Every drug or biologic agent or medical device carries with it some potential risk. If society required that only “completely” safe drugs could be marketed, the drug approval process would likely take decades and few if any new drugs would be made available. The individual and societal cost of adverse drug events, in terms of patient morbidity and mortality is well appreciated. Therefore, the FDA and the pharmaceutical industry must significantly rely on postmarketing surveillance to detect meaningful safety signals associated with the use of a medical product after approval.

The postmarketing surveillance system of the FDA began in the late 1950s after the discovery of cases of aplastic anemia due to chloramphenicol.<sup>14</sup> The process expanded and in 1962 when it became more formalized the drug industry was required for the first time to report ADEs to the FDA. In 1993, the FDA introduced the **MedWatch** system for adverse event reporting. This widely publicized rollout aimed to encourage reporting of ADEs and to simplify the process overall. This system relies on spontaneous reports by health care professionals or patients regarding the occurrence of deleterious effects associated with the use of a medical product. By its nature, this system is passive surveillance. MedWatch reporting to the FDA can be accomplished online, by fax or by telephone. The next important step by the FDA in postapproval monitoring of drug safety came with the passage of the 2007 FDA reauthorization (FDAAA) that included several safety-focused components. The ADE reporting requirements for sponsors became more rigorous, an enabling mechanism for making safety-related changes to the drug label was provided, risk evaluation and mitigation strategies (REMS) surrounding drug approvals were introduced, and the initiation of an active postmarketing risk identification system known as the FDA Sentinel Initiative occurred, which is discussed briefly below.

The FDA postmarketing surveillance system is in place to monitor postapproval drug safety and is intended to detect signals of unanticipated or previously unrecognized adverse events or to identify an at-risk population in whom the safety profile differs from that which was expected based on data collected prior to marketing. Individual pharmaceutical manufacturers are responsible for monitoring the safety of their marketed products and to regularly report any detected ADEs to the FDA. All ADEs reported to the FDA become part of the **FDA Adverse Event Reporting System (FAERS)**.<sup>16</sup> The FAERS ADEs database is fully computerized and searchable and contains adverse event reports from human drug and biologic products and medical devices. The data set is made up of sponsor-reported ADEs and MedWatch ADE reports from patients, consumers, physicians, and other health care providers. Approximately 95% of reports in FAERS come from the mandatory reporting from pharmaceutical manufacturers. Since 1969, more than

10 million reports have been filed into FAERS, although since 2013, the FDA has received more than 1 million cases per calendar year into this database (personal communication, Dr Robert Ball, FDA, March 22, 2017).

Because the MedWatch system is passive in nature, the overall rate for spontaneous adverse event reporting is estimated at only 1% to 10%. Despite this, the number of serious adverse events reported to MedWatch continues to increase,<sup>35</sup> although the quality and rigor of the reports are limited.<sup>22</sup> Improved attitudes toward reporting, perhaps due to an appreciation of the risk of error and adverse drug effects, leads to better MedWatch reporting.<sup>21</sup>

The primary goals of the MedWatch system are the following:

- To increase awareness of drug- and device-induced disease.
- To clarify what should (and should not) be reported.
- To facilitate reporting of adverse effects by creating a single system for health professionals to use in reporting ADEs and drug, biologic, and device product problems.
- To provide regular feedback to the health care community about safety issues involving these products.<sup>16</sup>

Establishing causality is not required before submission of a MedWatch report. The FDA is primarily interested in the reporting of serious adverse events, or an ADE previously not associated with the medical product being administered or utilized, whether or not a causal relationship is established. Although any potential ADE should be reported, the FDA strongly encourages reporting of “serious” ADEs, which are events associated with a patient outcome that is one or more of the following:

- Death: If the death is suspected to be a direct result of the adverse event
- Life threatening: If the patient was at substantial risk of dying at the time of the adverse event or the use or continued use of the medical product would result in the patient’s death (eg, gastrointestinal hemorrhage, bone marrow suppression, pacemaker failure, and infusion pump failure that permits uncontrolled free flow and results in excessive drug dosing)
- Hospitalization (initial or prolonged): If admission to the hospital or prolongation of a hospital stay resulted from the adverse event (eg, anaphylaxis, pseudomembranous colitis, bleeding that causes or prolongs hospitalization)
- Disability: If the adverse event resulted in a significant, persistent, or permanent change, impairment, damage, or disruption in the patient’s body function/structure, physical activities, or quality of life (eg, cerebrovascular accidents caused by drug-induced coagulopathy, toxicity, peripheral neuropathy)
- Congenital anomaly: If there is a suspicion that exposure to a medical product before conception or during pregnancy resulted in an adverse effect on the child (eg, vaginal cancer in female offspring from maternal exposure to diethylstilbestrol during pregnancy or limb malformations in the offspring from thalidomide use during pregnancy)
- Requires intervention to prevent permanent impairment or damage if use of a medical product is suspected to result in a condition requiring medical or surgical intervention to preclude permanent impairment or damage to a patient (eg, acetaminophen overdose–induced hepatotoxicity requiring treatment with *N*-acetylcysteine to prevent permanent liver damage, burns from radiation equipment requiring drug therapy).

Health care professionals are given priority for review by the FDA in the MedWatch system. A well-documented case of a serious adverse event is a significant and useful contribution to the MedWatch system.

Reports of serious ADEs to the FDA or to the manufacturer can become an epidemiologically detectable signal that can trigger a more detailed investigation, several examples of which are provided later in this chapter. On occasion, serious ADEs detected in the AERS database have led to the withdrawal of products from the US market without conducting additional studies.

Currently, the MedWatch program is supported by more than 140 organizations, representing health care professionals and industry collaborating

as MedWatch Partners to help achieve these goals. These organizations include medical societies and organizations such as the American Medical Association (AMA), the American Academy of Clinical Toxicology (AACT), the American Society of Clinical Pharmacology and Therapeutics (ASCPT), the American College of Emergency Physicians (ACEP), the American College of Medical Toxicology (ACMT), and the American Academy of Pediatrics (AAP) that have encouraged their members to report to the MedWatch system. As a requirement for hospital accreditation, the Joint Commission mandates that hospitals collect, analyze, and report significant and unexpected ADEs to the FDA.

The primary limitation of the MedWatch system is the exclusive reliance on spontaneous reporting of ADEs. This passive surveillance system has several important limitations. Significant underreporting is known to occur in such systems. The uncertainty about the significance of a signal in the AERS database is exacerbated by the low estimated rate for adverse event reporting and the fact that the true incidence of the reported ADE is almost never precisely known because the denominator, which is the number of actual exposures to the drug, is rarely accurately known. Despite these limitations, the MedWatch system has detected significant ADEs during the postmarketing period, especially those that have very low background rates.

Drug regulators must rely on passive surveillance systems like the FAERS database to detect potential uncommon or rare but serious ADEs postapproval. Passive surveillance for drug safety signals is useful for serious and rare ADEs. This is primarily because a relatively small number of patients or participants are exposed to the drug during phases 1 to 3 prior to approval for marketing. For example, to detect an uncommon ADE occurring in approximately 1 of 5,000 individuals exposed to a drug with 95% probability that the ADE resulted from exposure to that drug, approximately 15,000 patients would have to be exposed to the drug. In a balanced (equal numbers of drug and placebo recipients) placebo-controlled clinical trial, 30,000 participants would need to be enrolled. Premarketing clinical studies (phases 1, 2, and 3) are usually inadequate to detect rare ADEs, ADEs that are incorrectly diagnosed, or ADEs that result from a drug interaction that were tested in the development program.

An example of a rare ADE not detected until postmarketing involves the drug felbamate, which was approved by the FDA in September 1993 and subsequently found to be associated with aplastic anemia during postmarketing surveillance. Felbamate-induced aplastic anemia was not detected during the drug development program. By July 1994, a total of 9 cases were reported from an estimated 100,000 patients exposed to felbamate in the United States.<sup>37</sup> Most of the aplastic anemia cases occurred in patients who had taken the drug for less than 1 year. The 9 cases represented an approximate 50-fold increase in aplastic anemia over the expected rate in the population with the very low background rate of 2 to 5 cases per million per year, allowing the FDA to attribute this rare condition to exposure to felbamate.

The primary role of the MedWatch system is to generate a hypothesis for potential association of an ADE with a specific drug. These hypotheses are sometimes further tested in subsequent phase 4 investigations. An example of this “hypothesis generation” function of MedWatch was the question of whether phenylpropanolamine (PPA) caused hemorrhagic stroke in patients using nonprescription diet suppressants or cough and cold preparations containing PPA. In the early 1990s, the Spontaneous Reporting System (SRS; now FAERS) detected a potential association of hemorrhagic stroke and nonprescription use of PPA. An industry-sponsored prospective, case-control study was designed to determine if such an association existed. The multicenter study demonstrated that an association did exist, especially for women aged 18 to 49 years. The Nonprescription Drug Advisory Committee (NDAC) of FDA reviewed this study and the associated MedWatch data in 2000 and decided that the evidence supported such an association. The committee advised the FDA to remove PPA from the market, which occurred a short time later. Although the entire process of signal identification from MedWatch to presentation of results from the prospective epidemiologic study required nearly a decade for PPA, the process demonstrates the value of the hypothesis-generating ability of the MedWatch system.

Potential outcomes of the detection of a safety signal for a marketed drug include a drug product label change for a dose reduction in all or certain high-risk patient populations, restriction of the sale of the specific drug to a more medically supervised environment or the development of a patient registry to more closely monitor use, and removal of the drug from the market. These options are further discussed later in this chapter.

Other types of phase 4 safety investigations include clinical studies, comparative studies with the new drug versus a competitor, or a special population study or drug interaction study when suspicion is raised that there may exist a different risk–benefit relationship in certain clinical settings. The enhancement of safety information is the primary goal of most phase 4 studies. Other than the specific prospective, randomized clinical study in patient subpopulations, the methods by which phase 4 safety studies are usually conducted are primarily observational and epidemiologic. The fields of pharmacovigilance and pharmacoepidemiology are often employed in the conduct of phase 4 studies. Attributing a serious ADE to a drug solely from MedWatch reports does occur, but it is much more common for the FAERS database to identify a safety signal, suggesting a possible drug-related safety problem.

Because of the significant limitations of passive surveillance systems for safety reporting, the FDA has initiated an active surveillance system for the detection of drug safety signals in the postapproval time frame. The system, known as Sentinel, was introduced on a small scale in 2008 to establish contracts and organizational relationships to create an active surveillance system within patient claims databases to be able to detect ADEs in marketed medical products. Currently the system consists of an accessible patient claims database that includes more than 100 million US individuals, with access to medical records and laboratory and pharmacy data.<sup>39</sup> The system is configured to ensure privacy and security, with the 18 data partners retaining control of the data (<https://www.sentinelinitiative.org/>). The FDA was mandated to create an Active Risk Identification and Analysis (ARIA) system in the FDAAA in 2007 and subsequent reauthorization bills for FDA since. Sentinel is an example of the use of real-world evidence for safety collected in an active surveillance setting.<sup>40</sup> Active Risk Identification and Analysis is a sub-component of Sentinel and uses blinded patient data and a set of analytical tools to probe for safety signals associated with the use of medical products. As this data mining system is further developed, the hope is that FDA's ability to detect and assess meaningful postapproval drug safety problems will be significantly enhanced. The regulatory use of ARIA will help the FDA decide if the sponsor of a newly approved medical product will need to perform a postmarketing required (PMR) study or not. If the ARIA system is likely to detect the safety problem of concern to the FDA, a PMR will not be necessary.

## ESTABLISHING THE DIAGNOSIS OF DRUG-INDUCED DISEASE

The recognition and diagnosis of a drug-induced disease, or an ADE, is an essential skill for all practitioners, and especially for clinical and medical toxicologists. The diagnosis of an ADE is typically established as the result of a systematic medical evaluation. One approach to establishing the diagnosis of drug-induced disease involves consideration of 6 related questions concerning the patient's clinical presentation and available medical data, as shown in Table 135–1.

The first question concerns the timing of the onset of the adverse event in relationship to the reported exposure to the drug. Perhaps because of publicity or word of mouth, ADEs are sometimes reported to the FDA MedWatch

system even when the onset of the adverse event occurs before the first exposure to the suspect drug. A careful reconstruction of the timeline of exposure to the suspected drug and onset of adverse effects is extremely important in assessing causality. The time course differs considerably for different adverse clinical events. An anaphylactic reaction to a drug usually occurs within minutes of exposure, whereas acute kidney injury caused by a drug is not likely to be clinically detectable for up to several days after the exposure. A drug that causes cancer (a carcinogen) may not produce a clinically detectable effect for decades. Establishing a time course that is biologically plausible with the type of ADE event under consideration is an essential first step in the process of making the diagnosis of drug-induced disease.

The second question is whether this adverse effect was reported previously for the suspect drug. An adverse drug effect that occurs commonly is likely to be known before the approval of the drug and therefore is typically found on the initial drug label or other reliable sources of drug information. For example, respiratory depression and mental status changes were well known before the approval of fentanyl, an opioid agonist. Less common ADEs for drugs that have been on the market for a period of time are sometimes found in case reports in the literature and in various medical databases. Many of these will eventually appear in a revised drug label. Previous reports linking the observed adverse effect to drug exposure are very helpful to the clinician trying to establish a sufficient level of probability for causality in the setting of an ADE.

However, in the setting of a newly approved drug or a previously unreported possible ADE, neither previous reports/medical literature nor the drug label will help establish causality. In this setting, the clinician must rely more on what is known of the pharmacology, the pharmacokinetics, and the anticipated pharmacodynamics of the suspect drug and the timing of the appearance and observed time course of the adverse event. The known pharmacology of the drug should include “target” effects as well as “off target” effects. The “target” effects are the intended, therapeutic pharmacology of the drug. Often, in the setting of the evaluation of the poisoned patient, the toxicologist is faced with significant “off-target” pharmacologic effects that become detectable when higher than therapeutic systemic exposure of the suspected drug is present. It is important to put “drug-induced disease” in the differential diagnosis for most patients presenting for medical care. Someone must be the first to report what is ultimately recognized as an ADE. Appropriate vigilance for the possibility of a new ADE significantly increases the probability that a finding can be made early after introduction of a new drug to prevent more widespread drug-induced morbidity or mortality.

The next question to consider is, “Is there evidence of excessive exposure to the drug?” Most ADEs that occur are predictable based on the known pharmacology, targeted and off-target, of the specific drug. Such ADEs are referred to as *type A* ADEs.<sup>5</sup> For example, antihistamines such as diphenhydramine are known to cause significant anticholinergic effects. When a patient presents with mental status changes and other clinical findings consistent with the anticholinergic toxidrome after significant exposure to an antihistamine-containing product, the observed effects are consistent with an ADE attributable to the antihistamine. Occasionally, proof of excess can come from measurement of the drug in serum. In the case of the patient with a history of manic-depression illness, who exhibits nausea, vomiting, tremor, hyperreflexia, and bradycardic dysrhythmias, the measurement of an elevated serum lithium concentration supports the diagnosis of lithium toxicity or an ADE attributable to lithium perhaps as an inadvertent or intentional overdose, drug interaction, or change in patient kidney function resulting in excessive circulating lithium concentration. The latter is an example of a drug–disease interaction when, acute kidney injury, can lead to reduced drug clearance and result in clinical toxicity due to excessive exposure. In any case, knowing the pharmacology of the drug, including the off-target effects, is important for establishing the diagnosis of an ADE.

When an ADE is caused by an allergic mechanism or another mechanism unrelated to the extent of the exposure to the drug, that is, a *type B* ADE, evidence of drug excess usually does not contribute to the diagnosis. In this setting, other factors such as allergy history or pharmacogenetic background

**TABLE 135–1** Questions to Answer to Help Establish the Diagnosis of an ADE

1. Was the timing of the event appropriate relative to the exposure to the drug?
2. Has the effect noted, which is the suspected ADE, been previously reported?
3. Is there evidence of excessive exposure to the drug?
4. Are there other more likely etiologies responsible for the condition suspected as being an ADE?
5. What is the patient's response to cessation of a suspect drug (dechallenge)?
6. What is the patient's response to rechallenge?

ADE = adverse drug event.

are weighed more heavily to support the diagnosis of an ADE. Patients are usually not aware of their genetically determined ability to metabolize or react to medications but most patients will recall a previously experienced allergic reaction.

The next issue to address in considering possible causality is whether there are other more likely etiologies that could be responsible for the observed effects. Although it is important to be appropriately vigilant for possible ADEs, it is equally important not to miss an alternative cause for the patient's condition by automatically attributing the patient's presentation to ADE. Based on the relative probabilities of other potential diagnoses on the differential diagnosis list, the probability of ADE can be estimated. There are certain clinical settings in which establishing an ADE becomes a diagnosis of exclusion. For example, in the case of persistent fever, the assignment of the diagnosis "drug fever" should not be made until a complete search for infectious or other, non-drug-induced causes has excluded this etiology.

A very important factor to consider in contemplating a diagnosis of ADE is "What is the patient's response to cessation of a suspect drug (*dechallenge*)?" In this case, the pharmacokinetics of the drug and the biologic timing of resolution of the specific condition must be carefully considered. In some instances, the resolution of a type A ADE closely follows the pharmacokinetics of the suspect drug. For example, in the case of  $\beta$ -adrenergic antagonist poisoning, cardiac effects resolve in association with decreasing serum concentrations of the drug in question. However, in other instances, onset and resolution of the ADE may not correlate with drug concentrations in the body, for example, in the case of a penicillin rash, which may develop within 1 or 2 days or longer after starting the medication but may take several days to weeks to completely resolve. In this later example of a type B ADE, the resolution of the condition (rash) occurs over a much longer time than would be predicted by the pharmacokinetics of the drug. In this case, the ADE resolution phase, or the toxicodynamic resolution, often significantly lags the toxic- or pharmacokinetic correlation. When a suspected ADE resolves after discontinuation of exposure to the offending drug, along a predictable time course, the result of this *dechallenge* would support the diagnosis of ADE.

Lastly, the clinician may have the opportunity or medical need to *rechallenge* the patient with the suspect drug. If the *rechallenge* results in the identical response or effect to that occurred in the initial presentation, this would be considered strong evidence to support a causal relationship for the suspect drug and the adverse event. In the setting of a serious or life-threatening adverse ADE, it is too dangerous to perform a *rechallenge* with the suspect drug, in which case the response to *rechallenge* will not be known. In this setting, the weight of evidence previously discussed will then be the only factors available to assess the probability of causality.

### FDA REGULATORY ACTIONS REGARDING DRUG SAFETY

When new information about a safety issue for an already marketed drug raises concern at FDA, several regulatory options are available to either attempt to improve the safety margin of the drug or remove the drug from the US market. The most common regulatory action taken by the FDA is modification of the drug label. These modifications can include restrictions as to whom should receive the drug, what doses should be given for which indications or to which patient populations, what type of monitoring should be performed during therapy, and how long treatment should be administered. A survey of safety-related FDA regulatory actions on drug labels over the 20-year period (from 1980 to 1999) revealed that the most common step taken by FDA was dosage reduction of the initially approved therapeutic dosage.<sup>9</sup> When potentially life-threatening safety information is discovered, and the FDA believes that the risk-benefit relationship remains in favor of continued availability of the drug, the FDA can require that a boxed warning (sometimes called a "black box" warning) be carried in the label. A black box warning is the most serious warning placed in the label of a drug. If a black box warning is established, then health care professional advertisements regarding product availability, known as reminder ads, are no longer permitted. Additionally, when the boxed warning is added to the label, the

manufacturer is required in most cases to send a "Dear Doctor" letter to potential prescribers informing them of the new black box warning. Dear Doctor letters may also be required when the FDA requires that prescribers be notified about a significant change in the drug label warning. An example of current medications with recently added black box warnings is antidepressant medication that now must warn about the increased risk of suicidality if children and adolescents are prescribed antidepressants. The antipsychotic clozapine currently has 4 distinct warnings contained in the boxed warning in its drug label for the following attributed ADEs: agranulocytosis, myocarditis, seizures, and "other cardiovascular and respiratory effects."

Another option employed by the FDA is the implementation of restricted availability measures to permit continued availability of the drug but only with specified restrictions. For example, use of the drug isotretinoin (Accutane) requires compliance with a multiple component REMS program called iPLEDGE that includes informed consent, prescriber and dispensing pharmacy registration, serial pregnancy testing if applicable, documentation of patient education, and completion of risk management programs by patients who will receive the medication.<sup>45</sup> This option is more commonly used today when there is concern about "off-label" use. The FDA authority to require companies to submit, prior to drug approval, and execute postapproval, an effective risk management plan is intended to improve both the monitoring and prevention of postapproval adverse drug events and their consequences.

When the FDA believes that a drug can no longer be safely used despite modification of the drug label or any of the aforementioned restrictions, the regulatory threshold is reached to initiate removal of the drug from the market. This occurs when an acceptable risk-benefit relationship for continued availability of a drug product is no longer possible. Table 17-2 in the seventh edition of this text, contains a listing of drug products that were withdrawn or removed from the market. In some cases, such as the withdrawn drug rofecoxib (formally marketed as Vioxx), withdrawal occurred because of the recognition of elevated cardiovascular risk.<sup>20</sup> In the case of the COX-2 inhibitor withdrawals, the precipitating factor for withdrawal was the findings of a strong safety signal for excess cardiovascular mortality and morbidity during the conduct of efficacy studies for other potential therapeutic indications for these drugs. The postmarketing surveillance system did not serve as the initial, precipitating data set for regulatory action in this instance.<sup>29,36</sup> The manufacturers voluntarily withdrew most of these COX-2 inhibitors from the US market after they were deemed unsafe by FDA. In most cases, the manufacturer ceases marketing the specific drug after notification by the FDA that regulatory action is being initiated to remove a specific drug from the market. Only very rarely has the FDA itself actually removed a drug from the market. The FDA did implement the removal of phenformin following due process. In the case of ephedra-containing dietary supplements, the FDA removed these products from the market based on their analysis of safety data obtained from the medical literature and from analysis of cases reported to the MedWatch system. In some cases, the pharmaceutical manufacturers file suit against the FDA to fight or delay the planned regulatory action against the product. The manufacturer's legal actions typically prolong the time the product remains on the market because the drug usually continues to be sold, while the legal proceedings and appeals proceed through the courts.

Some legislators and legal experts feel that approval of a drug by FDA should preempt legal action for safety issues identified in the drug labeling. However, the FDA decision-making process regarding drug approval is largely reliant on efficacy and safety data provided by the manufacturer or in the publicly available medical literature. Plaintiff actions, taken against drug and device manufacturers, are sometimes a source of significant publicity and confidential disclosures regarding questionable behaviors practiced by companies that market medicinal products. The patient's right to tort action against a product's manufacturer provides an important mechanism to ensure drug safety following approval and marketing.<sup>10</sup> Recent US Supreme Court appeals have challenged this position seeking to reinforce the legal position of federal preemption. In the case of *Wyeth v. Levine*, the manufacturer appealed to the US Supreme Court to uphold the federal preemption status for FDA-approved

**TABLE 135–2 US Drug Product Withdrawals or Removal From the Market for Safety or Lack of Efficacy Concerns**

Adenosine	Etretinate	Potassium arsenite
Adrenal cortex	Fenfluramine	Potassium chloride <sup>i</sup>
Alatrofloxacin	Flosequinan	Povidone
Aminopyrine	Gatifloxacin	Propoxyphene
Astemizole	Gelatin <sup>f</sup>	Rapacuronium
Azaribine	Glycerol	Reserpine <sup>j</sup>
Benoxaprofen	Gonadotropin, chorionic <sup>g</sup>	Rofecoxib
Bithionol	Grepafloxacin	Sibutramine
Bromfenac <sup>d</sup>	Mepazine	Sparteine sulfate
Butamben	Metabromsalan	Sulfadimethoxine
Camphorated oil	Methamphetamine	Sulfathiazole <sup>k</sup>
Carbetapentane <sup>b</sup>	Methapyrilene	Suprofen <sup>l</sup>
Casein	Methopholine	Sweet spirits of nitre
Cerivastatin	Methoxyflurane	Tegaserod
Chloramphenicol	Mibefradil	Temafloxacin
Chlorhexidine <sup>c</sup>	Nitrofurazone <sup>h</sup>	Terfenadine
Chlormadinone	Nomifensine	3,3',4',5'-tetrachlorosalicylanilide
Chloroform	Novobiocin	Tetracycline <sup>m</sup>
Cisapride	Oxyphenisatin	Ticrynafen
Cobalt <sup>d</sup>	Oxyphenisatin	Tribromsalan
Dexfenfluramine	Pemoline	Trichloroethane <sup>n</sup>
Diamthazole	Pergolide	Troglitazone
Dibromsalan	Phenacetin	Trovafoxacin
Diethylstilbestrol	Phenformin	Urethane
Dihydrostreptomycin	Phenylpropanolamine	Valdecobix
Dipyron	Pipamazine	Vinyl chloride <sup>o</sup>
Encainide	Polyethylene glycol 3350	Zirconium <sup>p</sup>
Esmolol <sup>e</sup>		Zomepirac

<sup>a</sup>Except ophthalmic solution. <sup>b</sup>Oral gel drug products containing carbetapentane citrate. <sup>c</sup>Tinctures of chlorhexidine gluconate formulated for use as a patient preoperative skin preparation. <sup>d</sup>Except radioactive forms of cobalt and its salts and cobalamin and its derivatives. <sup>e</sup>Products that supply 250 mg/mL of concentrated esmolol per 10-mL ampule. <sup>f</sup>Intravenous drug products containing gelatin. <sup>g</sup>Containing chorionic gonadotropins of animal origin. <sup>h</sup>Except topical drug products formulated for dermatologic application. <sup>i</sup>Solid oral dosage containing potassium chloride that supply 100 mg or more. <sup>j</sup>Products containing more than 1 mg of reserpine. <sup>k</sup>Except for those formulated for vaginal use. <sup>l</sup>Except ophthalmic solutions. <sup>m</sup>Liquid oral drug products formulated for pediatric use containing tetracycline in a concentration greater than 25 mg/mL. <sup>n</sup>Aerosol drug products intended for inhalation containing trichloroethane. <sup>o</sup>Aerosol drug products containing vinyl chloride. <sup>p</sup>Aerosol drug products containing zirconium.

Data from Food and Drug Administration, HHS: Additions and Modifications to the List of Drug Products That Have Been Withdrawn or Removed From the Market for Reasons of Safety or Effectiveness. *Final rule, Fed Regist* 2016 Oct 7;81(195):69668-69677.

