limited, efficacy in Wilson disease, has an unknown role in the treatment of acute copper poisoning.<sup>103</sup> The need for several weeks of zinc therapy prior to realizing full efficacy makes its therapeutic use in acutely poisoned patients questionable. Although large oral doses of zinc salts can limit the absorption of copper ion, the concomitant gastrointestinal irritant effects of zinc ion make this therapy impractical.

Tetrathiomolybdate, an FDA-recognized chelator with orphan drug status although not marketed, can be available through compounding pharmacies, typically as ammonium tetrathiomolybdate. Tetrathiomolybdate is suggested to benefit copper-poisoned animals in uncontrolled studies,<sup>88</sup> but its use in acute copper poisoning in humans is unstudied and is unlikely to be beneficial. Tetrathiomolybdate depleted the copper stores in a patient with cancer who purchased the compound over the Internet as an “alternative” antiangiogenesis therapy.<sup>66</sup> We do not recommend the use of this inadequately studied antidote.

Clioquinol, a xenobiotic used 50 years ago as an antiparasitic, was discontinued because of an epidemic of optic neuropathy that may have been due to its ability to chelate copper ions.<sup>104</sup> Clioquinol has been more recently investigated as a therapy for Alzheimer disease.<sup>10</sup> It has not been studied for patients with acute or chronic copper poisoning and is not recommended.

## Extracorporeal Elimination

There are limited data regarding the extent to which copper ion is eliminated by various extracorporeal means. Hemodialysis membranes undoubtedly allow the passage of copper ions, based on the epidemics in which hemodialysis using copper-rich water inadvertently resulted in copper poisoning.<sup>33</sup> Although copper should be cleared by hemodialysis, its relatively large volume of distribution limits the potential clinical usefulness of this technique. Furthermore, copper ions are highly protein bound, and the dialyzable concentration is typically less than 1 pmol/L, suggesting that hemodialysis would have little clinical usefulness. This fact is supported by case reports in which serum, tissue, or dialysate concentrations of copper were assessed.<sup>5,86</sup> Furthermore, given the propensity of hemodialysis to lyse erythrocytes, which will release stored copper and potentially worsen toxicity, hemodialysis is not recommended to enhance copper elimination, but it should be used for the standard nephrologic indications.

Molecular Adsorbents Recirculating System (MARS) and Single Pass Albumin Dialysis (SPAD), modified forms of hemodialysis in which albumin is included in the dialysate, are reported to rapidly and substantially lower the serum copper concentrations in patients with fulminant Wilson disease, allowing a bridge to hepatic transplantation.<sup>24,29</sup> One patient was treated with albumin dialysis using a 44 g/L albumin-containing dialysate and a slow dialysate flow rate (1–2 L/h) in a manner similar to routine continuous venovenous hemodiafiltration reportedly removed 105 mg of copper and normalized the serum copper concentration.<sup>62</sup> Caution should be used when extrapolating therapy from Wilson disease to exogenous copper poisoning, but it seems reasonable to utilize this technique if readily available. No evidence exists to support its use in patients with acute copper poisoning and the risk associated with hemolysis likely remains, preventing a recommendation for its use.

Exchange transfusion is of undefined, but probably limited, benefit in acute copper sulfate poisoning.<sup>72,123</sup> Plasma exchange enhanced the elimination of copper in patients with fulminant Wilson disease.<sup>60,62</sup> Copper removal ranged from 3 to 12 mg per treatment, but it is unclear if either of these removal techniques would be beneficial following an ingestion of gram quantities of copper sulfate. The same aforementioned risks of iatrogenic red cell lysis apply. However, in some settings exchange transfusion may be the only available practical therapy and it seem reasonable to attempt.

Peritoneal dialysis is not useful in patients with fulminant Wilson disease.<sup>64</sup> Peritoneal dialysis removed less than 700 mcg in a copper sulfate-poisoned child whose copper concentration was 207 mcg/dL.<sup>45</sup> However, in the same patient, the addition of albumin to the dialysate removed 9 mg of copper at a time when the child's serum copper concentration had already fallen substantially. Given the limited potential for removal of copper ion, this technique is not recommended.

There are no controlled data on the treatment of acute copper poisoning in pregnancy. The available data on pregnant women with Wilson disease document that D-penicillamine is teratogenic and that zinc is the preferred treatment.

## SUMMARY

- The toxic effects of copper salts are primarily mediated by oxidative stress on the erythrocyte and hepatocyte, and this similarity to iron salt poisoning adds a framework for the conceptual understanding of the pathophysiology.
- Chelation is most commonly performed with D-penicillamine if the patient can tolerate oral medications and does not have renal failure, or dimercaprol if either of these findings are present. Both of these chelators have significant adverse effects.
- Succimer is more familiar to most clinicians and has fewer associated adverse effects; therefore, it is a reasonable alternative chelator.
- For patients with findings of impending hepatic failure, consultation or transfer to a liver transplantation center should be initiated.

## LEAD

Diane P. Calello and Fred M. Henretig

<b>Lead (Pb)</b>	
Atomic number	= 82
Atomic weight	= 207.21 Da
Whole blood	< 5 mcg/dL (<0.24 mmol/L)

### HISTORY AND EPIDEMIOLOGY

The low melting point and high malleability of lead made it one of the first metals smelted and used by humans. Ancient Egyptians and Hebrews used lead, and the Phoenicians established lead mines in Spain circa 2000 B.C. The Greeks and Romans released lead during the process of extracting silver from ore. Roman society found many uses for lead, including pipes, cooking utensils, and ceramic glazes, and a common practice was to use sapa, a grape syrup simmered down in lead vessels, as a sweetener and preservative.<sup>139</sup> Postindustrial lead use increased dramatically, and today lead is used widely for its waterproofing and electrical- and radiation-shielding properties.<sup>96</sup> Use of both lead-based paint for house paint and leaded gasoline has been essentially eliminated by regulation in the United States since the 1980s, but is still a concern in many nations, and persistence of lead paint in older US homes and water-supply systems still constitutes an enormous environmental challenge.<sup>4,5,80</sup>

Recognition of the clinical effects of excess lead exposure can be traced back to antiquity. Dioscorides, a Greek physician in the second century B.C., observed adverse cognitive effects, and Pliny cautioned the Romans of the danger of inhaled fumes from lead smelting.<sup>134</sup> Modern authors suggest that extensive use of sapa in Roman aristocratic society contributed to the downfall of Roman dominance.<sup>139</sup> Lead poisoning was also recognized in American colonial times. Benjamin Franklin observed in 1763 the “dry gripes” (abdominal colic) and “dangles” (wrist drop) that afflicted tinkers, painters, and typesetters, as well as the “gripes” caused by rum distillation in leaden condensing coils.<sup>123</sup> Lead salts, particularly lead acetate (sugar of lead), were used medicinally in the early 19th century to control bleeding and diarrhea. With the 19th-century Industrial Revolution, lead poisoning became a common occupational disease. The reproductive effects of lead poisoning were recognized by the turn of the 20th century, including the high rate of stillbirths, infertility, and abortions among women in the pottery industry or who were married to pottery workers.

The majority of health effects that occur today in the United States concern childhood lead poisoning due to residential house paint. In this chapter we will use the synonyms lead poisoning and plumbism interchangeably. The modern history of childhood plumbism can be traced to the recognition of lead-paint poisoning in Brisbane, Australia, in 1897.<sup>134</sup> Lead poisoning was reported in American children in 1917, and by 1943, it was established that children who recovered from clinical plumbism were frequently left with neurologic sequelae and intellectual impairment. Symptomatic childhood lead poisoning was a frequent occurrence in American pediatric medical centers throughout the 1950s and 1960s, a period during which research established effective chelation therapy protocols with British anti-Lewisite (dimercaprol) and edetate calcium disodium (CaNa<sub>2</sub>EDTA).<sup>36,207</sup> From the 1970s to the present, the research thrust in childhood lead poisoning has centered on the recognition and quantification of more subtle neurocognitive impairment caused by subclinical lead poisoning.<sup>19,135</sup> Over this time period, the US Centers for Disease Control and Prevention (CDC) has steadily revised downward the definitions of an elevated blood lead concentration or thresholds of concern in children, from 60 mcg/dL in the early 1960s to 5 mcg/dL today.<sup>28</sup>

Numerous sources of lead exposure exist and are generally classified as perinatal, environmental, occupational, or additional (somewhat “exotic”) sources. Perinatal lead exposures relate to placental transfer and subsequent breast feeding for infants whose mothers have elevated blood lead concentrations.<sup>25</sup> Environmental exposures affect the entire population, particularly young children. Elevated lead concentrations in drinking water are being detected with increasing frequency as plumbing infrastructure ages. However, the health impact of these elevations in drinking water is not yet clear.<sup>14,80</sup> Most environmental lead poisoning of consequence in the United States still results from exposure to residential lead paint (Table 93–1).

Lead pigments (typically lead carbonate) account for up to 40% by weight of many white house paints from the pre–World War II era.<sup>134</sup> Since 1978, paint intended for interior or exterior residential surfaces, toys, or furniture in the United States is allowed, by law, to contain no more than 0.06% lead. However, an estimated 3 million tons of lead remain in 57 million US homes built before 1980 and painted with lead-based paint. This aging housing stock has created an enormous environmental hazard of lead exposure to children and to adult homeowners, house painters, and construction workers who become involved in sanding, scraping, and restoration of painted surfaces in these homes. Furthermore, lead-based paint is still allowed for industrial, military, marine, and some outdoor uses, such as structural components of bridges and highways; occasionally, some of this paint is inadvertently used in homes. Attempts to abate lead-painted outdoor structures can pollute entire communities.<sup>104</sup>

Although paint-derived lead exposure results from overt pica of lead paint chips in some children, most lead paint exposure in childhood relates to the crumbling, peeling, flaking, or chalking of aging paint.<sup>5</sup> These fine paint particles are incorporated into household dust and yard soil, where ordinary childhood hand–mouth activity results in ingestion.<sup>5</sup> Seasonal variations in house dust contamination occur, with higher house dust lead concentrations and increased blood lead concentrations in exposed preschool children noted during the summer.

Adults with occupational exposures to lead constitute another large group of persons at risk. It is estimated that more than 3 million workers in

**TABLE 93–1 Environmental Lead Sources**

Source	Comment
Air	Leaded gasoline (pre-1976 United States; still prevalent worldwide), industrial emissions
Dust	House dust from deteriorated lead paint
Food	Lead solder in cans (pre-1991 United States; still prevalent in imported canned foods); “natural” dietary supplements; “moonshine” whiskey and lead foil-covered wines; contaminated flour, paprika, other imported foods and candy; lead leached from leaded crystal, ceramics, vinyl lunch boxes
Other	Complementary and alternative medicines, children’s toys and jewelry (especially imported products), cosmetics, leaded ink, vinyl mini-blinds
Paint	Especially pre-1978 homes
Soil	From yards contaminated by deteriorated lead paint, lead industry emissions, roadways with high leaded gasoline usage
Water	Leached from leaded plumbing (pipes, solder), cooking utensils, water coolers

the United States, employed in more than 100 occupations, are exposed to lead.<sup>98</sup> The most important route of absorption in occupational settings is inhalation of lead dust and fumes. In addition, ingestion also results when workers eat, drink, or smoke in lead dust–contaminated areas. However, the presence of lead in the workplace, per se, does not imply a significant risk of poisoning. Some types of lead-related work are more hazardous than others (Table 93–2).<sup>2</sup> For example, lead smelting is categorized as primary (from raw ore) and secondary (reclamation, such as from used car batteries). Secondary lead production workers are at higher risk of poisoning because this job

**TABLE 93–2 Occupational and Recreational Lead Sources**

#### High-Risk Occupations

- Automobile radiator repairers
- Crystal glass makers
- Firing range instructors, bullet salvagers
- Lead smelters, refiners
- Metal welders, cutters (includes bridge and highway reconstruction workers)
- Painters, construction workers (sanding, scraping, or spraying of lead paint; demolition of lead-painted sites)
- Polyvinyl chloride plastic manufacturers
- Shipbreakers
- Storage battery manufacturers, repairers, recyclers

#### Moderate-Risk Occupations

- Automobile factory workers and mechanics
- Enamellers
- Glass blowers
- Lead miners
- Plumbers
- Pottery glazers
- Ship repairers
- Shot makers
- Solderers
- Type founders
- Varnish makers
- Wire and cable workers

#### Possible Increased-Risk Occupations

- Electronics manufacturers
- Jewelers
- Pipefitters
- Printers
- Rubber product manufacturers
- Traffic police officers, taxi drivers, garage workers, turnpike tollbooth operators, gas station attendants (exposed to leaded gasoline exhaust fumes; unlikely now in the United States but still a hazard in developing countries)

#### Recreational and Hobby Sources

- Ceramic crafts
- Furniture refinishing, restoring
- Home remodeling, refinishing
- Painting (fine artist's pigments)
- Repair of automobiles, boats
- Stained-glass making
- Target shooting, recasting lead for bullets

#### Additional Sources

- Ingested lead foreign bodies and retained lead bullets
- Illicit substance abuse (heroin, methamphetamine, leaded gasoline “huffing”)
- Burning batteries, leaded paper, or wood for fuel
- Hand–mouth contact with pool cue chalk, glazes, leaded ink

more typically involves small, sometimes “backyard,” operations that are less likely to adhere to industry safety regulations than large, well-regulated primary smelters.<sup>47</sup> A significant hazard exists for workers at firearm shooting ranges, where workplace conditions frequently fail on several fronts to protect workers from lead dust hazards. This is particularly true with the use of unjacketed bullets, the handling of targets after practice that contain splintered fragments and lead dust, and shooting in a prone position.<sup>10,68</sup>

For convenience, environmental and occupational or recreational lead exposures are discussed separately, although there is considerable overlap. For example, workers who fail to change lead dust–covered work clothes or shoes inevitably bring this occupational lead hazard home and secondarily contaminate their children's environment.<sup>161</sup>

Finally, numerous additional sources of lead exposure are also reported, including contaminated folk medications or cosmetics,<sup>95,207</sup> imported food,<sup>79</sup> ingested lead foreign bodies,<sup>124,193</sup> and retained bullets.<sup>58,110,169</sup> Ayurveda and other folk medicine, specifically “rasa shastra,” where heavy metals are incorporated into products for their medicinal value, is a frequent source of lead exposure in children and adults.<sup>26,94,127,164</sup> Since 2010, an outbreak of lead encephalopathy from artisanal gold mining in Nigeria has claimed hundreds of lives, with the toll still growing.<sup>77,184</sup>

Some potential exposures raised considerable community concern and media coverage in recent years—for example, the discovery of lead contamination of some artificial turfs,<sup>31</sup> imported toys coated with lead paint,<sup>111</sup> the disposition of electronic waste,<sup>100</sup> and elevated drinking water concentrations.<sup>14,80</sup> These, too, are highlighted separately in Table 93–2.

Several recent national and regional surveys evaluated current US population-based trends in blood lead concentrations and sociodemographic correlates. The CDC and individual experts estimate that 450,000 to 500,000 children aged 1 to 5 years have blood lead concentrations greater than 5 mcg/dL.<sup>11,32</sup> The 2012 revised reference value representing primarily excessive household exposure, and that in 2013 approximately 5,200 adults are reported each year with blood lead concentrations greater than 24 mcg/dL typically reflecting excessive occupational exposure.<sup>2</sup> Although such numbers are impressive, they represent a considerable decrease from prevalence rates reported in prior decades,<sup>11</sup> and it is certainly the observed clinical experience that symptomatic lead poisoning in children, in particular, is far less common than it was a generation ago. Nevertheless, for children who reside in the deteriorating cities of the United States, the battle is far from won. The CDC reported in 2000 that children enrolled in Medicaid had a prevalence of elevated blood lead concentrations 3 times greater than those not enrolled.<sup>22</sup> Refugee, immigrant, and foreign-born adopted children remain at particularly high risk,<sup>24</sup> and remarkable cases of extremely elevated blood lead concentrations (>100 mcg/dL) are still be detected on routine screening.<sup>46</sup>

## CHEMICAL PRINCIPLES

Lead is a silvery-gray, soft metal ubiquitous element in the Earth's crust, with an atomic weight of 207.21 Da and an atomic number of 82. It has a low melting point, 621.3°F (327.4°C), and boils at 2,948°F (1,620°C) at atmospheric pressure.<sup>192</sup> It occurs principally as 2 isotopes: <sup>206</sup>Pb and <sup>208</sup>Pb. Metallic lead is relatively insoluble in water and dilute acids but dissolves in nitric, acetic, and hot, concentrated sulfuric acids. In compounds, lead assumes valence states of +2 and +4. Inorganic lead compounds are often brightly colored and vary widely in water solubility; several are used extensively as pigments in paints such as lead chromate (yellow) and lead oxide (red). Lead also forms organic compounds, of which 2, tetramethyl and tetraethyl lead (TEL), were used commercially as gasoline additives.<sup>96</sup> These are essentially insoluble in water but readily soluble in organic solvents.<sup>165</sup> Lead complexes with ligands containing sulfur, oxygen, or nitrogen as electron donors. It thus forms stable complexes with several ligands common to biologic molecules, including –OH, –SH, and –NH<sub>2</sub>. Complexes with endogenous sulfhydryl (–SH) groups are the most toxicologically important. There is no known physiologic role for lead, and thus any lead presence in human tissue represents contamination.

## PHARMACOLOGY

### Inorganic and Metallic Lead

#### Absorption

Gastrointestinal (GI) absorption is less efficient than pulmonary absorption. Adults absorb an estimated 10% to 15% of ingested lead in food, and children have a higher GI absorption rate, averaging 40% to 50%.<sup>1,72</sup> In animal studies, this varies by type of lead compound studied.<sup>8</sup> However, it should be noted that fasting and diets deficient in iron, calcium, and zinc—factors that are frequent among groups of young children—enhance GI absorption of lead.<sup>72,116,175</sup> The role of essential trace elements in decreasing lead absorption is assumed to be a consequence of competitive absorption processes, particularly of the apical divalent metal transporter (DMT1) in the small intestine.<sup>100</sup> Metallic lead, such as potentially encountered in fishing weights swallowed by young children or retained bullets in gunshot victims, is also absorbed, albeit less readily than most lead compounds.<sup>8</sup> The rate of absorption of ingested metallic lead is related to particle size, total surface area, and GI tract location; whereas gastric acidity favors dissolution, the small bowel is likely the site of maximal absorption.<sup>193</sup>

The overall absorption of inhaled lead averages 30% to 40%. Of note, both minute ventilation and the concentration of lead in air determine airborne lead exposure, so a worker engaged in vigorous physical activity will absorb considerably more lead than a person in the same atmosphere at rest. Likewise, children, having relatively greater volume of inhaled air per unit of body size because of higher metabolic rates, are proportionally at greater risk in a given degree of atmospheric lead pollution. It is estimated that children have a 2.7-fold higher lung deposition rate of lead than do adults.<sup>1</sup>

Cutaneous absorption of inorganic lead has been traditionally considered low; one study found an average absorption of 0.06% through intact skin.<sup>129</sup> However, a few more recent studies have questioned this dogma and suggest that cutaneous exposure is a potential source of exposure in workers.<sup>61,63,181</sup> Anecdotal cases exist of pediatric lead toxicity ascribed to application of lead-contaminated ethnic cosmetics.<sup>27,128,144</sup> Some of these exposures likely also involve occult conjunctival absorption and ingestion,<sup>144</sup> but given especially the thinner skin of children, it seems plausible that some dermal absorption is occurring in such cases. Soft tissue absorption of metallic lead follows exposure to retained bullets, and similar to ingested lead foreign bodies, also depends on particle size, total surface area, and location; multiple small shot and location in which particles are bathed by synovial, serosal, or spinal fluid favor a more rapid increase in blood lead concentration.<sup>58,110,169</sup> This is most likely due to increased solvency of lead in organic acids, such as hyaluronic acid in synovial fluid, as well as mechanical forces from joint motion.