Over the years, there have been highly publicized drug withdrawals for risk of cardiovascular ADEs such as terfenadine (QT prolongation) or the COX-2 inhibitors (increased risk of major cardiac events such as myocardial ischemia). Until recently, the most common reasons for FDA-initiated drug withdrawals in the United States have been prolongation of the QTc interval followed by drug-induced hepatotoxicity. Advances in nonclinical testing and early-phase human testing have significantly reduced the rate of drug withdrawals for these reasons. These ADEs, as well as the propensity to cause significant drug–drug interactions, occur much less often but are still important examples of drug safety–related regulatory action in the United States.

### Prolongation of the QT Interval

Three significant drug withdrawals in the mid- to late 1990s exemplified a serious drug safety issue regarding drug-related prolongation of the QT interval when administered alone or as the result of increasing plasma concentrations due to inhibition of its metabolism by other. The 3 examples in this category are terfenadine (Seldane), astemizole (Hismanal), and cisapride (Propulsid). Several deaths were reported to the MedWatch system for patients taking these medications. In the case of terfenadine, the initial publication of a case report for polymorphic ventricular tachycardia in the setting of routine use of this non-sedating antihistamine with the self-administration of ketoconazole, a known inhibitor of drug metabolism, led to FDA-funded, small prospective clinical studies to confirm a previously unrecognized ability of terfenadine to dramatically alter cardiac repolarization, which led to torsade de pointes. The drug was marketed in 1985, cardiac toxicity was detected in clinical use in 1990,<sup>34</sup> the FDA-funded clinical cardiac safety research was performed in 1991,<sup>24</sup> and, ultimately, the drug was withdrawn from the market in 1998. The medicolegal course of the other 2 drugs is similar except that prospective controlled studies to document the extent of QT interval prolongation were not performed before regulatory action was taken. These early experiences led to new rigorous regulatory requirements and significant preclinical screening and intensive, prospective controlled clinical study of QT interval effects by manufacturers of all drugs worldwide.

These 3 drug withdrawals demonstrated that the preapproval assessment of cardiac repolarization effects at that time was incapable of detecting even the most potent dysrhythmic drugs during their respective development and FDA review. Based on this dramatic systematic failure, the FDA (as well as the European and Japanese drug regulatory agencies) now requires a thorough QT study (TQT) for all new molecular entities.<sup>33</sup> These studies are designed to detect as little as a 5-millisecond increase in the corrected QT interval in healthy volunteer participants and must include a positive control to demonstrate the sensitivity of the study to detect this low-level change reliably. Since this new requirement was introduced, no newly approved drugs have subsequently been removed from the US market for QT interval safety reasons, although concern remains about the possibility of effective drugs being discarded early in development by sponsors perceiving excess cardiac QT interval prolongation risk.<sup>3</sup>

### Significant Drug–Drug Interactions

Removal of mibefradil (Posicor) is an example of a drug withdrawn from the US market because of postmarketing discovery of a plethora of drug–drug interactions. Mibefradil, a pharmacologically unique calcium channel blocker, was approved by the FDA for the treatment of patients with hypertension and chronic stable angina. The FDA approved mibefradil for marketing in 1997 with the knowledge that the compound possessed the ability to inhibit certain hepatic CYP enzymes; these facts were included on the drug label. The initial labeling for mibefradil specifically listed 3 drug–drug interactions: astemizole, cisapride, and terfenadine (CYP3A pathway interactions). During the one year that mibefradil was marketed, information accumulated regarding drug–drug interactions with many other drugs and CYP pathways. As the in vitro and in vivo drug interaction data continued to accumulate for mibefradil, the FDA made labeling changes and issued a public warning for these potential drug interactions within 5 months of its initial approval. Additionally, the sponsor distributed a letter to health care

drugs.<sup>27</sup> On March 4, 2009, the US Supreme Court ruled that federal law does not preempt this particular plaintiff from seeking and obtaining a judgment from the product manufacturer because the product was approved by the FDA. The case provided the opportunity to debate the extent of protection afforded by the FDA approval status and the issue of product liability litigation as a part of postmarketing surveillance of drug products in the United States.

professionals warning of drug–drug interactions. In the face of a growing and significant list of drug–drug interactions, and a 3-year international study demonstrating no clinical benefit of mibefradil over placebo for congestive heart failure, the FDA initiated regulatory action. In an unprecedented step for a drug with numerous drug interactions, the FDA requested that it be withdrawn from the market approximately one year after it was approved.<sup>41</sup> The FDA felt that the extensive drug–drug interactions could not be addressed by standard drug label instructions and additional public warnings. In the years following, the preclinical study and early human study, of potential human drug–drug interactions has evolved such that discovery of a clinically significant drug–drug interaction postapproval is now relatively uncommon.

### Drug-Induced Hepatotoxicity

Another category of ADE of regulatory concern is those drugs that cause hepatotoxicity. In June 1998, the manufacturer of the nonsteroidal antiinflammatory drug (NSAID) bromfenac sodium (Duract) withdrew this drug from the US market.<sup>23</sup> The NDA was submitted for review to the FDA in 1994 and after 28 months of review was approved. The drug was withdrawn approximately 11 months later after postmarketing discovery of significant hepatotoxicity. Although no cases of serious liver injury were reported during premarketing clinical trials, after introduction to the market, a higher incidence of liver enzyme elevation was found in patients who were being treated with the drug. Postapproval exposure of patients to bromfenac generally resulted in longer periods of treatment than that of the participants in the clinical trials. Because of a preapproval concern by the FDA that long-term exposure to bromfenac could cause hepatotoxicity, bromfenac labeling specified that the product was to be used for 10 days or less. This dosing limitation appeared to be inconsistent with the initial approved drug indication for treatment of a chronic condition (eg, osteoarthritis). Information concerning elevated hepatic enzymes was included in the original product labeling. The postmarketing surveillance of this product identified rare cases of hepatitis and liver failure, including some patients who required liver transplantation, among those using the drug for more than the 10 days as specified on the label. In February 1998, approximately 6 months after approval for marketing, the FDA added a black box warning indicating that the drug should not be taken for more than 10 days. Nonetheless, severe injury and death from long-term use of bromfenac sodium continued to be reported, and ultimately, the sponsor agreed to voluntarily withdraw bromfenac sodium from the market. The withdrawal of bromfenac sodium raised several important questions concerning interpretation of “safety laboratory testing,” such as liver enzymes during the drug development program, and raised questions to some extent, concerning the effectiveness of drug labeling.

The FDA has issued specific guidance on how to evaluate drug-induced liver injury (DILI) during drug development.<sup>15</sup> As in the case of many other adverse drug effects, severe DILI is uncommon so despite extensive preapproval study, few cases will be found prior to, and even in the postmarketing period. Proper evaluation for evidence of lesser injury such as drug databases may offer insight into the potential for more severe liver injury. One of the common guidelines utilized by FDA is Hy’s law, which states that severe liver injury is predicted by laboratory assessment that includes an alanine aminotransferase of more than 3 times the upper limit of normal and a bilirubin of more than twice the upper limit of normal in a patient with no other reason for such an abnormality.<sup>31</sup> Although imperfect, this approach has been demonstrated to be very effective in preventing hepatotoxic new drugs from reaching the US market and has aided our postapproval safety evaluation of already approved drugs that demonstrate a liver toxicity safety signal.

### Other Examples of Postmarketing Safety Problems Leading to Drug Withdrawal

One voluntary drug product withdrawal involving 2 separate drugs used in combination is particularly noteworthy as an example of a serious adverse event discovered years after the individual drugs were approved but after a

significant increase in the prescription use of these agents as a combination product. The drug fenfluramine was approved in 1973 after an FDA review period of 75 months. A significant increase in prescription use of a combination product of fenfluramine with phentermine, for weight loss (referred to as “fen-phen”), began in the 1990s when clinical data suggested that this drug combination was effective in a weight loss program.<sup>43</sup> However, use of the fen-phen drug combination was never fully approved by the FDA and was therefore considered an “off-label” use of the products. The number of prescriptions for the drug combination soared in the mid-1990s because of the weight loss publications and associated media coverage. In 1997, research from the Mayo Clinic reported 24 cases of an unusual form of cardiac valvular disease causing aortic and mitral regurgitation in patients using the fen-phen combination.<sup>8</sup> The publicity surrounding the potential linkage of this drug combination to an unusual adverse event led to a significant increase in reports of possible adverse events associated with this drug combination. The FDA issued a public health advisory and initiated further epidemiologic studies to ascertain its prevalence. The FDA also encouraged echocardiographic studies of valvular diseases in patients taking fenfluramine or dexfenfluramine either alone or in combination with phentermine. Although at the onset the FDA, the product manufacturers, and the medical community did not expect valvular lesions to be associated with either fenfluramine or dexfenfluramine, the epidemiologic evidence suggested a possible association, leading the FDA to conclude that these drugs should be removed from the US market. The potential association of valvular heart disease with these drugs is an example of the use of a case–control study to explore a possible causal relationship between drug exposure and an ADE. In this case, it is unclear what the strength of the MedWatch signal was for the possible association of cardiac valvular disease with exposure to the fen-phen combination. The association between cardiac valvular lesions and exposure to the drug combination serves as an example of elucidation of a rare, unexpected ADE as the result of a dramatic increase in the number of exposed patients using a product.

### ROLE OF THE TOXICOLOGIST IN THE DETECTION AND PREVENTION OF ADVERSE DRUG EVENTS

Toxicologists can play a very important role in ADE diagnosis and prevention, through efforts in patient care, education, and administrative functions. In patient care, it is common for the medical and clinical toxicologists to be the first medical specialists consulted for a patient with a potential ADE. Perhaps more than any other medical specialty, medical and clinical toxicologists are likely to include a thorough medication history that also includes prescription and non-prescription products, as well as dietary supplements. The medical toxicologist’s active involvement in the clinical arena, especially in settings in which the initial diagnosis of ADEs can be made, also serves to provide an important role model: the medical toxicologist as an educator to promote the detection, reporting, and prevention of ADEs often in the academic setting of a medical school and affiliated teaching hospitals. Here, the academic toxicologist can champion the inclusion of education in therapeutics in the curriculum for medical and pharmacy students and house officers, and take an active role in the implementation of the instruction. Ensuring that the curriculum in therapeutics includes recognition and prevention of ADEs and medical errors that lead to ADEs could have a significant beneficial impact on the ultimate outcome of the education process toward reduction of preventable ADEs. In addition to making sure that quality information is presented in the curriculum for trainees, the medical toxicologist can often create a special teaching opportunity for this type of education by establishing an elective or, in some cases, a required experience in the curriculum for training in therapeutics that involves recognition and management of ADEs. Participation in a quality learning experience can significantly impact the graduates’ knowledge of and attitudes toward therapeutics and risk reduction in patient care. Although the Institute of Medicine report on medical errors<sup>30</sup> did not focus on education initiatives in its main recommendations for reduction of medical errors in the United States, it seems logical that education be considered an important

tool to improve medication use and prevent ADEs and medical errors with drugs and devices.

The growth of the discipline of medication safety as part of the increasingly visible overall patient safety initiatives has provided new venues for involvement of both clinical and medical toxicologists. Creation of interdisciplinary teams at many medical centers has allowed a system-oriented approach to the detection, mitigation, and prevention of adverse drug events. These take the form of pharmacy and therapeutics, medication safety, and quality improvement committees and provide important opportunities to impact on the drug-induced disease problem. Proactive interventions include targeted education programs, system modifications to reduce error rates, or a limitation of a specific drug usage to certain units of the organization or by certain specialties.

A well-documented, complete report to MedWatch made by a health care professional is given priority review by the FDA. The medical toxicologist is likely to encounter a significant number of patients with drug-induced disease cases from a diagnostic and management standpoint; therefore, practitioners of the specialty can have a significant impact on ADE reporting. All staff, including medical and clinical toxicologists and their trainees, should always submit an adverse event report locally for appropriate cases they encounter. Hospitals generally do not mandate or request that the reported event be “serious” as a requirement. The FDA MedWatch system requests that the reported events be serious in nature or not previously associated with the medication involved. Other organizations that collect data on medication errors, such as the Institute for Safe Medication Practices, provide valuable insight and support to the drug safety community. They maintain a database, as do poison control centers (PCC), and reporting is voluntary but important. In addition to reporting of the ADE, the toxicologist should promote publication of case reports of all new adverse events or adverse events occurring with newly approved products. Such publication often stimulates appropriate reporting of ADEs from other practitioners and generally raises awareness concerning a new ADE.

Toxicologists already work to facilitate the accurate reporting of PCC data to the National Poison Data System in a timely manner. Poison control center data are invariably considered in the overall safety evaluation of an approved and marketed drug and have obvious value in terms of national security. Accurate case information and causality assignment for ADEs including fatalities by toxicologists working with PCCs can greatly aid regulatory decisions and guide efforts to improve drug safety at the national and international levels. Pharmaceutical sponsors are required to query and report PCC data to the FDA on a periodic basis to add to the safety data set of their respective products. This is especially true for drugs with the potential for abuse and misuse. At the current time, the substance abuse epidemic facing the US, involving increased prevalence of drug abuse, rising national mortality from illicit drug overdose, and expanding availability of potentially deadly “designer” drugs of abuse provides the toxicologist with an opportunity for an even greater role in overall public health.

## SUMMARY

- Drug-induced disease is common in both inpatient and outpatient settings.
- Despite significant advances in regulatory science and drug development, ADEs continue to occur in the postmarketing setting and will continue to do so for the foreseeable future in part because of the relatively small number of healthy subjects and patient volunteers who are exposed to a drug or biologic candidate prior to approval.
- Adverse drug events have a significant impact on patient mortality and morbidity in addition to producing a significant burden on the health care system.
- Vigilance for ADEs in routine medical practice will aid in detection and minimization of the negative impact on patients.
- Clinical and medical toxicologists are uniquely qualified and positioned in the health care setting to diagnose and report ADEs.

- Active participation in clinical, teaching, health care, and medical education administrative roles by medical and clinical toxicologists can lead to improved ADE detection and patient clinical outcomes.
- Maintaining a high level of commitment to the ADE recognition, reporting, and education as individuals and as a specialty will ultimately allow toxicologists to make significant contributions to the improvement in patient safety.

Sari Soghoian

Poisoning is a worldwide problem, but the major effects are felt in the developing world. At least 150,000 people die every year from acute pesticide poisoning (Chap. 110), and an estimated 20,000 to 94,000 from snake bites,<sup>89</sup> the vast majority of whom live in rural farming areas of lower- and middle-income countries. Hundreds of thousands of people are affected by groundwater arsenic contamination in Bangladesh and India,<sup>155</sup> and outbreaks of poisoning from contaminated food<sup>63</sup> and environmental pollution from poorly regulated industrial activity<sup>40,135</sup> affect whole communities throughout the developing world.

The resources for dealing with these problems are limited in many countries. Public health education about poisons and infrastructure limiting access and exposure to the most highly toxic chemicals are practically absent in much of the developing world. Access to medical care is often limited for financial, cultural, and geographic reasons. Medical toxicology is frequently not a recognized specialty, and patients are usually evaluated by general physicians with little formal training in medical toxicology although often with great experience. Diagnostic facilities are few, effective treatment options even more rare. Where antidotes exist, there is rarely enough knowledge or experience to use them effectively.<sup>22</sup> Intensive care beds for invasive monitoring and long-term ventilatory support are scarce. This chapter outlines some of the major poisoning risks and challenges for medical toxicology in the developing world.

## POISONING AND THE GLOBAL BURDEN OF DISEASE

The World Health Organization (WHO) estimates that one in 10 deaths worldwide are due to injury and ranks self-inflicted injury, including poisoning, among the top 15 causes of death.<sup>114,178</sup> Acute and chronic exposure to chemicals caused more than 4.9 million deaths and 86 million disability-adjusted life years (DALYs) worldwide in 2004—more than cancer, sexually transmitted diseases, or diabetes.<sup>135</sup> Children younger than 15 years of age bore more than one-half of this burden.

Tremendous regional disparities in the health impact of poisoning are apparent. The global mortality burden from poisoning is disproportionately shouldered by lower- and middle-income countries. Overall, 75% or more of all poisoning-related deaths occur in the developing world,<sup>76</sup> and an estimated 95% of children who die each year from acute poisoning live in low- and middle-income countries.<sup>130</sup> Children living in Sub-Saharan Africa are at highest risk, with an estimated annual mortality rate of 4 children per 100,000 population.<sup>144</sup> This is double the global average and higher than that in any other region.

These figures are striking, yet most likely underestimate the contribution of poisoning to the global burden of disease and disability. Much of the existing data on poisoning epidemiology from lower-income countries reflects the experience in larger hospital centers. By contrast, most people live in rural areas, and many patients with poisoning never reach such facilities for a variety of financial, cultural, or geographic reasons. For example, logistical difficulty with accessing health care facilities was responsible in part for the high mortality from snakebite noted in one community-based study in Nepal.<sup>151</sup> Social or economic barriers often contribute to “healer shopping” within traditional or spiritual systems, with allopathic medical care delayed or avoided in many African countries.<sup>46,81,125</sup>

Unintentional poisoning risks from occupational, environmental, food, or medication sources are also poorly recognized in communities, or by health care workers.<sup>121</sup> The diagnosis of poisoning is often not suspected if a clear history of exposure is not given, because many symptoms of poisoning mimic infectious or other processes and few medical centers have ready access to laboratory tests for specific poisons. When poisoning is suspect,

many countries lack detailed injury surveillance systems or other standardized reporting mechanisms. The WHO has undertaken several initiatives to improve global poisoning surveillance, including support for poison control center (PCC) development in underrepresented regions worldwide, and the international efforts of the IPCS/INTOX programs to harmonize data collection and reporting terminology represent an important step toward this goal. However, the interpretation of PCC data as evidence of epidemiologic trends must be approached with some caution (Chap. 130).

## COMMON XENOBIOTICS AND PATTERNS OF POISONING

Xenobiotics commonly involved in acute poisoning differ substantially among communities, both within and among countries. For example, a comparison of poisoning cases seen at a major public teaching hospital in New York City with 2 large rural hospitals in Sri Lanka found striking differences in the classes of xenobiotics involved. A total of 70% of the patients in New York City were poisoned with pharmaceuticals, and 90% of patients in the Sri Lankan cohort were poisoned with nonpharmaceuticals, primarily pesticides and botanicals, such as yellow oleander, with a 10 times higher case fatality rate.<sup>76</sup> A study comparing poisoning epidemiology in district (rural) and regional (urban) hospitals in Zimbabwe found that poisoning from pesticides was equally common in both settings, but animal envenomation was reported nearly twice as often at the district facilities compared to regional centers, and poisoning with pharmaceuticals was a problem that was uniquely reported at the regional hospital.<sup>160</sup>

Understanding the local patterns and specific risks for poisoning in particular communities is of critical importance because it provides an evidence base for designing and prioritizing strategies to prevent or limit harm. This section reviews some of the more common xenobiotics implicated in poisoning in developing countries worldwide.

### Pesticides

Pesticide poisoning is responsible for millions of hospital admissions and at least 150,000 deaths each year (Chap. 110). Most of these deaths occur in Asia, particularly in China and India, and most are related to intentional self-harm.<sup>66</sup> The WHO considers pesticide poisoning to be the single most important means of suicide, accounting for 30% of all suicides worldwide.<sup>177</sup> The total number of deaths worldwide from occupational or unintentional pesticide poisoning is unknown but was estimated nearly 30 years ago at 20,000 per year.<sup>84</sup> Although many classes of pesticides are implicated (Chaps. 109–111), organic phosphorus (OP) pesticides are responsible for the majority of pesticide-related deaths reported in the developing world.<sup>50</sup>

Deliberate self-poisoning with OP pesticides carries a high mortality rate and puts a high intensive care burden on the health care system (Chap. 110). In one study examining the experience in Sri Lanka, OP pesticide poisoning was responsible for 943 of 2,559 (36%) admissions to a secondary hospital for poisoning.<sup>52</sup> The case fatality rate for OP poisoning was 21%, and pesticide poisoned patients occupied 41% of all medical intensive care beds. A systematic review from Iran found that OP compounds were implicated in only 16% of acute poisonings, but with a 13% case fatality rate that accounted for nearly 40% of all poisoning-related mortalities.<sup>148</sup> Similar situations are reported from across the world.<sup>50</sup>

Factors contributing to the high mortality of self-poisoning with pesticides in the developing world include the intrinsic lethality of many pesticides, and health care systems that are poorly prepared to care for such critically ill patients (Table 136–1). Pesticides are often easily available in highly concentrated preparations in rural communities throughout the

**TABLE 136–1** Factors Contributing to High Mortality From Self-Poisoning With Pesticides in the Developing World

1. Ease of access to pesticides in rural, agrarian households
2. Poor storage practices
3. Inadequate labeling of lethal pesticide products
4. High potency of pesticides
5. Lack of evidence-based practice guidelines appropriate for resource-poor areas
6. Lack of clear guidelines
7. Distance from and time to health care facilities and resources available at health care facilities

developing world. The ease of drinking liquid pesticides is also a factor facilitating massive intentional ingestions, as are inadequate pesticide storage systems.<sup>93</sup> The extraordinarily high human, economic, and social costs of pesticide-related mortality worldwide reinforce the importance of developing simple, economical, and evidence-based strategies specifically designed to care for acutely poisoned patients in resource limited environments.<sup>21,24</sup>

### Envenomation

Envenomation by snakes and other animals represents another significant cause of morbidity and mortality with disproportionate effects in the developing world. Few countries mandate the reporting of animal bites, making it difficult to estimate global incidence, severity, and outcome. Current data estimate that between 421,000 and 1.8 million envenomings and about 20,000 to 94,000 deaths occur globally each year from snakebite, the vast majority of which occur in South Asia, South East Asia, and sub-Saharan Africa.<sup>89</sup> By contrast, less than 100 snakebite deaths per year are estimated to occur in Europe, the United States, Canada, and Australia combined.<sup>32,89</sup> This disparity reflects the combination of increased incidence and decreased access to standards of care for snakebite, such as antivenoms and trained personnel to administer them, among the rural poor in tropical regions.<sup>74</sup>

Snakebites are environmental, household, and important occupational hazards in the rural tropics, particularly within the agricultural sector.<sup>74</sup> Working in large plantations and subsistence farms places rural people in frequent contact with venomous snakes. In Benin, the annual incidence of snake envenomation ranges from 200 in 100,000 in rural villagers to 1,300 in 100,000 in sugarcane plantation workers.<sup>35</sup> With simultaneous changes in global climate and expansion of human settlements, it is likely that the range of venomous snakes will enlarge to include urban areas and regions previously considered too temperate to support them.<sup>77</sup> Snakebites from members of the Elapidae and Viperidae families are responsible for the majority of deaths worldwide, although several other families are also medically important (Colubridae and Atractaspididae species, in particular; Chap. 119 and Special Considerations: SC10).<sup>173</sup>

The global distribution of snakebite is highly correlated with poverty, and the burden of snake envenomation on local economies and health resources can be substantial.<sup>74</sup> In many cases, it is greater than that of other neglected tropical diseases (NTDs) included in the 2009 WHO list.<sup>68,71</sup> The total number of DALYs attributable to snakebites in West Africa is an estimated 319,874 annually, of which more than 90% are associated with early mortality.<sup>71</sup> Throughout the tropics, about 10% of hospital beds are occupied by victims of snakebite, with seasonal and regional variations.<sup>34</sup> During the rainy season in Benin, snakebites account for up to 20% of all hospital admissions, with an estimated case fatality rate of 3% to 6%.<sup>35</sup>

Despite the burden on hospital services, relatively few snakebite victims in the developing world seek allopathic medical care for their injuries.<sup>32,156</sup> For example, a study of rural Philippine rice farmers found that only 8% of cobra (*Naja philippinensis*) bite victims reached a hospital in the 1980s.<sup>171</sup> A more recent household survey in Bangladesh found that 86% of snakebite victims went to snake charmers for initial management, and only 10% later visited a doctor or hospital.<sup>137</sup> Reliance on traditional healers contributes to morbidity and mortality since many still employ potentially harmful therapeutic techniques such as tourniquet application and making incisions around the

bite site. However, changes in treatment seeking can occur. Studies over the last decade in Sri Lanka show that patients have started going to the hospital rapidly after common krait (*Bungarus caeruleus*) snakebite, bypassing traditional healers.<sup>97</sup> A study in Ghana found that the incidence of snakebite victims at a district hospital increased significantly after the introduction of a new treatment protocol including early antivenom administration, possibly reflecting increased confidence in the ability of the health care system to manage these cases.<sup>170</sup>

After snakebites, the second most common cause of mortality and morbidity from venomous animals is scorpion stings (Chap. 115 and Antidotes in Depth: A37, A38). Medically important scorpion species are widely distributed throughout the tropics, being particularly common causes of morbidity in North Africa, Mexico, India, and Brazil.<sup>33</sup> The total number of medically significant scorpion stings that occurs annually is unknown; a recent review estimated 1.2 million stings, leading to more than 3,250 deaths (case fatality 0.27%).<sup>33</sup> Other venomous insects, such as Arachnida (spiders) and Hymenoptera (bees, ants, and wasps), are rarely sources of significant mortality on a global scale<sup>83</sup> (Chap. 115).

### Herbal and Traditional Medicines

The use of traditional medicine (TM) to treat or prevent health problems is widespread. The WHO estimates that around 80% of the world's population consults traditional healers regularly.<sup>180</sup> Frequently cited reasons for this preference or reliance on TM include financial considerations, sociocultural preferences, beliefs about the relative safety and efficacy of TM compared to allopathic medicines, and mistrust or relative inaccessibility of doctors.<sup>81,125</sup> Traditional practitioners still greatly outnumber medical professionals in many regions. For example, there were an estimated 25 times more traditional healers than physicians practicing in Mali in 2004.<sup>64</sup>

Although TM also encompasses a variety of spiritual, religious, or physical manipulation therapies, it often includes administration of “herbal” remedies orally, topically, or via enema. These are typically prepared using a combination of aqueous plant materials, sometimes mixed with insect or other animal parts, metallic salts, or both. Although traditional medicinal preparations are usually tested by generations of practitioners and the concentrations of active ingredients are generally low, both intentional and unintentional poisonings are common.<sup>29,158,159</sup> In a 2-year retrospective review of acutely poisoned patients from South Africa, TM was the second most common cause of admission (15.8% of cases) and had the highest mortality rate (15.2%), accounting for more than half of all deaths in the series.<sup>87</sup> Traditional medicine was the most common cause of admission (23% of cases) for and death from acute poisoning in a 10-year retrospective review of cases from Zimbabwe.<sup>159</sup>

The specific chemical constituents responsible for TM poisoning vary widely between geographic and cultural areas. Laboratory analysis and ethnopharmacologic surveys in a number of countries have begun to elucidate some of the chemical constituents of commonly prescribed recipes. Interestingly, a review of 41 autopsies in South Africa for which the cause was presumed to be a herbal medicine found that cardiac glycosides were present in 44% of cases.<sup>108</sup> Contamination and erroneous substitution of herbal products is most often the culprit<sup>26</sup> but adulterants are also implicated in poisoning from TM formulations. For example, these are common in traditional Ayurvedic medicines (particularly heavy metals and corticosteroids<sup>67</sup>) and Asian medicines (particularly synthetic pharmaceuticals<sup>58</sup> and heavy metals<sup>28</sup>) (Chap. 43). A Taiwanese study of 2,609 TM samples found that 23% were adulterated with pharmaceutical products such as caffeine, nonsteroidal antiinflammatory drugs, acetaminophen, and diuretics.<sup>80</sup>

### Pharmaceuticals

In many lower-income countries, pharmaceuticals are relatively uncommon causes of acute poisoning. However, the incidence appears to be rising in conjunction with larger global demographic shifts toward increased urbanization and industrialization. Access to pharmaceuticals is generally

greater among urban dwellers than rural ones, and more people in urban communities have the financial means to buy them. In a retrospective review of poisoning cases admitted to urban versus rural health centers in Zimbabwe, poisoning with pharmaceuticals was uniquely reported at the urban facilities, accounting for more than 15% of poisoning cases at regional hospitals surveyed and none of the cases presenting for care at the district level.<sup>160</sup>

The relative importance of poisoning with pharmaceuticals and the specific xenobiotics involved will likely change as more and more societies develop a “dual burden of disease” pattern including chronic illnesses that require long-term drug therapy.<sup>15,119</sup> Previously the most common xenobiotics implicated in acute poisoning in the developing world were those used to treat tropical infectious diseases. For example, self-poisoning with the anti-malarial chloroquine (Chap. 55) is widely reported in Sub-Saharan Africa,<sup>14,136</sup> although this medication is now rarely used so the incidence is expected to decrease. Intentional and unintentional poisoning with the leprosy drug dapsone, as well as the antituberculous drug isoniazid (Chap. 56), are also well reported.<sup>132,162,168</sup>

Criminal poisoning of commuters with benzodiazepines to facilitate robbery is a common problem across South Asia. As many as 300 people are admitted unconscious with this problem to a single university medical unit in Dhaka, Bangladesh, each year.<sup>104</sup> In Pakistan, benzodiazepines are implicated in 60% of drug-facilitated street and public transportation related crimes.<sup>91</sup>

A more general issue of toxicologic concern is the prevalence of poor-quality medicines in use worldwide. Although data estimating the extent of the problem and its impact on health are limited, recent estimates suggest that more than one-third of all medicines on sale in Southeast Asia and Sub-Saharan Africa are substandard or counterfeit.<sup>17,117,118</sup> The major problem with these medications is an absence or subtherapeutic concentration of active ingredient, leading to treatment failures and an increase in drug-resistant pathogens where antimicrobials are involved. However, substandard medications sometimes contain more active ingredients than stated, leading to adverse drug effects,<sup>164</sup> or contain harmful adulterants or contaminants.

Epidemic poisonings from such poor-quality medicines underscore the dangers of inadequate regulation and oversight of pharmaceutical manufacture and sales. Examples include the deaths of more than 120 patients in Karachi, Pakistan, from exposure to a batch of isosorbide mononitrate contaminated with pyrimethamine,<sup>10</sup> the hospitalization of more than 50,000 infants in China with melamine poisoning from adulterated formula,<sup>82</sup> and the numerous epidemics of diethylene glycol poisoning (Special Considerations: SC9) in multiple countries over the past few decades from contaminated glycerine, paracetamol syrups, cough syrups, toothpastes, teething mixtures, and other medications.<sup>16,73,142,154</sup>

## Household Products and Chemicals

Poisoning with common household products, such as fuels, cleansing products, rat poisons, insecticides, body care products, and cosmetics, is a global problem. This general category of diverse xenobiotics is consistently implicated as a significant source of unintentional childhood poisoning worldwide. The PC movement that began in the 1950s in North America grew out of an increasing recognition of the child health risks associated with exploratory household poison ingestions. Household chemicals are a similarly well recognized risk for unintentional childhood poisoning internationally.<sup>30,31,56,90,100,120,157</sup> The specific risks are remarkably consistent around the world, including age younger than 6 years (with toddlers younger than 3 years of age most affected), male sex, low socioeconomic status, and unsafe storage practices in the home.

Among specific household products, hydrocarbon poisoning from unintentional ingestion of kerosene (paraffin) is widely reported as the most common cause of pediatric admissions in low-income countries around the world.<sup>20,31,88,95,107</sup> Kerosene is a common fuel used to power stoves and lamps in many relatively poor communities. It is pale in color with an appearance

similar to water, and it is often purchased or stored in used beverage containers, making it easy to misidentify (Chap. 105).<sup>57</sup> In Sub-Saharan Africa, household chemicals account for up to 80% of all pediatric admissions for poisoning,<sup>15,31,56,88,123</sup> and kerosene poisoning, specifically, accounts for some 25% to 75% of all poisoning-related hospital visits among children younger than 6 years of age.<sup>56,120,161</sup> Several studies document an increase in poisoning-related admissions during the warmer months of the year,<sup>95</sup> when children are more likely to become thirsty and to drink from any beverage container at hand.

As with other categories of poison, patterns of self-harm using domestic products tend to demonstrate regional particularities. For example, ingestion of caustics is another common scenario implicated in both intentional and unintentional poisoning around the world, and the specific agents most commonly encountered vary by location. In Sierra Leone, children are most likely to ingest alkaline substances such as sodium hydroxide,<sup>39</sup> whereas ingestion of acids is more common in Taiwan<sup>75</sup> and south India.<sup>42</sup> In Hong Kong, there is significant morbidity reported in association with self-poisoning using detergent products such as Dettol (4.8% chloroxylenol, pine oil, and isopropyl alcohol) and Savlon (cetrimide).<sup>27,30</sup> Frequent use of potassium permanganate for self-harm is also reported from Hong Kong.<sup>126,183</sup> Fatal poisoning with hair dye (paraphenylenediamine) is a well-recognized problem in the Middle East, India, and parts of Africa where henna is used cosmetically.<sup>145,146,152</sup>

## Plants

Poisonous plants have been used to induce abortion, for recreational intoxication, in homicidal acts, and for self-harm throughout human history (Chap. 118). This section briefly mentions select toxic plants that are most commonly used in self-poisoning, or that have caused epidemic poisoning in the developing world.

Self-poisoning with seeds of plants containing cardioactive steroids are important clinical problems globally. Yellow oleander (*Thevetia peruviana*) kills hundreds of people each year in Sri Lanka and India (Chap. 62).<sup>51,140</sup> Sea mango or suicide tree (*Cerbera* sp) has killed hundreds of people in Kerala, India,<sup>111</sup> and is a focal problem in eastern Sri Lanka.<sup>54</sup> The superb lily (*Gloriosa superba*) contains colchicine alkaloids and is another plant that is used both medicinally and for self-harm in South Asia (Chap. 34).<sup>59,110,133</sup> Numerous plant species contain atropinelike alkaloids, causing an anticholinergic syndrome when ingested. Intentional ingestion of *Datura* species as a recreational drug for their hallucinatory effects<sup>2,61</sup> or as part of traditional medical preparations,<sup>26</sup> and unintentional poisoning from food contamination<sup>131</sup> or plant substitution in meals<sup>48,128</sup> is widely reported from nearly all parts of the globe.<sup>96</sup>

Oduvan (*Cleistanthus collinus*) leaf contains the glycosides cleistanthin A and B, which produce severe hypokalemia and cardiac dysrhythmias.<sup>7</sup> Self-poisoning has killed hundreds of people in South India.<sup>112,149</sup> Poisoning by castor beans (*Ricinus communis*) or other lectin-containing plants such as *Jatropha* spp (African purging nut) is well reported from Africa and South Asia (Chap. 118).<sup>1,44,103</sup>

Ackee tree fruit (*Blighia sapida*), which contains hypoglycin when unripe, is widely consumed as a food source. Epidemics of fatal poisoning with unripe Ackee fruit have occurred throughout the Caribbean and in Africa.<sup>86,105,109</sup> Hypoglycin and its analog methylenecyclopropylglycine (MCPG) were recently implicated in previously unexplained outbreaks of acute toxic encephalopathy linked to litchi fruit consumption in Muzaffarpur, India.<sup>153</sup>

## Occupational and Environmental Sources

Poisoning from occupational and environmental sources is a significant global health problem, with disproportionate effects on persons living in lower-income communities around the world. Exposure to “traditional” environmental health hazards, such as indoor air pollution from the combustion of solid fuels, and naturally occurring contaminants in groundwater, soil, and food, is still a major cause of morbidity and mortality in much of

the world. Around 50% of the world's people rely on solid fuels such as coal, dung, wood, or crop residues for cooking and heating.<sup>23</sup> Resultant indoor air pollution was estimated to cause 1,965,000 deaths and 41,009,000 DALYs (disability adjusted life years) from lower respiratory tract infections, cancers, and COPD in 2004.<sup>179</sup> Consumption of inorganic arsenic in drinking water and foods affects millions of people worldwide, contributing to the global burden of cancer, cardio- and cerebrovascular disease, diabetes mellitus, and other chronic disease conditions. In Bangladesh, one survey estimated that 9,100 deaths and 125,000 DALYs could be attributed to chronic consumption of arsenic-contaminated groundwater in 2001,<sup>102</sup> and data from another prospective longitudinal study estimated that more than 20% of all deaths in this population are linked to arsenic exposure greater than 10 mcg/L in drinking water.<sup>9</sup> Dental and skeletal fluorosis from excessive fluoride in drinking water is endemic in at least 17 countries worldwide.<sup>60</sup>

Increasingly, modern environmental health hazards (MEHs) also play a large role in global poisoning risks.<sup>40,122</sup> Modern environmental health hazards include outdoor air pollution from automobiles and factories; soil and water contamination by plastics, heavy metals, pesticides and other industrial chemicals and wastes; radiation hazards; land degradation; and climate change produced by rapid urbanization and industrial development in the absence of strong regulatory controls.<sup>40</sup> These are important sources of both occupational and environmental exposure to a wide range of toxins with acute and chronic health effects. Inadequate safeguards to control the selection, sale, and application of pesticides in parts of Africa and Asia are linked to pesticide poisoning both as an occupational hazard<sup>45,85</sup> and from residues left on food.<sup>6,38,121</sup> Occupational lead poisoning has largely been controlled in developed countries through improved working conditions and occupational health screens, but it remains an enormous problem in developing countries where occupational and environmental health protection measures are often underdeveloped or practically nonexistent.<sup>167,172</sup>

Industrial factories are often placed in urban areas, or the areas around factories are rapidly urbanized, placing large numbers of people at risk not only from pollution but from industrial errors as well. The 1984 Bhopal tragedy in which a Union Carbide pesticide plant malfunctioned, releasing isocyanate gas into the surrounding community and causing an estimated 3,787 deaths and 558,125 injuries, is emblematic of such disasters.<sup>8,150</sup>

Several international agreements on chemical safety provide legal frameworks to mitigate the human and environmental impact of global industrialization; however, the actual implementation of regulatory controls has lagged behind the expansion of toxic exposures. For example, at the governance level a total of 39 Sub-Saharan African countries have ratified the Rotterdam Convention on chemical safety. Yet industrial pollution is now becoming so highly concentrated in growing urban areas that the continent's pollution intensity (pollution generated per unit of production output) is now rated among the world's highest, attesting to significant regional difficulties in enforcing such regulations.<sup>169</sup>

The predominance of informal sector activity in agricultural and industrial work in lower-income countries poses serious regulatory challenges. Fumes and dusts from small-scale domestic businesses involved in smelting, battery recycling or manufacture, welding, pottery, ceramic production, and artisanal mining are common sources of exposure to lead and other heavy metals in developing countries, and put not only workers but whole communities at risk.<sup>167</sup> More recently, unregulated electronic waste (e-waste) recycling, in which salable metals are reclaimed from old electronics by burning, has emerged as a significant human and environmental health hazard in parts of China, West Africa, and India.<sup>4,98,163</sup> Workers are often aware of the health risks, yet economic hardship and lack of alternative employment make them unwilling or unable to change.

Easy access to industrial chemicals from inadequate regulation of packaging and sales also facilitates their use for intentional self-harm. For example, formic and acetic acids are used in the manufacture of rubber, and cases of poisoning are reported from areas surrounding rubber factories in India

and Sri Lanka.<sup>42,139</sup> Copper sulfate is widely used for self-poisoning in parts of South Asia, and carries a high mortality rate because of direct damage to the gastrointestinal tract, hepatorenal failure, and hemolysis (Chap. 92).<sup>115,116</sup> Cyanide self-poisoning has become a commonly used method in Korea over the last 20 years (Chap. 123).<sup>92</sup>

## REDUCING THE GLOBAL IMPACT OF POISONING

Regulatory science and the coordinated actions of agencies and programs across multiple sectors play a vital role in preventing or reducing the impact of poisoning in society. An integrated approach is needed, combining the implementation of policies to improve product and environmental safety; development of more robust health information systems to collect reliable data on the burden of poisoning globally; prioritization and funding for research; improving the availability and accessibility of safe and effective treatments; health workforce training in best practices for both acute care and the follow-up of affected patients, including the recognition and management of psychological causes and sequelae; and the design and implementation of community-based education and prevention campaigns.

Timely access to medical care has a major impact on poisoning outcomes. Significant global disparities in the infrastructure to provide acute care and to meet WHO minimum standards for essential emergency supplies exist and must be addressed to improve this.<sup>12,13,78</sup> Lack of human resources for health care is also an enormous problem in many parts of the developing world. There are more than 60 times more physicians per unit population working in North America as compared to Sub-Saharan Africa, and at least 4.3 million more health workers are needed to address critical shortfalls in access to primary medical care globally.<sup>41</sup> Policies and programs encouraging sustainable and equitable health workforce development are urgently needed to address these gaps.

Beyond rectifying the raw numbers deficit, clinical training programs in many low- and middle-income countries must be upgraded to promote broad exposure and specialist development in clinical toxicology and acute care. Input from experts in medical toxicology improves outcomes, reduces hospital stays and health care costs associated with acute poisoning,<sup>25,36,62</sup> but practitioners in many parts of the world have limited or no access to consultation with such specialists. Less than half of all WHO member states have Poison Control Centers, and these are underfunded and understaffed in many countries (Chap. 130).<sup>181</sup> The mission of the International Union of Toxicology is to foster international scientific cooperation, ensure the development of toxicologists, and promote the dissemination of knowledge in toxicology worldwide.<sup>49</sup> Through the efforts of this and other professional societies, an increasing number of local, regional, and international forums now offer educational and professional development opportunities in clinical toxicology around the globe. International collaboration through online forums such as the teleconferencing networks being developed through the Global Educational Toxicology Uniting Project (GETUP) is an important mechanism to bridge the education gaps.<sup>176</sup> Increasing local and international commitment to the growth of emergency medicine in low- and middle-income countries also promises to support the dissemination of scientific knowledge and improve provider competence in advanced resuscitation techniques.<sup>5,11,147</sup>

In addition to global disparities in acute care infrastructure and resources generally, access to antidotes for specific poisons is either lacking or inadequate in much of the world.<sup>3,175</sup> Where antidotes are available, knowledge and experience to know how to use them safely and effectively is often lacking.<sup>24</sup> Poor antidote availability is not unique to the developing world,<sup>43</sup> and many antidotes are considered either adjunctive or unnecessary therapies. However, in certain cases they significantly reduce the need for other medical interventions, and this is particularly important in rural or underdeveloped areas where critical care facilities are not readily available.<sup>134</sup> For example, the most important challenge to improving the treatment of patients with snakebite worldwide is poor antivenom availability, particularly in rural areas where it is most needed to reduce critical delays in administration.<sup>165,166</sup>

Currently, many available antivenoms are prohibitively expensive; ineffective; require refrigeration, which is not practical in rural areas; or have a high rate of adverse reactions. The need for regionally specific formulations makes it difficult to achieve economies of scale that include higher-paying markets.<sup>34,68</sup> Critical evaluation of existing antivenoms and development of new marketing and purchasing strategies that can ensure access to affordable and safe products within the developing world are thus desperately needed (Special Considerations: SC10).<sup>19,22,69,165,166,173,174</sup>

Improving health care access and health system preparedness is only one aspect of the coordinated, multilevel, national, and international public health responses needed to reduce the global impact of poisoning. Prevention and risk reduction efforts must involve locally appropriate community-level education and awareness raising, strong governance to support the design, implementation, and monitoring of regulatory controls, and the involvement of multiple stakeholders and sectors including water, waste management, energy, agriculture, transportation, industry, and civil society. Effective legislative frameworks developed in countries with more advanced public health infrastructure have been successfully disseminated in some cases. For example, between 2000 and 2004 the proportion of people with blood lead concentrations above 10 mcg/dL globally decreased from 20% to 14%, largely because of the widespread phaseout of leaded gasoline.<sup>135</sup> Other strategies, such as pharmaceutical and food safety regulations enacted through the US Food and Drug Administration, have influenced “duplicative legislation” in other countries but continue to pose significant implementation challenges in low- and middle-income countries that lack the necessary financing, human resources, and infrastructure to enforce them well.<sup>129</sup>

Many public health measures with proven efficacy, such as routine lead testing during childhood, the regulation of vehicle emissions, the detection of carbon monoxide, and the incorporation of childproof containers may seem prohibitively resource intensive in many parts of the world. The development of new, low-cost technologies such as solar heating and electrical sources, chemical assays and residue detectors, and electronic devices to identify and track pharmaceuticals hold some promise to reduce global risks for unintentional poisoning. More research is needed to propose and evaluate the effectiveness, acceptability, and sustainability of new and proven poison prevention techniques in resource-limited environments.

Recognizing that self-harm from pesticide ingestion is responsible for a majority of acute poisoning deaths worldwide, public health interventions specifically designed to limit access are an important goal. A minimum pesticide list, based on the WHO essential xenobiotic list initiative, was proposed.<sup>55</sup> Such a list would provide policy makers and farmers with unbiased information about relative risks. However, voluntary initiatives such as international policy statements and industry-sponsored programs often suffer from a lack of resources, a shortage of political will, and non-existent enforcement mechanisms.<sup>94</sup> A dramatic illustration of an effective national program to reduce pesticide poisoning risks is the ban of all WHO high-risk OP insecticides and the organic chlorine endosulfan in Sri Lanka, which effectively arrested a previously exponential increase in the incidence of pesticide poisoning and halved the national suicide rate between 1995 and 2005 (Chap. 110).<sup>65</sup> This program is estimated to have saved more than 20,000 lives in 10 years.

Ironically, some programs to remove the most environmentally persistent and toxic chemicals from use have inadvertently replaced them with chemicals highly toxic to humans. The replacement of persistent organic chlorine compounds with carbamates in malaria control programs is an example. The opposite effect also occurred, for example, by replacing OP insecticides with pyrethroids to reduce human toxicity.<sup>94</sup> Coordinated pesticide harm reduction strategies should take into account concerns regarding both environmental and human toxicity, and anticipate which xenobiotics will enter into use as replacements as specific chemicals are phased out. A strategy based on industrial hygiene models of a hierarchy of controls has been proposed (Table 136–2).<sup>143</sup>

**TABLE 136–2** Hierarchical Strategies to Reduce Pesticide Poisoning Mortality in the Developing World<sup>143</sup>

E	Most	Eliminate the most highly toxic pesticides
F		Substitute with less toxic, equally effective alternatives
F		Reduce use through improved equipment
I		Isolate people from the hazard
C		Label products and train applicators in safe handling practices
A		Promote use of personal protective equipment
C		
Y	Least	Institute administrative controls

## SUMMARY

- Poisoning is common worldwide. Fatal poisoning is disproportionately concentrated in lower- and middle-income countries, where public health systems and acute care resources to detect, manage, prevent, and collect data on poisoning are often less well developed.
- Global poisoning estimates are mostly derived from health care sources in a minority of developing world countries; current data likely underrepresent the true burden and distribution of injuries from poisoning.
- Efforts to develop international poisoning surveillance systems and establish harmonized definitions of poisoning cases will help generate a more complete picture to inform local, national, and international policies and interventions.
- Pesticides are the most important cause of death from acute poisoning worldwide, with a majority of these cases attributable to acts of deliberate self-harm.
- Improving access to health care and health system preparedness to provide acute care is essential to reduce global disparities in poisoning outcomes.
- Randomized controlled trials and cost-effectiveness research are needed to critically evaluate the utility of specific public health and treatment interventions in resource-limited settings.

# PRINCIPLES OF EPIDEMIOLOGY AND RESEARCH DESIGN

Alex F. Manini

Galen, an influential physician from the second century, remarked of his clinical trial, “All who drink of this remedy recover in a short time, except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases.” Unfortunately, error in contemporary clinical investigation of poisoning tends to be more insidious than the error in logic in Galen’s conclusion, and skillful scrutiny of published research remains an important endeavor.

Advances in medical toxicology are achieved through the scientific method, but must first rely on observations derived from xenobiotic exposures for hypothesis generation. Subsequent research questions are analyzed with epidemiological investigation, and preliminary studies are examined with methodological scrutiny. Initial analytical techniques are improved, and confirmatory studies are performed. Ultimately, models relating cause to effect are formulated.

To optimize patient care, it is useful to grade the quality of available scientific evidence used to justify treatment recommendations. Decisions about how strongly to recommend a medical action will be based on the careful consideration of the risks of leaving a patient untreated, the potential benefits and harms of treatment, the quality of the guiding evidence, a balanced view of resource utilization, and ultimately the values of the person to be treated. The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) Working Group has provided a framework for assessing and communicating levels of scientific evidence (Table 137-1).<sup>26</sup> An understanding of basic principles of research design and epidemiology is required to interpret published studies and to lay the groundwork for future investigation in toxicology.

## EPIDEMIOLOGIC TECHNIQUES AVAILABLE TO INVESTIGATE CLINICAL PROBLEMS

Table 137-2 lists the different study formats discussed below.

### Observational Design: Descriptive

Toxicologists rely on good descriptive data regarding the staggering array of xenobiotics that are able to cause injury. Through 2015, the National Poison Data System (NPDS) of the American Association of Poison Control Centers (AAPCC) has amassed a database of more than 50 million human exposures (Chap. 130). Descriptive case reporting serves a valuable purpose in describing the characteristics of a medical condition or procedure and remains a fundamental tool of epidemiologic investigation. A *case report* is a clinical description of a single patient or procedure in a unique context. Case reports are most useful for hypothesis generation. However, single case reports are not always generalizable, as the reported exposure, patients’ circumstances, and treatment may be atypical. Certain aspects of a toxicologic case report should be included to maximize their utility and minimize bias.<sup>41</sup> A number of case reports can be grouped on the basis of similarities into a *case series*. Case series can be used to characterize an illness or syndrome, but without a control group they are severely limited in their ability to imply cause and effect. In 1966, a case series of 2 patients with acute liver necrosis following overdose of acetaminophen (APAP)<sup>14</sup> was accompanied by a case report of liver damage and impaired glucose tolerance after APAP overdose,<sup>47</sup> which led to further study and the eventual creation of the Rumack-Matthew nomogram (Chap. 33). The important role for descriptive data in guiding clinical research, focusing educational efforts, and formulating public policy are often underappreciated.

*Cross-sectional studies* assess a population for the presence or absence of an exposure and condition simultaneously. Such data often provide

estimates of prevalence—the fraction of individuals in a population sharing a characteristic or condition at a point in time. These studies are particularly helpful in public health planning and are extremely useful in monitoring common environmental exposures, such as childhood lead poisoning, or population-wide drug use, such as occurs with tobacco, marijuana, and alcohol. A prime example is the US National Health and Nutrition Examination Survey, which demonstrated that the percentage of children with blood lead concentration greater than 10 mcg/dL decreased from 88.2% to 4.4% between 1976 and 1991, after the introduction of unleaded gasoline and paint to reduce populational lead exposure.<sup>5</sup>

An *analysis of secular trend* is a study type that compares changes in illness over time or geography to changes in environmental risk factors. These analyses often lend circumstantial support to a hypothesis; however, because of the environmental nature of their design, individual data on risk factors are not available to allow exclusion of alternative hypotheses also consistent with the data. A prime example of an analysis of secular trends is the finding that there was not a decline in new autism diagnoses after mercury was removed

**TABLE 137-1** GRADE System for Evaluating Clinical Recommendations

Strength of Recommendation	Quality of Evidence
Strong	High
Weak	Moderate Low or very low
Strength/Quality Aggregate	Implications
Strong/high	<ul style="list-style-type: none"> <li>Recommendation can apply to most patients in most circumstances</li> <li>Further research is unlikely to change our confidence in the estimate of effect</li> </ul>
Strong/moderate	<ul style="list-style-type: none"> <li>Recommendation can apply to most patients in most circumstances</li> <li>Further research (if performed) is likely to have an important impact on our confidence in the estimate of effect and may change the estimate</li> </ul>

TABLE 137-2 Epidemiologic Study Designs: Types, Measurements, and Advantages		
Study Design <sup>a</sup>	Main Measurement	Advantages
Clinical trial	Efficacy	Gold standard for drug development
Noninferiority trial	Safety	Noninferior drugs may be better tolerated, cheaper, or easier to use
Cohort	Incidence, risk factors	Provides more robust evidence of association Reduced bias in exposure data Can study many outcomes simultaneously Allows direct calculation of incidence Allows direct calculation of relative risk
Case control	Association	Smaller sample required when outcome is rare Reduced bias in outcome data Can study many exposures simultaneously Allows estimation of relative risk May obviate need for long follow-up period
Analysis of secular trends	Population Trends	Examine trends in disease events over time Study across different geographic locations Can correlate them with trends in putative exposures
Cross sectional	Prevalence	Uncover relationships for future study Highly feasible
Case series	Descriptive	Characterize new syndromes or exposures
Case report	Descriptive	Identify signals for hypothesis generation

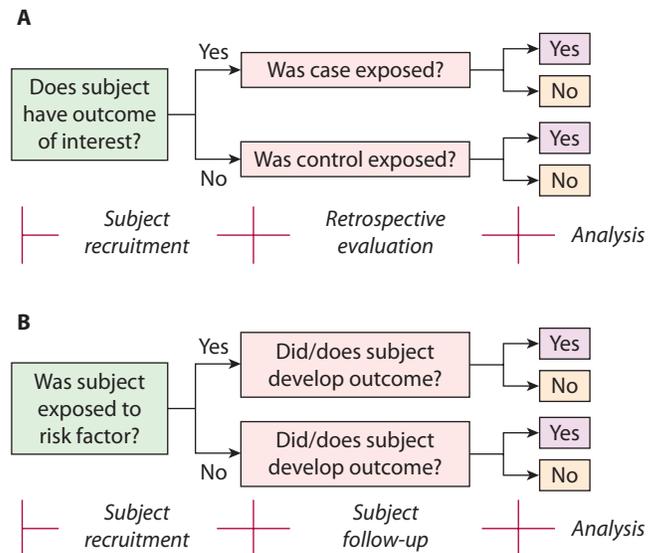

<sup>a</sup>Study designs are listed in descending order from the design that offers the best epidemiologic evidence for association to that which offers the least evidence.

from vaccines.<sup>44</sup> This investigation found a lack of consistent evidence for an association between autism and thimerosal-containing vaccines.