Transplacental lead transfer is critical in fetal and neonatal lead exposure. Lead readily crosses the placental barrier throughout gestation, and lead uptake is cumulative until birth.<sup>25,154</sup> Breast milk also contains lead in relatively low concentration, and it is a significant source of neonatal exposure at maternal blood lead concentrations of approximately 40 mcg/dL or greater.<sup>9</sup> One study demonstrated that the relationship between breast milk and maternal blood and plasma lead was not linear, although overall breast milk concentrations were still quite low (see also Management, Adults, Pregnancy and Lactation).<sup>53</sup>

#### Distribution

Absorbed lead enters the bloodstream, in which at least 99% is bound to erythrocytes.<sup>113</sup> From blood, lead is distributed into both a relatively labile soft tissue pool and into a more stable bone compartment. This classic 3-compartment model is somewhat of an oversimplification. At least 2 bone compartments are recognized: a more labile pool in trabecular bone and a more stable pool in cortical bone. In adults, approximately 95% of the body lead burden is stored in bone versus only 70% for children. The remainder is distributed to the major soft tissue lead-storage sites, including the liver, kidney, bone marrow, and brain. Lead uptake into soft tissues occurs in a complex fashion that depends on numerous factors, including blood lead concentrations, external exposure factors, and specific tissue kinetics. Most of the toxicity associated

with lead is a result of soft tissue uptake, so that the relative decrease in bone storage is another comparative disadvantage for children.

Lead in the central nervous system (CNS) is of particular toxicologic importance. Lead preferentially concentrates in gray matter and certain nuclei.<sup>73</sup> Fetal brain uptake is relatively higher than that which occurs with postnatal exposure in animal models. The highest brain concentrations are found in the hippocampus, cerebellum, cerebral cortex, and medulla.

Unlike soft tissue storage, bone lead accumulates throughout life. Bone storage begins in utero and occurs across all ranges of exposure, so that there is no threshold for bone lead uptake.<sup>1</sup> Bone lead was thought to be relatively metabolically inert, but it can be mobilized from the more labile compartments and contributes as much as 50% of the blood lead content. This is of particular importance during times of rapid bone turnover such as pregnancy and lactation, in elderly persons with osteoporosis,<sup>174</sup> and in children with immobilization.<sup>121</sup> Lead also accumulates in the teeth, particularly the dentine of children's teeth, a phenomenon that has been used to quantify cumulative lead exposure in young children.<sup>135</sup>

#### Excretion

Absorbed lead that is not retained is primarily excreted in urine (approximately 65%) and bile (approximately 35%).<sup>1</sup> A miniscule amount is lost via sweat, hair, and nails. Children excrete less of their daily uptake than adults, with an average retention of 33% versus 1% to 4%, respectively.<sup>208</sup> Biologic half-lives for lead are estimated as follows: blood 25 days (adults, short-term experiments) and 10 months (children, natural exposure); soft tissues (adults, short-term exposure), 40 days; bone (labile, trabecular pool), 90 days; and bone (cortical, stable pool), 10 to 20 years.<sup>1,118,155</sup> As mentioned, trace amounts of lead are also excreted in breast milk.<sup>9,53</sup>

#### Organic Lead

Alkyl lead compounds are lipid soluble and have unique pharmacokinetics that are less well characterized than those of inorganic lead.<sup>12</sup> Animal studies and human clinical experience with acute ingestions and leaded gasoline sniffing demonstrate TEL absorption through ingestion, inhalation, and intact skin, with subsequent distribution to lipophilic tissues, including the brain.<sup>165,182,203</sup> Tetraethyl lead is metabolized to triethyl lead, which is likely the major toxic compound. Alkyl lead also slowly releases lead as the inorganic form, with subsequent kinetics as noted above.<sup>12</sup>

## PATHOPHYSIOLOGY

### General Mechanisms

Similar to many metals, lead is a complex xenobiotic exerting numerous pathophysiologic effects in many organ systems.<sup>113</sup> Furthermore, genetic polymorphism impacts an individual's susceptibility to lead.<sup>142</sup> Several examples of such include the genes for apolipoprotein E, the vitamin D receptor, Na<sup>+</sup>,K<sup>+</sup>-ATPase (adenosine triphosphatase),  $\delta$ -aminolevulinic acid, and protein kinase C.<sup>168</sup> At the biomolecular level, lead functions in 3 general ways. First, its affinity for biologic electron-donor ligands, especially sulfhydryl groups, allows it to bind and impact numerous enzymatic, receptor, and structural proteins. Second, lead is chemically similar to the divalent cations calcium, magnesium, and zinc, and it interferes with numerous calcium and perhaps magnesium and zinc mediated metabolic pathways, particularly in mitochondria and in second-messenger systems regulating cellular energy metabolism.<sup>107,178</sup> Lead-induced mitochondrial injury results in apoptosis, a phenomenon particularly well studied in animal models of retinal cells.<sup>107</sup> Lead also functions as an antagonist or agonist of calcium-dependent processes. For example, lead inhibits neuronal voltage-sensitive calcium channels<sup>8</sup> and membrane-bound Na<sup>+</sup>,K<sup>+</sup>-ATPase (adenosine triphosphatase)<sup>176</sup> but activates calcium-dependent protein kinase C.<sup>119</sup> These effects adversely impact neurotransmitter function.<sup>198</sup> Third, lead affects nucleic acids by mechanisms not fully understood, though some evidence exists for alteration of DNA methylation.<sup>106,206</sup> It exhibits mutagenic and mitogenic effects in mammalian cells in vitro and is carcinogenic in rats and mice.<sup>51</sup> There is mechanistic plausibility and some epidemiologic evidence for at least a facilitative role of lead in human carcinogenesis,<sup>87</sup> and the International

Agency for Research on Cancer (IARC) has assigned inorganic lead compounds to the group 2A category, which is the class probably carcinogenic to humans.<sup>86</sup>

### Neurotoxicity

The neurotoxicity of lead involves multiple targets, including cerebrovascular endothelium, mitochondria, neural cell adhesion molecules, neurotransmitter and second-messenger function, regulation of apoptosis, and myelin formation.<sup>107,156,198</sup> Lead-induced dysfunction in several neurotransmitter systems is linked to its calcium-mimetic properties. Through blockade of calcium influx at voltage-sensitive calcium channels, lead inhibits depolarization-triggered release of acetylcholine, dopamine, and  $\gamma$ -aminobutyric acid (GABA) but augments the background rate of spontaneous release.<sup>41,91,107,113,198</sup> The dampening of the evoked neurotransmitter response in conjunction with enhanced background release results in a decreased “signal-to-noise” ratio.<sup>69,91</sup> In addition, lead decreases calcium currents at the *N*-methyl-D-aspartate (NMDA) glutamate receptor and directly activates the intracellular second-messenger protein kinase C.<sup>91</sup> These effects on neurotransmitter release, receptor activity, and intracellular signaling adversely affect “synaptic pruning” in the developing brain, a process by which the volume of excessive synaptic connections is selectively reduced. This disruption results in suboptimal cortical microarchitecture and function, and it particularly affects the hippocampus, an important locus of learning and memory.<sup>69,91,198</sup>

Lead also interferes with the 78-kDa chaperone glucose-regulated protein (GRP78) in astrocytes, which results in adverse protein conformational effects that are thought to be associated with conditions such as Alzheimer disease and parkinsonism.<sup>198</sup> In severe cases, pathologic changes in cerebral microvasculature result in cerebral edema and increased intracranial pressure (ICP), which are associated with the clinical syndrome of acute lead encephalopathy (Fig. 93–1). Peripheral neuropathy is a classic effect of lead poisoning in adults, and is reported rarely in

lead-exposed children with associated sickle cell disease.<sup>52</sup> The neuropathology in humans is poorly characterized. In animal models, it is associated with Schwann cell destruction, segmental demyelination, and axonal degeneration.<sup>113</sup> Sensory nerves are rarely affected.

### Hematologic Toxicity

Lead is hematotoxic in several ways, including via potent inhibition of several enzymes in the heme biosynthetic pathway (Chap. 20 and Fig. 20–3). It also induces a defect in erythropoietin function secondary to associated kidney damage.<sup>76</sup> A shortened erythrocyte life span is caused by increased membrane fragility with resultant hemolysis. Inhibition of  $\text{Na}^+, \text{K}^+$ -ATPase and pyrimidine-5'-nucleotidase impair erythrocyte membrane stability by altering energy metabolism. The inhibition of pyrimidine-5'-nucleotidase also underlies the appearance of basophilic stippling in erythrocytes, representing clumping of degraded RNA, which is normally eliminated by this enzyme<sup>143</sup> (Fig. 93–2).

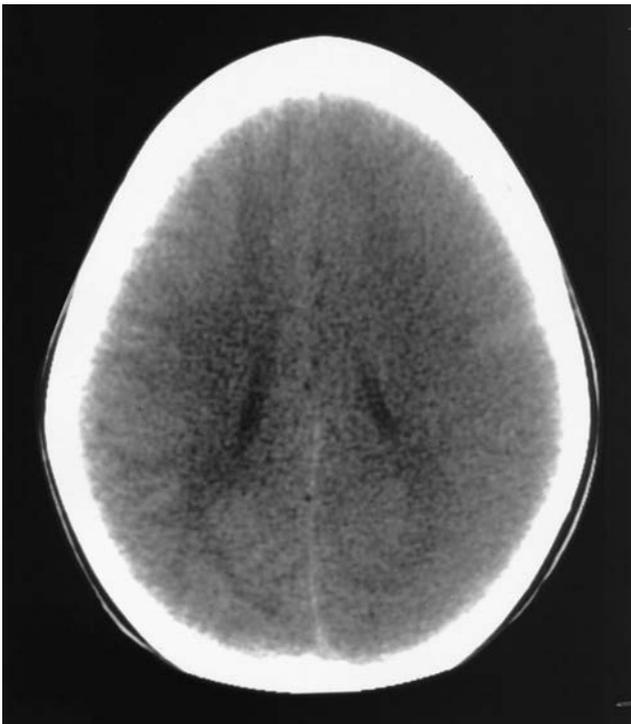

### Nephrotoxicity

Functional changes associated with acute lead nephropathy include decreased energy-dependent transport, resulting in a Fanconilike syndrome of aminoaciduria, glycosuria, and phosphaturia. These changes are related to disturbed mitochondrial respiration and phosphorylation and are reversible with discontinuation of exposure or treatment.<sup>136</sup> A pathologic finding is characteristic nuclear inclusion bodies in renal tubular cells composed of lead-protein complex. Chronic high-dose lead poisoning is associated with progressive interstitial fibrosis.<sup>136</sup> Lead is a renal carcinogen in rodent models, but its status in humans is uncertain.<sup>51</sup>

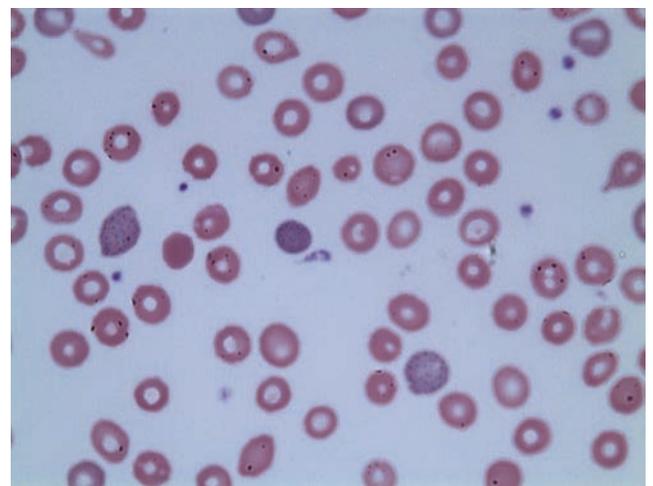

The association of plumbism with gout (“saturnine gout”) was noted more than 100 years ago. Lead competitively decreases uric acid excretion in the distal tubule, resulting in elevated blood urate concentrations and urate crystal deposition in joints. Kidney function is virtually always impaired in patients with saturnine gout.<sup>44</sup>

### Cardiotoxicity

The most important manifestation of lead toxicity on the cardiovascular system is hypertension. This is likely caused by altered calcium-activated changes in contractility of vascular smooth muscle cells secondary to decreased  $\text{Na}^+, \text{K}^+$ -ATPase activity and stimulation of the  $\text{Na}^+ - \text{Ca}^{2+}$  exchange pump. Lead also affects blood vessels by altering neuroendocrine input or sensitivity to such stimuli or by increasing reactive oxygen species that enhance nitric oxide inactivation.<sup>109</sup> Elevated serum renin activity is found with moderate toxicity but is normal or decreased in chronic severe

**FIGURE 93–1.** Computed tomography scan of the brain reveals diffuse cerebral edema and loss of gray–white matter differentiation on day 1 of hospitalization of a 3-year-old boy. He had presented with a brief prodrome of vomiting and altered mental status followed by status epilepticus, characteristic of acute lead encephalopathy. His blood lead concentration was 220 mcg/dL. (Used with permission from Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA.)

**FIGURE 93–2.** This peripheral smear of blood examined under high-power microscopy demonstrates the classic basophilic stippling associated with lead poisoning. The patient’s blood lead concentration was >100 mcg/dL. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

plumbism.<sup>194</sup> Rarely, direct cardiotoxicity is reported.<sup>134,157</sup> Animal models demonstrate increased sensitivity to norepinephrine-induced dysrhythmias and decreased myocardial contractility, protein phosphorylation, and high-energy phosphate generation.<sup>99</sup> Lead-induced impairment of intracellular calcium metabolism impacts cardiac electrophysiology.<sup>7</sup>

### Reproductive Toxicity

Impairment of both male and female reproductive function is associated with overt plumbism. Gametotoxic effects in animals of both sexes and chromosomal abnormalities in workers with blood lead concentrations above 60 mcg/dL are reported.<sup>113</sup> Male infertility arises from 3 mechanisms: hypothalamic–pituitary–testicular axis disruption, impairment of spermatogenesis, and inhibition of sperm function, at blood lead concentrations of 40 mcg/dL and above.<sup>66,159</sup>

### Endocrine Toxicity

Reduced thyroid and adrenopituitary function are found in adult lead workers.<sup>62,163</sup> Children with elevated blood lead concentrations have a depressed secretion of human growth hormone and insulinlike growth factor.<sup>85</sup>

### Skeletal Toxicity

In addition to the importance of the skeletal system as the largest repository of lead body burden, studies suggest that bone metabolism also is adversely affected by lead.<sup>113</sup> Hormonal response is altered by reduced 1,25-dihydroxyvitamin D<sub>3</sub> concentrations and by inhibition of osteocalcin. Both new bone formation and coupling of normal osteoblast and osteoclast function can thus be impaired.<sup>113</sup> Bands of increased metaphyseal density on radiographs of long bones (“lead lines”) in young children with heavy lead exposure represent increased calcium deposition (not primarily lead) in the zones of provisional calcification (Fig. 93–3). Impaired bone growth and shortened stature are associated with childhood lead poisoning. Impaired calcium or cyclic adenosine monophosphate (cAMP) messenger systems underlie these cellular effects.<sup>151</sup>

### Gastrointestinal Toxicity

Lead toxicity causes constipation, anorexia, and colicky abdominal pain. Although the mechanisms are not fully elucidated, theories include impaired

intestinal motility, alterations in luminal ion transport, and spasmodic contraction of intestinal wall smooth muscle.<sup>45,165</sup>

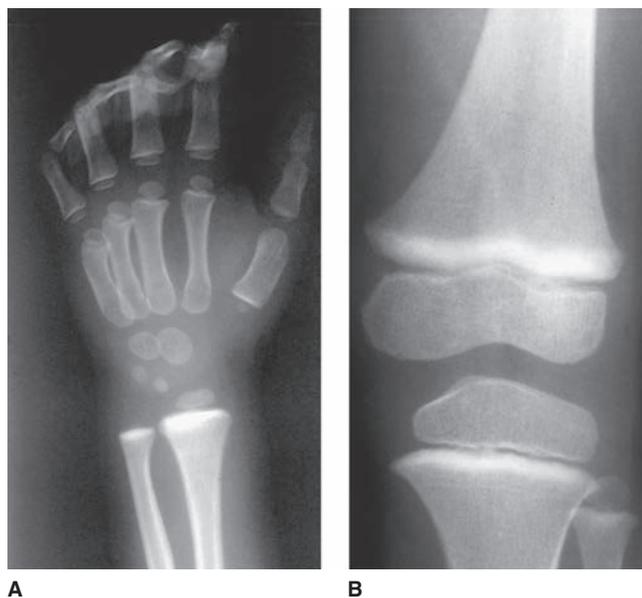

## CLINICAL MANIFESTATIONS

### Inorganic Lead

The numerous observed lead-induced pathophysiologic effects accurately predict that the clinical manifestations of lead poisoning are diverse. These manifestations of lead toxicity are characterized into distinct acute and chronic syndromes (Tables 93–3 and 93–4). In most cases, these distinctions really describe a continuum of dose- and time-related severity, and the occurrence of overt clinical effects in lead poisoning is, in most cases, the culmination of a long-term lead exposure. As the total dose increases, these effects are usually preceded first by biochemical and physiologic impairment followed, in turn, by subtle prodromal clinical effects that only become apparent in hindsight. In general, children are considered to be more susceptible than adults to toxicity for a given measured blood lead concentration, a distinction that applies primarily to CNS effects.

### Asymptomatic Children

Children with *elevated body lead burdens but without overt symptoms* represent the largest group of persons at risk for chronic lead toxicity. The subclinical toxicity of lead in this population centers around subtle effects on growth, hearing, and neurocognitive development. This last effect, in particular, is the subject of intense research interest and scrutiny. Numerous population-based studies report significant inverse associations with blood lead concentration and IQ, with an overall magnitude of 1 to 2 IQ points for chronic blood lead concentration increases from 10 to 20 mcg/dL.<sup>149</sup> A landmark study evaluating IQ in children from 6 months to 5 years of age found that blood lead concentrations were inversely correlated with IQ at 3 and 5 years of age and that the magnitude of effect for all subjects was an average 4.6-point decrement in IQ for each 10-mcg/dL increase in blood lead concentration.<sup>19</sup> Of particular concern, this effect was even greater, with an estimated 7.4-point loss, for the subset of children in the 1- to 10-mcg/dL blood lead concentration range, which other epidemiologic studies also reported.<sup>19,92,105</sup> In response to this steeper dose–response curve at blood lead concentrations below 10 mcg/dL, the CDC and American Academy of Pediatrics eliminated the term *threshold*, declared there to be no safe blood lead concentration for childhood intellectual development, and lowered the action blood lead concentration to 5 mcg/dL, a reference value to be evaluated every 4 years based on the 97.5 percentile in

**FIGURE 93–3.** (A) Radiograph of the wrist reveals increased bands of calcification (“lead lines”) in the same patient as in Fig. 93–1. **TABLE 93–3** Clinical Manifestations of Lead Poisoning in Children

Clinical Severity	Typical Blood Lead Concentrations (mcg/dL)
<b>Severe</b> CNS: Encephalopathy (coma, altered sensorium, seizures, bizarre behavior, ataxia, apathy, incoordination, loss of developmental skills, papilledema, cranial nerve palsies, signs of increased ICP) GI: Persistent vomiting Hematologic: Pallor (anemia)	>70–100
<b>Moderate</b> CNS: Hyperirritable behavior, intermittent lethargy, decreased interest in play, “difficult” child GI: Intermittent vomiting, abdominal pain, anorexia	50–70
<b>Mild</b> CNS: Impaired cognition, behavior, balance, fine-motor coordination Miscellaneous: Impaired hearing, impaired growth	≤49

CNS = central nervous system; GI = gastrointestinal; ICP = intracranial pressure.

**TABLE 93-4 Clinical Manifestations of Lead Poisoning in Adults**

Clinical Severity	Typical Blood Lead Concentrations (mcg/dL)
<b>Severe</b> CNS: Encephalopathy (coma, seizures, obtundation, delirium, focal motor disturbances, headaches, papilledema, optic neuritis, signs of increased ICP) PNS: Foot drop, wrist drop GI: Abdominal colic Hematologic: Pallor (anemia) Renal: Nephropathy	>100
<b>Moderate</b> CNS: Headache, memory loss, decreased libido, insomnia PNS: Peripheral neuropathy GI: Metallic taste, abdominal pain, anorexia, constipation Kidney: Arthritis due to saturnine gout (impaired urate excretion) Miscellaneous: Mild anemia, myalgias, muscle weakness, arthralgias	70–100
<b>Mild</b> CNS: Fatigue, somnolence, moodiness, lessened interest in leisure activities Miscellaneous: Adverse effects on cognition, reproduction, kidney function, or bone density; hypertension and cardiovascular disease; possible increased risk of bladder, lung and stomach cancer	20–69 <sup>a</sup>

<sup>a</sup>Chronic lead exposure at lower blood lead concentrations leads to cumulative body burdens of lead associated with these clinical findings.

CNS = central nervous system; GI = gastrointestinal; ICP = intracranial pressure; PNS = peripheral nervous system.

most recent NHANES data.<sup>5,28</sup> Nevertheless, it should be noted that some recent reviewers of this body of work, including the National Health and Medical Research Council of Australia, citing methodologic flaws such as uncontrolled confounding in many studies, questioned the evidence for a causal relationship between very low lead concentrations (<10 mcg/dL) and negative impact on IQ and academic achievement.<sup>133,204</sup> Additional consequences of low-level lead exposure include increased propensity for a variety of behavioral problems as well as dental caries.<sup>114,200</sup>

### Symptomatic Children

Subencephalopathic symptomatic plumbism usually occurs in children 1 to 5 years of age and is associated with blood lead concentrations above 70 mcg/dL but may occur with concentrations as low as 50 mcg/dL. Unfortunately, common behavioral and abdominal manifestations in well children of this age, including the “terrible twos” temperamental outbursts, functional constipation, abdominal pain, and not eating as much as parents expect, often overlap with the milder range of reported symptoms of lead poisoning. Frequently, parents of children diagnosed by routine blood screening recognize milder symptoms only in hindsight after chelation treatment results in clinical improvement (“it seemed as if the child was going through a phase”).<sup>64</sup> Other uncommon clinical presentations are described, including isolated seizures without encephalopathy (indistinguishable from idiopathic epilepsy), chronic hyperactive behavior disorder, isolated developmental delay, progressive loss of cortical function simulating degenerative cerebral disease, peripheral neuropathy (reported particularly in children with sickle cell hemoglobinopathy), and the occurrence of GI effects (colicky abdominal pain, vomiting, constipation) with myalgias of the trunk and proximal girdle muscles.<sup>36,52</sup>

Acute lead encephalopathy is the most severe presentation of pediatric plumbism (Table 93-3). It is associated with cerebral edema and increased

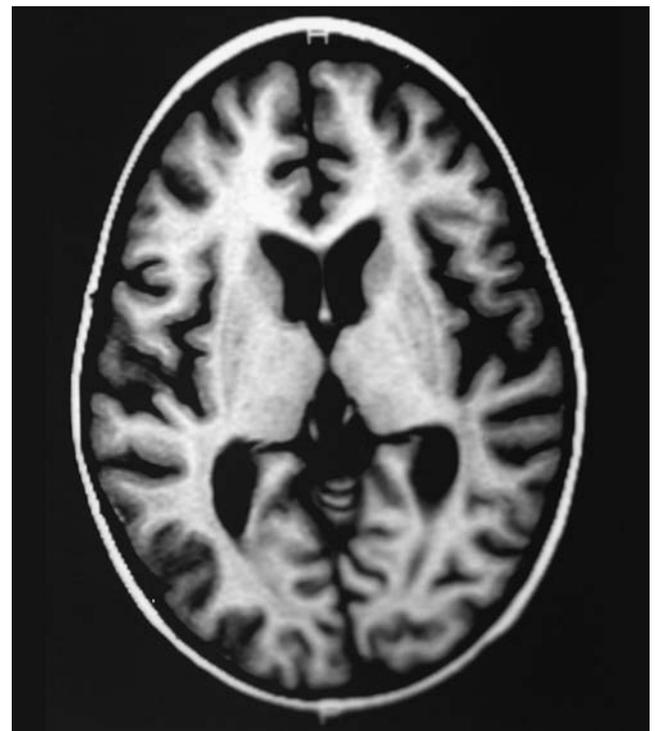

intracranial pressure (ICP) in severe cases (Fig. 93-1). Encephalopathy is characterized by severe vomiting and apathy, bizarre behavior, loss of recently acquired developmental skills, ataxia, incoordination, seizures, altered sensorium, or coma. Physical examination often reveals papilledema, oculomotor or facial nerve palsy, diminished deep tendon reflexes, or other evidence of increased ICP.<sup>20,201</sup>

Milder but ominous findings that portend incipient encephalopathy include anorexia, constipation, intermittent abdominal pain, sporadic vomiting, hyperirritable or aggressive behavior, periods of lethargy interspersed with lucid intervals, and decreased interest in play activities. Patients frequently seek medical advice for vomiting and lethargy during the 2 to 7 days before onset of frank encephalopathy.<sup>36,147</sup> Physical examination of such children usually reveals no specific abnormalities beyond, possibly, pallor reflecting concomitant anemia.

Encephalopathy usually occurs in children ages 15 to 30 months; is associated with blood lead concentrations above 100 mcg/dL, although it is reported with blood lead concentrations as low as 70 mcg/dL; and tends to occur more commonly in summer months, when blood lead concentrations peak.<sup>147</sup> A cohort of 972 Nigerian children demonstrated overt neurologic features with blood lead concentrations above 80 mcg/dL, although the majority occurred over 100 mcg/dL. Additional risk factors in this study included age 1 to 2 years and concomitant malaria infection.<sup>77</sup> Mortality caused by encephalopathy was 65% in the prechelation era, decreasing to below 5% with the advent of effective chelation. The incidence of permanent neurologic sequelae, including mental retardation, seizure disorder, blindness, and hemiparesis, is 25% to 30% in patients who develop encephalopathic symptoms before the onset of chelation (Fig. 93-4).<sup>36</sup>

### Adults

Adults with occupational lead exposure typically manifest numerous signs and symptoms representing disorders of several organ systems. Severity of

**FIGURE 93-4.** Magnetic resonance image of the brain reveals cortical atrophy and multiple areas of cerebral infarction in the same patient as in Fig. 93-1, done on hospital day 22. At this time, the child’s clinical status was notable for choreoathetoid movements and generalized hypotonia, inability to localize visual or auditory stimuli, and nonpurposeful movements of the extremities. (Used with permission from Eric Faerber, MD, Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA.)

symptoms correlates roughly with blood lead concentrations, although many conditions thought to be associated with low-dose chronic lead exposure are better correlated with markers of cumulative dose, such as bone lead or the cumulative blood lead index (area under the curve of blood lead concentrations versus time)<sup>84,103</sup> (Table 93–4). True acute poisoning occurs rarely, after very high inhalational,<sup>96</sup> large oral,<sup>137</sup> or intravenous (IV) exposures.<sup>138</sup> Clinical manifestations in such patients include colicky abdominal pain, hepatitis, pancreatitis, hemolytic anemia, and encephalopathy over days or weeks. Most adult plumbism is related to chronic respiratory exposure, although some authors have used the term “acute poisoning” to include patients with such exposure whose symptoms are severe and of relatively recent onset (within 6 weeks of presentation) and whose exposure is relatively brief (average, one year or less).<sup>43</sup>

In severe plumbism, the hallmark of toxicity is acute encephalopathy, which has been rarely reported in adults since the 1920s.<sup>43</sup> The majority of modern cases are actually not associated with occupational exposures but rather with more exotic exposures, such as ingestion of lead-contaminated illicit “moonshine” whiskey and ethnic alternative medications.<sup>94,179</sup> Encephalopathy in adults is usually associated with very high blood lead concentrations (typically >150 mcg/dL) and is manifested by seizures (75% of cases), obtundation, confusion, focal motor disturbances, papilledema, headaches, and optic neuritis.<sup>122,199</sup> In addition, adult patients with severe plumbism often manifest attacks of abdominal colic, are virtually always anemic, and are at significant risk for severe peripheral neuropathy that manifests as wrist drop and foot drop. Nephrotoxic effects include a Fanconilike syndrome, impaired kidney function, and progressive interstitial fibrosis. Rarely, ventricular dysrhythmias are reported, and long-standing lead toxicity is associated with prolonged QT intervals and widened QRS complexes.<sup>56,157</sup>

Moderate plumbism in adults typically involves CNS, peripheral nerves, hematologic, kidney, GI, rheumatologic, endocrine or reproductive, and cardiovascular findings.<sup>65,96,165</sup> At blood lead concentrations higher than 70 mcg/dL, such symptoms include headache, memory loss, decreased libido, and insomnia. Gastrointestinal symptoms include metallic taste, abdominal pain, decreased appetite, weight loss, and constipation. Abdominal guarding and tenderness are occasionally observed. Musculoskeletal and rheumatologic complaints at this stage include muscle pain and joint tenderness. Patients with saturnine gout have typical joint findings of acute arthritis. In contrast to gouty arthritis not associated with lead, there is a more equal gender ratio and increased tendency for polyarticular involvement, particularly in the knee.<sup>44</sup> Peripheral neuropathy occurs, primarily motor, manifesting initially in the wrist and finger extensors, then other muscular involvement including foot drop and tremor. Sensory involvement is generally minimal. Many patients at this stage have mild anemia, and those with chronic exposure are at risk for nephropathy as described above.

Mild plumbism manifests as minor CNS findings, such as changes in mood and cognition. Subtle abnormalities detectable by careful neuropsychiatric testing are found in both adults and children with modest elevations in blood concentrations and include impaired memory span, rapid motor tapping, visual motor coordination, and grip strength.<sup>43</sup> Studies document abnormal psychometrics and nerve conduction in workers recently exposed to lead as blood lead concentrations increased to above 30 mcg/dL.<sup>117</sup> Early psychiatric effects, manifesting at blood lead concentrations of 40 to 70 mcg/dL, include increased tiredness at the end of the day, disinterest in leisure-time pursuits, falling asleep easily, moodiness, and irritability. Chronic lead exposure is associated with higher depressive and phobic anxiety scores on surveys in premenopausal women.<sup>57</sup> The physical examination is usually normal,<sup>47</sup> or hypertension is present. A bluish-purple gingival lead line (Burton line), representing lead sulfide precipitation in patients with poor dentition, is rarely described. Ophthalmic lead toxicity results in myriad abnormalities including cataract formation, optic neuritis, optic atrophy, pigmented retinal deposits, and increased thickness of retinal, macular, and choroidal fibers, which lead to amblyopia, decreased visual acuity, ophthalmoplegia, decreased color vision, and scotoma.<sup>50</sup>

Effects on reproductive function are also apparent in this range of exposure. Historically, infertility and stillbirths were common among heavily

exposed women lead workers. More recent studies found reduced sperm counts, impaired motility, and abnormal morphology in men who work in the battery industry with blood lead concentrations above 40 mcg/dL<sup>66</sup> and an increased incidence of menstrual irregularity and spontaneous abortion in lead-exposed women who worked in China<sup>90</sup> and Mexico.<sup>13</sup> Prematurity is more common in children of pregnancies associated with elevated maternal blood lead concentrations.<sup>112</sup>

Increased blood pressure is probably the most prevalent adverse health effect observed from lead toxicity in adults. Epidemiologic studies document significant associations between hypertension and body lead burdens. The association is particularly strong for adult men aged 40 to 59 years, with an approximate 1.5– to 3.0–mm Hg increase in systolic pressure for every doubling of blood lead concentration beginning at 7 mcg/dL.<sup>148,187</sup> Additional studies correlate body lead burden with several other disorders of aging, including a decline in cognitive ability,<sup>173</sup> essential tremor,<sup>49</sup> cardiac and cerebrovascular events,<sup>88,103</sup> electrocardiographic abnormalities,<sup>34</sup> chronic kidney disease,<sup>103,109</sup> osteoporosis,<sup>18</sup> cataract prevalence,<sup>166</sup> and all-cause and cardiovascular mortality.<sup>197</sup>

### Organic Lead

Clinical symptoms of TEL toxicity are usually nonspecific initially and include nausea, vomiting, anorexia, insomnia, and emotional instability.<sup>12,165</sup> Patients exhibit tremor and increased deep tendon reflexes, as well as hepatic or renal injury. In more severe cases, these symptoms progress to encephalopathy with delusions, hallucinations, and hyperactivity, which resolve or deteriorate to coma and, occasionally, death. Because many reported patients were exposed via intentional abuse of leaded gasoline, much of the literature reporting this syndrome is confounded by accompanying volatile hydrocarbon toxicity.<sup>182</sup> Of note, in contrast to inorganic lead poisoning, patients with significant TEL toxicity do not consistently manifest hematologic abnormalities or elevations of heme synthesis pathway biomarkers. In addition, significant neurotoxicity occurs at blood lead concentrations considerably lower than those typically associated with inorganic lead poisoning.<sup>81</sup> A case report details the clinical course of a 13-year-old boy who unintentionally ingested a mouthful of fuel stabilizer containing 80% to 90% TEL. He developed progressive tremor, weakness, hallucinations, myoclonus, and hyperreflexia and required mechanical ventilation for 2 days and prolonged hospitalization for management of persistent hallucinations, weakness, dysphagia, and urinary and fecal incontinence. His blood lead concentration peaked on the third day after ingestion at only 62 mcg/dL.<sup>203</sup>

## DIAGNOSTIC TESTING

### Clinical Diagnosis in Symptomatic Patients

The medical evaluation should first include a comprehensive medical history. Further inquiry should elicit environmental, occupational, or recreational sources of exposure as detailed earlier (Tables 93–1 and 93–2). Plumbism is more likely in a child between the ages of 1 and 5 years with prior plumbism or noted elevated blood lead concentrations; history of pica or acute unintentional ingestions;<sup>78</sup> aural, nasal, or esophageal foreign bodies;<sup>202</sup> history of iron-deficiency anemia; residence in a pre-1960s–built home, especially with deteriorated paint, or one that has undergone recent remodeling; family history of lead poisoning; or foreign-born status.<sup>5</sup> Affected children manifest persistent vomiting, lethargy, irritability, clumsiness, or loss of recently acquired developmental skills; afebrile seizures; or evidence of child abuse or neglect.<sup>60,170</sup> In adults, the history should focus on occupational and recreational activities involving lead exposure (Table 93–2), a history of plumbism, and gunshot wounds with retained bullets.

The differential diagnosis of plumbism is broad. Adult patients are misdiagnosed as having carpal tunnel syndrome, Guillain-Barré syndrome, sickle cell crisis, acute appendicitis, renal colic, or infectious encephalitis. Children are often initially considered to have viral gastroenteritis or even to have insidious symptoms passed off as a difficult developmental phase.

A patient who presents to the emergency department with potential lead encephalopathy presents the physician with a dilemma: severe lead toxicity

requires urgent diagnosis, but confirmatory blood lead assays are not usually rapidly available.<sup>141</sup> For adults, a history of occupational exposure is often available from medical records or family members, and lead encephalopathy can be strongly considered with positive supportive laboratory findings such as anemia, basophilic stippling, elevated erythrocyte protoporphyrin (especially >250 mcg/dL, sometimes available on an urgent basis), and abnormal urinalysis. In this context, it is reasonable to institute presumptive chelation therapy while awaiting a blood lead concentration. In children, a similar indication for presumptive treatment would be suggested by a constellation of clinical features and ancillary studies, such as age 1 to 5 years, a prodromal illness of several days' to weeks' duration (suggestive of milder lead-related symptoms), history of pica and source of lead exposure, the laboratory features noted above (which are equally helpful in young children), and suggestive radiologic findings (detailed below) such as dense metaphyseal "lead lines" or ingested foreign bodies. In both adults and children, the decision to institute empiric chelation treatment should not deter additional emergent diagnostic efforts to exclude or to confirm other important entities while blood lead concentrations are pending. An important consideration in this context is the suspicion of an acute, potentially treatable CNS infection (eg, bacterial meningitis or herpetic encephalitis). Lumbar puncture should be generally avoided in patients with suspected lead encephalopathy because of the risk of cerebral herniation.<sup>40</sup> If there is a significant suspicion of such CNS infection, we recommend empiric treatment be instituted while awaiting blood lead concentration results, and a delayed lumbar puncture be considered if the blood lead concentration is normal.<sup>141</sup>

### Laboratory Evaluation

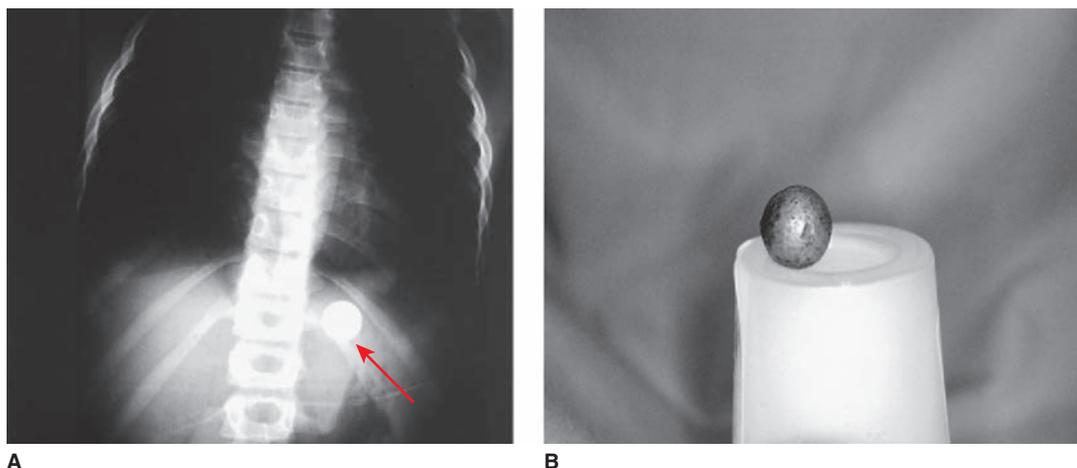

In patients suspected of having plumbism, laboratory testing is used to augment the evaluation of both lead exposure and lead toxicity. The whole blood lead concentration is the principal measure of lead exposure available in clinical practice, reflecting both recent and remote exposure. In any patient suspected of symptomatic plumbism, whole blood should be collected by venipuncture into special lead-free evacuated tubes. The most accurate method for measurement of blood lead concentration is inductively coupled plasma mass spectrometry (ICP-MS); however, many laboratories still utilize atomic absorption spectrophotometry, graphite furnace spectrophotometry, and anodic stripping voltammetry, with variable performance at very low blood lead concentrations near the CDC threshold.<sup>16</sup> A commonly used point-of-care testing device was recalled for inaccurate results on venous samples, prompting the CDC to recommend re-screening many children.<sup>30,188</sup>

For asymptomatic children, blood lead concentration screening is often performed by capillary blood testing for convenience; however, venous confirmation of elevated capillary lead concentrations, unless extremely high (eg,  $\geq 70$  mcg/dL) or unless the patient is clearly symptomatic, is still warranted before chelation or other significant interventions. Hair and urine

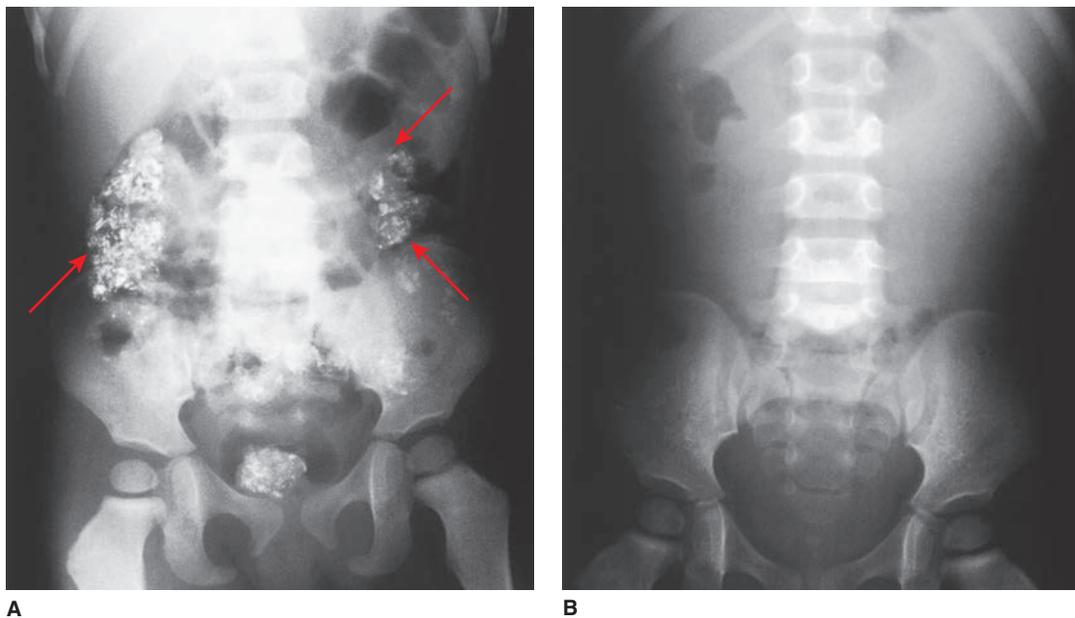

**FIGURE 93-5.** Abdominal radiograph of an 8-year-old child who sustained a shotgun wound to the right paraspinous area, with resultant paraplegia and multiple visceral injuries. The blood lead concentration was found to be 60 mcg/dL at 11 weeks after injury, and chelation therapy was commenced. (Used with permission from Children's Hospital of Philadelphia, Department of Radiology, Philadelphia, PA.)

lead concentrations have no clinical utility. The erythrocyte protoporphyrin concentration reflects inhibition of the heme synthesis pathway (Chap. 20) and was used as a screening tool in the past, but it is no longer considered sufficiently sensitive. The erythrocyte protoporphyrin concentration tests are useful for tracking response to therapy and in distinguishing acute from chronic lead poisoning; as an adjunct to the emergency diagnosis of symptomatic plumbism if emergent blood lead concentration determination is not available and, rarely, in the evaluation of suspected factitious plumbism. Routine serum chemistries, kidney function tests, liver function tests, urinalysis, and complete blood count are recommended in patients who are symptomatic or about to undergo chelation therapy. Radiographic studies should be

**FIGURE 93-6.** An unusual source of lead poisoning. (A) Radiograph of the abdomen reveals (↑) ingested metallic foreign body. (B) The ingested foreign body was a Civil War–era musketball from the collection of the patient's father. (Used with permission from Evaline Alessandrini, MD, Division of Emergency Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.)