### Observational Design: Analytical

Hypotheses that are generated by theoretical reasoning or anecdotal association require analytical testing. Case-control studies and cohort studies are analytical techniques that use observational data, and each technique has its own advantages and disadvantages (Table 137-2). Case-control studies compare affected, treated, or diseased patients (cases) to nonaffected patients (controls) and evaluate for a difference in prior risk factors or exposures (Fig. 137-1A). Because participants are recruited into the study based on prior presence or absence of a particular outcome, case-control studies are always retrospective in nature. They are especially useful when the outcome being studied is rare, and they enable the investigation of any number of potential etiologies for a single disease.

The connection between CYP2C9 variants and the risk for nonsteroidal antiinflammatory drug (NSAID)-related gastrointestinal hemorrhage served as a prime example of a hypothesis that was well suited to case-control study design. Presence of variants of CYP2C9, the main CYP enzyme involved in the metabolism of NSAIDs, was common; however,

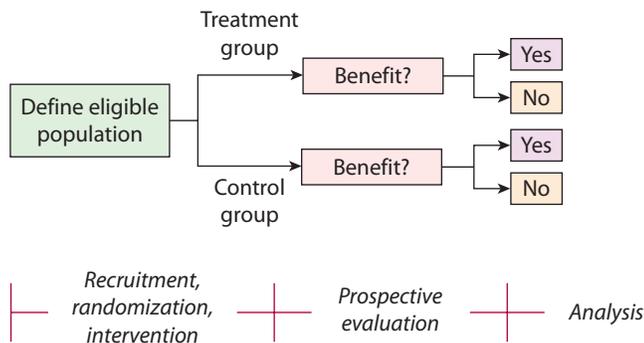

**FIGURE 137-1.** (A) Schematic representation of the case-control study design. Participants with an outcome or condition of interest are selected, along with control participants, and then are evaluated for previous exposure to a risk factor of interest. (B) Schematic representation of the cohort study design. Participants are recruited based on the presence or absence of a risk factor or exposure, then followed to see if they develop an outcome.

gastrointestinal hemorrhage is generally rare among those taking NSAIDs. Other putative risk factors such as daily NSAID doses were identifiable and could be studied simultaneously. In a case-control analysis of 577 cases who were patients older than 18 years with a diagnosis of upper gastrointestinal (GI) bleeding (UGIB), and 1,343 matched controls, the presence of the CYP2C9\*3 variant increased the risk for UGIB associated with NSAID for daily doses greater than 0.5.<sup>16</sup>

*Cohort studies* compare patients with certain risk factors or exposures to those patients without the exposure, and then follow these cohorts to see which participants develop the outcome of interest (Fig. 137-1B). In this respect, they allow the comparison of *incidence* (the number of new outcomes occurring within a population initially free of disease over a period of time) between populations who share an exposure and populations who do not. They may be retrospective or prospective and enable the study of any number of outcomes from a single exposure. They are particularly well suited to investigations in which the outcome of interest is relatively common. In circumstances when an outcome of interest is very uncommon, such as the case with stroke after phenylpropanolamine use, the large number of study participants required might make a cohort study impractical. A cohort of 981 APAP overdose participants was used retrospectively to investigate whether administration of activated charcoal might be beneficial therapy for APAP poisoning.<sup>9</sup> Participants were separated on the basis of whether or not they were treated with activated charcoal and were subsequently followed to see if they developed concentrations deemed toxic by the Rumack-Matthew nomogram. Perhaps the most famous cohort study was the Framingham Heart Study in which 5,209 residents of Framingham, MA, aged 30 to 62 years, were followed for over 50 years. This study provided a useful tool for studying the incidence of lung cancer, stroke, and cardiovascular disease in those exposed to cigarette smoke and other hazardous xenobiotics.<sup>17</sup>

### Experimental Design

Experimental studies are those in which the treatment, risk factor, or exposure of interest can be controlled by the investigator to study differences in outcome between the groups (Fig. 137-2). The prototype is the randomized, blinded, controlled clinical trial. Among epidemiologic study

**FIGURE 137-2.** Schematic representation of the design of a randomized clinical trial.

types, these provide the most convincing demonstration of causality. Clinical trials are used to measure the *efficacy* (the treatment effect within a controlled experimental setting) of treatment regimens and to draw inferences about the *effectiveness* of a treatment applied to the general population. Sometimes a trial can be designed to study drug treatments that are hampered by nonresponders to therapy, expensive drugs, or poorly tolerated regimens. Such trials are termed *noninferiority trials*, and operate on the null hypothesis that the new (study) drug is worse than the control (standard) drug. Thus, finding a difference between groups in a noninferiority trial means that the alternative hypothesis can be accepted that the new drug is not worse than the standard treatment. In this way, noninferiority trials introduce a concept of *equivalence margins* of noninferiority. The term *equivalent* is not used here in the strict sense, but rather to mean that the efficacies of the 2 therapies are close enough so that one cannot be considered superior or inferior to the other. This concept is formalized in the definition of a term called the equivalence margin.

Unfortunately, interventional studies are the most complex to perform, and several questions must be addressed by investigators before performing a clinical trial (Table 137-3). Human clinical trials, despite some recent successes (such as antivenom for scorpion stings),<sup>3</sup> have been traditionally difficult to apply to the practice of toxicology. Table 137-4 lists characteristics of poisoned patients that hamper attempts at performing clinical trials. Volunteer studies, using nontoxic xenobiotics or nontoxic doses of toxic xenobiotics, are often used to circumvent some of the problems in controlling human toxicology studies. However, it is typically difficult to apply results from these studies to the actual clinical context of poisoning. In experimental human studies, activated charcoal reduced absorption of ampicillin by 57%,<sup>46</sup> and had a mortality benefit for yellow oleander poisoning.<sup>15</sup> Taken out of these settings, a trial of single-dose oral activated charcoal was unable to prove benefit to outcome among 1,479 heterogeneous participants presenting to an emergency department

**TABLE 137-3** Considerations in Designing a Clinical Trial

What is the question of interest?
What is the target patient population?
How will the safety of subjects be assured?
What is a suitable control group?
How will outcomes be measured?
What difference in outcomes between groups is considered important?
What is the analysis plan?
How many subjects will be required?
How will randomization and blinding be achieved and maintained?
How long a follow-up period will be required?
How will loss of study subjects be addressed?
How will treatment compliance be evaluated?

**TABLE 137-4** Difficulties in Utilizing Clinical Trials to Study Human Poisoning

It is unethical to intentionally “poison” subjects.
Poisoned patients represent a broad spectrum of demographic patterns.
A wide variety of xenobiotics exist.
Exposures to any single xenobiotic are usually limited.
A limited number of poisoned patients are available at any one study site.
Uncertainty often exists as to type, quantity, and timing of most xenobiotic exposures.
Poisoning typically results in a relatively short course of illness.

(ED) for possible poisoning.<sup>33</sup> Unfortunately, none of these studies directly addresses whether activated charcoal reduces morbidity even if administered while the xenobiotic is still in the stomach and amenable to adsorption to activated charcoal.

### MEASURES USED TO QUANTIFY THE STRENGTH OF AN EPIDEMIOLOGIC ASSOCIATION

The objective of analytical studies is to define and quantify the degree of statistical dependence between an exposure and an outcome. Such associations are ideally represented by the relative risk of developing an outcome if exposed in comparison to being unexposed. Thus, the *relative risk* can be defined as the incidence of outcome in exposed versus unexposed individuals, and can be calculated directly from cohort and interventional studies. However, in a case-control study, an investigator chooses the numbers of cases and controls to be studied, so true incidence data are not obtained. In case-control studies, an *odds ratio* can be calculated, and the odds ratio will provide an estimate for relative risk in situations in which the outcome is rare, such as when the outcome occurs in fewer than 10% of exposed individuals. Figure 137-3 demonstrates the calculation of relative risk or odds ratio from analytic studies.

A relative risk of 1.0 signifies that an outcome is equally likely to occur whether an individual either is exposed or is not exposed and implies that no association exists between the exposure and the outcome. A relative risk approaching 0 suggests that an exposure is a marker of protection regarding the outcome, and a relative risk approaching infinity suggests the exposure predicts a tendency toward developing the outcome. Among men and women using phenylpropanolamine appetite suppressants, the odds ratio for development of hemorrhagic stroke was 15.9, which indicates a strong association.<sup>26a</sup>

		Outcome	
		Yes	No
Exposure	Yes	a	b
	No	c	d

Cohort study

$$\text{Relative risk} = \frac{a}{a + b} \bigg/ \frac{c}{c + d}$$

Case-control study

$$\text{Odds ratio} = ad/bc$$

**FIGURE 137-3.** Use of a 2 × 2 table to calculate or estimate relative risk from analytic studies. In cohort studies, study participants are selected on the basis of exposure. In case-control studies, participants are selected on the basis of outcome. The letters a, b, c, and d represent the number of participants either exposed or unexposed to a “risk factor” or treatment, with or without the outcome of interest. The odds hazard ratios estimate the relative risk if the outcome of interest is rare.

**MEASURES USED TO QUANTIFY THE SIGNIFICANCE OF AN EPIDEMIOLOGIC ASSOCIATION**

One of the essential features of research in medical toxicology is integration of the available data, whether clinical or experimental, into logical assumptions about how the overall system functions. Systems that are studied in medical toxicology research typically involve either elucidation of how a toxic insult influences normal physiology, or the mechanism and degree to which an antidote mitigates toxicity. Prior to undertaking an interventional study, ethical principles dictate that there must exist clinical *equipoise* regarding whether the intervention will have a benefit; otherwise, it should already be administered to everyone with the condition being studied and not withheld from the placebo group. Thus, a priori hypotheses are tested by performing experiments or by sampling observed data in an organized fashion. If the results are consistent with the predictions, then the hypothesis is retained; if not, then the prior hypothesis is rejected and a new hypothesis is formulated. This process is the basis of the scientific method and is also known as hypothesis testing.

Determination of whether the observed data in a toxicology investigation allow us to retain or refute our a priori hypothesis depends on our ability to gauge the certainty that the data were arrived at by chance. When observing a set of data, investigators can never be 100% certain that what they observed actually happened; it is possible that confounding factors biased what was observed, and it is possible that the observation was made simply by chance. To deal with this problem of interpretation, researchers use statistical methods to evaluate whether their data were arrived at by chance. The presence of an association between 2 factors in any given study has a number of possible explanations (Table 137–5).

To differentiate between differences due to chance and potentially real differences between comparison groups, researchers can use a philosophical approach known as the *null hypothesis*. The null hypothesis involves beginning experiments with the assumption that there is no difference between groups being compared. Thus, any significant deviation from observed and expected results under the null hypothesis allows the investigator to reject the null hypothesis and adopt the alternative hypothesis. The alternative hypothesis to the null is that the groups being compared are significantly different from one another (ie, not the same).

To begin, one must assign a probability percentage or *P* value to the likelihood that their observed results are *really* the case assuming the null hypothesis to be true. With some exceptions, the standard *P* value deemed to represent ability to reject the null hypothesis has historically been set to 5% (or  $P < .05$ ) in epidemiologic science. This value is also termed the alpha ( $\alpha$ ), the significance level, the *Type 1 error*, and represents the chance of falsely finding a difference between groups when one does not exist. *Type 2 error*, or a beta ( $\beta$ ) error, is the possibility that an investigator will be unable to find an association when one is really present. In some cases, investigators must use a *P* value even lower than .05 when testing multiple hypotheses at once, for example, in genetic marker studies examining multiple genes across an entire genome. Such a correction is termed the *Bonferroni correction* and is applied as the *P* value divided by the number of variables being tested at once:  $P = (\text{significance level}) / (\text{no. of concurrent variables})$ .<sup>43</sup> The result is a

smaller (ie, more stringent) corrected significance level for studies that test multiple hypotheses at once. For example, if a study protocol uses a genetic “chip” assay to evaluate 50 markers at once for an association with a pre-determined disease in a population, the Bonferroni correction would require significance at  $(0.05)/(50) = 0.001$  in order to deem any association to be statistically significant.

Perhaps a more informative description of the significance of an association is provided through the confidence interval (CI). The CI not only provides a test of statistical significance, it also offers information pertaining to the degree (and possible range) of differences observed. In an unbiased study, the 95% CI provides a range between which, if the study could be repeated an infinite number of times, the observed point estimate would fall between the CI 95% of the time. For example, one study reported that no toddlers ingesting one or 2 calcium channel blocker tablets became seriously ill, but a subsequent analysis of the CI around this small set of data demonstrated that the true incidence could be as high as 18%.<sup>36</sup> A CI around a relative risk or odds ratio is not statistically significant if it includes 1.0, and the narrower the CI the more precise the estimate of the magnitude of effect.

The likelihood that a study will find a difference if one truly exists is termed statistical *power* and relates to the likelihood of a false-negative study (Type 2 error). Power of a study is usually preset by an investigator before a study is performed and is typically 80% or 90% to set limits on the number of study participants needed. Table 137–6 lists considerations applicable to the choice of sample size. The sample size of a study is determined by the frequency of the exposure and outcome within the study population, the strength of association deemed clinically relevant, and the amount of error deemed acceptable in the study. Because power is often set relatively low, it is difficult to state that an association does not exist. It is more appropriate to state that a study was unable to reject the null hypothesis to find an association.

Although the clinical significance of an association is ultimately left to the judgment of the individual (or group) interpreting a study, ideally a working definition of clinical significance is developed before a study is performed. The finding of a low *P* value indicates a statistically high level of certainty that a difference between study groups exists, but unfortunately offers no indication that the difference is clinically relevant. This especially becomes problematic to interpret when small actual differences between groups are found to be statistically significant because of large numbers of participants; conversely, impressive associations of cause and effect can seem trivial if few participants are in a study. Therefore, interpretation of statistical versus clinical significance is often required, and may be facilitated either by calculating CIs around the point estimate, or alternatively by estimating the *effect size*.

Calculating the effect size is often used to complement statistical hypothesis testing by providing a quantifiable measure of the strength of a phenomenon. The effect size also plays an important role in power calculations and study sample size requirements. The reporting of effect sizes

**TABLE 137–5** Types of Associations Between Exposures and Outcomes That May Be Found With a Clinical Study

No association	The outcome is independent of exposure.
Artifactual association	
Chance	The association demonstrated by the study resulted from random error.
Bias	Systematic error in the study led to the noted association.
Indirect association	The association is real, but not truly cause and effect (confounding).
Causal association	The outcome is dependent on the exposure.

**TABLE 137–6** Considerations in Choice of Sample Size

	Sample Size	
	Large	Small
Pros	<ul style="list-style-type: none"> <li>• Able to detect associations of small magnitude</li> <li>• Less susceptible to some biases</li> <li>• More robust analysis</li> </ul>	<ul style="list-style-type: none"> <li>• Less work</li> <li>• Less cost</li> </ul>
Cons	<ul style="list-style-type: none"> <li>• More work</li> <li>• More cost</li> </ul>	<ul style="list-style-type: none"> <li>• Might not detect associations of small magnitude</li> <li>• More susceptible to biases associated with patient differences</li> </ul>

facilitates the interpretation of the substantive, as opposed to the statistical, significance of a research result. Although there are a variety of methods to estimate and calculate effect size, a useful method applicable to many studies in the medical toxicology literature is to calculate the *Cohen's d*. Cohen's *d* is defined as the difference between the means of 2 groups ( $x_1, x_2$ ) divided by the standard deviation ( $s$ ) of the mean, that is:  $d = (x_1 - x_2)/s$ . A larger absolute value of  $d$  represents a stronger effect. Cohen originally defined effect sizes as small,  $d \sim 0.2$ , medium,  $d \sim 0.5$ , and large,  $d \sim 0.8$ .<sup>13</sup> Effect sizes can also be thought of as the average percentile standing of the average treated (or experimental) participant relative to the average untreated (or control) participant; thus, a Cohen's  $d$  of 0.8 indicates that the mean of the experimental group is at the 80th percentile of the control group. Reporting effect size, by any appropriate method, should generally be considered a good practice when presenting empirical research findings in the field of medical toxicology.

## METHODOLOGIC PROBLEMS FOUND WITHIN CLINICAL STUDIES

The calculation of a *P* value or CI to quantify the influence of random error/chance does nothing to assess the adequacy of study design. Clinical research is particularly susceptible to *bias*, defined as systematic error in the collection or interpretation of data. Because such error can lead to inappropriate estimates of the causal relationship between an exposure and an outcome, careful evaluation of potential bias affecting a clinical study is of paramount importance.

*Selection bias* refers to error introduced into a study by the manner in which participants are selected for inclusion in the study. This type of bias is most problematic for retrospective studies in which exposures and outcomes have both occurred at the time of participant recruitment. Selection bias are introduced into a prospective clinical study if the study fails to enroll potential participants, or if potential participants refuse to participate, on a systematic basis. Selection bias may even influence the results of clinical trials. In a 1995 trial that found no difference in outcome between acutely poisoned patients treated with gastric emptying and patients from whom gastric emptying was withheld, all patients presenting to the ED after acute overdose were enrolled.<sup>39</sup> Because most patients with poisoning exposure are likely to do well with minimal support, selection of patients on this basis might be expected to bias this study to find no effect. Reasoning suggests that the patients most likely to benefit from gastric emptying are those with life-threatening toxic ingestion presenting within the first hour after exposure. Indeed, subgroup analysis of this paper suggests clinical benefit within this group of patients, but without conclusive power.

*Information bias* refers to error introduced into a study as a result of systematic differences in the quality of data obtained between exposed and unexposed groups, or between those with and without the outcome of interest. Several distinct types of information bias exist. Affected and nonaffected individuals may have differential memories regarding exposures, so recall bias is a concern in retrospective studies. The potential for *recall bias* is often cited as criticism of retrospective case-control studies, such as the seminal study documenting the association between phenylpropanolamine and hemorrhagic stroke, in which patients and families were asked to recollect their phenylpropanolamine use history. Stroke victims and their families might be more vigorous in their recall of exposures than control participants, thus biasing away from the null hypothesis. Similarly, *interviewer bias* occurs if study personnel differ in how they solicit, record, or interpret information as a result of knowledge of participant status regarding exposures or outcomes.

Prospective studies may be limited by loss to follow-up, especially if participants' data are lost from the study for reasons relating to either exposure or outcome (such as when participants withdraw from a study because they are feeling better), or are unable to be contacted because the patients have expired or changed contact information. *Misclassification bias* occurs when investigators incorrectly categorize participants with respect to exposure or

outcome. In a retrospective study of 378 children regarding the predictability of caustic esophageal injury from clinical signs and symptoms, it was found that 11 of 80 asymptomatic children had significant burns.<sup>18</sup> A potential limitation is that "asymptomatic" children were misclassified because of lack of rigorous written documentation of symptoms or signs within the medical charts. In addition, studies that use "cause of death" as an outcome are vulnerable to misclassification as well. For example, in a large study comparing 414 poison control center deaths with 7,050 poisonings in the corresponding vital statistics database, the medical examiner and a medical toxicologist adjudication panel concurred on "cause of death" in only 66%, which the authors interpreted as only fair (ie, less than good) agreement.<sup>29</sup> Thus, when investigators define "cause of death" as their study outcome, their results may be biased depending on which specialists are used to provide the "cause of death" interpretation. Similarly, there are limitations to studies of large administrative databases where the outcome of interest is subject to multiple biases.<sup>31,40</sup>

Bias is best minimized through careful study design. It is important to precisely define the study question and the population at risk and to carefully define rigorous inclusion and exclusion criteria. The outcome should also be defined precisely. During data acquisition the best way to reduce bias is to keep study personnel gathering exposure data blinded to outcome, and vice versa. Often, it is also advisable to keep study participants unaware of their status within a study to the extent that it is ethical (thus, "double-blinded"—neither investigators nor participants are aware of the participants' status within a study). Use of *placebos* or "sham treatments" is a way to facilitate blinding. One of the strongest criticisms of a 1995 trial of hyperbaric oxygen (HBO) for the prevention of delayed neurologic syndromes after CO poisoning<sup>42</sup> has been the failure to blind patients and investigators to the treatment in question,<sup>35</sup> a flaw that was corrected in a follow-up study published in 2002.<sup>40</sup> It is inevitable that some degree of potential bias will be present in any clinical study. Such bias should be reviewed in the analysis, and estimations of its magnitude and direction (bias toward or away from rejection of the null hypothesis) should be considered.

Unlike selection and information biases, which are errors introduced into studies primarily by the investigators or participants, *confounding* is a special type of problem that occurs within a study as a result of interrelationships between the exposure of interest and another exposure. Confounding is a bias wherein an observed association is not a product of cause and effect but instead results from linking of the exposure of interest to another associated exposure. Studies pertaining to adverse effects of drugs of abuse are especially prone to confounding by variables such as concomitant caffeine use, alcohol use, tobacco use, nutritional deficiency, and/or psychiatric illness. Analytic studies often restrict characteristics of enrolled participants or match participant characteristics between comparison groups in an effort to reduce confounding. Accordingly, it has been suggested that future studies on delayed neuropsychiatric manifestations following CO poisoning control for potential confounding from depression and cyanide exposure.<sup>30</sup> During data analysis, confounding can often be controlled through stratification of data into subgroups or through multivariate analysis techniques.

*Randomization* is of central importance in clinical trials. It prevents selection bias and insures against unintended bias. It is also an important method to ensure that unsuspected confounding factors are equally distributed between treatment groups within interventional studies. The 4 common types of randomization include (1) simple, (2) block, (3) stratified, and (4) unequal randomization. The *simple* method is equivalent to tossing a coin for each participant who enters a trial, such as heads = treatment, tails = placebo. Generally, a random number generator is used for this type of randomization. *Block* randomization is often used to guarantee balance in numbers during a clinical trial. The basic idea of block randomization is to divide potential patients into  $m$  blocks of size  $2n$ , randomize each block such that  $n$  patients are allocated to *A* and  $n$  to *B*, and then to choose the blocks randomly. Less common is *stratified* randomization to prevent imbalance in prognostic factors that may confound estimating treatment effect. Stratified

randomization achieves balance within important subgroups. For example, using block randomization separately for diabetics and nondiabetics in a cardiovascular trial. And finally, *unequal* randomization is used when 2 or more treatments under evaluation have a cost difference such that it is more economically efficient to randomize fewer patients to the expensive treatment and more to the cheaper one.

To improve the reporting of clinical trials, and to improve the recognition and interpretation of biases within them, guidelines referred to as the Consensus Standards of Reporting Trials (CONSORT) have been adopted by many medical journals.<sup>34</sup> The CONSORT guidelines provide a checklist to allow authors to systematically and uniformly report data and limitations. When interpreting published studies, it is also important to consider the potential for *publication bias*. Publication bias refers to the tendency for researchers, editors, and pharmaceutical companies to handle the reporting of studies with positive results differently from those with negative or inconclusive results.<sup>45</sup> Many journals now require that researchers register all planned clinical trials into a registry as a prerequisite for subsequent publication.

### EVIDENTIARY CRITERIA USED TO LINK CAUSE AND EFFECT

As is illustrated in Table 137–5, association of an exposure to an illness does not necessarily equate to cause and effect. In assessing causation, it must be determined if bias is present in the selection or measurement of exposure or outcome. If a study is unbiased, then the role of chance in the occurrence of the observed association must be explored. If an association is unbiased, unlikely to result from random error, and is not subject to confounding, then assumptions regarding causation can be derived. Table 137–7 provides a list of evidentiary criteria, first proposed by Bradford Hill in 1965,<sup>22</sup> that are often used to support causation.

In large part due to the inability to perform randomized trials, it is extremely difficult in medical toxicology to prove causal relationships. The goal is to build empiric evidence so that associations can be confirmed or refuted with conviction. However, many toxicologists deem clinical trials unconvincing, such as those investigating benefits from gastric emptying or HBO therapy for CO intoxication, due to the degree of bias present in the relevant published clinical trials. To address this issue, some consensus works (from position papers to formal consensus studies) attempt to provide guidance to clinical toxicologists regarding interventions where equipoise remains despite published clinical trials. For example, the Appraisal of Guidelines for Research and Evaluation (AGREE) Instrument is widely used in consensus guidelines. The instrument in its present form has been updated as “AGREE II” and is composed of 23 items organized into 6 quality domains (scope, stakeholders, rigor, clarity, applicability, independence).<sup>6</sup>

**TABLE 137–7 Bradford Hill Criteria for Determining Causation**

Strength	What degree of relative risk or odds ratio was demonstrated in the analysis?
Consistency	Does the cause and effect hold true in different studies, locations, and populations?
Specificity	Does the effect occur without the cause in question, or vice versa?
Temporality	Does the cause precede the effect?
Biologic gradient	Is there a dose–response effect?
Plausibility	Is the association consistent with the current understanding of the biological system?
Coherence	Is the association compatible with existing theory and knowledge?
Experiment	Was the association demonstrated in a well-designed study?
Analogy	Is there another cause–effect relationship in nature that is similar to the one in question?

### INFERENCE STATISTICAL TESTS

As discussed previously, researchers must devise an appropriate statistical test to determine whether or not their data were arrived at by chance, a process known as inferential statistics. Once the significance level has been chosen, the inferential statistical test of choice depends on the type of data that are being collected. It should be noted that using the wrong statistical test for a given set of data will invalidate the reported results of a study; thus, choosing the correct statistical test is of paramount importance for study design, as well as for toxicologists who try to interpret published medical literature.

Once the significance level has been set, then the data must be classified by type. Generally, data are either (1) categorical/nominal ( $\geq 2$  categories of data with no intrinsic ordering, eg, presence/absence of medical comorbidities), (2) continuous/interval (data along a scale where each value is equidistant from one another, eg, dollar values), or (3) ordinal/ranked ( $\geq 2$  categories of data with clear intrinsic ordering, eg, grade in high school). The method used to compare groups of data thus depends on whether data are categorical, continuous, or ordinal. Most commonly, categorical data are compared in terms of ratios/percentages (chi-squared test) and continuous data are compared in terms of means (Student *t* test) or medians (Mann-Whitney *U* test). As a general rule of thumb, an ideal analysis involves comparing interval/ratio data between groups because these data contain more information than any of the other forms of data. Finally, the number and relatedness of the independent variables for analysis must be determined. Most commonly, 2 unrelated samples are compared to assess for associations. However, there are times when groups are paired or related, such as in clinical trials with before/after data in the same participants. Additionally, it is possible to use more advanced techniques to compare 3 or more independent variables at once (Table 137–8).

Inferential statistical tests are generally classified into parametric versus nonparametric techniques. This distinction is based on the fact that statistical tests make varying assumptions with regard to the population parameters that characterize the distributions for which the test is employed. Parametric tests generally make more stringent assumptions upon the data to produce valid results, while nonparametric tests make few if any assumptions about the data parameters and can thus be thought of as a “backup” test if the parametric assumptions are not met. For example, the *t* test assumes that the 2 groups being compared are independent of each other and that the dependent variable is continuous and normally distributed along a bell-shaped

**TABLE 137–8 Parametric vs Nonparametric Inferential Tests Based on Data Type**

Data Type	Parametric Test	Nonparametric Test
Continuous/interval		
Related samples	Paired <i>t</i> test	Wilcoxon signed rank
Unrelated samples	Independent samples <i>t</i> test	Mann-Whitney <i>U</i>
$\geq 3$ groups	ANOVA	Kruskal Wallis
Correlation	Pearson <i>R</i>	Spearman rho
Nominal/categorical		
Related samples	Chi-squared Fisher exact	McNemar
Unrelated samples	Chi-squared Fisher exact	Mantel Haenszel trend
$\geq 3$ groups	Chi-squared	Cochran-Armitage
Correlation	Kappa	Spearman rho
Ordinal/ranked		
Same scales	Not applicable (NA)	Mann Whitney <i>U</i>
Different scales	NA	Wilcoxon signed rank
$\geq 3$ groups	NA	Cochran-Armitage
Correlation	Spearman rho	NA

curve (also known as a Gaussian distribution). Similarly, the chi-squared test assumes independent observation from a random selection of a given population with a large enough sample size such that any cell in the resultant  $2 \times 2$  table is greater than 5. A violation of one or more of these basic assumptions renders the test results invalid and mandates application of the nonparametric versions of these tests. The common parametric and nonparametric tests based on data classifications are summarized in Table 137–8.

## EVALUATION OF DIAGNOSTIC TESTS AND CRITERIA

In clinical practice it is often useful to have a test, which may be a laboratory result or clinical paradigm, to help arrive at a diagnosis or predict an outcome. For instance, historical questionnaires, capillary blood lead concentrations, and venous blood lead concentrations might all be used to identify children at risk of neurocognitive injury from plumbism.<sup>10</sup> However, each of these approaches is likely to have certain disadvantages in terms of effort, cost, discomfort, and/or accuracy. Targeting lead evaluation and therapy in children on the basis of exposure history is expected to be easy and inexpensive, but will not identify some children with significant poisoning; thus, the test is susceptible to being falsely negative. Capillary blood testing is more costly and uncomfortable and is susceptible to false-positive test results because of environmental lead dust present on fingertips. The possibility of false-positive or false-negative results must be considered with any diagnostic test (Fig. 137–4).

The utility of diagnostic testing is often described in terms of sensitivity, specificity, predictive value of a positive test (PPV), and predictive value of a negative test (NPV). A cross-sectional design is often used to study diagnostic tests, as we seek to determine the prevalence of positive tests among the diseased (*sensitivity*), and the prevalence of negative tests among the healthy (*specificity*). A perfect test would be highly sensitive and specific, but this is seldom possible. A highly sensitive test is often used in screening programs because they rarely lead to false-negative diagnoses. Specific tests (eg, urine benzoylcegonine for cocaine exposure) are typically used to “rule-in” a

		Presence of disease	
		+	-
Test result	+	True positive (a)	False positive (b)
	-	False negative (c)	True negative (d)

$$\text{Sensitivity} = \frac{a}{a + c} = \frac{\text{True positives}}{\text{True positives} + \text{False negatives}}$$

$$\text{Specificity} = \frac{d}{b + d} = \frac{\text{True negatives}}{\text{False positives} + \text{True negatives}}$$

$$\text{PPV} = \frac{a}{a + b} = \frac{\text{True positives}}{\text{True positives} + \text{False positives}}$$

$$\text{NPV} = \frac{d}{c + d} = \frac{\text{True negatives}}{\text{False negatives} + \text{True negatives}}$$

PPV = Positive predictive value  
NPV = Negative predictive value

**FIGURE 137–4.** Possible results of diagnostic testing and the statistical characteristics used to describe the utility of diagnostic tests. The letters a, b, c, and d represent the numbers of tested individuals with or without the disease of interest.

**TABLE 137–9** Questions to Consider When Evaluating a Study

Research objectives
What is the study question?
What is the studied population?
Study design
What type of study was performed?
How were participants recruited and enrolled?
Why were participants excluded?
What was the nature of the comparison group?
Data accrual
How were the data collected?
Are the exposures and outcomes clearly defined?
Are the observations reliable and reproducible?
Was randomization and/or blinding used?
Were participants lost to follow-up?
Analysis
Are the results statistically significant?
Are the results clinically significant?
Are potential confounding variables controlled?
Was the study powered to detect important differences?
Conclusions
Are the conclusions justified by data?

diagnosis, as they rarely yield false-positive results. Whereas sensitivity and specificity are inherent properties of a diagnostic test applied to a given population, the probability of disease—based on the results of a test—is highly dependent on the prevalence of disease within the population being tested. The PPV is the probability of having disease in a patient with a positive test; the NPV is the probability of not having disease when the test result is negative. Numerous studies have tried to examine the utility of vomiting, leukocytosis, hyperglycemia, total iron-binding capacity, and radiographic findings in predicting toxicity after acute iron overdose. In a retrospective assessment of 40 adults with oral iron overdose, vomiting was found to predict a serum iron concentration above 300 mcg/dL with a sensitivity rate of 84%, specificity of 50%, NPV of 44%, and PPV of 87%.<sup>37</sup> This suggested that the presence of vomiting should raise concern for iron toxicity but that the lack of vomiting was not particularly useful. Figure 137–4 outlines the calculation of the sensitivity, specificity, PPV, and NPV. It is important to remember that these calculations, too, are subject to bias and are best accompanied by CIs.

## SUMMARY

- Medical toxicology has embraced the vision of incorporating evidence-based medicine into practice.
- Randomized clinical trials, although the gold standard study design, have proven difficult to perform within medical toxicology.
- As toxicologists move beyond descriptive data reporting, there remains great potential for scientific advancement in the field of toxicology via hypothesis-testing from observational clinical research.
- Clinical investigators are charged with the imperative to perform studies based on sound epidemiologic principles.
- All studies, by nature of population sampling, are at the mercy of chance, but such random error can be quantified using statistical techniques.
- Systematic error (bias) can be limited, but not entirely excluded, through careful study design.
- Clinicians interpreting published toxicology research need to thoroughly evaluate a study’s research objectives, design, data acquisition, analysis, and conclusions before applying the results to patient care (Table 137–9).
- Future epidemiologic investigation should allow more valid conclusions to be drawn regarding the associations between exposures and outcomes, or regarding the value of treatments for poisonings, discussed in the preceding chapters of this text.

## RISK MANAGEMENT AND LEGAL PRINCIPLES

Barbara M. Kirrane

The number and diversity of toxicologic emergencies faced by emergency department (ED) staff have increased steadily since the early 1970s and continue to rise today. This chapter discusses the medicolegal management of patients who are exposed to xenobiotics that alter their ability to think. It also addresses the legal and ethical dilemmas routinely encountered by emergency medicine practitioners.

Patients with toxicologic emergencies require immediate care, and yet are often unable to give consent because their impaired consciousness prevents them from making informed decisions. Treating patients who present with an acute organic impairment manifested by confusion, irrational thought, or even dangerous behavior is very challenging. Emergency practitioners must recognize the medicolegal problems created when the impaired patient refuses treatment and insists on leaving against medical advice. The issue is further complicated by the variations in relevant state laws. Emergency practitioners must become familiar with the legal requirements of informed consent and the essential management necessary to avoid liability for negligence and abandonment within the state in which they practice. Of particular concern are the risk management and liability issues that relate to impaired patients attempting to leave the ED before medical care is complete. The legal requirements of informed consent in emergency settings, the duty to treat, medical malpractice risk, battery, and negligence allegations, are examined here. Guidelines based on generally accepted common law principles are suggested for developing appropriate patient care plans and departmental policies. These issues and principles are best illustrated by case examples.

### INFORMED CONSENT

#### Patient 1

An 18-year-old college student was brought by ambulance to the ED after a friend reported seeing her in the bathroom with slit wrists and an empty bottle of acetaminophen (APAP). In the ED, the patient was alert and oriented to time, place and person. Vital signs were as follows: blood pressure, 120/65 mm Hg; pulse, 95 beats/min; respiratory rate, 16 breaths/min; and temperature, 99.1°F (37.3°C). A rapid bedside glucose concentration was 120 mg/dL. The patient stated that she ingested the APAP approximately 5 hours earlier in an attempt to kill herself. The health care team wished to measure an APAP concentration to determine whether *N*-acetylcysteine should be administered. The patient refused venipuncture and stated that she would refuse any medications. The physicians informed the patient that she might suffer irreparable damage to her liver and possibly die if not treated immediately. This type of clinical dilemma is the ideal moment to discuss strategies with the local poison control center and medical toxicologist. The poison control center staff will have great experience in addressing complex unorthodox management strategies, suggesting how much time the physician has in the emergency department to achieve a solution without substantially compromising the patient's care and how much of the normal strategy can be altered or eliminated and still render quality care.

Medically treating patients against their will poses a difficult problem. Forcible treatment violates the principle of autonomy and the patient's right to privacy. However, harm to the patient may ensue if the appropriate evaluation and treatments are not performed. In the case above, the patient gives a history of ingesting a large amount of APAP, which risks causing

hepatotoxicity and even death if not treated (Chap. 33). Her refusal to be evaluated raises the important question of whether a physician is ever justified in performing an assessment of someone who is alert and oriented, refuses treatment, yet is poisoned. Do most patients suffering from a mental illness such as depression require treatment against their will? As in this case, if the harm that the patient faces is not immediate, but certain in the near future, does the physician have the duty and authority to treat? General principles of patient autonomy, informed consent and battery will be elucidated here.

A patient's right to choose a course of medical treatment was first recognized in the early twentieth century in a landmark case decided by the New York State (NYS) Court of Appeals in *Schloendorff v. Society of New York Hospital*.<sup>26</sup> Mary Schloendorff was admitted for abdominal pain and was found on physical examination to have a mass. Her physicians offered her a more thorough examination under anesthesia and the option for surgery. Although she consented only to the exploratory surgery, during the procedure the mass was removed. Postoperatively, Schloendorff developed an infection, gangrene, and several fingers had to be amputated. She sued the hospital. In its decision, the Court acknowledged Schloendorff's right to self-determination, and the right to refuse treatment. It stated:

Every human being of adult years and sound mind has a right to determine what shall be done with his own body and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency in which the patient is unconscious and it is necessary to operate before consent can be obtained.<sup>26</sup>

This decision formed the foundation for the "Doctrine of Informed Consent." Informed consent serves to protect a patient's autonomy, and creates the concept that each individual has the right to choose a personal course of medical treatment.<sup>45</sup> This includes the right to refuse care, and the right to terminate care already in process. In a nonemergent situation, it is the responsibility of the physician to obtain approval from a patient with decision making capacity or a legally recognized surrogate for those patients lacking such capacity before rendering treatment.

The core elements of the informed consent process consist of (1) an explanation of the treatment or procedure; (2) the disclosure of alternative choices to the proposed intervention; and (3) a discussion of the relevant risks, benefits, and uncertainties associated with each alternative; and (4) the likely outcomes with the various treatment options including the choice of no treatment. This discussion must take place whether the patient is either consenting to a procedure or refusing a recommended procedure. A patient does not automatically assume the risks of rejecting the recommendations of the physician if the patient is not fully apprised of the consequences of his or her decision.<sup>35</sup> Furthermore, it is the duty of the physician to assess how well the patient understands the above information. Before a physician accepts a patient's consent or refusal of care, the patient must demonstrate to the physician an adequate understanding of the nature and consequences of the decision made.

Depending on the state, courts apply one of 2 standards to determine if the information communicated by the physician was sufficient to satisfy common law obligations. The reasonable person standard requires a physician to disclose information that a reasonable person in the same position as

the patient would need in order to make an informed decision.<sup>11</sup> The alternative legal approach is the reasonable physician standard, which requires that a physician to reveal information that a reasonable physician in a similar circumstance would disclose to the patient.<sup>11</sup> States vary on which standard they apply, and it is incumbent on physicians to know the legal standard of the state in which they practice.

Courts recognize that the requirement for informed consent has exceptions for situations where physicians do not need to obtain permission before rendering treatment. In *Schloendorff v. Society of New York Hospital*, the Court recognized that consent is not required in emergency situations and is implied. Situations are generally considered emergent if care of the patient would be compromised with a delay in treatment. For example, in New York State, an emergency is defined as a situation that includes both the immediate endangerment of life or health and the need for the immediate alleviation of pain.<sup>32</sup> Physicians need to determine the specific requirements of informed consent in their respective states.

Often well-intended efforts on the part of the physician to fully communicate treatment information to an impaired patient prove ineffectual and then present the practitioner with a medicolegal dilemma. Physicians are frequently unable to discuss in a meaningful way the implications of the proposed treatment with the patient. Nevertheless, there remains a duty to treat the patient who presents with a life-threatening condition or one with the potential for permanent disability. In these situations, consent is considered to be implied, and emergent treatment should be provided. The principle of implied consent is a general tenet of tort law.<sup>22</sup> In our case, although the physicians have explained the risks, they must have a more extensive conversation to determine if the patient is of sound mind. Suicide ideation raises the concern that the patient is not exhibiting rational thought and a thorough investigation needs to take place to determine if the patient has decision-making capacity. Given the fact that timely evaluation and intervention are necessary to prevent hepatotoxicity in overdose, the physician needs to draw blood early even if the patient does not consent, as she is at risk of harm if there is a delay in her care. So in this case, it is essential to begin management by any number of approaches including administering activated charcoal, obtaining blood specimen to assess hepatotoxicity, coagulation profile, basic metabolic and toxicologic evaluation of acetaminophen concentrations and/or initiating *N*-acetylcysteine with or without agreement of the patient. These options are all possible appropriate recommendations for the clinician. Decisions of this complexity should be accomplished with the full support of the local poison control center, a medical toxicologist, and an excellent team in the emergency department.

## RISK MANAGEMENT CONSIDERATION AND DOCUMENTATION

### Patient 2

A 28-year-old woman was brought to the ED by police who believed she ingested a large quantity of drugs to avoid arrest minutes before their arrival. The triage nurse helped the patient onto a stretcher, brought her to the treatment area, and recorded normal vital signs. The patient became combative and uncooperative as the physician initiated the examination and he verbally ordered that the patient be restrained. The patient was given 40% oxygen via face mask, cardiac monitoring was initiated, and an intravenous line was inserted and 0.9% sodium chloride at a rate of 125 mL/h was administered. A fingerstick glucose was determined to be normal and 100 mg of thiamine were administered intravenously (IV). Three doses of IV diazepam (5 mg) in 5-minute intervals were administered until light sedation was achieved. The physician ordered a basic set of laboratory studies, a urine drug screen and ordered an abdominal radiograph. The laboratory values and the radiographic findings were normal and the urine drug screen was negative. The treatment plan was then to continue monitoring and to reassess the patient at a later time. This was an ideal time for the physician to contact the local poison control center or a medical toxicologist to better understand the management of a body stuffer (Special Considerations: SC5). There are critical decisions to be made immediately: protection of the patient's airway, management of the ingested toxin, and a high level of supervision of the

patient in an intensive care unit (ICU). This case demonstrates inadequate knowledge of the management of an unknown toxin. It demonstrates the risks of management without utilization of available hospital (ICU) and health system resources (Chap. 130).

One hour after arrival the patient's vital signs were blood pressure, 120/70 mm Hg; pulse, 82 beats/min; and respiratory, rate 18 breaths/min. The patient was noted to be stable and was transferred to an observation unit. Oxygen and cardiac monitoring were discontinued. No further orders were written, and the patient remained restrained. Three hours later, the vital signs were blood pressure, 110/60 mm Hg; pulse, 92 beats/min; and respiratory rate, 18 breaths/min. A nursing note stated the patient was resting comfortably.

Forty-five minutes later, at midnight, the initial treating physician completed his shift and informed his replacement that the patient was stable and resting in the observation unit.

At 4:20 AM the patient was found unresponsive, hypotensive, with agonal respirations and with a weakly palpable pulse. The patient felt very hot to the touch and had a rectal temperature of 108°F (42.4°C). Resuscitative efforts were initiated but were unsuccessful. Thirty minutes later, the patient was pronounced dead.

Several important risk management questions frequently arise in emergency medicine malpractice litigation. To prove that a case constitutes medical malpractice, a plaintiff's attorney must show by a preponderance of evidence that a deviation from accepted practice by the physician occurred. The attorney must further demonstrate that this deviation or negligent act or omission by the physician proximately caused the patient's injury. Courts have held that where "there is substantial probability that the [defendant physician's] negligent conduct caused the resulting injury, that sufficient evidence has been developed against [the] physician."<sup>42</sup>

When the attorney for the patient (plaintiff's attorney) introduces evidence to advance the case, the ED record is likely to become the central focus in the medical malpractice trial. The problems associated with an improperly documented ED record are numerous, but they can be minimized if the practitioner is cognizant of risk management principles. Every entry in that record is scrutinized by both parties (plaintiff and defendants). The importance of completing the record with knowledge of risk management implications should be a priority for all health care professionals.

The physician is required to complete a medical record that amply supports the basis for the medical judgments exercised. When a physician opts to complete only a summary statement on the record without noting supporting clinical data or patient history, claims alleging a failure to diagnose will be extremely difficult, if not impossible, to defend. One of the basic tactics of the defense in a medical malpractice case is the argument that the physician's judgment was appropriate given the clinical facts and the patient's history available at that time. Therefore, physicians who do not record supporting clinical data and history undermine their "medical judgment" defense.

Notations in the medical record related to patient monitoring are considered inadequate when those notes do not provide insight into the patient's clinical status. Thus, any note for a restrained patient in the ED for a lengthy period of evaluation, observation, or until an inpatient bed becomes available must include specific clinical data and observations overtime (including relevant laboratory results, radiographic findings, hemodynamic changes, and intravenous medications and solutions). Any deficiencies in this area would undoubtedly be noticed and highlighted at trial by a plaintiff's expert, who usually is a board-certified physician in the same specialty.

Documentation supporting the restraint of an impaired patient against his or her will must include a description of the clinical situation to support such a forcible impediment to the patient's right to liberty and freedom of movement. Such a description should specifically document any manifestation of agitation and/or behavior that might place the patient at risk. The record should incorporate a description of the specific acts of the patient of concern and, most importantly, should comment on the difficulties in providing care to the patient because of those acts. Documentation of patient conduct should be factual, accurate, detailed, and nonjudgmental.

The transition to electronic health records (EHRs) was introduced as a way to improve the health care process by enhancing communication, workflow, decision making, and increasing patient safety while simultaneously decreasing errors. Despite their many actual and potential benefits, EHRs have introduced new concerns not previously encountered in written record keeping. Some of the new errors encountered include poor data display, alert fatigue, wrong order/wrong patient error, and communication failure.<sup>10</sup> An additional concern that could lead to errors and increase physician liability is the potential to overlook pertinent data given the large volume of information that is provided on every aspect of care for each patient regardless of when it took place. For example, every laboratory test that a patient has ever undergone in one hospital system will often be available to the physician as she or he opens the chart to document on a patient's current visit, yet the physician will only want to focus on what is important for the patient's current encounter. The copy and paste function that is often used by providers to save time risks leading to repeating information that is no longer correct.<sup>28</sup> Computerized provider order entry (CPOE) was introduced to improve all aspects of the medication process from prescribing to administration but ultimately introduced new problems. Common errors associated with CPOE include wrong medication selection, incorrect input of patient data, wrong dose or strength selection, and scheduling errors (Chap. 134).<sup>25,43</sup>

To summarize, a well-documented ED record reflecting the practice of accepted risk management principles is the best course to follow for the physician and nursing team managing a difficult overdose situation and one in which legal concerns may appear to present problems in providing proper medical management.

## FORCIBLE RESTRAINT OF THE IMPAIRED PATIENT

### Patient 3

A 23-year-old woman was found unresponsive on the street and transported to the ED by ambulance. Friends on the scene reported that the patient regularly uses opioids recreationally. In the ED, she was unresponsive and apneic. Oxygen was immediately administered by bag–valve–mask and intravenous access was established. Naloxone was administered, and shortly thereafter the patient regained consciousness. After 20 minutes of care in the ED, the patient became fully alert and oriented, with no evidence of hypoxia or other clinical signs to suggest impaired judgment. The patient stated that she had taken a sustained-release oxycodone and demanded to be discharged immediately.

The ability of a hospital to retain and physically restrain a person who has an altered level of consciousness for evaluation and emergency intervention is generally well supported by state statutes and case law.<sup>11</sup> Reasonably clear guidelines for the management of such impaired patients have evolved from legal precedents governing appropriate medical assessment, from risk management considerations, and from the predictability of patient injury in the event of premature discharge.

A staff decision to allow a treated or partially treated patient with a drug overdose who subsequently becomes alert to return to the community must be based on an assessment of several factors. The initial concern is the capacity of the patient; is the patient able to fully comprehend the current medical situation and associated risks of not receiving treatment? To demonstrate capacity, patients must be able to (1) understand the facts involved in the decision; (2) appreciate the nature and the significance of the decision; (3) weigh the risks and benefits and potential alternatives; and (4) express their choice.<sup>16</sup> The next consideration is that of medical stability. Has the initial process that caused the clinical scenario completed its course? The history of drug use in this patient raises the concern that the underlying toxic metabolic process is not yet resolved, and alteration in mental status, significant respiratory compromise, or other medical symptoms will recur when the naloxone is metabolized, again placing the patient at risk.

Common ED practice and sound legal principles suggest that both the hospital and its staff have a duty to prevent such a person from leaving if the duration of the effect of the involved xenobiotic is longer than that expected for the antidote. Because the duration of effect for naloxone is considerably

shorter than that of sustained-release oxycodone, the physician can predict with reasonable certainty that coma or apnea will recur in the near future. The physician has the duty to inform the individual of the life-threatening nature of the condition, and then to retain, with restraints if necessary, the patient in the hospital until medically stable.

Legal liability in this situation is further reduced if the chart substantiates the medical judgment that was the basis for the decision to retain the patient and, if applicable, the use of restraints. Such documentation should specifically note the likely relapse of the patient into a symptomatic state and that this occurrence could place the patient in a life-threatening situation. When documented in a clear manner, legal challenges to the decision to restrain the patient have a limited chance of success. Sound risk management principles support treatment and detainment. Conversely, prematurely releasing a patient with a significant overdose exposes both the physician and the hospital to a claim of negligence on the grounds of failure to foresee a likely and harmful event. From a practical perspective, the legal risk and liability of the latter scenario is far greater than the former.

In the above case, the patient responded to the opioid antagonist naloxone. Given that there are many different opioids available with variation in half-lives and duration of action, the patient needs to be kept in an acute care setting until the naloxone is metabolized to ensure the patient has not been exposed to a long-acting opioid that will cause recurrent life-threatening toxicity. Once the antidote has worn off the patient must be reassessed to determine possible damage from the initial event (hypoxic brain injury, aspiration, end organ impairment) as well as decision-making capacity and possible underlying psychiatric illness, such as suicidal ideation and the need for a psychiatry consultation. If it is determined that the patient is safe for discharge from the hospital consideration should be made to ensure that available family and social support is arranged and harm reduction including overdose education, naloxone prescriptions for family and friends, and access to counseling and medication-assisted treatment modalities (methadone buprenorphine naltrexone programs) after discharge are performed (Special Considerations: SC6).<sup>12</sup>

## BLOOD ALCOHOL CONCENTRATION AND EVIDENCE COLLECTION

### Patient 4

A 41-year-old man who was a driver involved in a motor vehicle crash was taken to the ED by ambulance. Two motorists in another vehicle were killed. The patient had no physical complaints, but was transported to the hospital for medical evaluation. On arrival, he was alert and oriented, responded appropriately to all commands, and demonstrated normal motor function and had a normal gait. Police officers suspected that he was driving while intoxicated, but he refused a breath alcohol test at the scene.

The police officers informed the ED staff that he was arrested and might be charged with vehicular homicide. The officers then requested that the emergency physician draw a blood specimen to determine the blood alcohol concentration. The patient stated that he would not allow the ED staff to draw blood for a determination of an alcohol concentration.

In 2015, there were 10,265 people who died in alcohol-related motor vehicle crashes, which comprised 29% of all traffic-related deaths in the United States.<sup>9</sup> In the United States, an alcohol-related motor vehicle crash kills someone every 51 minutes.<sup>9</sup> In 2015, crashes resulting from alcohol-induced impairment were responsible for 16% of fatalities in children younger than 14 years who were killed in motor vehicle crashes.<sup>9</sup> The estimated economic cost of alcohol-impaired motor vehicle crashes in 2015 was \$44 billion.<sup>9</sup> The judicial system has historically been one of the most effective tools to combat drunk driving and its effectiveness depends on the ability to identify and punish individuals who violate the law. See Special Considerations: SC11 for more in-depth discussion on “*per se*” limits. It is essential, however, that the collection of evidence does not violate the rights afforded by Constitutional law or specific state law. Does forced phlebotomy for patients suspected of driving while intoxicated violate these protected rights? This has long been debated in the courts, and legal authority specifically brought into question include the Fourth Amendment,<sup>39</sup> the right

against unreasonable search and seizure; the Fifth Amendment,<sup>40</sup> the right against self-incrimination, and the Due Process clause of the Fourteenth Amendment.<sup>38</sup> Past court decisions applying Constitutional or statutory law on these issues help guide current clinical practices and also contribute to further evolution of legal standards.