**FIGURE 93-7.** (A) Abdominal radiograph of a child who had massive paint chip ingestion. The dispersed radiodense (white) fragments are noted (↖) to follow the outline of the large intestine. (B) No remaining lead is seen on follow-up radiograph after whole-bowel irrigation. (Used with permission from Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)

obtained according to relevant history, to determine the presence of ingested foreign bodies, retained bullets or shrapnel (Figs. 93-5, 93-6, 93-7).<sup>58,110,169</sup> In addition, the presence of “lead lines” can strengthen the clinical diagnosis of childhood plumbism before blood lead concentrations are available (Fig. 93-3), although dense metaphyseal bands are sometimes caused by other causes, including other metals (arsenic, bismuth, and mercury), healing rickets, and recovery from scurvy.<sup>153,203</sup> Cerebrospinal fluid examination in lead encephalopathy reveals characteristic findings such as increased protein concentration, lymphocytic pleocytosis, and increased intracranial pressure (ICP);<sup>40,141</sup> however, as discussed above, lumbar puncture is not recommended for routine diagnosis because of risk of herniation.

Two measures of cumulative lead exposure are available. X-ray fluorescence technology measures bone lead, and thus indirectly estimates total body lead burden. The cumulative blood lead index, derived from several blood lead concentrations measured over the presumed course of lifetime lead exposure, calculated as an area under the concentration curve, is also described.<sup>84</sup> Both techniques are used in research studies of issues concerning past chronic lead exposure and a variety of current health outcomes.<sup>83,196</sup> Another putative measure of body lead burden is the use of provoked challenge urine testing, in which urinary lead is measured after the administration of chelator. We recommended against its use as results are difficult to interpret and often misleading.<sup>162</sup>

## SCREENING

Screening is an essential public health practice for the prevention of severe plumbism in children, pregnant women, and other adults from high-risk settings. Table 93-5 outlines the current CDC<sup>28,32</sup> pediatric guidelines, which also are endorsed by the American Academy of Pediatrics and we recommend as well.<sup>5</sup> Likewise, the Occupational Safety and Health Administration (OSHA) maintains a lead standard for US workers formulated to reduce workplace exposure to lead, decrease symptomatic lead poisoning, and provide quality medical care to workers with elevated blood lead concentrations.<sup>189-192</sup> Table 93-6A summarizes the OSHA-mandated action blood lead concentration values for worker notification, removal, and reinstatement. An expert panel convened by the Association of Occupational and Environmental Clinics (AOEC) published an alternative set of health-based management recommendations for lead-exposed workers, which we support. The AOEC authors propose that their recommendations are more reflective of recent research

linking adverse health outcomes to chronic, low-dose lead exposure.<sup>103</sup> These guidelines are summarized in Table 93-6B.

## MANAGEMENT

There are several caveats about the management of patients with lead poisoning. First, the most important aspect of treatment is removal from further exposure to lead. Unfortunately, effective implementation of this therapy is often beyond the control of the clinician but rather depends on a complex interplay of public health, social, and political actions. Currently, the ability to control exposure is generally more applicable to adults with occupational exposures than to children exposed to residential hazards. Second, in children for whom some residual lead exposure potentially continues, optimization of nutritional status is vital in order to minimize absorption. Finally, pharmacologic therapy with chelators, although a mainstay of therapy for symptomatic patients, is an inexact science, with numerous unanswered questions despite more than 50 years of clinical use.<sup>3,101</sup> The rationale for chelation therapy of lead-poisoned patients is that chelators complex with lead, forming a chelate that is excreted in urine, feces, or both. Chelation therapy increases lead excretion, reduces blood concentrations, and reverses hematologic markers of toxicity during therapy. Reports from the 1950s found symptomatic improvement in adults chelated for lead colic.<sup>195</sup> The institution of effective combination chelation treatment of childhood lead encephalopathy in the 1960s contributed to the dramatic decline in mortality and morbidity of that devastating degree of plumbism.<sup>36</sup> However, the same era saw major advances in pediatric critical care in general and medical management of increased ICP in particular. The situation of chelation therapy for asymptomatic patients with mildly to moderately increased body burdens of lead is even less clear, and many questions regarding efficacy and safety remain.<sup>37,101,146</sup> To date, long-term reduction of target tissue lead content or reversal of toxicity is not demonstrated in human trials.<sup>48,120,160</sup>

## Decreasing Exposure

All patients with significantly elevated blood lead concentrations warrant identification of the lead exposure source, and specific environmental and medical interventions, or both (Table 93-7). In adults, this usually involves worksite changes.<sup>47,103,165</sup> The risk of occupational lead exposure correlates with several factors that contribute to the occurrence of respirable lead fumes or dust particles in the worksite atmosphere.<sup>165</sup> First, there are hazards

**TABLE 93–5 Pediatric Screening and Follow-up Guidelines<sup>5,29,32</sup>**

Screening	
1. Screening is recommended for all children who are Medicaid eligible at age 1 and 2 years (and those ages 3–6 years who have not been screened previously). Children who may not be Medicaid eligible but whose families participate in any poverty assistance program should also be screened.	
2. Certain local health departments (eg, New York, Chicago, and Philadelphia) recommend screening at younger ages or more frequently. Such recommendations include starting at age 6–9 months, testing every 6 months for children younger than 2 years, and provision of additional education and more rapid follow-up testing for children younger than 12 months whose blood lead concentrations are 6–9 mcg/dL.	
3. In addition, children who are not Medicaid eligible but are designated high-risk by their state or local health departments should be screened as per these local policies. <sup>a</sup>	
4. For children who are neither Medicaid eligible nor live in areas with locale-specific health department guidelines, recommendations are less clear. The AAP supports universal screening of such children as well. <sup>b</sup>	
5. Recent immigrants, refugees, or international adoptee children should be screened on arrival to the United States.	
Follow-Up	
Blood Lead Concentration (mcg/dL)	Recommended Action and Confirmatory Testing Schedule
≤5	Retest in one year, or more frequently if at high risk for lead exposure <sup>c</sup> ; anticipatory guidance
5–14	Retest in 1–3 months; education, environmental history, nutritional counseling <sup>5</sup>
15–19	Retest in 1–4 weeks; education; if the blood lead concentration is 15–19 mcg/dL twice, refer for case management; consider abdominal radiograph if excessive mouthing behaviors <sup>5</sup>
20–44	Clinical evaluation; education; environmental investigation and lead hazard control; obtain abdominal film, iron studies, and hemoglobin/hematocrit <sup>32</sup>
45–69	Clinical evaluation and case management within 48 hours; education; environmental investigation and lead hazard control; abdominal film, iron studies and hemoglobin/hematocrit; chelation therapy <sup>5,23</sup>
≥70	Hospitalize child; obtain studies as above; immediate chelation therapy; education; environmental investigation and lead hazard control

<sup>a</sup>Many relevant state and city health department contacts may be located at: <http://www.cdc.gov/nceh/lead/about/program.htm>. <sup>b</sup>The 1997 CDC guidance<sup>21</sup> allowed for targeted screening of some children of low-risk geographic and demographic background based on a personal risk questionnaire. A listing of potential risk factors is instructive and is summarized here. <sup>c</sup>Screening was recommended if a child had any of the following high-risk factors:

**Housing:** Lives in or regularly visits a home built before 1960; lives in or regularly visits a home built before 1978 undergoing remodeling or renovation (or renovated within 6 months).

**Medical history:** Pica for paint chips or dirt; iron deficiency.

**Personal, family, and social history:** Personal, family, or playmate history of lead poisoning; parental occupational, industrial, hobby exposures; live in proximity to major roadway; use of hot tap water for consumption; use of complementary remedies, cosmetics, ceramic food containers; trips or residence outside United States; parents are migrant farm workers, receive poverty assistance.

Educational interventions as per [Table 93–7](#).

Chelation therapy as per [Table 93–8](#).

AAP = American Academy of Pediatrics; BPb = venous blood lead; CDC = Centers for Disease Control and Prevention.

inherent in the work process itself, including high temperatures; significant aerosol, dust, or fume production; and a less mechanized workplace (with resulting greater “hands-on” employee exposure). Second, the adequacy of dust elimination, such as local and general ventilation, is critical. The third category is that of worksite and personal hygiene, including proper use of

**TABLE 93–6A Occupational Safety and Health Administration General Industry<sup>a</sup> Standards for Various Blood Lead Concentrations**

Number of Tests	Blood Lead Concentration (mcg/dL)	Action Required
1	≥40	Notification of worker in writing; medical examination of worker and consultation
3 (average)	≥50	Removal of worker from job with potential lead exposure
1	≥60	Removal of worker from job with potential lead exposure
2	<40	Reinstatement of worker in job with potential lead exposure

<sup>a</sup>The construction industry standard is similar for worker notification (at 40 mcg/dL) and reinstatement (<40 mcg/dL twice) but requires worker removal for a single value ≥50 mcg/dL.

Data from US Department of Labor, Occupational Safety and Health Administration: Medical Surveillance Guidelines—1910.1025 App C.

[http://www.osha.gov/pls/oshaweb/owadisp.show\\_document?p\\_table=STANDARDS&p\\_id=10033](http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS&p_id=10033) and US Department of Labor, Occupational Safety and Health Administration: Medical Surveillance Guidelines. Lead—1926.

protective clothes and equipment, and thorough housekeeping. Remedial actions include improvements in ventilation, modification of personal hygiene habits, and optimal use of respiratory apparatus. It is vital to prohibit smoking, eating, and drinking in a lead-exposed work area. Work clothes should be changed after each shift and should not be lockered together with street clothes.

In patients with plumbism or consequential elevated blood lead concentrations believed due to retained bullets, surgical removal of this lead source is recommended when anatomically feasible.<sup>33,110,126</sup> [Table 93–7](#) also summarizes several specific educational guidelines that should be offered to parents of lead-exposed children.<sup>5,17,23</sup> Overarching principles include home lead paint abatement (done preferably by professionals, with the family out of the home), home dust reduction techniques, decreasing soil lead exposure, and nutritional evaluation and counseling. Patients manifesting iron deficiency

**TABLE 93–6B Health-Based Occupational Surveillance Recommendations<sup>a</sup>**

Blood Lead Concentration (mcg/dL)	Recommendation
<10	Check every month for 3 months and then every 6 months (unless exposure increases); if blood lead concentration increases >4 mcg/dL, exposure evaluation or reduction effort; exposure evaluation or reduction if blood lead concentration 5–9 mcg/dL for women who are or may become pregnant
10–19	As for blood lead concentration <10 mcg/dL and check every 3 months; exposure evaluation and reduction effort; consider removal if no improvement with exposure reduction or complicating medical condition; <sup>b</sup> resume check every 6 months if 3 blood level concentrations <10 mcg/dL
≥19	Remove from exposure if blood lead concentration >30 mcg/dL or repeat blood lead concentration in 4 weeks; check every month; consider return to work after blood lead concentration <15 mcg/dL twice

<sup>a</sup>All potentially lead-exposed workers warrant preemployment clinical evaluation, baseline blood lead concentration, and serum creatinine concentration. <sup>b</sup>Such conditions include chronic kidney disease, hypertension, neurologic disorders, and cognitive dysfunction.

Data from Kosnett MJ, Wedeen RP, Rothenberg SJ, et al. Recommendations for medical management of adult lead exposure. *Environ Health Perspect*. 2007 Mar;115(3):463–471.

**TABLE 93-7** Evaluation and Management of Patients with Lead Exposure**Adults**

- Implement careful lead exposure monitoring (Table 93-6A and 6B)
- Improve ventilation
- Use a respiratory protective apparatus
- Wear protective clothing; change from work clothes before leaving worksite
- Modify personal hygiene habits
- Prohibit eating, drinking, and smoking at the worksite
- Evaluate possible sources beyond occupational setting (Tables 93-1 and 93-2)

**Children**

- Notify the local health department to initiate home inspection and abatement as needed
- Home lead paint abatement (professional contractors if possible; use plastic sheeting, low dust-generating paint removal; replacement of lead-painted windows, floor treatment; final cleanup with high-efficiency particle air vacuum, wet mopping)
- Avoid most hazardous areas of the home and yard
- Dust control: Wet mopping, sponging with high-phosphate detergent; frequent hand, toy, and pacifier washing
- Soil lead exposure reduction by planting grass and shrubs around the house
- Use only cold, flushed tap water for consumption
- Optimize nutrition to reduce lead absorption: avoid fasting; give an iron-, calcium-, vitamin C-sufficient diet; supplement iron and calcium as necessary
- Avoid food storage in open cans
- Avoid imported ceramic containers for food and beverage use
- Evaluate parental occupations and hobbies and eliminate high-risk activity
- Evaluate possible sources beyond lead paint exposure (Tables 93-1 and 93-2)

mild to moderate excess lead burdens. Unfortunately, D-penicillamine has a toxicity profile that includes life-threatening hematologic disorders and reversible, but serious, dermatologic and kidney effects; consequently, since 1991, its role in lead poisoning treatment at most centers has been largely replaced by succimer. Currently, D-penicillamine use is only recommended when unacceptable adverse reactions to both succimer and  $\text{CaNa}_2\text{EDTA}$  occur, and it remains important to continue chelation.<sup>3</sup>

Chelation is not a panacea for lead poisoning. It is a relatively inefficient process, with a typical course of therapy decreasing body content of metal by only 1% to 2%.<sup>101,131</sup> Furthermore, there is little evidence that chelators have significant access to critical sites in target organs, particularly in the brain.<sup>42</sup> Assumptions that reducing blood lead concentration will improve subtle neurocognitive dysfunction or other subclinical organ toxicity are appealing theoretically but unproven.<sup>48,160</sup>

**Children**

Lead encephalopathy is an acute life-threatening emergency and should be treated under the guidance of a multidisciplinary team in the intensive care unit of a hospital experienced in the management of critically ill children. The recommended treatment for encephalopathy is combination parenteral chelation therapy with maximum-dose dimercaprol and  $\text{CaNa}_2\text{EDTA}$  along with meticulous supportive care.<sup>3,23,36</sup> Such combination therapy has a dramatic effect on decreasing blood lead concentration—to 50% or less of baseline within 15 hours and to 75% to 80% of baseline by 48 to 72 hours. It is far superior to monotherapy with  $\text{CaNa}_2\text{EDTA}$  in this regard.<sup>36</sup>

Chelation is instituted with 450 mg/m<sup>2</sup>/day (or 25 mg/kg/day) of intramuscular (IM) dimercaprol in 6 divided doses.<sup>3,23</sup> The second dose of dimercaprol is given 4 hours later followed immediately by IV  $\text{CaNa}_2\text{EDTA}$ , in maximum concentration of 0.5% solution, at 1,500 mg/m<sup>2</sup>/day (or 50 mg/kg/day) as a continuous infusion or in divided-dose infusions over several hours.<sup>3,23,147</sup> The delay in initiating  $\text{CaNa}_2\text{EDTA}$  infusion is based on past observations of clinical deterioration in encephalopathic patients treated with  $\text{CaNa}_2\text{EDTA}$  alone.<sup>3,36</sup> Therapy is typically continued with both antidotes for 5 days, although in milder cases with prompt resolution of encephalopathy and decrease of blood lead concentration to below 50 mcg/dL, it is reasonable to discontinue dimercaprol after 3 days, with continuation of  $\text{CaNa}_2\text{EDTA}$  alone for 2 more days.

The presence of radiopaque material in the GI tract on radiography has raised concern that parenteral chelation might enhance absorption of residual gut lead. This issue is not settled fully,<sup>37</sup> but we recommend the initiation of parenteral chelation without delay in seriously symptomatic patients. It seems reasonable in such cases to simultaneously attempt WBI with a polyethylene glycol preparation.<sup>3</sup> One case report described the successful use of parenteral chelation therapy begun simultaneously with WBI, followed by enteral succimer on day 3 for a child with lead encephalopathy and an extraordinarily high blood lead concentration of 550 mcg/dL.<sup>70</sup> This issue applies as well to ingested lead foreign bodies, as noted above.<sup>124,193</sup> Generally, oral fluids, feedings, and medications are withheld for at least the first several days. Careful provision of adequate IV fluids optimizes kidney function while avoiding overhydration and the risk of exacerbating cerebral edema. The occurrence of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is associated with lead encephalopathy,<sup>36,180</sup> so urine volume, urine osmolarity, specific gravity, and serum electrolytes should be closely monitored, especially as fluids are gradually liberalized with clinical improvement (Chap. 12). In the context of lead encephalopathy, this approach would need to be tempered by the requirement for maintaining good urine output to optimize chelation efficacy.

Intravenous benzodiazepines are recommended as initial therapy to achieve seizure control. Although, in general, phenytoin or fosphenytoin is the second-line therapy for pediatric status epilepticus, in the context of toxin-induced status, we recommend sequential use of benzodiazepines, phenobarbital, or propofol,<sup>201</sup> followed by valproate or levetiracetam and, if needed, inhalational anesthetics.<sup>71,97</sup> This should be

should be treated, and for others, ensuring a diet sufficient in trace nutrients, particularly iron, calcium and vitamin C, is reasonable.<sup>5,175</sup> Clinicians who have primary responsibility for children with elevated blood lead concentrations should refer to the exhaustive monograph developed by the CDC and recent American Academy of Pediatrics (AAP) guidance, both of which detail such pediatric case management.<sup>5,23</sup>

Occasionally, children require urgent GI decontamination to reduce ongoing acute lead exposure. We recommend the prompt institution of whole-bowel irrigation (WBI) for those patients with large burdens of lead paint chips (Fig. 93-6) (Antidotes in Depth: A2). Another unique situation arises when children ingest solid lead foreign bodies, such as fishing sinkers, bullets, or curtain weights. Several case reports document rapid absorption in this scenario, with significantly elevated blood lead concentrations measured within 24 hours of ingestion.<sup>124,132,193</sup> Such patients warrant a baseline blood lead concentration determination and frequent repeat evaluation. We recommend prompt endoscopic removal for gastric foreign bodies, particularly with increasing blood lead concentrations. Proton pump inhibitor and prokinetic therapy are also reasonable adjuncts for gastric foreign bodies to decrease gastric acidity, retention time, and resultant lead dissolution.<sup>59</sup> For foreign bodies in the small bowel, a trial of WBI is reasonable but has not been uniformly successful.<sup>132,193</sup> Endoscopic or surgical removal is also recommended for such foreign bodies, if there is delayed passage, failure of WBI, or rapid elevations in blood lead concentrations.<sup>59,193</sup> The issue of concomitant chelation therapy in patients with significant GI lead burdens is addressed in the following section.

**Chelation Therapy**

The indications for and specifics of chelation therapy are determined by the age of the patient, the blood lead concentration, and clinical symptomatology (Table 93-8). Three chelators are currently recommended for the treatment of lead poisoning: dimercaprol (Antidotes in Depth: A28) and edetate calcium disodium ( $\text{CaNa}_2\text{EDTA}$ ) (Antidotes in Depth: A30) are used parenterally for more severe cases, and succimer (Antidotes in Depth: A29) is available for oral therapy. A fourth drug, D-penicillamine, was used orally for patients with

**TABLE 93–8** Chelation Therapy Guidelines<sup>3,5,23,96,147,150</sup> for Initial Course of Treatment<sup>a</sup>

Condition, Blood Lead Concentration (mcg/dL)	Dose	Regimen/Comments
<b>Adults</b>		
Encephalopathy	Dimercaprol 450 mg/m <sup>2</sup> /d <sup>a,b</sup> and CaNa <sub>2</sub> EDTA 1,000–1,500 mg/m <sup>2</sup> /d <sup>a</sup>	75 mg/m <sup>2</sup> IM every 4 hours for 5 days Continuous infusion or 2–4 divided IV doses for 5 days (start 4 hours after dimercaprol)
Symptoms suggestive of encephalopathy or >100	Dimercaprol 300–450 mg/m <sup>2</sup> /d <sup>a,b</sup> and CaNa <sub>2</sub> EDTA 1,500 mg/m <sup>2</sup> /d <sup>a</sup>	50–75 mg/m <sup>2</sup> IM every 4 hours for 3–5 days (base dose, duration on blood lead concentration, severity of symptoms; see text) Continuous infusion or 2–4 divided IV doses for 5 days (start 4 hours after dimercaprol)
Mild symptoms or 70–100	Succimer 700–1,050 mg/m <sup>2</sup> /d	350 mg/m <sup>2</sup> 3 times per day orally for 5 days, then twice per day for 14 days. Remove from exposure (Table 93–7) Lab: Baseline CT scan; CBC, Ca <sup>2+</sup> , blood lead concentration, BUN, Cr, LFTs, U/A; repeat CBC, Ca <sup>2+</sup> , BUN, Cr, LFTs, U/A daily; blood lead concentration on days 3 and 5
Asymptomatic and <70	Usually not indicated	–
<b>Children</b>		
Encephalopathy	Dimercaprol 450 mg/m <sup>2</sup> /d <sup>a</sup> and CaNa <sub>2</sub> EDTA 1,500 mg/m <sup>2</sup> /d <sup>a</sup>	75 mg/m <sup>2</sup> IM every 4 hours for 5 days Continuous infusion or 2–4 divided IV doses for 5 days (start 4 hours after dimercaprol) Lab: Baseline AXR, CT scan, CBC, Ca <sup>2+</sup> , Na <sup>+</sup> , blood lead concentration, BUN, Cr, LFTs, U/A; repeat CBC, Ca <sup>2+</sup> , Na <sup>+</sup> , BUN, Cr, LFTs, U/A daily; blood lead concentration on days 3 and 5
Symptomatic (without encephalopathy) or >69	Dimercaprol 300–450 mg/m <sup>2</sup> /d <sup>a</sup> and CaNa <sub>2</sub> EDTA 1,000–1,500 mg/m <sup>2</sup> /d <sup>a</sup>	50–75 mg/m <sup>2</sup> IM every 4 hours for 3–5 days (base dose, duration on blood lead concentration, severity of symptoms; see text) Continuous infusion or 2–4 divided IV doses for 5 days (start 4 hours after dimercaprol) Lab: Baseline AXR, CBC, Ca <sup>2+</sup> , blood lead concentration, BUN, Cr, LFTs, U/A; repeat CBC, Ca <sup>2+</sup> , BUN, Cr, LFTs, U/A on days 3 and 5 and blood lead concentration day 5
Asymptomatic: 45–69	Succimer 700–1,050 mg/m <sup>2</sup> /d <sup>a</sup> or CaNa <sub>2</sub> EDTA, 1,000 mg/m <sup>2</sup> /d <sup>a</sup>	350 mg/m <sup>2</sup> 3 times per day orally for 5 days and then twice per day for 14 days Lab: Baseline AXR, CBC, blood lead concentration, LFTs; repeat CBC, LFTs, blood lead concentration days 7 and 21 Continuous infusion or 2–4 divided IV doses for 5 days (see text) Lab: Baseline AXR, CBC, Ca <sup>2+</sup> , blood lead concentration, BUN, Cr, LFTs, U/A; repeat Ca <sup>2+</sup> , BUN, Cr, LFTs, U/A on days 3 and 5 and blood lead concentration on day 5
20–44	Routine chelation not indicated (see text)	If succimer used, same regimen as per above group (Table 93–7)
<20	Chelation not indicated	(Table 93–7)

<sup>a</sup>Subsequent treatment regimens should be based on post-chelation blood lead concentration and clinical symptoms (see text).

Approximate equivalent doses are expressed in milligrams per kilogram of body weight: dimercaprol 450 mg/m<sup>2</sup>/d (~24 mg/kg/d); 300 mg/m<sup>2</sup>/d (~18 mg/kg/d).

CaNa<sub>2</sub>EDTA 1,000 mg/m<sup>2</sup>/d (~25–50 mg/kg/d); 1,500 mg/m<sup>2</sup>/d (~50–75 mg/kg/d); adult maximum dose 2–3 g/d; succimer 350 mg/m<sup>2</sup> (~10 mg/kg).

<sup>b</sup>Some clinicians recommend CaNa<sub>2</sub>EDTA alone in these contexts (see text).

AXR = abdominal radiography; BPb = venous blood lead; BUN = blood urea nitrogen; Ca = calcium; CaNa<sub>2</sub>EDTA = edetate calcium disodium; CBC = complete blood count; Cr = creatinine, CT scan = computed tomography scan of the brain; IM = intramuscular; IV = intravenous; Lab = suggested laboratory and radiologic evaluation; LFTs = hepatic aminotransferases; U/A = urinalysis with microscopy (frequent monitoring of urine dipstick analysis for hematuria and proteinuria also advised during CaNa<sub>2</sub>EDTA therapy).

done in conjunction with pediatric neurology consultation and bedside EEG monitoring.<sup>71,97</sup> Modern approaches to the management of cerebral edema and increased ICP have not been critically evaluated in the context of lead encephalopathy. As noted previously, we recommend lumbar puncture be avoided in concern for cerebral herniation if lead encephalopathy is highly suspected. Of note, repeated lumbar puncture was used as an adjunct to the treatment of lead encephalopathy associated with increased ICP in the 1950s, but was complicated by proximate death when signs of impending herniation were present.<sup>40</sup> It seems reasonable to utilize noninvasive measures considered today in the context of intracranial hypertension associated with severe head trauma, in consultation with pediatric intensive care and neurosurgical teams, such as prevention of hypoxia and hypercarbia with tracheal intubation and controlled ventilation, maintenance of intravascular volume to provide effective cerebral perfusion pressure, seizure control, and neutral head positioning with elevation of the head of the bed to 30 degrees.<sup>125</sup> If such measures are not adequate, hyperosmolar therapy with mannitol or hypertonic saline is also reasonable, particularly mannitol if cerebral edema is complicated by SIADH or impaired kidney function.<sup>40</sup> Whether more aggressive measures, including acute hyperventilation for impending herniation, drainage of ventricular cerebrospinal fluid, or decompressive craniectomy, would

decrease mortality or morbidity further in advanced lead encephalopathy is unknown.<sup>125</sup>

For children with milder effects or who are asymptomatic with blood lead concentration greater than or equal to 70 mcg/dL, chelation with a 2-drug regimen similar to that used for encephalopathy is recommended. It is likely that this group of patients will require only 3 days of dimercaprol in addition to 5 days of CaNa<sub>2</sub>EDTA.<sup>3</sup> For asymptomatic patients in this group, particularly those with blood lead concentrations lower than 100 mcg/dL, some authors have suggested CaNa<sub>2</sub>EDTA alone,<sup>205</sup> succimer plus CaNa<sub>2</sub>EDTA, or even succimer alone in resource-limited locales. However, if resources allow, we recommend chelation with both dimercaprol and CaNa<sub>2</sub>EDTA. Most recently a large cohort of 3,130 Nigerian children with moderate to severe lead poisoning were managed with succimer alone. Although data concerning long-term efficacy is still emerging, this appears to be a safe alternative if circumstances preclude standard 2-drug chelation.<sup>184</sup> Intensive care monitoring is reasonable for such patients as well, particularly those with blood lead concentrations greater than or equal to 70 mcg/dL, at least during the initiation of chelation therapy.

Chelation therapy is recommended for asymptomatic children with blood lead concentrations between 45 and 69 mcg/dL.<sup>3,23</sup> For children

without overt symptoms, we recommend treatment with succimer alone, which has documented efficacy in lowering blood lead concentrations and short-term safety since its approval by the US Food and Drug Administration in 1991.<sup>75</sup> Succimer is initiated at 30 mg/kg/day (or 1,050 mg/m<sup>2</sup>/day) orally in 3 divided doses; this is continued for 5 days and then decreased to 20 mg/kg/day (or 700 mg/m<sup>2</sup>/day) in 2 divided doses for 14 additional days.<sup>3,74</sup> The original data establishing this empiric dosing regimen were based on body surface area rather than weight.<sup>74</sup> For younger children, the alternative dosing by body weight results in suboptimal dosing.<sup>158</sup> Although the ability to chelate children orally with succimer makes it tempting to prescribe routinely for outpatient therapy and some animal evidence suggests succimer does not enhance enteral lead absorption,<sup>93</sup> clinical experience has shown that children must be protected from continued lead exposure during succimer chelation.<sup>38,39</sup> Home abatement and reinspection should be accomplished before initiation of ambulatory succimer therapy; if this is not feasible, hospitalization is still warranted. Alternative regimens (for rare patients with succimer intolerance or allergy or because of parental non-compliance) include parenteral chelation with CaNa<sub>2</sub>EDTA at 25 mg/kg/day for 5 days.<sup>3</sup>

After initial chelation therapy, decisions to repeat treatment are based on clinical symptoms and follow-up blood lead concentrations. For patients with encephalopathy or any severe symptoms or with an initial blood lead concentration above 100 mcg/dL we recommend repeated courses of treatment. It is reasonable that at least 2 days elapse before restarting chelation.<sup>147</sup> The precise regimen and dosing of chelator are determined by ongoing symptomatology and the repeat blood lead concentrations (Table 93–8). A third course of chelation is rarely necessary sooner than 5 to 7 days after the second course ends.<sup>147</sup> For patients with milder degrees of plumbism (eg, asymptomatic, initial blood lead concentration <70 mcg/dL), it is reasonable to allow 10 to 14 days of reequilibration before restarting treatment according to the indications outlined in Table 93–8.<sup>2</sup>

The management of asymptomatic children with blood lead concentrations of 20 to 44 mcg/dL is controversial.<sup>38,130,186</sup> The National Institutes of Health–sponsored Treatment of Lead-exposed Children (TLC) trial found only modest efficacy of succimer in reducing blood lead concentrations. Furthermore, at 3 years post-enrollment, no benefit was noted in treated patients on measures of cognition, neuropsychiatric function, or behavior.<sup>160</sup> This large study enrolled 780 children in a multicenter, randomized, placebo-controlled, double-blind trial, but is still criticized, particularly for using a single chelator and having failed to lower blood lead concentrations significantly over time between treated and control groups.<sup>171</sup> Of note, small but statistically significant decrements in growth velocity were noted in the treatment group, which might reflect trace mineral depletion.<sup>146</sup> Since its initial publication, the primary findings of the TLC trial on lack of cognitive improvement were confirmed in a 7 year follow-up study.<sup>48</sup> In addition, a reanalysis of the original data found that decreasing blood concentrations did correlate with improved cognitive scores over the initial 36-month trial period (approximately 4 IQ points for each 10-mcg/dL decrease in blood lead concentration), but only in the placebo group.<sup>115</sup> Nevertheless, we believe it is reasonable to perform chelation for such children with blood lead concentrations at the higher end of the range (eg, 35–44 mcg/dL), especially if they remain the same or increase over several months after rigorous environmental controls, in younger children (eg, younger than 2 years), in children with evidence of biochemical toxicity (an elevated erythrocyte protoporphyrin concentration after iron supplementation, for example), or any hint of subtle symptoms. Currently, the CDC<sup>19</sup> and the American Academy of Pediatrics<sup>3,5</sup> recommend neurodevelopmental assessment, aggressive environmental assessment and lead hazard reduction, laboratory evaluation and abdominal radiograph, along with routine nutritional interventions with close monitoring of blood lead concentrations, without routine chelation therapy, for such children. While the efficacy of aggressive home environment control efforts in reducing lead exposure to young children remains unproven,<sup>140</sup> these measures should be instituted

as good practice to both minimize exposure and facilitate family engagement in lead hazard reduction.

For children with blood lead concentrations of 5 to 19 mcg/dL, we recommend general measures of anticipatory guidance and nutritional counseling, along with environmental assessments, with follow-up monitoring of blood lead concentrations, as endorsed by the AAP and CDC.<sup>3,5,23</sup> The educational approaches outlined earlier should be included in the case management of all children with even modestly elevated lead concentrations. These interventions are summarized in Table 93–7.

## Adults

### General Considerations

The first principle in the treatment of adults with lead poisoning is that chelation therapy is not a substitute for adherence to OSHA lead standards at the worksite and should never be given prophylactically.<sup>47,96</sup> In addition to the guidelines for decreasing lead exposure noted earlier, chelation therapy is recommended for adults with significant symptoms (encephalopathy, abdominal colic, severe arthralgias, or myalgias), evidence of target organ damage (neuropathy or nephropathy), and possibly in asymptomatic workers with markedly elevated blood lead concentrations or evidence of biochemical toxicity.<sup>103,165</sup> Table 93–8 outlines recommended chelation therapy regimens for adults. For encephalopathic adult patients, we recommend combined dimercaprol and CaNa<sub>2</sub>EDTA therapy, just as for children, although some clinicians suggest that adults with severe lead poisoning may be successfully treated with CaNa<sub>2</sub>EDTA alone in doses of 2 to 4 g/day by continuous IV infusion.<sup>102</sup> Recent reports support the use of succimer in adult patients with mild to moderate plumbism after environmental and occupational remedies are instituted.<sup>108,150</sup> Chelation therapy using similar clinical and blood lead concentration–based guidelines is recommended in the perioperative period for patients undergoing surgical removal of retained bullets or débridement of adjacent lead-contaminated tissue.<sup>110,126,169</sup> Treatment of patients with acute TEL toxicity is largely supportive, with sedation as necessary. For patients evaluated soon after a large-volume ingestion, nasogastric suction is recommended with airway protection performed as needed. In general, chelation therapy for TEL toxicity is associated with enhanced lead excretion<sup>15</sup> but has not been found to be clinically efficacious.<sup>165,182,203</sup> However, for symptomatic, especially encephalopathic, patients (in whom there may be a significant component of metabolically derived inorganic lead toxicity) or those with very elevated blood lead concentrations, we do recommend chelation therapy.

### Pregnancy, Neonatal, and Lactation Issues

An area of particular concern in the management of adult plumbism involves decisions regarding therapy during pregnancy. As noted previously, lead freely passes the placental barrier and accumulates in the fetus throughout gestation. Screening of pregnant women for lead exposure, although not universal, is indicated in the presence of certain risk factors. Women of lower socioeconomic status and some ethnic groups (South American, Mexican, Asian, African American) are reported to engage in pica behavior, specifically geophagia (eating dirt or clay) at much higher rates than other groups, up to 30%.<sup>183</sup> Ayurvedic and other folk remedies are intended to improve fetal health, but reports of lead contamination are frequent.<sup>26</sup> Maternal bone stores are also a potential endogenous source of elevated blood lead concentrations in pregnancy, and contribute to modest increases in blood lead concentration during the third trimester, particularly in women with low calcium intake.<sup>25,82</sup> Screening should be conducted at prenatal visits and blood lead concentration obtained if any concern arises. Guidelines from the CDC and American College of Obstetrics and Gynecology outline appropriate screening and follow-up of elevated blood lead concentrations in pregnancy.<sup>25</sup> In general, any pregnant woman with a blood lead concentration of greater than 5 mcg/dL requires close follow-up testing, along with careful environmental and occupational exposure investigation and nutritional counseling. Appropriate calcium intake (2,000 mg/day) through adequate diet or supplementation should be ensured because its use is associated with decreased bone resorption during pregnancy, which likely lessens fetal lead

exposure.<sup>89</sup> Adequate maternal iron intake is also associated with lower neonatal blood lead concentration.<sup>167</sup> Iron-deficient patients should be treated; otherwise an iron-sufficient diet should be advised. Women with blood lead concentrations greater than 10 mcg/dL should be reported to the lead poisoning program of the local health department, and if an occupational source is suspected, a consult to an occupational medicine specialist obtained. Pregnant patients with blood lead concentrations greater than 45 mcg/dL should undergo medical toxicology and high-risk pregnancy consultation.

Chelation therapy during early pregnancy poses theoretical problems of teratogenicity, particularly that caused by enhanced excretion of potentially vital trace elements, or translocation of lead from mother to fetus (Antidotes in Depth: A28, A29, and A30). However, of some reassurance regarding fetal health, a case series and 25-year literature review of lead poisoning during pregnancy found no reports of chelation-associated birth defects in the handful of published cases.<sup>172</sup> It should be noted that despite decreases in maternal blood lead concentration in most treated women, the effect on cord or neonatal blood lead concentrations is more variable, and in some cases these approximate the pretreatment maternal blood lead concentration.<sup>25</sup> In general, there currently seems little support for routine chelation therapy in asymptomatic pregnant women with only moderate increases in blood lead concentration (eg, <45 mcg/dL), particularly during the first-trimester period of fetal organogenesis. Symptomatic women and those with blood lead concentrations greater than or equal to 70 mcg/dL should undergo chelation, regardless of trimester. For pregnant patients whose blood lead concentrations are 45 to 69 mcg/dL, medical toxicology and high-risk obstetric consultation is recommended<sup>25</sup> as well as for women with lower blood lead concentrations for whom substantial questions exist about source of lead exposure, or for whom blood lead concentrations are rising significantly during their pregnancy on follow-up testing.

Postnatally, infant blood lead concentrations usually decline over time without chelation, but this occurs very slowly, and the course is variable. For example, in 2 reported neonates exposed to prenatal maternal chelation who were then monitored for 2 weeks postpartum, the blood lead concentration remained stable or increased until chelation therapy was instituted.<sup>145,185</sup> In 2 additional cases of neonates whose mothers were not treated prepartum, blood lead concentrations also remained stable or increased for 17 days to 3 weeks.<sup>67,177</sup> Thus, postpartum chelation therapy should be conducted for neonates, according to blood lead concentrations, as per the guidelines described above for older children. For overtly symptomatic neonates or those with extremely elevated blood lead concentrations, both chelation therapy and exchange transfusion are reasonable treatment modalities.<sup>35</sup> However, many practitioners are unfamiliar with exchange transfusion, and there are several reports of safe and effective chelation therapy with edetate calcium disodium, dimercaprol, and/or succimer in the newborn.<sup>152,172</sup> Taking these considerations into account, for the majority of neonates with blood lead concentration at or above 45 mcg/dL, we recommend chelation.