Every state and the District of Columbia have driver “implied consent” laws. When a person obtains a driver’s license, he or she consents at the time of acquisition to a chemical alcohol test if suspected of driving while intoxicated. Under implied consent laws, when a person suspected of driving while intoxicated refuses to take an alcohol test, a penalty is imposed. Specific penalties for refusals vary from state to state. At a minimum, the refusal results in suspension or revocation of a driver’s license. Some states assign additional fines and penalties for this action. A few states allow the refusal itself to be submitted at trial in support of the prosecution, making it possible to be convicted of an intoxication charge without chemical evidence.<sup>5</sup> Certain states (eg, Texas, Illinois) allow blood tests to be performed on patients as ordered by an officer of the law when there is probable cause that driving while intoxicated resulted in severe injury.<sup>21,33</sup> Other states, such as New York and Wyoming, allow forced blood samples with a warrant issued by a judge.<sup>7,19</sup> State laws in this area vary with respect to amount of force that may be used, requirements of warrants, who may perform the blood draw, and other blood draw restrictions and it is important that the ED staff be familiar with the specific requirements of law in the state in which they practice.<sup>2</sup>

How much force may be used to collect chemical evidence? Does a physician violate human dignity and privacy in obtaining evidence for the State? These issues were addressed by the United States Supreme Court. In *Rochin v. California*,<sup>24</sup> the Court overturned a conviction of drug possession based on violation of the Fourteenth Amendment. In this case, police were informed that Rochin was selling drugs. While entering the home of the defendant, the police witnessed the defendant swallow 2 pills that were lying on the night stand. When the officers failed to recover the pills on the scene, the officers took Rochin to the ED, where they directed the physician to administer an emetic through a nasogastric tube. The capsules were recovered from the vomit, and Mr. Rochin was convicted by the trial court for possessing morphine.<sup>24</sup> The Supreme Court reversed the lower court decision based on Fourteenth Amendment grounds stating that “nor shall any State deprive any person of life, liberty or property, without due process of law.”<sup>24</sup> The term *due process* is vague, and is defined on a case-by-case basis; essentially, however, it means that states must use fair legal procedures when depriving an individual of life, liberty, or property. In *Rochin*, the court concluded that forced emesis by a physician was believed to violate “due process,” stating:

This is conduct that shocks the conscience. Illegally breaking into the privacy of the petitioner, the struggle to open his mouth and remove what was there, the forcible extraction of stomach contents—this course of proceeding by agents of government to obtain evidence is bound to offend even hardened sensibilities. They are methods too close to the rack and the screw to permit constitutional differentiation.<sup>24</sup>

The Supreme Court revisited the issues presented in *Rochin* 4 years later in *Breithaupt v. Abram*.<sup>5</sup> Breithaupt was the driver of a truck who killed 3 occupants of another vehicle. In the ED, a police officer requested that a blood alcohol concentration be drawn. The blood, drawn while the patient was unconscious, was above the legal limit for alcohol and the patient was convicted of involuntary manslaughter. Making an analogy to the forced emesis scenario in *Rochin*, Breithaupt argued that the blood draw violated due process because he did not consent to its collection. Justice Clark disagreed, stating “the distinction rests on the fact that there is nothing ‘brutal’ or ‘offensive’ when done, as in this case, under the protective eye of a physician” and that the “blood test procedure has become routine in our everyday life.”<sup>5,6</sup> Phlebotomy while the patient is unconscious and unable to give consent was determined not to violate the due process clause of the Fourteenth Amendment.

The Supreme Court continued to expand the scope of permissible phlebotomy in *Schmerber v. California*.<sup>27</sup> Schmerber was involved in a motor

vehicle crash in which the police officer suspected he was intoxicated. Unlike the *Breithaupt* case, Schmerber was conscious, and a physician drew a blood sample at the officer’s request despite the patient’s verbal refusal. The attorney for Schmerber asserted that forced phlebotomy violated several constitutional rights. Specifically, it violated the Fourth, Fifth, and Fourteenth Amendments of the US Constitution. He alleged that forced phlebotomy denied him due process of law, it violated his privilege against self-incrimination, and it violated his right against unreasonable search and seizure.<sup>5,27</sup>

The Supreme Court rejected all of these arguments holding that the phlebotomy did not violate the due process clause because “the extraction was made by a physician in a simple, medically acceptable manner in a hospital environment. . . . We cannot see that it should make any difference whether one states unequivocally that he objects or resorts to physical violence in protest or is in such condition that he is unable to protest.”<sup>27</sup> Furthermore, the court found that the forced blood draw did not violate the Fifth Amendment’s Privilege Against Self-Incrimination because the Fifth Amendment only protects evidence of a “testimonial or communicative nature,” such as writings or speech. Finally the court found there was no violation of the Fourth and Fourteenth Amendments’ protections against unreasonable search and seizure as the delay necessary to obtain a warrant threatened the destruction of evidence.

Considering the “totality of the circumstances” in *Schmerber*, the blood alcohol test fell under the Court’s exigent circumstances exception to the general requirement of a warrant.

The percentage of alcohol in the blood begins to diminish shortly after drinking stops as the body eliminates it from the system. Particularly in a case such as this where time elapsed to bring the accused to a hospital and to investigate the scene of the crash, there was no time to seek out a magistrate and secure a warrant.

To ensure compliance with standards set forth in *Schmerber*, the states have tailored laws and regulations governing the seizure of blood for the purpose of blood alcohol testing. Laws generally require the procedure be (1) performed in a reasonable, medically approved manner; (2) incident to a lawful arrest; and (3) based on the belief that the arrestee is intoxicated. It should be remembered that the issues raised by any one case are complex and the application to situations in real time is difficult. Laws and regulations governing blood draws for alcohol testing vary from state to state and are the subject of frequent review and amendment. Medical staff should review with hospital counsel the local laws and regulations that pertain to these issues. The benefits of determining a patient’s blood alcohol concentration must be weighed against the risks of the procedure. For example, drawing blood in an agitated patient may place the staff at risk for a needle stick and the patient at risk of vascular injury. It is important to remember that the role of physicians are to be the patient’s advocate and they are not serving as representatives of the court. Physicians must order tests they deem to be of clinical benefit and that may assist the court as necessary in obtaining evidence. One way to assist is talking to the agitated patient; if the patient is agitated because of a defense emphasizing that no drinking of alcohol occurred then it would be a good idea to have blood drawn to support that, as refusal of a blood draw is frequently perceived as a presumption of guilt by the court.

It should also be noted that the US Supreme Court in *Missouri v. McNeely* limited the holding of *Schmerber* for warrantless blood alcohol testing.<sup>18</sup> In *McNeely*, the state court in Missouri argued that the metabolism of alcohol over time, by itself, was justification to obtain warrantless blood alcohol testing in the hospital. The US Supreme Court rejected this argument. While the dissipation of alcohol from the bloodstream over time is one of the factors to consider when evaluating the “totality of the circumstances,” it does not meet the exigency exception to the warrant requirement by itself. The majority opinion held that “when officers in drunk driving investigations can reasonably obtain a warrant before having a blood sample drawn without significantly undermining the efficacy of the search, the Fourth Amendment mandates that they do so.” This does not suggest that a physician should insist on a warrant when an officer requests a blood alcohol test as this is

a protection afforded retrospectively by the courts. Familiarity with local regulations is necessary to properly manage requests by law enforcement for blood alcohol testing.

When patients agree to have their blood drawn, it is important that a chain of custody process be carefully followed. The chain of custody process in a legal context refers to the chronological documentation showing the collection, transfer, analysis, and storage of a blood sample from the time it is collected until it is presented at trial. It is used to prevent contamination of evidence. If the proper chain of custody process is not maintained, the evidence collected in general will not be admissible at trial. If the evidence is admissible, and if there are deficits in the chain of custody, the defense attorney will try to cast doubt on the reliability of the information presented.

## CONFIDENTIALITY

### Patient 5

A 32-year-old woman was fired from her job as a high school mathematics teacher. The school board called for her termination after learning that she had a history of alcohol dependence and had a previous hospitalization for detoxification at the local community hospital. A parent on the school board was also employed as a nurse at the hospital where the teacher had received therapy. The school board member (and nurse) had inadvertently accessed the medical record of the teacher while caring for a patient with the same last name.

The Health Insurance Portability and Accountability Act (HIPAA) was enacted by Congress in 1996 and signed by President Clinton. Initially, the purpose of HIPAA was to increase the portability of health insurance and allow employees to maintain insurance when they changed jobs. The Act called for the establishment of several provisions, among them an electronic database designed to facilitate the exchange of information between health care professionals, insurance companies, and those involved in financial and administrative transactions.<sup>17</sup> However, the idea of developing an electronic database brought to light already growing concerns regarding the maintenance of patient privacy. For the first time, medical records would be accessible to an unlimited number of people working in health care, everyone from bill processors to pharmacists to clinicians. Could the right to privacy be jeopardized by a system designed to increase efficiency?

Prior to HIPAA, individual hospitals or physician offices designed their own methods for maintaining confidential patient information. Records were maintained on computers in some circumstances and on paper in others. Accessibility to that information was largely regulated by state laws and some federal regulations. Ethical codes of conduct also provided guidance. During the 1990s, however, the weaknesses of the existing systems gained attention as multiple high-profile breaches of confidentiality became public. For example, the medical records of a congresswoman were released to the media during her campaign, making her history of depression and a past suicide attempt public knowledge.<sup>30</sup> There were also several cases in which the medical records of hospital employees were read by staff members not involved in the employees' care, health insurance companies released health care information to employers without permission, and physicians released information to pharmaceutical companies that subsequently solicited the patient.<sup>46</sup> These breaches of ethics were each a testament to the fact that the right to privacy needed more stringent regulation. If such breaches occurred in the previous systems for recording personal health information, then it was clearly apparent that further opportunities for transgressions would be created with increased access through an electronic database.

The Privacy Rule of HIPAA has become the most well-publicized aspect of this Act among health care personnel. The Privacy Rule governs the use and disclosure of protected health information in the hands of health care professionals, health plans, and health care clearinghouses.<sup>17</sup> The terminology used in the Privacy Rule is extensively defined. The following is a brief summary of the terms used.

## Protected Health Information

Protected health information includes any individually identifiable information concerning the past, present, or future health of an individual including medical information pertaining to assessment and treatment of an individual and payment and billing information. All forms of information, written, oral, or electronic, are protected by this rule. Deidentified data is not considered protected health information.

## Covered Entities

The term "covered entities" includes any person or business that provides health-related services or products. All those providing health-related services fall within this provision, including, for example, clinicians, pharmacists, medical equipment providers, and other health care professionals. Companies that provide disability insurance, car insurance, or casualty insurance are not included in the rule.<sup>17,37</sup>

## Health Care Clearinghouses

Health care clearinghouses are entities that compile health care information, such as billing companies or data processing centers.

Institutions are required to provide all individuals with written notice of the institutional privacy policy when each individual first seeks medical care. Patients must be informed of how the institution may use and disclose information. The notice must also describe the patients' rights, including the right to access their medical information and their right to file a complaint if they believe their rights were violated. The notice must be written in plain language, and the patient must provide written acknowledgment of receipt of the information in the notice.

The Privacy Rule of HIPAA was not intended to impede health care. There are several exceptions to the nondisclosure rule. A covered entity is permitted to use and disclose protected health information for the purposes of ongoing evaluation and treatment. For example, physicians have the freedom to consult with each other, both within and outside their own institution in order to provide clinical care. Additionally, there are several specific exceptions to the Privacy Rule delineated within the legislation—situations in which protected health information will be and often must be disclosed, even without an individual's permission. For example, activities related to public health, such as reporting communicable diseases; information necessary to report actual or suspected abuse, neglect, or domestic violence; or information pertaining to cadaver organ or tissue donation are all specifically exempt from the Privacy Rule.<sup>13</sup>

Examples of the application of the HIPAA rule occur in everyday emergency medicine. For example, only persons directly involved in a patient's care are allowed to access and view the chart. Occasionally well-recognized politicians, actors and actresses, or even work colleagues seek medical treatment, and previously hospital workers were able to read their medical records. Today, these patients would be protected from the curiosity of medical personnel not directly caring for them. Another example is communication with family, friends, and even law enforcement. Whereas in the past clinical teams periodically discussed questions about a person's health care with anyone who asked, today clinicians may only speak with those individuals to whom the patient specifically has given permission.

The HIPAA Privacy Rule specifically addresses consultations with poison control centers. It states:

We consider the counseling and follow-up consultations provided by poison control centers with individual providers regarding patient outcomes to be treatment. Therefore, poison control centers and other health care professionals can share protected health information about the treatment of an individual without a business associate contract.<sup>13</sup>

This is important to remember, and individuals seeking assistance from poison control centers to assess risk after exposures to xenobiotics or who need assistance in managing complex cases should never be concerned that they are violating the HIPAA rule by seeking help. The same is true for managing medication safety. The FDA and pharmaceutical

industry rely on postmarketing surveillance to obtain further safety information regarding the toxicity of a medication after it has been granted approval for use. The FDA's program MedWatch is a postmarket surveillance tool that relies on reports by health care professionals and/or patients regarding the occurrence of harmful effects associated with the use of a medication or medical device. For a more in-depth discussion of the FDA and MedWatch, see Chaps. 134 and 135. Reports made to MedWatch are in compliance with the HIPAA Privacy Rule, as the rule recognizes the need for public health authorities to have access to protected health information to carry out their mission of ensuring safety and health to the public at large.<sup>36</sup>

Violations of the Privacy Rule are subject to penalties, the severity of which is dependent on the type of infraction. Simple noncompliance will result in financial penalties. Moreover, significant or intentional disclosures of information carries steeper fines in addition to criminal charges and potential imprisonment.<sup>36</sup> In 2009, as part of the economic stimulus plan, the Health Information Technology for Economic and Clinical Health Act (HITECH) under the American Recovery and Reinvestment Act (ARRA) was passed.<sup>23</sup> This Act was primarily created to encourage the use of electronic health records and supporting technology. However, it also widened the scope of privacy and security protections defined by HIPAA. Several notable changes brought forth by this act include an increase in civil penalties for willful neglect, extending up to \$250,000 for a single violation, to as much as \$1.5 million for repeated or uncorrected violations. Furthermore, HIPAA provisions now apply to business associates. Business associates are defined as persons who, on behalf of a covered entity, perform or assist in performing a function or activity that involves the use or disclosure of individually identifiable health information.

## OTHER LEGAL CONSIDERATIONS FOR POISON CONTROL CENTERS AND CERTIFIED SPECIALISTS IN POISON INFORMATION

### Patient 6

The poison control center received a call from a concerned mother that her daughter might have ingested one of her grandmother's diabetes medications. The mother stated that the child was acting normally all day at the grandmothers' house, but when the family returned home, the child had become drowsy. When contacted, the grandmother had confirmed that one pill was missing from her purse although she did not know the name of her medication. The poison control center advised that the parents give the child juice and closely observe her over the next 6 hours. Approximately 2 hours later, while sleeping, the child had a seizure. The child continued to seize in the hospital, where medical evaluation revealed hypoglycemia. The patient subsequently suffered permanent neurologic damage. The medication was later identified as glyburide. A negligence action was brought against the poison control center, alleging inappropriate advice and failure to recommend transport to a hospital.

As a general rule, any physician who decides to treat a patient enters into a physician–patient relationship and this creates well-established legal duties. Courts have ruled that the physician–patient encounter need not be a face-to-face interaction to have legal consequences. For example, the absence of physical contact between a physician and patient, as in the practice of radiology and pathology, does not preclude a patient from asserting that a duty of care exists.<sup>6</sup> More particularly and quite relevant to the practice of a poison control center, a New York State court ruled that an initial telephone call from a patient to a physician can be sufficient basis to hold that physician responsible for inappropriate advice or a significant error in judgment.<sup>20</sup> Given these legal precedents, it is clear that contact with a certified specialist of poison information provides sufficient grounds for a subsequent legal action if inappropriate advice was given and that advice was a proximate cause of patient injury.

### Standards of Care Applicable in Poison Control Centers

Standards of care applicable to medical toxicologists who supervise or direct a patient's care in a poison control center are examined under the same legal framework as other medical specialists. The basic medical malpractice concepts are universal, with some variations from state to state. Generally, for

patients to prevail in medical malpractice cases, they must demonstrate “by a preponderance of the evidence: (1) that the medical toxicologist's supervision of the care fell below the ordinary standard of care expected of a physician in his [or her] medical specialty, and (2) the existence of a causal relationship between the alleged negligent treatment and the injury sustained.”<sup>44</sup> While the standard of care is recognized not to ensure perfection, what constitutes the “ordinary standard of care” has much room for interpretation.

In the 19th century, courts determined what the “ordinary standard of care” was by introducing testimony from physicians practicing in the community where the event occurred. This was known as the strict locality rule.<sup>41</sup> The strict locality rule was intended to prevent the inequities of comparing rural physicians working with limited resources and under exigent conditions from physicians working in large urban hospital settings.<sup>15</sup> In many jurisdictions, however, the strict locality rule was rejected because (1) it was difficult to find an expert witness in a small community to testify against another physician in the community, and (2) the strict locality rule permitted some small medical communities to set unacceptably low standards of care.<sup>41</sup> In response, some states adopted the modified locality rule, which compares the physician in question with physicians practicing “in similar localities.”<sup>41</sup> Over time, the basis for the modified locality rule was also called into question. Advances in transportation, communication, and education continued to minimize the disparity between rural and urban medical practice. Most states have abandoned the locality rule altogether, permitting the introduction of evidence of nationwide medical practices. As described by one court:

[A] physician must exercise that degree of care, skill, and proficiency exercised by reasonably careful, skillful, and prudent practitioners in the same class to which he [or she] belongs, acting under the same or similar circumstances. Rather than focusing on different standards for different communities, this standard uses locality as but one of the factors to be considered in determining whether the doctor acted reasonably.<sup>4</sup>

Although there is movement toward reviewing nationwide medical practices, depending on the jurisdiction where the event occurs, any one of the above rules may apply. In New York, courts allow evidence from the specific locality where the event occurred, from statewide practice, or from nationwide practice.<sup>14</sup>

A discussion of standard of care for certified specialists in poison information should also mention several operational aspects of poison control centers. Certified specialists in poison information are required to have rapid and accurate access to a standard information resource system that contains both basic information and recommendations to deal with most toxic exposures. If a patient were to bring a negligence action against the poison control center, the plaintiff might attempt to demonstrate deviations from the standard recommendations in these resources.

It would be inaccurate to suggest, however, that the care required by a certified specialist in poison information should be measured only by how closely the advice given compares with these standard resources. Frequently, a certified specialist in poison information encounters situations that cannot be managed in accordance with an information system alone, and may seek consultation from a clinical pharmacist or a medical toxicologist working with the poison control center. For example, in this chapter, patient 2 and patient 6 are examples of complicated cases that would involve the expertise of a medical toxicologist. In the above case, the report of only one pill missing and possibly ingested can create a feeling of false reassurance. Life-threatening hypoglycemia can occur after the ingestion of a single pill in children. Additionally, the onset of hypoglycemia may be delayed up to 21 hours after ingestion (Chap. 47).<sup>29</sup> Knowing this, the parents should be advised to bring the patient to a hospital where fingerstick glucoses can be monitored every hour, and dextrose can be administered if necessary. If the certified specialist in poison information were to enlist the help of a medical toxicologist then any subsequent legal proceeding would also carefully review the accuracy of the content of the information provided to the consultant.

## State Statutes Limiting Liability of Poison Control Center Consultants

A comprehensive review of state-enacted legislation providing additional liability protection to poison control center consultants is outlined elsewhere.<sup>8</sup> These state statutes provide either immunity from malpractice claims or indemnity for a successful claim against a poison control center consultant. The statutes are state specific and poison control center consultants should review them with local counsel, particularly if the statute has not been challenged in the jurisdiction in question.

Several states have enacted laws granting immunity to poison control center consultants. Immunity is an affirmative defense to medical malpractice liability. In other words, even if a lawsuit were to satisfy all of the elements for a successful malpractice claim, the lawsuit would not lead to compensation for injuries sustained because of this state-conferred protection. Examples of states that have enacted statutes providing immunity include Arkansas, California, Florida, Louisiana, Ohio, Tennessee, and Washington.<sup>1</sup> These statutes are not absolute protections from liability. State statutes granting immunity usually stipulate that the poison control center consultant act in good faith while performing the duties required. In some instances, the poison control center consultant must have been providing information in accordance with protocols established by the poison control center. These laws do not protect against gross negligence, nor do they provide protection against intentional misconduct by the poison control center consultant.

Other states have enacted laws that require the state itself to indemnify poison control center consultants in the case of a successful malpractice claim. In other words, a patient may bring a medical malpractice claim against a poison control center consultant, but if the claim is successful, the state itself compensates the patient rather than the poison control center consultant. States that have enacted indemnity statutes include Illinois and Texas.<sup>48</sup> Statutes providing state indemnification for medical malpractice claims are also limited in that they do not provide protection in the case of gross negligence, nor do they provide indemnity in the case of intentional misconduct.

In addition to state statutes that specifically limit liability for poison control center consultants, it has been argued that some states may hypothetically provide protections under common law or general “public immunity” statutes.<sup>47</sup> Neither poison control centers nor poison control center consultants are specifically delineated under these state laws, but may still be afforded immunity protection. States with general common law or “public immunity” statutes include North Carolina, Missouri, Illinois, Connecticut, and Georgia. Finally, many states have sovereign immunity statutes that afford liability protection to any entity created, funded, and operated by the state. Poison control centers and staff may be considered such an entity and, therefore, granted such protection.

## Practices of Regional Poison Control Centers That Can Reduce Potential Liabilities

There are some inherent risks creating potential liability for a poison control center. To minimize these risks and the subsequent risk of civil action against a poison control center, quality assurance and risk management programs should be a regular function. Daily audits or monitoring of the advice given by certified specialists in poison information should be conducted. Such processes enhance care and ensure patient safety for the individual and establish a higher general standard of performance.

The medical toxicologists and clinical pharmacists responsible for supervising the certified specialists in poison information must be able to adequately assess the competence and capabilities of the staff, make recommendations, take corrective actions, and provide suggestions for improvement to involved members. This process is facilitated by such actions as audiotaping calls made to the poison control center, and the subsequent advice given, and reviewing written records maintained by the information specialist on each particular case. Documentation is extremely important because in the event of a lawsuit, the most likely area of dispute will be what was actually said to the patient.

## REPORTING IMPAIRED PHYSICIANS

It is well recognized that physicians suffer from substance abuse and misuse disorders just like the general population. Though there are few formalized studies on physician impairment, there are certain factors unique to the medical community, such as knowledge of the medications and ability to prescribe that leads to easier access.<sup>31</sup> Impairment in the medical profession is a serious issue as physicians make daily decisions that affect the health of their patients, and their conduct has the potential to affect the quality and safety of the health care delivered. In 1973, the American Medical Association (AMA) formerly recognized physician impairment in its landmark paper “The Sick Physician: Impairment by Psychiatric Disorders, Including Alcoholism and Drug Dependence.”<sup>34</sup> This paper declared that physicians had an ethical obligation to recognize a colleague’s impairment due to substance abuse.<sup>3</sup> Subsequently, local, state, and national programs designed to help physicians struggling with impairment were formed. Today there are physician health programs (PHPs) in all 50 states, and they are administered by the state medical boards or medical societies. Physicians may self-refer to these programs or be referred by a colleague or an administrator. These programs seek to provide detection, assessment, and referral to treatment facilities. Physicians entering contracts with PHP can maintain confidentiality and may keep their license after completing treatment and avoids formal disciplinary action.<sup>31</sup> Identifying an impaired colleague may be challenging as physicians can be good at hiding such disorders until it becomes severe. Signs to look for include deteriorating social and interpersonal behaviors, inaccessibility to patients and staff, frequent conflicts with staff members, unexplained absenteeism, and frequent moves to different locations for jobs.<sup>31</sup> Colleagues may be hesitant to report such behaviors because of fear of damaging a career or the fear of confrontation. However, in addition to an ethical obligation as determined by the AMA, many states have laws in place requiring the reporting of impaired colleagues.

## SUMMARY

- The risk management and legal issues of an ED with patients exposed to xenobiotics, often with impaired judgment, are complex. The substantial practical challenges in initiating emergent treatment to an individual unable to provide proper informed consent vary depending on individual state laws.
- Medical care is further complicated by the difficulties inherent in documenting these interactions with our patients.
- Both forcible restraint (often desired by the physician) and evidence collection (requested by law enforcement) have significant potential legal ramifications for the care provider.
- Maintaining patient confidentiality outside the ED, despite circumstances often visibly volatile within the department, often seem futile, yet legal obligations to protect patient privacy are stringent.
- A hospital must ensure a close working relationship among the legal department, risk management, and medical personnel. Only in this manner can everyone learn, cooperate, and meet each other’s needs in the ever-evolving and challenging clinical scenarios confronted.

# MEDICOLEGAL INTERPRETIVE TOXICOLOGY

Robert A. Middleberg

One of the potential areas of collaboration for toxicologists is the medicolegal setting. This includes working with forensic toxicologists, medical examiners, law enforcement, lawyers, and regulators. In this arena, interpretive toxicology, whether based on analytical findings or theoretical concepts, is routinely used or required to explain issues in criminal and civil proceedings and as the basis for policy making. Often, the concepts associated with forensic interpretive toxicology are presumed to be associated with deceased individuals. In practice, the preponderance of cases involving toxicologic interpretation involves living people and includes specialty testing such as human performance toxicology. Regardless, interpreting the role, or potential role, of xenobiotics in an adverse outcome is typically not straightforward. For example, the use of generally applied pharmacokinetic equations is usually inappropriate, especially in the postmortem setting, yet it is in widespread practice by individuals unfamiliar with the nuances of case-related issues.<sup>27</sup> Rarely is any given case accurately interpreted solely based on toxicologic assessment. As such, forensic interpretive toxicology generally involves an integrative approach that draws on an understanding of case history in addition to analytical, toxicologic, pathophysiologic, and specimen-related issues. Individuals called on to interpret the role of xenobiotics in any given case must understand the factors that affect such interpretations and associated limitations. Furthermore, although difficult in many situations, they should attempt to have their opinions firmly supported by science. Other chapters in this text (Chaps. 7, 41 and 140, Special Considerations: SC11 and SC12) cover much of the basic science associated with interpretive issues. This section is meant to focus on specific issues as they relate to medicolegal (forensic) interpretive toxicology.