Lastly, the issue of allowing mothers with elevated blood lead concentrations to breastfeed their infants will arise. Breast milk from heavily exposed mothers is a potential source of lead exposure.<sup>9,53,54</sup> One small case series found that breast milk from 2 women with blood lead concentrations of 34 and 29 mcg/dL, respectively, had clinically insignificant lead content (<0.01 mcg/mL).<sup>9</sup> Another study calculated the estimated rise in infant blood lead concentration at 1 month postpartum to be expected from breastfeeding, suggesting a rise of 0.12 mcg/dL for each mcg/dL of maternal blood lead concentration.<sup>54</sup> Given these considerations, the majority of lead-exposed mothers should still be encouraged to breastfeed with monitoring of the infant's blood lead concentration.<sup>53</sup> For mothers with blood lead concentrations of less than or equal to 40 mcg/dL, breastfeeding should be encouraged with close follow-up of maternal and infant blood lead concentrations (Table 93–9).<sup>25,53</sup> We also recommend maternal calcium supplementation (1,200 mg/day of elemental calcium as calcium carbonate), a simple intervention that reduces breast milk lead content by 5% to 10%.<sup>55</sup>

**TABLE 93–9 Summary of Guidelines for Breastfeeding with Perinatal Lead Exposure<sup>a</sup>**

#### Recommendations for Initiation of Breastfeeding<sup>b</sup>

- Measurement of concentrations of lead in breast milk is not recommended.
- Mothers with blood lead concentrations <40 mcg/dL should breastfeed if there are no other contraindications.
- Mothers with confirmed blood lead concentrations  $\geq$ 40 mcg/dL should begin breastfeeding when their blood lead concentrations drop below 40 mcg/dL. Until then, they should pump and discard their breast milk (*chelation therapy of mother with blood lead concentration  $\geq$ 45 mcg/dL is reasonable<sup>b</sup>*)
- These recommendations are likely not appropriate in countries where infant mortality from infectious diseases is high.

#### Recommendations for Continuation of Breastfeeding<sup>b</sup>

- Breastfeeding should continue for infants with blood level concentrations below 5 mcg/dL.
- Infants born to mothers with blood lead concentration  $\geq$ 5 mcg/dL, but <40 mcg/dL can continue to breastfeed unless there are indications that the breast milk is contributing to elevating blood lead concentrations. These infants should have blood lead concentration tests at birth and be followed, according to the following schedule:

Infant blood lead concentration 5–24 mcg/dL: Follow-up test, within 1 month (*we recommend at 1 and 3 weeks until trend established*)<sup>b</sup>

Infant blood lead concentration 25–44 mcg/dL: Follow-up blood lead concentration within 2 weeks (*we recommend at 1 week, then weekly during first month*)<sup>b</sup>

Infant blood lead concentration  $\geq$ 45 mcg/dL: Follow-up test within 24 hours and then frequently (*also see above if maternal blood lead concentrations >40 mcg/dL*)<sup>b</sup>

For infants whose blood lead concentrations are rising or failing to decline by 5 mcg/dL or more, environmental and other sources of lead exposure should be evaluated. If no external source is identified, and maternal blood lead concentrations are >20 mcg/dL and infant blood lead concentration  $\geq$ 5 mcg/dL, then breast milk should be suspected as the source, and breastfeeding should be temporarily interrupted until maternal blood lead concentrations decline.<sup>b</sup>

<sup>a</sup>Data from Centers for Disease Control and Prevention. Guidelines for the identification and management of lead exposure in pregnant and lactating women. <http://www.cdc.gov/nceh/lead/publications/LeadandPregnancy2010.pdf>. Published 2010.<sup>25</sup>

Comments in italics are the opinions of the authors. It should be noted that these guidelines were developed at a time when the CDC threshold of concern for infant blood lead concentration was 10 mcg/dL. In light of the new lowered threshold to 5 mcg/dL, more conservative guidelines may be developed in the foreseeable future.

<sup>b</sup>Owing to the complexity of these cases and varied data regarding the contribution of maternal blood lead concentration and breast milk to infant exposure and clinical effects, pediatric toxicology consultation is advised to assist with risk assessment, interpretation, and management.

## SUMMARY

- Lead is a widely distributed element that has long been used by humans for a variety of purposes, including waterproofing; electrical and radiation shielding; and the production of ammunitions, paints, plastics, ceramics, glass, and explosives.
- Lead poisoning, or plumbism, has an equally long history, but today it is primarily manifest in young children exposed to deteriorated lead paint and as an occupational toxic exposure for adult workers.
- Lead causes multiorgan toxicity, affecting especially the hematologic and neurologic systems in patients of all ages and causing hypertension in adults. The broad spectrum of clinical effects range from subtle neurocognitive insults to vague constitutional symptoms to acute encephalopathy, intracranial hypertension, cerebral edema, and death.
- The mainstays of treatment are removal from exposure for all patients, and chelation therapy for patients with symptoms or significantly elevated blood lead concentrations. Defining a group of asymptomatic patients that will benefit from chelation therapy has been difficult and controversial.
- Parenteral chelation with CaNa<sub>2</sub>EDTA and dimercaprol is efficacious in lowering blood lead concentrations and reducing mortality and morbidity from severe lead poisoning. Succimer, an oral chelator, also has efficacy in reducing blood lead concentrations in asymptomatic children, although the neurocognitive benefit of doing so is unproven.

# SUCCIMER (2,3-DIMERCAPTOSUCCINIC ACID) AND DMPS (2,3-DIMERCAPTO-1-PROPANESULFONIC ACID)

Mary Ann Howland

## INTRODUCTION

Succimer (meso-2,3-dimercaptosuccinic acid, DMSA) is an orally active metal chelator that is approved by the US Food and Drug Administration (FDA) for the treatment of lead poisoning in children with blood lead concentrations greater than 45 mcg/dL. Succimer is also used to treat patients poisoned with arsenic and mercury. Succimer has a wider therapeutic index and exhibits many advantages over dimercaprol and ethylenediaminetetraacetic acid calcium disodium ( $\text{CaNa}_2\text{EDTA}$ ), the 2 other chelators used for similar clinical problems. Animal studies demonstrate that succimer does not redistribute lead or arsenic to the central nervous system. The role of succimer alone and in conjunction with other chelators to treat lead encephalopathy continues to be defined.<sup>64,78,107</sup>

## HISTORY

Succimer was initially synthesized in 1949 in England.<sup>76</sup> In 1954, antimony-a,a'-dimercaptopotassium succinate (TWSb) was developed to treat schistosomiasis.<sup>45</sup> Antimony-a,a'-dimercaptopotassium succinate is antimony bound to the potassium salt of succimer in a 2:3 ratio, forming a water-soluble xenobiotic with 50 times less toxicity than the previously employed antimony compound, tartar emetic. Chinese investigators subsequently demonstrated the ability of the sodium salt of succimer to increase the  $\text{LD}_{50}$  of tartar emetic 16-fold in mice (Chap. 85).<sup>119</sup> An early review of the Chinese experience with intravenous (IV) succimer in the treatment of occupational lead and mercury poisoning suggested efficacy similar to IV  $\text{CaNa}_2\text{EDTA}$  in increasing urinary lead and to intramuscular (IM) DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid) for mercury, with little observed toxicity.<sup>105</sup> This experience, the subsequent widespread use in Asia<sup>80,83,95,115,116,122</sup> and Europe,<sup>18,37,43,46,67,105</sup> and the realization that succimer could be used orally,<sup>7,52</sup> led to US-based animal experiments, human trials, and FDA approval in 1991 for the treatment of lead-poisoned children.

## PHARMACOLOGY

### Chemistry

Succimer is a white crystalline powder with a molecular weight of 182 Da and a characteristic sulfur odor and taste.<sup>6</sup> Succimer is the highly polar and water soluble form of 2,3-dimercaptosuccinic acid.

### Related Chelators

Racemic-2,3-dimercapto-1-propanesulfonic acid (DMPS) is a chelator that, like succimer, is a water-soluble analog of dimercaprol (British anti-Lewisite

{BAL}).<sup>7,9,25</sup> A dose of 15 mg/kg of DMPS is equimolar to 12 mg/kg of succimer. 2,3-Dimercapto-1-propanesulfonic acid has been used in the Soviet Union since the late 1950s and continues to be used in Russia and Eastern Europe. 2,3-Dimercapto-1-propanesulfonic acid, which is an investigational drug in the United States, is marketed in both oral and parenteral forms in Germany as Dimaval. Dimercaptopropane sulfonate seems promising in mercury and arsenic poisoning.<sup>3,5,7,9,11,14,25,48</sup> Dimercaptopropane sulfonate is associated with an increase in the urinary excretion of copper and the development of Stevens-Johnson syndrome.<sup>28,111</sup> Like succimer, DMPS does not appear to redistribute mercury or lead to the brain. Additional research is needed to determine whether DMPS is more advantageous than succimer, given its lower  $\text{LD}_{50}$  in mice (5.22 mmol/kg versus 13.58 mmol/kg for succimer) when administered intraperitoneally.<sup>4</sup>

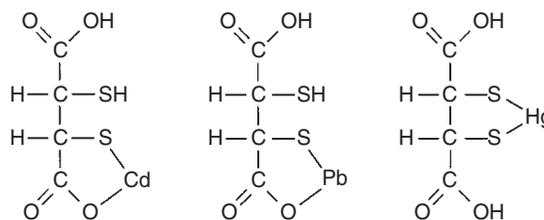

### Mechanisms of Action

Succimer contains 4 ionizable hydrogen ions, giving it 4 different  $\text{pK}_a$ s—2.31, 3.69, 9.68, and 11.14—with the dissociation of the 2 lower values representing the carboxyl groups and the 2 higher values the sulfur groups.<sup>4</sup> Lead and cadmium bind to the adjoining sulfur and oxygen atoms, whereas arsenic and mercury bind to the 2 sulfur moieties, forming pH-dependent water-soluble complexes (Fig. A29-1).<sup>90</sup>

### Pharmacokinetics and Pharmacodynamics

Succimer is highly protein bound to albumin through a disulfide bond. Sub-human primate studies of IV and oral<sup>24</sup> succimer indicate that following an IV dose, radiolabeled succimer is eliminated almost exclusively via the kidney, with only trace amounts (<1%) excreted via feces or expired air.<sup>24,76</sup> Following the administration of a single oral dose of 10 mg/kg, succimer is rapidly and extensively metabolized.<sup>73</sup> Approximately 20% of the administered oral dose is recovered in the urine, presumably reflecting the low bioavailability of the drug.<sup>10</sup> Of the total drug eliminated in the urine (20%), 89% is altered and in the form of disulfides of L-cysteine. The majority of the altered succimer is in the form of a mixed disulfide with 2 molecules of L-cysteine to one molecule of succimer.<sup>8</sup> The remaining 11% is excreted as unaltered free succimer.<sup>73</sup> Maximal excretion of succimer occurs in urine specimens collected between 2 and 4 hours after administration. Surprisingly, the blood only contains albumin-bound succimer and no evidence of the altered disulfide moieties, which suggests that the kidney is involved in the biotransformation of succimer. It is likely that succimer gains entry to the kidney via an active organic anion transporter.<sup>9,22,121</sup>

The pharmacokinetics of a single oral dose of succimer were determined in 3 children and 3 adults with lead poisoning and in 5 healthy adult

**FIGURE A29-1.** The chelation of cadmium, lead, and mercury with succimer.

volunteers.<sup>36</sup> Children received 350 mg/m<sup>2</sup> of succimer, and adults received 10 mg/kg of succimer. The peak concentration and the time to peak blood concentration of total succimer (parent plus altered oxidized metabolites) were similar for all 3 groups. The half-life of total succimer was 1.5 times longer in the children than in either adult group. The renal clearance of total succimer was greater in healthy adults ( $Cl_{cr} > 77$  mL/min) than in lead-poisoned adults ( $Cl_{cr} = 25$  mL/min) and children ( $Cl_{cr} = 17$  mL/min) with reduced creatinine clearances. Distribution of succimer (parent and/or oxidized metabolites) into erythrocytes appeared greater in poisoned patients than in the healthy adults, whereas another study in human volunteers revealed no distribution into the red blood cells.<sup>36,72</sup>

The metabolism of succimer was studied in lead-poisoned children and in normal adults.<sup>15</sup> The results indicate that succimer undergoes an enterohepatic circulation facilitated by gastrointestinal (GI) microbiome. Similar to the previous pharmacokinetic study, moderate lead exposure impaired the renal elimination of succimer.

A simulation model of the plasma pharmacokinetics of succimer was developed in 2016. This model<sup>113</sup> was then expanded to predict the efficacy of succimer in reducing blood lead concentrations when prechelation concentrations were between 99 and 150 mcg/dL<sup>112</sup> and the duration of lead exposure is known. This model is likely to have utility when blood lead concentrations are not easily obtained.

## ROLE IN LEAD POISONING

In addition to precise analysis of metal elimination kinetics, measures of clinical outcome are essential for an understanding of the utility of this chelator. The Treatment of Lead-Exposed Children (TLC) trial was a step in that direction.<sup>109</sup> The TLC trial was a randomized, multicenter, double-blind, placebo-controlled study of 780 children to examine the effects of succimer on cognitive development, behavior, stature, and blood pressure in children 1 to 3 years of age with blood lead concentrations between 20 and 44 mcg/dL.<sup>91</sup> The children received up to 3 courses of 26 days each of succimer compared to placebo. For the first 7 days, the children received 350 mg/m<sup>2</sup> 3 times a day and for the remaining 19 days they received 350 mg/m<sup>2</sup> twice a day. The largest drop in blood lead occurred within the first week of therapy with succimer and then rebounded somewhat. This pattern recurred with subsequent courses. However, at the end of one year, there was no difference in the blood lead concentrations between the succimer and the placebo groups. There was also no difference in test scores on cognition, behavior, or neuropsychological function.<sup>91</sup> A follow-up study conducted on those children at age 7 confirmed the lack of benefit in chelating children with succimer whose blood lead concentrations were 20 to 44 mcg/dL, at ages 1 to 3 years.<sup>38</sup> Similarly, succimer showed no benefit on growth in children aged 12 to 33 months with blood lead concentrations of 20 to 44 mcg/dL.<sup>87</sup>

Several groups are studying the efficacy of succimer in reducing blood, brain, and tissue lead by using rat and nonhuman primate models of childhood and adult lead poisoning.<sup>96,98,100</sup> Although monkeys most closely resemble humans in their lead-associated toxicity, using them in studies is costly;<sup>82</sup> the rat model is economical but limited because of species differences in lead and succimer metabolism and efficacy.

The validity of using blood lead concentrations as a marker of brain lead was studied in the adult rhesus monkey. Lead was administered orally for 5 weeks to achieve a target blood lead concentration of 35 to 40 mcg/dL.<sup>35</sup> Five days after the cessation of lead exposure, succimer chelation was initiated in the currently approved dosage regimen. Two IV doses of radioactive lead tracer were administered prior to succimer chelation to study the kinetics of recent versus chronic lead uptake and distribution. Four areas of the brain, as well as blood and bone, were assayed for lead. Merely stopping further lead exposure significantly reduced blood lead concentrations by 63% and brain lead concentrations by 34% compared with pretreatment concentrations, a finding that was not statistically different from succimer administration after halting exposure. However, when an integrated area under the serum lead concentration versus time curve (AUC) blood analysis was used over the 19-day succimer treatment course, instead of a single blood

lead concentration, the differences between succimer and control were statistically significant. The clinical significance of these differences is unclear. Succimer-treated animals showed the greatest drop in blood lead concentrations over the first 5 days, whereas a similar end point was gradually achieved in the control. The lead from both the recent exposure (radioactive tracer lead) and chronic exposure declined to the same extent, independent of treatment with succimer. A better correlation was found between brain prefrontal cortex lead concentrations and an integrated blood lead analysis than with a single blood lead measurement.

Similarly, a study in neonatal rats demonstrated that increasing the duration of succimer chelation from 7 to 21 days decreased brain lead concentrations without a corresponding decrease in blood lead concentrations.<sup>96</sup> The authors proposed that a slow rate of egress of brain lead to the blood was responsible for the demonstrable benefit of prolonging therapy to 21 days. In this study, succimer decreased blood lead concentration by approximately 50% when compared with the vehicle as the control, and this difference persisted for the 21 days of treatment. With succimer treatment, brain lead concentration decreased by 38% at 7 days and by 68% at 21 days. This same group also demonstrated that rats exposed to lead from postnatal days 1 to 30, then treated with succimer, demonstrated reductions in blood and brain lead concentrations and an improvement in cognitive deficits.<sup>101</sup> Previous animal studies demonstrated the ability of succimer to enhance urinary lead elimination<sup>44,52,100</sup> and to reduce blood,<sup>17,32,41,42,57,85,98,100,102,104</sup> brain,<sup>17,32,85,103,104</sup> liver,<sup>100</sup> and kidney lead concentrations,<sup>17,32,41,57,85,104</sup> while either reducing<sup>17,57,85,104</sup> or demonstrating no effect on bone lead concentrations.<sup>32,100</sup> These studies differ in the amounts and duration of lead administration prior to chelation, as well as in route, dose, and duration of chelation; however, several months after a course of succimer chelation, tissue lead concentrations had returned to concentrations found in the pretreatment stage.<sup>32</sup> Given the limited absolute amount of lead that is actually eliminated by chelation in comparison to the total body burden, particularly bone, these transient effects are not surprising.

Under a variety of experimental conditions in animals, succimer prevents the deleterious effect of lead on heme synthesis,<sup>17,52,85</sup> blood pressure,<sup>61</sup> and behavior.<sup>102</sup>

The use of succimer in both children and adults with chronic lead poisoning demonstrated consistent findings.<sup>19,29,53–55,68,81</sup> During the first 5 days of succimer chelation (1,050 mg/m<sup>2</sup>/day in children and 30 mg/kg/day in adults, both in 3 divided doses), the blood lead concentration dropped precipitously by approximately 60% to 70%. This blood lead concentration remained unchanged during the next 14 to 23 days of continued therapy. Increases in urinary lead excretion are concurrent with the reduction in blood lead concentration, with maximal excretion occurring on day 1.<sup>29,54</sup> Urinary lead excretion exceeds estimated blood content, which suggests that some lead is being removed from soft tissues as a concentration gradient is established from tissue to blood to urine.<sup>29,55</sup> Typically, 2 weeks after the completion of succimer, the blood lead concentration rebounds to values 20% to 40% lower than pretreatment values. In the one randomized, double-blind, placebo-controlled trial of succimer use in children with pretreatment blood lead concentrations of 30 to 45 mcg/dL, follow-up at one month and at 6 months showed no differences between succimer-treated children and controls.<sup>81</sup> Succimer restored red blood cell Delta-aminolevulinic acid dehydratase activity, decreased erythrocyte protoporphyrin, and decreased urinary excretion of Delta-aminolevulinic acid and coproporphyrin.<sup>19,29,54,55,81</sup>

There is a large body of evidence documenting on usage and safety profile of succimer in adults with chronic lead poisoning.<sup>13,18,29,43,46,47,50,51,62,65,74,88,106,110</sup> The published experience outside the United States with the use of oral succimer for metal poisoning includes nearly 100 adult cases and contributes considerably to the supporting evidence. At least 74 additional individuals were successfully treated parenterally (IM or IV) with the sodium salt of succimer.<sup>13,18,43,46</sup>

## Role in Lead Encephalopathy

The experience with the use of succimer in severely lead-poisoned patients, including those with encephalopathy, is limited to case studies and a large retrospective analysis.<sup>43,46,54,107</sup> Three children with mean blood lead

concentrations higher than 70 mcg/dL who were treated with 5 days of succimer achieved comparable declines in blood lead concentration to 2 similar children who had been treated previously with a combination of dimercaprol for 3 days and CaNa<sub>2</sub>EDTA for 5 days.<sup>54</sup> Three adult patients with encephalopathy achieved significant improvement following succimer chelation.<sup>43</sup> An adult woman presented to the ED with seizures of unknown origin that resolved.<sup>15</sup> Two weeks later, she presented to another ED with worsening headache, weakness, and confusion and a CT scan of the brain that showed cerebral edema. She was intubated and ventilated for almost 2 weeks after extubation and with a persistent altered mental status a heavy metal screen revealed a lead concentration of 148 mcg/dL. One dose of dimercaprol was administered followed by succimer since CaNa<sub>2</sub>EDTA was unavailable. Within 4 days her mental status returned to baseline and her weakness resolved. An analysis of her blood lead concentrations demonstrated an initial rise to 164 mcg/dL after succimer was administered followed by a steep decline to 102 mcg/dL in a day and 56 mcg/dL after 8 days. A 3-year-old child with a massive lead exposure superimposed on chronic lead poisoning and a blood lead concentration of 550 mcg/dL was given dimercaprol and CaNa<sub>2</sub>EDTA for 5 days, with whole-bowel irrigation (WBI) was performed during the first 3 days and succimer following WBI beginning on day 3 and continuing for 19 days. When blood lead concentration was reduced from 550 to 70 mcg/dL on day 5, but rebounded to 99 mcg/dL 2 days after dimercaprol and CaNa<sub>2</sub>EDTA were discontinued but not the succimer was discontinued.<sup>49</sup> Most recently, a retrospective analysis of more than 3,000 children with moderate to severe lead poisoning in resource-poor Nigeria were treated with succimer alone.<sup>107</sup> About one-third of the children had lead concentrations greater than 80 mcg/dL, 6% had concentrations >120 mcg/dL, and 24 had lead encephalopathy. The geometric mean of the postcourse blood lead concentration divided by the precourse blood lead concentration in patients treated with succimer and a precourse blood lead concentration greater than 120 mcg/dL was 68%. In the 3 months before the institution of succimer, there were 400 fatalities attributed to lead compared with 6 deaths during the 13 months when succimer was used.

## ROLE IN ARSENIC POISONING

Succimer was used for arsenic toxicity in China and the Soviet Union since 1965.<sup>7,13</sup> Animal<sup>63</sup> studies with sodium arsenite and lewisite demonstrate the ability of succimer to improve the LD<sub>50</sub> with a good therapeutic index, lack of redistribution of arsenic to the brain as compared to dimercaprol or control, and reduced kidney and liver arsenic concentrations.<sup>7,13,66,86,92</sup> A few case reports of concentrations following ingestion of arsenic trioxide ant bait by toddlers attest to the ability of succimer to enhance the urinary excretion of arsenic,<sup>34,93</sup> and after 2 to 7 weeks of chelation, urinary arsenic returned to normal.<sup>117</sup> A randomized, placebo-controlled trial of succimer to treat 21 patients with chronic arsenic poisoning in India who had stopped ingesting arsenic contaminated water 5 months previously demonstrated improved clinical results and enhanced urinary excretion of arsenic in both the treatment and placebo groups, but no statistical differences could be demonstrated.<sup>75</sup> A comparison of dimercaprol, succimer, and DMPS as arsenic antidotes demonstrated higher therapeutic indices for succimer and DMPS over dimercaprol in chronic arsenic poisoning.<sup>79</sup>

## ROLE IN MERCURY POISONING

Succimer enhances the elimination of mercury and has been used to treat patients poisoned with inorganic, elemental, and methylmercury. It improves survival, decreases kidney damage, and enhances the elimination of mercury in animals following exposure to inorganic mercury<sup>4,24,57,60,69,89,120</sup> and methylmercury.<sup>1,29,70</sup> However, one study in mice subjected to intraperitoneal mercuric chloride demonstrated an enhanced deposition of mercury in motor neurons following chelation with succimer or DMPS.<sup>40</sup> Of 53 construction workers who were exposed to mercury vapor, 11 received succimer and *N*-acetyl-D,L-penicillamine in a crossover study.<sup>21</sup> Mercury elimination was increased during the period of succimer administration compared with the period of *N*-acetyl-D,L-penicillamine administration. Because the chelators

were administered for only 2 weeks and late in the clinical course, therapeutic benefit could not be evaluated. When succimer was given to victims of an extensive Iraqi methylmercury exposure, blood methylmercury half-life decreased from 63 days to 10 days.<sup>7</sup> Animal studies suggest that succimer is not able to reduce brain mercury concentrations following inhalation of elemental mercury vapor although renal mercury concentrations did decrease.<sup>63</sup>

## ADVERSE EVENTS AND SAFETY ISSUES

Succimer is generally well tolerated, with few serious adverse events reported.<sup>29,30,91,108</sup> Common adverse events are typically GI in nature, including nausea, vomiting, flatus, diarrhea, and a metallic taste in 10% to 20% of patients. Rashes are reported in about 4% of patients.<sup>26</sup> Fever and oropharyngeal ulcers with rash or rash alone are uncommon and are theorized to be fixed drug eruptions.<sup>114</sup> Some of these adverse events required discontinuation of the succimer. Mild elevations in aspartate aminotransferase and alanine aminotransferase considerations are reported.<sup>22,28,30,55,68,84</sup> In the Nigeria experience, ALT did not exceed 500 U/L and no hepatic failure was noted.<sup>107,121</sup> Rarely, chills, fever, urticaria, reversible neutropenia, and eosinophilia are reported.<sup>19,29,30,50</sup> Because neutropenia was observed in some patients taking succimer and because bone marrow effects are reported with other drugs in the same chemical class, we recommend a complete blood count with a differential and a platelet count before initiating treatment and weekly during treatment.<sup>26</sup> Therapy should be discontinued if the absolute neutrophil count drops to less than 1,200/ $\mu$ L.<sup>26</sup> During the latest open label prospective study in children, apparently unrelated adverse events included an elevation in bone-derived alkaline phosphatase, eosinophils, and elevated serum aminotransferases.<sup>29</sup> One patient developed severe hyperthermia and hypotension reportedly related to succimer administration.<sup>84</sup>

Chinese clinicians reported a high incidence of more serious adverse effects (including dizziness and weakness) in response to either IV or IM succimer.<sup>116,122</sup> This discrepancy is undoubtedly related to the substantially greater dose of succimer delivered from parenteral administration compared with the relatively low (20%)<sup>76</sup> oral bioavailability of succimer as a result of first-pass metabolism.

Incidental chelation of essential elements is always a concern with the use of chelators. A number of studies using succimer demonstrate no rise in urinary zinc, copper, iron, or calcium.<sup>29,43,46,53–55</sup> Urinary excretion of essential elements was the focus of a study in a primate model of childhood lead poisoning.<sup>98</sup> Infant rhesus monkeys were exposed to lead for the first year of life to achieve blood lead concentrations of 40 to 50 mcg/dL. Succimer was administered in the standard dosage regimen and complete urine collections over the first 5 days were analyzed for calcium, cobalt, copper, iron, magnesium, manganese, nickel, and zinc. Only when the data were analyzed collectively for all 8 elements on all 5 days was there a statistically significant increased urinary elimination. These results raise concern that children subjected to repeated succimer chelation are also be at risk for enhanced elimination of essential elements.<sup>29,98,100</sup> Therefore, children should be monitored and repleted with these essential elements as needed based on measured concentrations. There is still relatively limited clinical experience with succimer, particularly with regard to long-term administration.

A 3-week course of succimer administered to control rats produced a significant and long-lasting dysfunction in cognition and affect that was comparable to effects that occurred in rats exposed to high concentrations of lead.<sup>97,101</sup> The explanation for this finding is unknown but may be related to chelation of essential trace metals.

One concern with administering succimer orally is that outpatient management might permit continued unintentional lead exposure and the possibility for succimer-facilitated lead absorption. Studies with D-penicillamine, dimercaprol,<sup>58</sup> and CaNa<sub>2</sub>EDTA demonstrate enhanced lead absorption and elevated blood lead concentrations.

Most blood lead concentrations are measured by graphite furnace atomic absorption spectrophotometry, in which case succimer does not interfere with the measurement. However, if blood lead concentrations were to be measured by anodic stripping voltammetry, succimer affects the results

by chelating the mercury in the electrode.<sup>26</sup> Succimer is reported to cause a false-positive result for urinary ketones when tests using nitroprusside reagents are used, and falsely decreased serum uric acid and creatine phosphokinase concentrations.<sup>26</sup>

Animal studies suggest that succimer does not promote lead retention in the setting of continued exposure unless lead exposure is overwhelming.<sup>52,59,85</sup> A radiolabeled lead tracer administered to adult volunteers suggested that succimer increased the net absorption of lead from the GI tract and have distributed it to other tissues, as well as having enhanced urinary elimination.<sup>99</sup> Absorption is bimodal and consistent with an initial phase, followed by a delayed increase attributable to an enterohepatic effect. Succimer-enhanced urinary lead elimination often exceeds enhanced lead absorption.<sup>86</sup> However, this was not supported by a more recent study using a juvenile nonhuman primate model of moderate childhood lead poisoning. Oral succimer administered for multiple days after the oral administration of an oral lead tracer significantly reduced the gastrointestinal absorption of lead and enhanced the renal elimination of lead.<sup>33</sup> One study reported 2 children with environmental exposure and dramatic rises in blood lead concentrations while receiving succimer which is further supported by the epidemic lead poisoning in Zamfara, Nigeria ... although the compliance with succimer was unclear in one of these patients.<sup>29</sup> In the event of exposure to a new oral lead source, decontamination of the GI tract should complement oral succimer.<sup>77</sup>

Although iron supplementation cannot be given concomitantly with dimercaprol, because the dimercaprol-iron complex is a potent emetic, iron has been given concomitantly to patients receiving oral succimer without any adverse events.<sup>56</sup> The prevalence of both iron deficiency and elevated blood lead concentrations is highest among poor, inner-city children.<sup>71</sup> Because heme is a constituent of all cells, including those of the brain, it appears clinically indicated to provide iron supplementation during chelation therapy, when the heme pathway is freed of the inhibitory effects of lead. The timing of administration of the iron should be separate from administration of the succimer by a few hours.<sup>29</sup>

Overdoses of succimer are rarely reported. A case report describes a 3-year-old child who reportedly ingested 185 mg/kg of succimer and was asymptomatic.<sup>94</sup> Rodent models suggest doses of 2 gm/kg caused ataxia, seizures, labored breathing, and death.<sup>26</sup>

## PREGNANCY AND LACTATION

Succimer is FDA pregnancy category C. There are no adequate studies in pregnant women. The use of succimer in pregnancy is restricted to women who warrant therapy based on their symptoms.<sup>29</sup> There was a dose-dependent effect of succimer on early and late fetal resorption and on fetal body weight and length when succimer was administered to pregnant mice during organogenesis. No observed teratogenic effects were noted when 410 mg/kg, or approximately 5% of the acute LD<sub>50</sub>, of succimer was administered subcutaneously.<sup>39</sup> However, doses of 410 to 1,640 mg/kg/day of succimer administered subcutaneously to pregnant mice during organogenesis are teratogenic and fetotoxic, and doses of more than 510 mg/kg/day to pregnant rats also showed problems with reflexes in the offspring.<sup>26</sup> Succimer 30 to 60 mg/kg/day was administered by gavage to lead-poisoned rats from days 6 to 21 of gestation.<sup>27</sup> These doses of succimer decreased embryonic and fetal blood lead concentrations and normalized offspring body weight at 13 weeks. Although succimer was able to reverse some lead-induced immunotoxic effects, succimer itself caused problems with the immune system that persisted into adulthood.<sup>27</sup> Female mice exposed to lead in utero and then administered succimer from the fourth day of gestation to parturition demonstrated decreased blood lead concentrations; however, fetal liver and bone concentrations increased and worsened neural development in the offspring.<sup>118</sup> The exact mechanism for these effects is unknown, but disturbances in zinc and copper are hypothesized to be involved.<sup>23</sup> The use of succimer during pregnancy should only be undertaken if the potential benefit to the mother justifies the potential risk to the fetus.<sup>26</sup> It is not known whether succimer is excreted in human milk, but breast feeding is a contraindication in some sources and is discouraged in the package insert.<sup>26</sup> However, in

the 2010 Centers for Disease Control and Prevention (CDC) Guidelines for the identification and management of lead exposure in pregnant and breastfeeding women the CDC suggests allowing breast feeding for mothers with blood lead concentrations of less than or equal to 40 mcg/dL. Mothers with BLLs of greater than 40 mcg/dL are encouraged to pump and discard their breast milk until their blood lead concentrations are reduced to less than 40 mcg/dL.

## COMBINED CHELATION THERAPY

Succimer can be combined with CaNa<sub>2</sub>EDTA to take advantage of the ability of succimer to remove lead from soft tissues, including the brain, while capitalizing on the ability of CaNa<sub>2</sub>EDTA to mobilize lead from bone.<sup>32</sup> This combination is recommended in patients in whom dimercaprol would be indicated but is not available. A number of rodent models have examined this combination and found it to be superior to either drug alone in enhancing the elimination of lead, in reducing tissue concentrations of lead, and in remediating some lead-induced biochemical abnormalities.<sup>41,42,103</sup> Although the addition of succimer to CaNa<sub>2</sub>EDTA prevented the redistribution of lead to the brain caused by CaNa<sub>2</sub>EDTA alone, the combination also increased urinary excretion of zinc, calcium, and iron.<sup>103,104</sup> A retrospective review comparing dimercaprol plus CaNa<sub>2</sub>EDTA to succimer plus CaNa<sub>2</sub>EDTA in children with blood lead concentrations greater than 45 mcg/mL, demonstrated a similar reduction in blood lead concentrations at the end of treatment and at 14 and 33 days following the termination of treatment.<sup>20</sup> Blood lead concentration reductions were approximately 75%, 40%, and 37% at the end of therapy and at 14 and 33 days posttreatment, respectively. The succimer plus CaNa<sub>2</sub>EDTA combination was better tolerated.

## DOSING AND ADMINISTRATION

The recommended dosage is 350 mg/m<sup>2</sup> in children, 3 times a day for 5 days, followed by 350 mg/m<sup>2</sup> twice a day for 14 days. In adults, the recommended dosage is 10 mg/kg 3 times a day for 5 days followed by 10 mg/kg twice a day for 14 days. At approximately 5 years of age, dosing based on body surface area approximates the 10-mg/kg dose, whereas for children younger than 5 years dosing by body surface area, as was done during the premarketing trials, resulted in higher doses and is recommended.<sup>31,78</sup> Repeated courses may be needed depending on the blood lead concentration (Chap. 93 and Table 93-8). However, a minimum of 2 weeks between courses is recommended unless blood lead concentrations are initially greater than 100 mcg/dL or the patient has lead encephalopathy.<sup>26</sup> For patients who cannot swallow the capsule whole, it can be separated immediately prior to use and the contents sprinkled into a small amount of juice or on apple sauce, ice cream, or any soft food, or placed on a spoon and followed by a fruit drink (Table A29-1).

## FORMULATION AND ACQUISITION

Succimer is available as 100-mg bead-filled capsules. Povidone, sodium starch glycolate, starch, and sucrose are the inactive ingredients in the beads. The capsule contains gelatin, iron oxide, titanium dioxide, and other ingredients as inactive ingredients.

## SUMMARY

- Succimer (meso-2,3-dimercaptosuccinic acid) is an orally active metal chelator that is FDA approved for the treatment of lead poisoning in children with blood lead concentrations greater than 45 mcg/dL.
- There is no evidence at this time that succimer improves cognitive performance in patients with blood lead concentrations less than 45 mcg/dL.
- Succimer is also used to treat patients poisoned with arsenic and mercury.
- The advantages of succimer use include oral administration, limited effects on trace metals such as zinc, enhanced patient tolerance, limited toxicity, and the ability to coadminister iron (if needed). It is acceptable to use in glucose-6-phosphate dehydrogenase-deficient patients.

TABLE A29–1A and B Examples of Dosing Calculations

## A. Succimer (available as 100-mg bead-filled capsules)

	Avg. Height (in.)	Avg. Weight (lb.)	m <sup>2</sup>	350 mg/m <sup>2a</sup>	10 mg/kg <sup>a</sup>
<b>Child</b>					
2-year-old boy	36	30.5	0.593	189 mg	
2-year-old girl	35	29	0.57	200 mg	
4-year-old boy	42	39.75	0.73	255 mg	
4-year-old girl	41.75	38.75	0.72	250 mg	
<b>Adult</b>					
50-kg					500 mg
70-kg					700 mg
90-kg					900 mg

## B. Chemet (Succimer) Pediatric Dosing Chart

Pounds	Kilograms	Dose (mg) <sup>a</sup>	Number of Capsules <sup>a</sup>
18–35	8–15	100	1
36–55	16–23	200	2
56–75	24–34	300	3
76–100	35–44	400	4
100	>45	500	5

<sup>a</sup>To be administered every 8 hours for 5 days, followed by dosing every 12 hours for 14 days.

- By contrast to CaNa<sub>2</sub>EDTA, succimer does not redistribute lead to the brain of poisoned animals.<sup>11,32</sup>
- Succimer was used in Nigeria, a resource-poor area without access to either dimercaprol or CaNa<sub>2</sub>EDTA, for patients with moderate to severe lead poisoning including some patients with lead encephalopathy with apparent efficacy and safety.

# EDETATE CALCIUM DISODIUM (CaNa<sub>2</sub>EDTA)

Mary Ann Howland

## INTRODUCTION

Edetate calcium disodium (CaNa<sub>2</sub>EDTA) is a chelator that is primarily used for the management of patients with severe lead poisoning (blood lead concentrations >70 mcg/dL) in conjunction with dimercaprol (British anti-Lewisite {BAL}). Edetate calcium disodium was replaced by succimer for the treatment of patients with lead concentrations between 45 and 70 mcg/dL. In a clinical trial with much criticism, disodium EDTA (Na<sub>2</sub>EDTA) reduced adverse cardiovascular outcomes in patients with a history of myocardial infarction.<sup>3,22,36,41</sup> We recommend against using this preparation (Na<sub>2</sub>EDTA) for lead chelation because of the potential for life-threatening hypocalcemia.

## HISTORY

Ethylenediaminetetraacetic acid (EDTA) was discovered and synthesized in the 1930s and approved by the US Food and Drug Administration (FDA) as a food additive in the 1940s. Investigations on CaNa<sub>2</sub>EDTA for lead toxicity and for Na<sub>2</sub>EDTA for the reversal of cardiovascular disease began in the 1950s.

## PHARMACOLOGY

### Chemistry

Edetate calcium disodium is an ionic, water-soluble compound with an anhydrous molecular weight of 374.27 Da. It is also referred to as calcium disodium versenate, calcium disodium EDTA, or calcium disodium ethylenediaminetetraacetic acid.

### Mechanism of Action

Edetate calcium disodium belongs to the family of polyaminocarboxylic acids. Although it is capable of chelating many metals, its current use is almost exclusively in the management of lead poisoning. The term *chelate* has its origin in the Greek word *chele*, which means “claw,” implying an ability to tightly grasp the metal.<sup>52</sup> Implicit in chelation is the formation of a ring-structured complex. When CaNa<sub>2</sub>EDTA chelates lead, the calcium is displaced and the lead takes its place, forming a stable ring compound.<sup>34</sup> Bone is the primary source of lead chelated by CaNa<sub>2</sub>EDTA. The blood lead concentration drops due to urinary elimination; however, once chelation is stopped, redistribution to soft tissues, including the brain, and then bone occurs.<sup>11</sup> Although zinc, iron, manganese, copper, and mercury are also capable of displacing calcium and forming a stable chelate, for a number of reasons, only the effect on zinc is clinically significant.

## PHARMACOKINETICS AND PHARMACODYNAMICS

Edetate calcium disodium is a highly polar drug with a small volume of distribution (V<sub>d</sub>) due to its polar nature and approximates that of the extracellular fluid compartment regardless of renal function.<sup>29,34,42</sup> In one study of 14 patients the V<sub>d</sub> was 0.05 to 0.23 L/kg.<sup>42</sup> Edetate calcium disodium appears to penetrate erythrocytes poorly,<sup>2,29</sup> and less than 5% of CaNa<sub>2</sub>EDTA gains

access to the spinal fluid.<sup>29,34</sup> Oral administration of CaNa<sub>2</sub>EDTA is not practical because the bioavailability is less than 5%. The half-life is about 20 to 60 minutes.<sup>5,29,34</sup> When CaNa<sub>2</sub>EDTA combines with lead, it forms a stable, soluble, nonionized compound subsequently excreted in the urine. Following CaNa<sub>2</sub>EDTA administration, urinary lead excretion is increased 20- to 50-fold.<sup>14,43</sup> Renal elimination approximates the glomerular filtration rate,<sup>40</sup> which correlates with creatinine clearance,<sup>9</sup> resulting in the excretion of 50% of CaNa<sub>2</sub>EDTA in the urine within 1 hour, and more than 95% within 24 hours.<sup>29,34</sup> Elimination is entirely via the kidney with no appreciable metabolism.