## CASE HISTORY

It is reported that case history plays a role in interpreting toxicologic findings in about 70% of cases.<sup>26</sup> A number of specific aspects of a case history will lead a seasoned toxicologist in a direction that narrows the scientific investigative focus and avoids a shotgun approach to defining the role of toxicology in an adverse outcome. Table 139–1 lists some of the more important aspects of the case history that should be evaluated from the outset to begin the interpretive process. Detailed information about the individual should optimally include anthropomorphic information, vocation, hobbies, medical history, timing of events to the extent possible, and other contextual information.<sup>19</sup> As an example of the importance of this information, consider a case in which an individual suspected of drunk driving worked at a company that manufactured chemicals. One of the chemicals known to be handled by the individual was a substance that co-eluted with ethyl alcohol in the gas chromatographic assay used to quantitate the blood alcohol concentration. Without his employment history, the potential for an incorrect interpretation of the data might have occurred.

Unfortunately, toxicology is often not initially considered with respect to field investigation of a case. Therefore, important information is often lost, especially in the case of purposeful poisonings. The longer the time between suspicion of a toxicologic aspect to a case and proper investigation, the greater the chance of lost evidence to achieve an understanding of the situation. The toxicologist can play a key role in mitigating this occurrence. As a significant point of contact with the poisoned individual, the toxicologist has the opportunity to not only ask the individual questions if he or she is conscious, but to also ask police, paramedics, and others questions that could assist in not only treatment of the patient, but also address serious questions that often later arise.

Unlike the confidence in the medical diagnosis of poisoning supported by clinical findings or analytical data, it should be recognized that there is rarely certainty in the use of toxicologic analysis for medicolegal purposes. However, a toxicologist's conclusions and opinions in this setting can only be attained by integrating pieces of information into a coherent analysis of the events.

## PREANALYTICAL ISSUES

Ample evidence exists that the major source of error in analytical toxicology is based not on laboratory error, but on preanalytical issues.<sup>20,41</sup> Preanalytical issues are defined as those events that affect an analytical result prior to the specimen(s) arriving at the laboratory. In accordance with ISO (International Organization for Standardization) requirements, mathematical uncertainty should be able to be determined by the analytical testing laboratory.<sup>28</sup> It is an expectation in certain areas of toxicologic testing that such errors be reported for acceptance into legal proceedings.<sup>34</sup> Although laboratory error can usually be relatively easily quantified, the error associated with events surrounding samples before arrival at the laboratory is not so easily measured. The myriad of potential preanalytical factors is summarized in Table 139–2.

## Clinical Specimens

With respect to living individuals, where and how specimens are collected from patients, in addition to specimen storage, can adversely affect not only the analytical test but its interpretation as well.<sup>54</sup> For example, although perhaps not protocol, occasionally samples for analysis are collected proximate to the site where medications are administered, such as close to an indwelling antecubital fossa catheter. Contamination of such specimens cannot

**TABLE 139–1** Important Aspects of Case History Related to Interpretation of Analytical Findings<sup>19,32</sup>

Aspect	Information to Be Gathered
Individual history	Age, gender, weight, nationality, habitus, vocation, hobbies, smoking status, drug abuse history
Medical history	Disease processes, known medications, recent treatments or surgeries, resuscitative efforts, history of snoring (important for cases involving opioids)
Recent activity	Last known activity of the individual; description of behaviors; observations of friends, family, acquaintances, and coworkers
Timing	When did an event occur? How much time between event and specimen collection? When was the patient last seen?
Cohabitants	Vocations, hobbies, medications
Scene	Description (kempt or unkempt) Search results of cabinets, trash cans, pill vials collected, ambient temperature, odors, plants or fungi, recent Internet searches, unusual books or literature, heating pads or hot water bottles
Position and description of body, if found unresponsive	Clothing, covered or uncovered, body temperature, vomitus
Notes or journals	Indications of intent, mindset

**TABLE 139–2** Preanalytical Factors That Can Affect Interpretation of Findings<sup>13,64</sup>

Preanalytical Factor	Specific Issue	Potential Effect
Specimen source	Site of collection (eg, collection near site of drug administration)	Falsely elevated results
Specimens	Collection tubes or containers to include preservative or anticoagulants used, storage conditions (temperature, humidity), mislabeling	Inability to detect specific analytes Analyte stability Wrong sample tested Addition of analytes not originally present
Contamination issues	Use of inappropriate collection techniques (eg, ethanol-based swabs, lack of metal-free devices and containers)	Introduction of unintended analytes, potential misassignment of poisoning
Postmortem-specific issues	Specimen collection techniques (eg, anatomical source of blood, nonspecified part of a solid organ, collection of only partial amount of gastric contents)	Falsely elevated or depressed analyte concentrations

be excluded and will lead to misinterpretation of findings. Although the treatment of patients is the primary concern during medical emergencies, consideration of potential medicolegal issues should be part of the treating professional's assessment, especially in cases involving children, victims of drug-facilitated sexual assault, motor vehicle operation, workplace incidents, suspected poisoning, and other ill-defined situations. Adequate analysis requires that specimen collection be performed appropriately and consideration given to the types of preservatives used in the collection device. Not all collection devices fit the need for all xenobiotics. For example, although fluoride-containing tubes work well to prevent microorganism-induced ethanol formation, this same preservative will lead to degradation of some organic phosphorus compounds and make the sample totally useless in cases of suspected fluoride poisoning.<sup>1,49</sup> In general, it is good practice to collect both preserved and unpreserved blood samples. Serum samples are generally a good choice from living individuals, but this is analyte specific and certainly not preferred for xenobiotics sequestered in red blood cells. Perhaps the most important precaution in this respect is the collection of specimens for legal blood alcohol determination. Not only are tubes containing fluoride (1%–5% w/v) and oxalate (anticoagulant) necessary, but skin-cleansing swabs containing ethanol should be avoided.<sup>2</sup> Specimen storage conditions can significantly adversely affect analyte stability and specimen integrity. Except for specimens such as hair and nail clippings, specimens for toxicologic analysis should not be maintained at room temperature. Minimally, refrigeration is required, but if it is anticipated that a delay between sample collection and testing will occur, then freezing the samples at  $-20^{\circ}$  or  $-60^{\circ}\text{C}$  (the choice of temperature being analyte specific) should be considered, making sure to take precautions to prevent tube cracking.<sup>11</sup> It is recommended that if a specific xenobiotic or class of xenobiotics is suspected, that laboratory personnel should be contacted before specimen collection for guidance on proper collection, preservation, and storage of specimens. Hospitals should have in place a mechanism that ensures retention of specimens beyond the routine time frame for suspect cases. Typically, hospitals maintain specimens from a few days to a few weeks after collection to up to one year or longer in most forensic cases.<sup>46,61</sup> In this regard, all available specimens should be maintained. This is especially important in cases in which death is preceded by a relatively long clinical course. Although it cannot be expected that a hospital maintain specimens under a legal chain of custody, maintaining tubes with original identifier labels often suffices for this purpose.<sup>21</sup>

## Postmortem Specimens

In postmortem situations, the potential for sample contamination is substantial, especially in the face of significant trauma. For example, the spread of gastric or intestinal contents containing xenobiotics of interest can contaminate sources of blood collection and visceral organs.<sup>17</sup> Additionally, other postmortem phenomena can mitigate the potential value of laboratory-based testing (Table 139–3) for interpretation purposes (see the Postmortem Redistribution section later). Specimen collection should be done by an experienced pathologist who understands the intricacies of site-specific sample collection. Postmortem blood can be obtained from 2 broadly categorized sources, central (eg, heart) and peripheral sites (eg, femoral and subclavian veins). Not all peripheral sites have the same interpretive value.<sup>56</sup> “Blind stick” samples should not be considered appropriate surrogates for proper dissection and visualization of the specimen source.<sup>42</sup> For example, heart blood should be collected from the right atrium after opening of the pericardial sack, removal of the pericardium, and drying of the heart.<sup>13,65</sup> Although there is no ideal postmortem specimen, femoral vein blood tends to better reflect circulating concentrations of xenobiotics closer to the time of death, but this is not always the case. Even femoral blood is subject to postmortem redistribution (PMR) in a manner similar to other blood sources. Whenever possible, both cardiac and femoral blood should be collected. Because of postmortem changes, heart blood tends to contain higher concentrations of xenobiotics than peripheral blood sites, thus making it a valuable screening specimen but limiting its actual interpretive value. To properly collect femoral vein blood, a dissection and visualization of the femoral vein followed by ligation or clamping of the vessel above the point of collection is recommended to avoid contamination by iliac blood, the latter seemingly representing a cross between peripheral and central blood.<sup>13</sup> Visceral organ specimens are of value in the interpretation of the meaning of blood concentrations in certain situations.<sup>5,43</sup> Although a plethora of data exist regarding toxicologic findings in blood, there tends to be less data regarding tissues. Nevertheless, certain organs are of substantial

**TABLE 139–3** Postmortem Phenomena That Can Affect Interpretation of Toxicologic Laboratory Results

Phenomenon	Potential Effect
Analyte stability	Can lead to increased or decreased concentrations of analytes (eg, ethanol and cyanide can both form and degrade in specimens); will affect interpretation of results by assuming too much or too little analyte present
Degree and type of decomposition	Can lead to analytical difficulties in recovery of xenobiotics; bacterial metabolism of xenobiotics can alter pre-existing concentrations
Embalming	Can destroy or form xenobiotics or metabolites (eg, cyanide can be destroyed by embalming chemicals; methylation of desmethyl metabolites can occur; can lead to misinterpretation of results)
Entomologic factors	Insect invasion can lead to decreased or altered concentrations of xenobiotics; insects can also be useful to detect xenobiotics in badly decomposed bodies
Plasma vs postmortem blood distribution differences	Blood and plasma concentrations of xenobiotics may differ widely, so reliance on kinetic data in living persons is not comparable to postmortem blood findings; postmortem blood is not the same as whole blood in living individuals
Postmortem redistribution or diffusion	Can lead to increased or decreased concentrations of xenobiotics; misinterpretation of findings
Toxicogenetics	Can lead to unpredictable effects on metabolism; analysis for metabolic status is tenuous as genotype may not equate to phenotype

**TABLE 139–4** Potential Value of Postmortem Traditional and Alternative Matrices

Specimen	Value	Factors Influencing Specimen
Bile	Accumulates xenobiotics eliminated fecally (eg, opiates); therefore, xenobiotics remain in bile after clearance from blood	Lack of interpretive data; presence of a xenobiotic does not necessarily provide temporal information for exposure
Blood	Largest amount of comparative data; easily obtained	Subject to PMR, diffusion, contamination; blind sticks are suboptimal; xenobiotic concentrations can be a combination of acute and chronic exposure, thus hampering interpretation; back calculation to dose ill-advised
Brain	For certain xenobiotics, some correlation to effects	Very difficult specimen to handle analytically because of fat content
Gastric contents	Assessment of overdose; investigative purposes in tracking pill source; potential high concentrations of xenobiotics	Time dependent; lack of homogeneity of specimen; difficult analytically because of food and other xenobiotics
Hair	Provides exposure history data	Delay between exposure and appearance in hair (~1 week) prevents acute exposure assessment; external contamination; contamination from sweat and sebum
Kidney	High concentrations of xenobiotics cleared renally allows for ease of detection	Lack of interpretive data; xenobiotics accumulate because of specific and nonspecific binding, potentially hampering interpretability
Liver	Contains high concentrations of xenobiotics cleared hepatically; can aid in determination of overdose	Xenobiotics accumulate in liver over time, potentially hampering interpretability; can be affected by both PMR and diffusion; xenobiotics not distributed evenly throughout liver
Urine	Xenobiotics (and metabolites) eliminated renally accumulate in urine; protect xenobiotics from common postmortem degradation factors	Not always present; not always an indicator of acute exposure; analytical issues (deconjugation); no correlation with effects; no back calculation to dose possible
Vitreous humor	Some protection from decompositional changes; ethanol determination; postmortem glucose determination	Delay between appearance of xenobiotic in blood vs vitreous

PMR = postmortem redistribution.

Data from Davis GG; National Association of Medical Examiners and American College of Medical Toxicology Expert Panel on Evaluating and Reporting Opioid Deaths: Complete republication: National Association of Medical Examiners position paper: Recommendations for the investigation, diagnosis, and certification of deaths related to opioid drugs. *J Med Toxicol.* 2014 Mar;10(1):100-106.

value when considering specific xenobiotics (Table 139–4). Specimen collection tubes and storage conditions, although similar to those described with clinical specimens, tend to be more important with postmortem specimens because of continuous postmortem changes in blood pH, autolysis, and cell lysis, which can affect analyte stability, recovery, and interpretation.<sup>61</sup>

Hair collection must be considered in practically all cases of toxicologic concern, especially in those involving children because this specimen can circumvent arguments of incidental exposure and other issues.<sup>47</sup> This specimen, after being collected, requires no special storage conditions and often reflects exposure history for the length of hair growth (~1 cm/mo). Controversy regarding external contamination of hair leading to positive findings, although of some concern, does not impugn the value of this specimen.<sup>27,36</sup>

Lastly, iatrogenic toxicologic injury or death, whether unintentional or purposeful, are often not considered or poorly investigated. The involvement of hospital-based risk management often occurs late and valuable evidence that can either incriminate or exculpate individuals gets destroyed before collection and preservation. Protocols in suspicious cases should exist for the area where the individual was located and considered to be a “crime scene.” That is, potential useful evidence, including devices, medications, and other xenobiotics should be gathered and stored.<sup>58</sup>

## SPECIAL LABORATORY CONSIDERATIONS

Testing for xenobiotics of interest is varied and inconsistent among laboratories. Hospital-based laboratories tend to be limited in scope compared with toxicology reference laboratories. Even in this latter group, wide variances exist with respect to capability and scope. No interpretation of toxicologic findings should take place without a complete understanding of the testing performed and its limitations in addition to a review of the analytical data by a toxicologist. With the development of robust, widely available analytical tools, inadequate testing with respect to medicolegal interpretive matters should no longer occur.

Ideally, all toxicologic analyses are performed under chain of custody, and all findings are confirmed by a separate and distinct analytical test, with

at least one, such as mass spectrometry, that provides specific molecular identification.<sup>48</sup> This process reduces uncertainty in the utility of a finding for interpretive purposes. For example, the use of gas chromatography to identify ethylene glycol in a hospital-based laboratory led to the wrongful conviction and jailing of a mother for poisoning her infant son. The gas chromatographic peak was actually propionic acid. Remarkably, the reporting of ethylene glycol was duplicated by another laboratory. Post-conviction analysis determined the misidentification of the peak. In this case, the propionic acid resulted from the inborn error of metabolism disease, methylmalonic acidemia. 2,3-Butanediol also co-elutes with ethylene glycol in some gas chromatographic systems.<sup>17,63</sup>

It is uncommon for hospital-based drug testing to be analytically confirmed. However, a positive screen using an immunoassay is rarely sufficient for medicolegal purposes given the general cross-reactivity of these tests. Most hospital laboratory reports include a disclaimer to this effect. Also, most of this testing is performed using urine, so such screening tests are neither quantitative nor interpretable with respect to effects on a given individual.

Today, advanced toxicology laboratories use a combination of tools to help identify xenobiotics of toxicological concern. Many of these tests are performed rapidly and, in some sense, inexpensively compared with the offered breadth of testing. Instruments such as liquid chromatography time of flight mass spectrometry (LC-TOF) have revolutionized broad-based toxicology testing. This technique allows for the rapid screening of a patient sample in minutes covering hundreds of chemically dissimilar compounds with identification using exact mass.<sup>25</sup> Liquid chromatography/tandem mass spectrometry (LC-MS/MS), although somewhat less amenable to broad-based screening, has a similar utility with an easier approach, in general, to quantitative analysis.<sup>44</sup> Both devices will be found in some larger hospital-based laboratories and should help the toxicologist significantly in evaluating potentially poisoned patients.<sup>24</sup> Other instruments, such as inductively coupled plasma mass spectrometry and inductively coupled plasma optical emission spectroscopy used for the analysis of the majority of metals, are typically found in specialty laboratories and most likely will not be cost effective

in the hospital laboratory (Chap. 7). In all cases, however, the toxicologist should understand the limitations of these devices that can lead to false-positive and false-negative findings.

### CORRELATING FINDINGS OR THEORY TO CASE-RELATED ISSUES

Ultimately, the toxicologist's role in forensic interpretive toxicology is to integrate analytical findings and theory to develop an explanation for an adverse outcome. Although explanations abound, both in concept and practice, plausible explanations are often few. It is rare that findings are simply taken at face value. For example, it is common for identical findings in 2 different cases to have 2 completely distinct interpretations, which should not be surprising or disconcerting. For example, the finding of a high concentration of morphine in the blood of a hospice patient would be expected and often not related to the cause of death, whereas the same concentration in a naïve heroin user would represent a cause of death. Toxicology has been described as both science and art, with the interpretive aspect based in science, knowledge, and experience.<sup>22</sup> Many of the following factors need to be considered in rendering rational opinions.

### Problems With Analytical Interpretations

Commonly, individuals render toxicologic opinions without careful review of the analytical data that help form the basis of the opinions. Acceptance of reported results at face value is a fundamental flaw in medicolegal interpretations. It is helpful to review all available information that led to a reported result before interpretation. Table 139–5 lists some of the important facets of analytical data review that lead to incorrectly reported results. Although there is no expectation that the toxicologist be an expert in analytical chemistry, familiarity with the key elements that lead to false-positive, false-negative, or poorly quantified findings should become part of the review process.

**TABLE 139–5** Important Aspects of Laboratory Data Leading to Reporting of Inaccurate Results

Factor	Examples	Effects
Inappropriate method validation	Unable to define limit of detection, limit of quantitation, analytical bias and precision, specificity, analyte and analytical stability, potential interferences	No confidence in the ability to produce a defensible result
No or poor analytical method	No written method to follow	Irreproducibility of results; lack of consistent direction to analysts
Lack of proper calibration or control	No controls included in analytical run, reporting results outside of the analytical measurement range, calibrators and controls prepared from the same stock solution	Unreliable results
Analytical characteristics	Poor chromatography, lack of proper internal standard, poor mass spectral characteristics, improper integration of peaks, improper baseline acceptance	Unreliable results
Administrative errors	Wrong demographics, case numbers, dates, etc assigned to the data; improper chain of custody	No confidence that correct patient specimens were tested
Failure to follow standard operating procedures	Specified steps in either administrative or technical standard operating procedures were not followed	Lack of confidence in correct patient specimen tested or in analytical results

Errors ranging from the wrong patient number on the analytical data to poor control and calibration of an analytical run to poorly integrated chromatographic peaks are all examples of errors that invalidate any given finding.

### Postmortem Redistribution

There are many factors related to postmortem changes that complicate the interpretation of well-performed toxicologic test results (Chap. 140).<sup>18,19,40,64</sup> However, the importance of PMR, a long-established principle in forensic toxicology, cannot be ignored or underestimated. Although recognized in the early 1980s, Prouty and Anderson authored the first codified report of this phenomenon in 1990.<sup>57</sup> Succinctly, PMR is the term given to changes in site-specific xenobiotic concentrations after death.<sup>53</sup> These xenobiotic movements postmortem generally result in elevated concentrations in common collection sites such as heart blood. The elevation for some xenobiotics are dramatic, giving the appearance of overdose when no such conclusion is supported by other evidence, including analysis of sites of blood collection where PMR may occur to a lesser degree, such as femoral blood. Although instructed to do otherwise, many pathologists still collect heart blood as a sole source of postmortem blood. In attempting to assist in such situations, investigators often publish ratios of heart blood concentrations to femoral blood concentrations over a series of cases from a given laboratory. The common observation is a wide-spread range of values often encompassing 3- to 5-fold or greater differences in magnitude.<sup>10</sup> The use of such ratios to convert a heart blood concentration to a femoral blood concentration, and by further analogy to a premortem circulating blood concentration, should not be performed. The greatest use of such ratios is to give an idea of the likelihood of PMR for any given xenobiotic based on the mean and range of ratios.<sup>45</sup> Because it cannot be predicted if PMR occurred in any given case and if so to what degree and over what time period, such calculations have no basis for antemortem blood concentration determination. Another confounder to the use of ratios is the possibility that site-specific differences are not due to PMR but merely a reflection of incomplete distribution before death.<sup>19</sup> It is unclear how many of the reported ratios of heart blood to femoral blood actually reflect this process as opposed to true PMR. The proposed mechanisms and influencing factors resulting in PMR are varied and are listed in Table 139–6. It is most likely a combination of factors that lead to PMR in any given case. Interestingly, as noted earlier, PMR is also reported to take place in femoral blood; thus, it should not be taken at face

**TABLE 139–6** Factors Affecting Postmortem Redistribution<sup>18,53</sup>

Factor	Issue or Potential Effect
Volume of distribution	Xenobiotics with high volumes of distribution often correlate with a greater degree of PMR; if PMR occurs, it leads to falsely elevated concentrations in fluids and tissues
pH of blood	pH of blood changes postmortem, becoming more acidic; this alters ionization of xenobiotics and promote or hinder PMR
Xenobiotic reservoirs	Organs of high blood content or flow, tissues that specifically or nonspecifically retain analytes (eg, liver, kidney), and holding vessels (eg, GI organs) facilitate movement to blood vessels and neighboring organs
Resuscitative efforts	Some demonstration that xenobiotics move in vivo as a result of resuscitative efforts
Breakdown of barriers	Cellular structural changes cause leaking of xenobiotics from one site to another, including from intracellular sequestration sites
Release of xenobiotics from proteins	Will alter the free to bound ratio, potentially leading to an unreliable reliance on free xenobiotic concentrations
Postmortem metabolism	Leads to decreased or increased concentrations of xenobiotics

GI = gastrointestinal; PMR = postmortem redistribution.

value that any postmortem blood concentration accurately reflects the circulating concentration at and around the time of death.

At one time it was believed that PMR was associated with basic xenobiotics with a large volume of distribution. Seemingly, however, most xenobiotics, including acidic and neutral xenobiotics, undergo PMR. Furthermore, PMR occurs for xenobiotics with wide-ranging volumes of distribution. Still other xenobiotics that would be predicted to undergo PMR have experimental evidence to the contrary.<sup>53</sup> Thus, a priori predictions of PMR for any given xenobiotic without experimental evidence should explicitly state the caveats associated with such a conclusion. It must be stated, however, that PMR does not preclude the interpretation of findings for cause of death determination because the findings represent only one piece of data in a potential myriad of other relevant information.

Another similarly related phenomenon is postmortem diffusion of xenobiotics. In this situation, diffusion of xenobiotics from an area of high concentration to that of a lower concentration occurs. This is most noted when the gastric contents contain a substantial amount of a xenobiotic that migrates across the wall of the stomach into neighboring tissues and blood sources, such as abdominal aorta and iliac vessels. Additionally, perimortem aspiration of gastric contents can lead to significant esophageal, tracheal, and lung concentrations of a xenobiotic, further facilitating diffusion processes.<sup>12,55</sup> One last concern is the administration of drugs via such mechanisms as a central line, whereby it can be reasonably expected that drugs will continue to accumulate in and around the heart postmortem.

### Alternative Matrices

Although most discussions regarding interpretive toxicology tend to focus on blood concentrations of xenobiotics, clearly in both the living and the dead, alternative matrices are extremely valuable. It should be recognized that there is no perfect specimen to assess exposure or provide analytical findings in support of impairment. In the living, alternative specimens including hair, oral fluid, and breath are useful. Hair gives a longer window of detection than most other easily obtained specimens.<sup>65</sup> Analytical precautions, such as rinsing procedures, are used to minimize some concerns with hair testing.<sup>59</sup> The utility of hair should not be underestimated, and despite some of its limitations, it can represent the best suited specimen in some cases, such as drug-facilitated sexual assault, especially when more than 24 to 48 hours passed before specimen collection from the time of event, thus often limiting the value of urine or blood testing.<sup>38</sup> In such cases, waiting 1 to 3 months before collecting hair will capture the potential exposure period in growing hair. It is especially useful in children to demonstrate acute versus chronic exposure to xenobiotics.<sup>47</sup> Collection of hair should be from the posterior vertex of the head, which can be easily approximated by drawing an imaginary line over the head connecting the tops of both ears and a line from the bridge of the nose to the nape of the neck.<sup>13,59</sup> The area where the 2 lines meet in the back of the head provides hair that grows most consistently on the head.<sup>37</sup> About a pencil thickness worth of hair should be clipped as closely to scalp as possible.<sup>14</sup> The root ends should be identified either by tying with string or wrapping in foil.<sup>13</sup> Virtually any other sources of hair are suitable for testing, such as pubic and axillary hair, although practical reasons and shorter growth rates tend to make such samples less suitable for testing.

Oral fluid (OF) is gaining ground as a viable specimen type to assess exposure and impairment because obtaining it is noninvasive, and it can be collected at the site of an event, thus eliminating time delays.<sup>5</sup> Such delays will result in clearance of a xenobiotic from other specimen types before collection. Oral fluid is composed of secretions from the parotid, submaxillary, sublingual, and other smaller glands. Numerous specimen collection devices exist today that circumvent the need to expectorate, which is not a desirable means of specimen collection.<sup>51</sup> For the most part, non-protein-bound parent compounds appear in OF, although there are exceptions (eg, benzoylcegonine).<sup>15</sup> Factors that affect how much of a xenobiotic gets into OF include pH of the blood and OF, the pKa of the xenobiotic, and the degree of protein binding. In general, basic xenobiotics get into OF more easily than acidic xenobiotics.<sup>68</sup> Oral fluid has been used for therapeutic

drug-monitoring purposes (eg, theophylline and digoxin).<sup>8</sup> Although some correlations between blood concentrations and a number of xenobiotics have been made, it must be remembered that OF is susceptible to contamination from residual drug in the oral cavity, smoked xenobiotics, and passive exposure.<sup>5,15</sup> Despite its promise, there is variability in OF concentrations of xenobiotics not only within the same individual but also among individuals based on influencing factors that facilitate or inhibit secretion of a xenobiotic into OF.<sup>5</sup> Finally, based on the relatively small specimen volumes after OF collection, specialized testing, including tandem mass spectrometry, is often needed to detect the concentrations of xenobiotics present.

Breath testing for alcohol is a mature subject matter, yet when it comes to impairment, there is a current trend for states to move back to blood alcohol determinations. Legal arguments are the force behind some of this movement.<sup>52</sup> The United States Supreme Court, however, rendered a decision in 2016 whereby blood collection related to driving under the influence can only be obtained after issuance of a search warrant, declaring blood collection to be invasive compared to breath testing. It is unclear how this latter decision will ultimately affect the decision as to what specimen is collected for analysis in driving under the influence cases.<sup>4</sup> In living individuals, particularly in the hospital setting, serum alcohol is typically measured. As such measurements for alcohol are often used in the medicolegal setting, it is imperative that toxicologists understand the differences between blood and serum alcohol concentrations and that such differences are related to attorneys (Special Considerations: SC11 for greater detail).