## ROLE IN LEAD EXPOSURE

### Animals

A mouse study demonstrated a decrease in tissue lead stores, including brain concentrations, when measurements are performed following CaNa<sub>2</sub>EDTA therapy.<sup>32</sup> A rat study examining the effect of a single dose of CaNa<sub>2</sub>EDTA on brain lead concentrations demonstrated a significant increase in brain lead concentrations,<sup>22</sup> suggesting that CaNa<sub>2</sub>EDTA initially mobilizes lead and facilitates adverse redistribution to the brain. Additional doses enhanced lead elimination, reduced blood lead concentrations, and subsequently reduced brain lead concentrations to prechelation concentrations but without any net loss from the brain.<sup>22</sup> The initial increase in brain lead offers an explanation to why some human case reports demonstrate worsening lead encephalopathy when CaNa<sub>2</sub>EDTA is used without concomitant dimercaprol (BAL) chelation therapy.<sup>19,43</sup>

### Humans

The CaNa<sub>2</sub>EDTA mobilization test was once widely recommended as a diagnostic aid for assessing the potential benefits of chelation therapy, but has since been abandoned.<sup>15,19,22,38,39</sup> Criticisms of the mobilization test include difficulties with administration of the antidote, unreliability as a predictor of total-body lead burden, expense, and the risk of worsening toxicity through redistribution of lead to either the kidney or the brain.<sup>19</sup>

Edetate calcium disodium is capable of reducing blood lead concentrations, enhancing renal excretion of lead, and reversing the effects of lead on hemoglobin synthesis.<sup>19</sup> With chronic lead exposure, blood lead concentrations rebound considerably in the days to weeks following cessation of CaNa<sub>2</sub>EDTA.<sup>1,2,31</sup> No rigorous clinical studies were ever performed to evaluate whether CaNa<sub>2</sub>EDTA reverses the neurobehavioral effects of lead.<sup>20,21</sup> Chelators are incapable of dramatically decreasing the body burden of lead, because only several milligrams of lead are eliminated during chelation.<sup>14,16,44</sup> Children evaluated with blood lead concentrations of 25 to 50 mcg/dL who were given CaNa<sub>2</sub>EDTA for 5 days revealed very little difference in blood lead, or bone lead, or erythrocyte protoporphyrin concentrations, when compared to pretreatment values in unchelated patients.<sup>37</sup> A study in children demonstrated no additional benefits of CaNa<sub>2</sub>EDTA on cognitive performance beyond that which was achieved by limiting further lead exposure and correcting iron deficiency anemia.<sup>43,45</sup> A follow-up study in children with initial blood lead concentrations between 25 and 55 mcg/dL also suggested an interaction between initial iron stores, blood lead concentration, and an improvement in perceptual motor performance over a 6-month period. Both the correction of iron deficiency and a reduction in blood lead concentration (accomplished with limiting further exposure and/or CaNa<sub>2</sub>EDTA chelation)

contributed to the improvement, emphasizing a critical need to correct iron deficiency anemia as well as limit lead exposure.<sup>46</sup>

## ADVERSE EVENTS AND SAFETY ISSUES

The principal toxicity of  $\text{CaNa}_2\text{EDTA}$  is related to the metal chelates it forms. In mice, the intraperitoneal (IP)  $\text{LD}_{50}$  values of various  $\text{CaNa}_2\text{EDTA}$  metal chelates are  $\text{CaNa}_2\text{EDTA}$ , 14.3 mmol/kg; lead EDTA, 3.1 mmol/kg; and mercury EDTA, 0.01 mmol/kg.

When  $\text{CaNa}_2\text{EDTA}$  is given to patients with lead poisoning, the resultant sites of major renal toxicity are the proximal convoluted tubule, the distal convoluted tubule, and the glomeruli, possibly caused by the release of lead in the kidneys during excretion.<sup>7,11,19,34</sup> We recommend monitoring urine output, proteinuria, serum creatinine, and BUN. Of the 130 children who received both dimercaprol and  $\text{CaNa}_2\text{EDTA}$ , 13% had biochemical evidence of nephrotoxicity, and 3% developed acute oliguric kidney injury, which resolved over time; none needed hemodialysis.<sup>39</sup> Because lead toxicity causes kidney damage independent of chelation, it is important to monitor kidney function closely during  $\text{CaNa}_2\text{EDTA}$  administration and to adjust the dose and schedule appropriately.<sup>11,40</sup> Nephrotoxicity is minimized by limiting the total daily dose of  $\text{CaNa}_2\text{EDTA}$  to 1 g in children or to 2 g in adults, although higher doses are recommended to treat lead encephalopathy.<sup>43</sup> Continuous infusion while maintaining good hydration increases efficacy and decreases toxicity.<sup>40</sup> Because the administration of disodium EDTA, a grave medical error can lead to life-threatening hypocalcemia and death,<sup>23,27</sup>  $\text{CaNa}_2\text{EDTA}$  is the preparation of choice for lead toxicity and the risk of hypocalcemia is no longer a clinical concern.<sup>49</sup> Other adverse clinical effects of  $\text{CaNa}_2\text{EDTA}$ , most of which are uncommon, include malaise, fatigue, thirst, chills, fever, myalgias, headache, anorexia, urinary frequency and urgency, sneezing, nasal congestion, lacrimation, glycosuria, anemia, transient hypotension, increased prothrombin time, and inverted T waves on the ECG.<sup>11,34</sup> Various mucocutaneous lesions described in 2 patients included cheilosis and sore throat, magenta tongue, and extensive papular lesions attributed to zinc deficiency.<sup>7</sup> Typically reversible, mild increases in alanine aminotransferase and aspartate aminotransferase, and decreases in alkaline phosphatase are frequently reported. Extravasation resulted in the development of painful calcinosis at the injection site.<sup>43,47</sup> Depletion of endogenous metals, particularly zinc, results from chronic therapy.<sup>12,50</sup> An animal study suggests that gastrointestinal lead absorption is enhanced by either IP or oral administration of  $\text{CaNa}_2\text{EDTA}$ ;<sup>33</sup> consequently, removal of lead from the environment should always remain the first strategy in the management of lead toxicity. In the event of exposure to a new lead source, decontamination of the gastrointestinal tract should complement chelation.<sup>38</sup>

## PREGNANCY AND LACTATION

Although  $\text{CaNa}_2\text{EDTA}$  is FDA pregnancy category B, there are no adequate and well-controlled studies in pregnant women and a risk-to-benefit analysis must be made prior to use. Lead encephalopathy is life threatening, and chelation should be commenced regardless of the trimester.<sup>13</sup> It is not known whether  $\text{CaNa}_2\text{EDTA}$  is excreted in human milk, but breastfeeding is a contraindication<sup>8</sup> in some sources and is listed as a caution in the package insert.<sup>11</sup> However, in the 2010 Centers for Disease and Prevention (CDC) Guidelines for the identification and management of lead exposure in pregnant and breastfeeding women, the CDC suggests allowing breastfeeding for mothers with blood lead concentrations of less than or equal to 40 mcg/dL. Mothers with blood lead concentrations of greater than 40 mcg/dL are encouraged to pump and discard their breast milk until their BLLs drop to less than 40 mcg/dL.

In a model of lead poisoning in pregnant rats, fetal resorption decreased and the number of live fetuses increased when  $\text{CaNa}_2\text{EDTA}$  was used, although the placental concentrations of lead were increased.<sup>25</sup> Zinc concentrations were not affected. However, another study found that when  $\text{CaNa}_2\text{EDTA}$  was given to pregnant rats not poisoned with lead, increases in submucous clefts, cleft palate, adactyly/syndactyly, curly tail, and abnormal ribs and vertebrae resulted.<sup>10</sup> These teratogenic effects occurred with doses of  $\text{CaNa}_2\text{EDTA}$  comparable to human doses and without causing noticeable

changes in the mother except for weight gain. Use of zinc calcium EDTA and zinc EDTA preparations in pregnant rats caused no teratogenic effects at low doses, but resulted in the development of submucous cleft palates in 30% of the offspring receiving the higher dose of zinc calcium EDTA.<sup>10</sup> Another study in rats with doses 25 to 40 times that used in humans revealed fetal malformations that were prevented by simultaneous zinc supplementation.<sup>11</sup>

Of 7 cases reported by the CDC of pregnant women who received chelation therapy, all but one was chelated in the seventh or eighth month. Six patients received  $\text{CaNa}_2\text{EDTA}$ , with one of those also receiving dimercaprol for a maternal BLL of 104 mcg/dL. One patient received succimer alone. The dosage regimens were variable as was the time from chelation to delivery. Four of 6 newborns had cord blood concentrations lower than the maternal prechelation concentration. Six of 7 newborns appeared healthy at delivery. One premature infant was born following an antepartum hemorrhage with subsequent developmental delay and hearing deficits after 36 hours of chelation to a mother with a pretreatment lead concentration of 104 mcg/dL.<sup>13</sup>

## DOSING AND ADMINISTRATION

There has never been a clinical trial to identify the best dose of  $\text{CaNa}_2\text{EDTA}$  or how best to administer the dose. The most commonly recommended dose is determined by the patient's by surface area or weight (up to a maximum dose), the severity of the poisoning, and kidney function (Chap. 93; Tables 93–8 and A30–1).<sup>19,37,43</sup> For patients with lead encephalopathy, the dose of  $\text{CaNa}_2\text{EDTA}$  recommended is 1,500 mg/m<sup>2</sup>/day, approximately 50 to 75 mg/kg/day, by continuous IV infusion, starting 4 hours after the first dose of dimercaprol. The initiation of an adequate urine flow is recommended before administering  $\text{CaNa}_2\text{EDTA}$ .<sup>14,18,19,43</sup> The dose in obese patients has not been studied. A maximum dose of 3 g is reasonable. Simultaneous dimercaprol and  $\text{CaNa}_2\text{EDTA}$  therapy is typically administered for 5 days, followed by a rest period of at least 2 to 4 days, which permits lead redistribution. For adults with lead nephropathy, the following dosage regimen is recommended: 500 mg/m<sup>2</sup> every 24 hours for 5 days for patients with a serum creatinine of 2 to 3 mg/dL; every 48 hours for 3 doses for a serum creatinine of 3 to 4 mg/dL; and one dose for a serum creatinine concentration greater than 4 mg/dL.<sup>11</sup> Previous recommendations were to limit the daily dose to 50 mg/kg when  $\text{CaNa}_2\text{EDTA}$  is used in patients with kidney dysfunction.<sup>29,40,42</sup> The data supporting the use of folic acid, pyridoxine, and thiamine to increase the efficacy of  $\text{CaNa}_2\text{EDTA}$ <sup>48</sup> is inadequate to recommend routine administration. A blood lead concentration should be measured no sooner than one hour after the  $\text{CaNa}_2\text{EDTA}$  infusion is discontinued in order to avoid falsely elevated blood lead concentrations.

In symptomatic children without manifestations of lead encephalopathy, the recommended dose of  $\text{CaNa}_2\text{EDTA}$  is 1,000 mg/m<sup>2</sup>/day, approximately 25 to 50 mg/kg/day, in addition to dimercaprol at 50 mg/m<sup>2</sup> every 4 hours.<sup>43</sup> The demonstrated ability of succimer to reduce brain lead concentrations in animals led to the replacement of  $\text{CaNa}_2\text{EDTA}$  by succimer as the chelator of choice in lead-poisoned children without encephalopathy and lead concentration less than 70 mcg/dL.<sup>16,31</sup> Adding to the evidence supporting succimer is a retrospective analysis of more than 3,000 children in a resource-poor area of Nigeria with moderate to severe lead poisoning. Treatment with succimer alone appeared safe and effective although long-term efficacy is still being determined.<sup>51</sup>

Because of the pain associated with intramuscular (IM) administration, it is recommended that  $\text{CaNa}_2\text{EDTA}$  be administered at concentrations of approximately 0.5% by continuous IV infusion in 5% dextrose or 0.9% NaCl over 24 hours. Higher concentrations may lead to thrombophlebitis.<sup>19</sup> The package insert recommends infusing the dose over 8 to 12 hours.<sup>11</sup> In light of the short half-life of  $\text{CaNa}_2\text{EDTA}$ , we think it is reasonable to infuse the dose continuously over 24 hours. Edetate calcium disodium is incompatible with other solutions. Careful attention to total fluid requirements in children and patients who have, or who are at risk for lead encephalopathy is paramount.<sup>34,43</sup> Rapid IV infusions in patients with lead encephalopathy is likely to increase intracranial pressure and cerebral edema. In children with acute lead encephalopathy, starting dimercaprol 4 hours prior to  $\text{CaNa}_2\text{EDTA}$  is

TABLE A30-1 Calculations for IV Edetate Calcium Disodium Infusion Over 24 hours

	Avg. Height (in.)	Avg. Weight (lb)	m <sup>2</sup>	1,000 mg/m <sup>2</sup> Over 24 hours IV	Dilute in D <sub>5</sub> W or NS and Infuse Over 24 Hours <sup>a</sup>	1,500 mg/m <sup>2</sup> Over 24 Hours IV	Dilute in D <sub>5</sub> W or NS and Infuse Over 24 Hours <sup>a</sup>
<b>Child<sup>b</sup></b>							
2-year-old boy	36	30.5	0.593	593 mg	200 mL	890 mg	300 mL
2-year-old girl	35	29	0.57	570 mg	200 mL	855 mg	300 mL
4-year-old boy	42	39.75	0.73	730 mg	250 mL	1,095 mg	400 mL
4-year-old girl	41.75	38.75	0.72	720 mg	250 mL	1,080 mg	400 mL
<b>Adult<sup>c,d</sup></b>							
50-kg			1.5	1,500 mg	500 mL	2,250 mg	750 mL
70-kg			1.8	1,800 mg	600 mL	2,700 mg	1,000 mL
90-kg			2.1	2,100 mg	700 mL	3,000 mg	1,000 mL

Edetate calcium disodium comes in 5-mL ampules of 200 mg/mL.

<sup>a</sup>Dilute in D<sub>5</sub>W or 0.9% NaCl to concentrations of less than 0.5% to avoid thrombophlebitis with IV administration. Be mindful of total fluid requirements if encephalopathic to avoid cerebral edema. If fluid overload is possible intramuscular injection is reasonable, otherwise infuse IV over 24 hours. <sup>b</sup>Do not exceed the adult dose. <sup>c</sup>For adults with lead nephropathy, the following dosing regimen has been suggested: 500 mg/m<sup>2</sup> every 24 hours for 5 days for patients with serum creatinine concentrations of 2–3 mg/dL, every 48 hours for three doses for patients with creatinine concentrations of 3–4 mg/dL, and once weekly for patients with creatinine concentrations above 4 mg/dL. <sup>d</sup>The dose in obese patients has not been studied. A maximum dose of 3 g seems reasonable.

D<sub>5</sub>W = 5% dextrose in water; IV = intravenous; NS = 0.9% sodium chloride solution.

more effective than starting CaNa<sub>2</sub>EDTA prior to and simultaneously with dimercaprol.<sup>14,15,19,43</sup> In addition, treating with 2 chelators also reduces the blood lead concentration significantly faster than CaNa<sub>2</sub>EDTA alone, while maintaining a better molar ratio of chelator to lead.<sup>16</sup>

If CaNa<sub>2</sub>EDTA is to be administered IM to avoid the use of an IV and fluid overload, then either procaine or lidocaine is added to the CaNa<sub>2</sub>EDTA in a dose sufficient to produce a final concentration of 0.5% (5 mg/mL). This can be accomplished by mixing 1 mL of a 1% procaine or 1% lidocaine solution with each milliliter of chelator.<sup>11,34</sup> The procaine or lidocaine minimizes pain at the injection site.

## COMBINATION THERAPY WITH SUCCIMER OR DMPS

The possible benefit of combining CaNa<sub>2</sub>EDTA with succimer or 2,3-dimercapto-1-propane-sulfonic acid (DMPS) is under investigation in animals.<sup>24,26,49</sup> The combination of CaNa<sub>2</sub>EDTA with succimer is more potent than either individual chelator in promoting urine and fecal lead excretion, and decreasing blood and liver lead concentrations.<sup>24,26</sup> However, this approach increases zinc depletion.<sup>24,26,49</sup>

A retrospective analysis compared the combination of dimercaprol and CaNa<sub>2</sub>EDTA with succimer and CaNa<sub>2</sub>EDTA in children with blood lead concentrations of 35 to 70 mcg/dL (<90 mcg/dL for the dimercaprol group).<sup>5</sup> Equivalent reductions in blood lead concentrations were demonstrated with fewer adverse events in the succimer group. One case report of a child with lead encephalopathy and an extremely high blood concentration of 550 mcg/dL employed initially a combination of dimercaprol and CaNa<sub>2</sub>EDTA followed by succimer alone, but a rebound increase in the lead concentration resulted in the addition of CaNa<sub>2</sub>EDTA.<sup>30</sup> More data are needed to confirm this approach.

## FORMULATION

Edetate calcium disodium is available as calcium disodium versenate in 5-mL ampules containing 200 mg of CaNa<sub>2</sub>EDTA per milliliter (1 g per ampule).<sup>34</sup> Disodium edetate (sodium EDTA) should not be used as an alternative to CaNa<sub>2</sub>EDTA because of the risk of life-threatening hypocalcemia and death associated with sodium EDTA use.

## SUMMARY

- Edetate calcium disodium reduces blood lead concentrations, enhances urinary lead excretion, and reverses lead-induced hematologic effects.
- Edetate calcium disodium remains the standard of care for patients with lead encephalopathy when used in conjunction with dimercaprol.

- In patients with lead encephalopathy, the first dose of dimercaprol should precede the first dose of CaNa<sub>2</sub>EDTA by 4 hours to prevent redistribution of lead to the brain.
- When dimercaprol is unavailable, it is reasonable to substitute succimer.
- Recommended doses and schedules should not be exceeded and should be reduced when the creatinine clearance is reduced.
- Patients should be well hydrated to achieve an adequate urine flow prior to and during CaNa<sub>2</sub>EDTA therapy.

## MANGANESE

Elizabeth Q. Hines and Sari Soghoian

### Manganese (Mn)

Atomic number	=	25
Atomic weight	=	54.94 Da
Normal concentrations		
Whole blood	=	4–15 mcg/L (72.8–273 nmol/L)
Serum	=	0.4–0.85 mcg/L (7.3–15.5 nmol/L)
Urine	<	10 mcg/L (<182 nmol/L)

### HISTORY AND EPIDEMIOLOGY

Manganese is the 12th most abundant element in the Earth's crust (0.106%). The name manganese derives from *Magnesia*, a prefecture of Thessaly in ancient Greece. Ores from this region are particularly abundant in manganese oxides and carbonates. Manganese salts are brightly pigmented, and the earliest known uses were artisanal. Manganese dioxide was found in prehistoric paints and was used as a decolorant in glassmaking during the Roman Empire.

Adding manganese to iron produces a stronger metal alloy, and manganese-iron alloys are found in weapons from ancient Sparta. By the early 19th century, manganese became an important component in the manufacture of steel, which remains the largest industrial use of manganese today. Currently, more than 85% of manganese is used in the production of ferromanganese alloys. Manganese chloride is used in dry-cell battery manufacture and the metal is a catalyst for chlorination of organic compounds. Manganese dioxide is used in batteries and glass production, and manganese sulfate is used to make ceramics, fungicides, and pesticides.

Most reported cases of manganese toxicity, or manganism, are associated with chronic occupational exposure. Manganism was first described in 1837, when the development of a characteristic neuropsychiatric syndrome in French pyrolusite mill workers was linked with exposure to high concentrations of manganese oxide dusts.<sup>23</sup> The release of manganese, primarily in the form of oxides, during mining, and inhalation exposure to dusts from grinding manganese ore has historically been the most important source of manganese toxicity. Inhalation of inorganic manganese compounds also occurs during smelting, welding, or burning of coal, oil, or fuel containing manganese compounds. A neuropsychiatric syndrome in welders is attributed to the inhalation of manganese oxide fumes.<sup>16,18,42,54,79</sup>