Breath testing for other xenobiotics is still in its fledgling state. Despite this, the future holds promise for the detection of other xenobiotics in breath with the possibility of roadside breath drug-testing devices.<sup>3</sup> The major advantage of this specimen is not only its lack of invasive nature, but rapid screening capability.

Alternative matrices from decedents are varied and include virtually all fluids and tissues (Table 139–4). Practically speaking, however, other than providing qualitative information, for most matrices, there is little data to support utility of a measured concentration to either allow for independent interpretation or correlation to blood concentrations. Although numerous studies exist that suggest such correlations, rarely is there consistency between studies. Even so, situational use of alternative matrices is sometimes warranted (eg, the use of fat or brain to detect volatiles). A specific exception is vitreous humor (vitreous), a specimen that is often extremely valuable postmortem. Vitreous electrolyte measurements provide data that cannot be gleaned from virtually any other specimen type (Table 139–7).<sup>9</sup> For most xenobiotics, vitreous concentrations lag behind blood concentrations by about 1 or 2 hours. Thereafter, some correlations have been made between vitreous concentrations and those in blood, with the greatest example being ethanol, where there is an approximately 1:1 correlation when equilibrium is reached. Vitreous represents a relatively pristine specimen during

**TABLE 139–7 Valuable Normal Vitreous Chemistries**

Analyte	Factors Affecting Analyte	Reported Normal (mmol/L)
Chloride	Dehydration, water intoxication	105–135
Potassium	Postmortem interval	<15
Sodium	Dehydration, water intoxication	135–150
Urea nitrogen	Dehydration, kidney problems (eg, azotemia)	8–20
Glucose	Hyperglycemia, DKA, hypoglycemia	<200
Ketones	Fasting or starvation, AKA, DKA, isopropanol exposure	None detected

DKA = diabetic ketoacidosis; AKA = alcoholic ketoacidosis.

Data from Collins K. Postmortem Vitreous Analyses. Medscape Reference (updated July 31, 2016) <http://emedicine.medscape.com/article/1966150-overview>.

decomposition, embalming, exsanguinations, severe peritoneal trauma, and other less ideal situations.<sup>23</sup>

### Toxicokinetics, Toxicodynamics, and Drug Interactions

The basics of toxicokinetics (TK) and toxicodynamics (TD) are covered in Chap. 9. The large and unpredictable degree of interindividual variability places practical limits on the use of TK and TD in postmortem interpretation. These same variations affect the pharmacologic response in living patients. Multiple elements related to TK and TD affect the ability to render interpretive opinions of xenobiotics related to an adverse outcome (Table 139–8) and the use of pharmacokinetic and toxicokinetic equations warrants special attention.

Toxicologic emergencies and overdoses alter normal physiological functions. Liver and kidney dysfunction significantly alter normal TK parameters.<sup>62,66</sup> Coupled with pharmacogenetics, drug–drug or drug–xenobiotic interactions, pathophysiology, and other significant factors, the use of routine TK equations usually leads to grossly under- or overestimates of a specific measured value. Nevertheless, in a living patient, TK equations are useful to estimate certain parameters (eg, dose and, in part, form the basis of such useful tools as nomograms). After death, because of PMR, postmortem diffusion and other issues, the use of TK formulas to predict premortem concentrations or dosing is not generally an acceptable practice. For example, the use of the following formulas will lead to either an absurd dose calculation or an inappropriate estimate of predicted concentration compared with that reported for compounds undergoing significant PMR.<sup>16,29</sup>

$$\text{Dose} = \text{Reported concentration} \times \text{Volume of distribution} \times \text{Body mass}$$

$$\text{Concentration} = \frac{\text{Dose}}{\text{Volume of distribution} \times \text{Body mass}}$$

Nevertheless, such calculations, although ill-advised, are routinely performed and can provide grossly misleading information. “Back extrapolating” from a postmortem concentration to some concentration earlier in time using half-life is fraught with the same perils in that the initial assumption

of an unchanged postmortem blood concentration should not be made.<sup>18</sup> Additionally, it is never known how much of any measured blood concentration resulted from single or multiple dosing exposure to a xenobiotic. Despite these and other issues, the toxicologist will be pressured into providing dosing information or predicting a blood concentration during life. The safest avenue in this respect is not to accede to such pressures because the scientific underpinnings are unreliable.

It should be stressed that metabolic drug interaction considerations alone, together, or in conjunction with additional information informs the toxicologist of many varied aspects of exposure and potential effect and outcomes. Often, the metabolic fate of a substance is under genetic control, but it must be understood that genotype does not often relate to phenotype, thus complicating interpretation of toxicologic findings or adversely affecting theoretical interpretive toxicology. Drug interactions occur through varied means, including metabolic inhibition or induction, receptor competition, allosteric modulation, etc. (Chap. 11). All such interactions affect the efficacy and toxicity of a given compound. In some cases, these effects reveal themselves through such factors as ratios of metabolite to parent compound, metabolite to metabolite ratios, etc. One such example is the determination of heroin use from postmortem blood and blood from impaired drivers. In most cases, a ratio of free morphine to free codeine greater than unity is strong evidence that the decedent used heroin. The same appears to hold true in the blood of living people. These latter findings will not hold true when exposure to both heroin and codeine together occurred or when the individual is exposed to both morphine and codeine simultaneously.<sup>7,31</sup>

### Assessing Impairment

There exist 2 broad areas of concern with respect to impairment, that from ethanol and that from other xenobiotics. Impairment caused by ethanol has been extensively studied, and general conclusions are usually reached with some confidence. The same cannot be stated for impairment caused by other xenobiotics. Ultimately, conclusions of xenobiotic impairment are based on a number of factors that include physical examination by a trained clinician, dosing information, length of time taking a xenobiotic, co-administered xenobiotics, pathophysiology, observed behaviors, measured concentrations in blood or serum or plasma, and any other useful information.<sup>35</sup> The use of the term “consistent with” is common in assessing impairment in any given individual and might very well be the best opinion that can be offered. Mitigating factors, including tolerance, single versus multiple dosing, reason for the presence of the substance, timing and route of administration, and pathophysiology, all make firm conclusions difficult, especially when blood findings are the first indication of potential impairment (ie, no visible signs of impairment).<sup>30,60</sup> Great care must be exercised in evaluating or predicting impairment from xenobiotics given the implications of such conclusions. There is currently no scientific support for back extrapolation of xenobiotic concentrations based on blood findings. It cannot be stressed enough that urine findings should never be used to assess impairment because the predictive value is limited.<sup>67</sup> Similar to blood ethanol concentration, many states and countries have developed *per se* xenobiotics laws that presume guilt by the presence of certain drugs or metabolites over some prescribed reportable concentration, even in urine, thus mitigating the need for interpretation in most cases. For example, the presence of  $\Delta^9$ -carboxy-tetrahydrocannabinol, an inactive metabolite of marijuana, is used to convict drivers of impaired driving; for clarity, this is a legal issue, not a scientific, issue.<sup>33,39</sup> Tables and texts that list xenobiotics and determined concentrations in blood and other specimens should only be used as a guide for interpretive purposes because every human toxicologic experience is unique.

### REASONABLE MEDICAL CERTAINTY

It is common for experts in the medicolegal setting to be asked to present opinions and conclusions with a reasonable degree of medical or scientific certainty. Although on the surface such a phrase appears to connote some level of confidence in what one opines or concludes, it has been declared a nebulous phrase without true meaning and at its worst, misleading for

**TABLE 139–8** Factors Affecting the Utility of Toxicokinetic and Toxicodynamic Principles in Interpretive Toxicology<sup>16,18,19,29</sup>

Criterion	Potential Effect
Xenobiotic–xenobiotic interactions	Can lead to increased or decreased concentrations of analytes, resulting in serious adverse effects; interactions can take place via increased or decreased metabolism or via competitive interactions at target sites (eg, receptors); can give the appearance of intentional overdose
Idiosyncratic response	There is little or no means of identifying an idiosyncratic response after the fact; can result in serious adverse effects, including fatalities
Pathology or pregnancy	Disease states can alter the toxicokinetic and toxicodynamic profiles for a given xenobiotic and resultant effects; pharmacokinetics and toxicokinetics change in pregnant women (eg, clearance)
Route of administration	Affects body burdens and speed of action of xenobiotics
Tolerance	Can lead to an overestimation of effect of a given xenobiotic concentration; there is no <i>a priori</i> means of determining tolerance
Toxicogenomics	Can lead to unpredictable effects on metabolism; analysis for metabolic status may not be useful because genotype may not equate to phenotype
Toxicokinetic variables	Prevents utility of classic pharmacokinetic or toxicokinetic equations; there is no <i>a priori</i> means of knowing the value for the necessary variables unique to an individual used in equations (eg, clearance)
Trauma or shock	Associated issues, including blood shunting and decreased organ perfusion, can alter toxicokinetic factors

a trier of fact.<sup>50</sup> The derivation of such a phrase is most likely a legal construct intended to persuade a trier of fact that the particular opinions of the retained expert are somehow weighted to such a degree that no other opinion or conclusion would make sense. However, that 2 toxicologists can give 2 distinctly differing opinions in the same case, both to a reasonable degree of medical certainty, demonstrates the lack of utility of the phrase. It is not common parlance for physicians or scientists to discuss matters with a reasonable degree of medical or scientific certainty and it is unclear why the term should carry into the medicolegal setting. Undoubtedly, there will be a slow retraction from the use of the phrase, but toxicologists can push the measure forward through discussions with attorneys prior to expert report generation or testimony by declaring that use of the phrase cannot be supported in a medical or scientific context.

## SUMMARY

- Toxicologists have the opportunity based on both contact with patients and as consultants to be involved with medicolegal cases.
- To properly assess such cases, a holistic approach should be taken that involves the integration of detailed historical information, preanalytical factors and understanding of the analytical work performed (including its limitations), specimen-specific utility, and special aspects that can weaken or strengthen the ability to form medically and scientifically sound conclusions.
- It should be understood that the burden on the toxicologist is not generally “absolute certainty” because this is something that is rarely achievable. However, the toxicologist must develop opinions and conclusions based upon sound medical and scientific principles and, if asked, be able to identify factors that weaken the stated opinions and conclusions.
- The purpose of the proffered opinions and conclusions offered should not be lost, that is, to educate someone or a group of individuals who have to make difficult decisions, some of which infringe on civil liberties and freedoms. In that respect, the burden assumed by toxicologists should be recognized as significant and warrant the same attention to detail with medicolegal opinions as treatment and diagnosis of a poisoned patient.

## ASSESSMENT OF ETHANOL-INDUCED IMPAIRMENT

Robert B. Palmer

## INTRODUCTION

Myriad medical texts describe the medical consequences of acute and chronic ethanol use. The purpose of this discussion is to describe the history and use of assessments of ethanol-induced impairment, primarily in a legal context. Some of the principles described, however, are extrapolated from the legal to the medical setting. Throughout this chapter, the terms *ethanol* and *alcohol* are used interchangeably in order to retain the forensic, legislative, and medical contexts in which the terms are used. Similarly, words such as *drunk* and *punishable* are also occasionally used in this chapter in order to preserve the specific language used in the early studies and legal writings.

## HISTORY

Numerous well-designed laboratory studies assessing alcohol-induced impairment are published. However, application of study results to actual cases of possible impaired driving or over service of alcohol in a drinking establishment may be inaccurate without an understanding of the origin of laws governing these activities. Although the intoxicating effects of ethanol have been known for centuries, the advent of mechanized transportation spawned increased public and legal scrutiny. Concern was expressed over the potential adverse safety implications of driving while intoxicated, not just for the impaired driver but also for other persons (passengers, other drivers, pedestrians) and property. Although railroads had regulations against the operation of equipment while intoxicated dating back to at least the 1850s, the first arrest for drunk driving in an automobile was that of a London taxicab driver in 1897.<sup>22</sup> The realization that alcohol intoxicated motor vehicle operators were a public health issue worthy of legal scrutiny soon followed, and legislation was enacted to combat “drunken driving.” In 1910, New York was the first US state to enact such a law.<sup>22</sup>

In early laws, “drunken driving” was poorly defined and relied heavily on observable signs of gross intoxication. Attempts at legislative clarification of language resulted in terms that were nearly as nebulous, such as “alcohol-impaired” and “under the influence.” Prior to the landmark work by Widmark<sup>67</sup> in Sweden, and by Heise<sup>27</sup> in the United States, evaluations of driver impairment were predominantly based on the “expert” testimony of an evaluating physician and the arresting police officer, as well as behaviors reported by witnesses. These evaluations were observational, rather than scientifically based, and such nonsystematic and nonobjective testimony was often dubious and frequently plagued by exaggeration of behaviors (eg, staggering gait, incoherent speech).

The development of analytical technology capable of measuring the concentration of alcohol in blood gave rise to the idea that diagnosis of intoxication might be assisted by an objective chemical test result. The theory behind this idea being simply, the higher the blood alcohol concentration (BAC), the more drinks the individual must have consumed and, therefore, the greater the degree of impairment. It was, therefore, reasoned that there is a legally punishable limit of alcohol in blood or other biological matrix. Although the assignment of a specific clinical effect to a given BAC is not rigorously applicable to evaluation of an individual case, the general trends when examined across a population formed the foundation of many modern driving while intoxicated (DWI) laws.

Despite centuries’ worth of knowledge of the effects of alcohol and decades of efforts to articulate drunk driving standards, a single universal definition of “alcohol intoxicated” does not exist. A typical medical definition

focuses on altered mental status, ataxia, or the ability to care for oneself, whereas the focus of a legal definition is on the ability to safely operate a motor vehicle or successfully perform field sobriety tests, or whether the patron of a bar or restaurant should be served additional alcohol. A lay public definition may include parts of both.

Although alcohol intoxication is an important factor in a nearly infinite number of settings, 2 of the most common legal circumstances involving toxicology consultation for alcohol-related issues are (a) alcohol-impaired operation of a motor vehicle and (b) so-called “dram-shop” cases when an already intoxicated individual is served additional alcohol. Discussion of alcohol use in the workplace and alcohol-abstinence monitoring are beyond the scope of this chapter.

## PER SE LIMITS

With the advent of analytical measurements capable of quantitatively determining BAC and the increasing public awareness of the dangers associated with drinking and driving, legislation based on BAC began to appear. Although the initial laws did not define the specific BAC that established illegality in the operation of a motor vehicle, they did allow for the use of BAC results as supportive evidence of intoxication. The first states to incorporate BAC into drunk-driving statutes were Indiana and Maine, which did so in 1939.<sup>28</sup> The approach taken by the Indiana legislature resulted in a 3-tiered statute, which stated that a BAC of less than 50 mg/dL was considered presumptive evidence of no intoxication, a BAC between 50 and 100 mg/dL was considered supportive evidence of intoxicated driving, and a BAC of greater than 150 mg/dL was considered *prima facie* (ie, obvious and evident without proof) evidence of guilt. From a legal perspective, *prima facie* evidence shifts the burden of proof from the accuser having to substantiate the charge to the defense to rebut the allegation. It is this legal perspective from which the so-called *per se* standards are derived—that is, an individual whose BAC exceeds a predetermined concentration is deemed guilty of driving while impaired by alcohol, even without any other evidence of intoxication or impairment.

Early drunk-driving standards established in the Uniform Vehicle Code made reference to a BAC at which there was “no doubt of obvious intoxication”; this BAC was defined as 150 mg/dL. However, by 1960, as data regarding alcohol-related motor vehicle crashes became available, most (but not all) states adopted a more rigorous *per se* BAC driving standard of 100 mg/dL.<sup>28</sup> This reduction in the *per se* legal BAC for an alcohol-impaired driving charge was supported by powerful medical and political groups, including the American Medical Association (AMA). Interestingly, the AMA recommendation also noted that some persons were “under the influence” or impaired in their ability to safely operate a motor vehicle at BACs of 50 to 100 mg/dL. Despite newer drinking and driving laws defined on the basis of an objective chemical test, many state laws still contained older vague language such as “intoxicated,” “visibly intoxicated,” and “obviously intoxicated,” which legislators were then forced to define more clearly and objectively.

Different states use different acronyms to apply to alcohol-impaired driving, including DUI (driving under the influence), DUIL (driving under the influence of liquor), DWI (driving while intoxicated), OUI (operating under the influence), OWI (operating while intoxicated), and OMVI (operating a motor vehicle while intoxicated). Regardless of the acronym used, the definitions are effectively the same. Depending on the state, the same terms may

also be used in drug-impaired driving, whereas in other states, a separate charge, such as DUID (driving under the influence of drugs) may be applied to nonalcohol drug-related driving impairment.

In 2000, the National Highway Traffic Safety Administration (NHTSA) reported that of 41,471 motor vehicle fatalities, 38.4% were alcohol-related; this corresponded to an average of one alcohol-related traffic fatality every 31 minutes.<sup>69</sup> The 2014 NHTSA data suggest a slight decrease in alcohol-related fatalities, with 31% of fatal motor vehicle crashes involving a driver with a BAC of 80 mg/dL or greater, corresponding to one alcohol-impaired-driving fatality occurring every 53 minutes.<sup>43</sup> However, it must be noted that NHTSA considers any fatal crash in which a driver has a BAC of 80 mg/dL or greater to be an alcohol-impaired driving crash; and, fatalities in these crashes are considered to be due to alcohol-impaired driving.<sup>43</sup> Critics of the NHTSA data claim this method for counting likely overestimates the number of actual fatalities involved in alcohol-related crashes as the mere fact that a driver had consumed alcohol and had a BAC of greater than or equal to 80 mg/dL does not prove crash causality. Nonetheless, there is little argument that alcohol use increases crash risk. Epidemiologic assessments demonstrate that the probability of causing an alcohol-related motor vehicle crash increases slightly at a breath alcohol concentration (BrAC) of 50 mg/dL. The risk of causing a crash is increased by roughly 4-fold at a BrAC of 80 mg/dL, 7-fold at a BrAC of 100 mg/dL, and 25-fold at a BrAC of 150 mg/dL.<sup>528</sup> In 1994, a successful campaign, vigorously supported by the AMA and Mothers Against Drunk Driving (MADD), encouraged all states in the US to lower the BAC used to define *per se* intoxicated driving to 80 mg/dL.<sup>22</sup> Although all states technically have the right to set drunk-driving statutes at their discretion, political advocates for more strict alcohol-impaired driving statutes were successful in convincing the US government to require a minimum legal drinking age of 21 years and a mandatory *per se* BAC statute of 80 mg/dL in order to receive federal highway funding.<sup>22</sup> Consequently, as of July 2004, all US states, the District of Columbia, and Puerto Rico conform with federal recommendations defining a BAC of 80 mg/dL as a violation of motor vehicle code. Lower *per se* BACs are applied to interstate commercial drivers (40 mg/dL) and pilots of aircraft (40 mg/dL, with no alcohol consumed within 8 hours prior to acting as pilot in command), as well as minors (10–20 mg/dL, depending on the state, and 20–50 mg/dL in some European countries). Additionally, some US states, such as Colorado, have lower *per se* statutes for the slightly lesser charge of driving while ability impaired (DWAI), which may be invoked when a driver's BAC is between 50 and 80 mg/dL. Some US states also have legal standards defining an "aggravated DUI." Definitions of "aggravated DUI" are variable by state, but some of the actions that may lead to this charge include, committing a DUI while under court order to use an approved ignition interlock device, committing a DUI while the offender's driver's license or driving privileges are suspended, canceled, or revoked because of a prior DUI violation, or committing multiple DUIs in a specified time period (eg, 10 years). States such as Montana have an additional standard that charges an individual with aggravated DUI if the driver's BAC is found to be 160 mg/dL, or more.

Laws addressing *per se* driving under the influence (DUI) limits are based on ethanol concentrations measured in whole blood. BrAC limits (which are arithmetically linked to BAC) are also frequently specified in *per se* statutes. As such, the use of appropriately conducted breath alcohol measurements eliminates the need to collect a blood specimen from a suspect. *Per se* limits, as described above, apply to the ability to safely accomplish specifically defined tasks such as driving an automobile or flying an aircraft. It is, however, imperative to understand that *per se* BACs do not define drunkenness or alcohol intoxication in nondriving situations, and their use in circumstances not involving motor vehicle operation is generally inappropriate.

The legal significance of a *per se* limit is that there is no requirement for behavioral evidence of intoxication, as long as the measured BAC exceeds that established by the legislature. Since their enactment, numerous legal arguments have challenged the constitutionality of *per se* drunk-driving laws. Issues including a lack of due process through application of the "void for vagueness" doctrine, reliability of breath testing results, and the distinction

between blood alcohol and breath alcohol concentrations have all formed bases for legal challenges to *per se* laws.<sup>22</sup> However, despite such challenges, the courts consistently uphold these laws.

## ANALYTICAL CONSIDERATIONS

Accurate measurement of ethanol concentration in various biological matrices can be done using a number of analytical techniques. Historically, Widmark employed wet chemical oxidation, using potassium dichromate and excess sulfuric acid, followed by iodometric titration of the remaining amount of oxidizing agent.<sup>67</sup> Although this method is effective, it is laborious and lacks specificity if other volatiles (eg, methanol, acetone, ether) are present, as these substances are also oxidized, causing a falsely elevated ethanol result. Such wet chemical methods are now obsolete and no longer used in forensic and clinical laboratories.

Enzymatic ethanol assays based on alcohol dehydrogenase (ADH) are commonly used, especially in high-throughput laboratories. The oxidation conditions of enzymatic methods are milder than wet chemical methods. Additionally, acetone, which caused the most troublesome interference with wet chemical methods, is not oxidized by ADH. Interferences by other aliphatic low-molecular-weight alcohols such as methanol and isopropanol occur with ADH isolated from humans and other animals; this interference is reduced by using yeast-derived ADH, which shows greater selectivity for ethanol.<sup>31,64</sup> Specific enzymatic methods used for ethanol analysis in body fluids include enzyme-multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), and radiative energy attenuation (REA), which is related to FPIA (Chap. 7). Comparative study of ethanol determination by REA and gas chromatography shows excellent agreement in precision and accuracy between the 2 techniques.<sup>12</sup> Both high serum lactate and elevated lactate dehydrogenase concentrations interfere with ADH-based methods of ethanol analysis, including providing false-positive results in serum specimens from alcohol-free patients.<sup>3,44</sup>

The greater selectivity for ethanol of gas chromatographic (GC) methods make this technique the mainstay for quantitative analysis in most forensic laboratories. Typically, the GC method involves head space sampling (HS-GC), which capitalizes on the volatility of ethanol, eliminates some potential interferences, and shortens run time. Samples to be run by HS-GC are first diluted (typically 1:5 or 1:10) with an aqueous solution of internal standard. This mixture is then sealed in a crimp-top vial with a rubber septum and gently heated to 122°F to 140°F (50°C–60°C) for 30 to 60 minutes in order to achieve equilibrium of volatiles between the gas and liquid phases. The vapor is then sampled with a syringe by puncturing the rubber septum and the withdrawn vapor injected into the instrument. Heating the sample for too long at a high temperature can result in oxidation from oxyhemoglobin.<sup>56</sup> This problem is solved by the addition of sodium azide or sodium dithionite to block the oxidation or simply reducing the equilibrium temperature to 104°F to 122°F (40°C–50°C).<sup>56</sup> Once chromatographic separation is achieved, various detection methods, including flame ionization (FID), electron capture (EC), and electrochemical sensing are used (Chap. 7). Dual detection (eg, FID and EC) can also be useful in circumstances where a larger number of volatiles may need to be screened.<sup>57</sup>

As ethanol distributes based on total body water, the water content of the matrix will affect the amount of ethanol present in a given volume or mass of biological sample. A common circumstance in which this is observed is in the difference between a whole blood ethanol determination and a plasma or serum ethanol determination. The water content of serum and plasma is 10% to 12% higher than whole blood, meaning that serum or plasma ethanol concentrations will be correspondingly higher than whole blood concentrations. Clinical laboratories most often use serum and plasma for analysis, whereas *per se* DUI statutes are written in terms of whole blood. Therefore, if a comparison is to be made between a serum or plasma analytical result and a legal standard, the result must be converted to an approximated whole blood ethanol concentration. Experimentally determined serum-to-whole blood ethanol ratios range from 1.12 to 1.17, whereas plasma-to-whole blood ethanol ratios range from 1.1 to 1.35.<sup>45</sup> Typically, a

ratio of 1.16 is used for this conversion, and no significant difference appears to exist between the serum-to-whole blood and plasma-to-whole blood ratios.<sup>69</sup> Ratios between whole blood and other biological matrices such as urine, saliva, cerebrospinal fluid, vitreous humor, brain, liver, kidney, and bone marrow are published, and a table listing these ratios and the sources from which they are derived is available.<sup>11</sup>

Breath testing is commonly performed to assess BAC because of its relative simplicity and less invasive collection compared to urine or blood. The analytical basis for sampling exhaled breath is that, at equilibrium, alcohol in expired air is present at a predictable ratio with blood. The gas exchange process in the lungs is complex, with significant theoretical variability.<sup>40</sup> In the United States, a blood-to-breath alcohol ratio of 2100:1 is commonly used in the calibration of breath alcohol testing devices, although some experimental evidence suggests that the ratio is actually closer to 2300:1.<sup>17</sup> As such, a systematic underestimation of BAC is expected when breath alcohol results are converted to whole blood alcohol results. Several studies document this underestimation with data from suspected impaired drivers and evidential breath alcohol testing instruments.<sup>20,25</sup> In 1983, Britain adopted a legal limit in breath of 35 mcg/100 mL, which corresponds to a blood alcohol of 80 mg/dL, using a 2300:1 blood-to-breath ratio.<sup>28</sup> Legal statutes that include in their offense definition breath alcohol results expressed in units of grams/210 L of exhaled air eliminate the need to convert breath alcohol to blood alcohol, largely mitigating arguments based on the breath-to-blood ratio.

## BREATH-TESTING DEVICES

Three general analytical detection principles have been extensively validated and are currently used in breath alcohol-testing instruments. These are infrared spectroscopy, electrochemical oxidation/fuel cell, and chemical oxidation/photometry.<sup>26</sup> Additionally, combination of multiple technologies is sometimes used, as in infrared/fuel cell dual detectors. Breath-testing instruments are generally divided into 4 broad categories: passive alcohol sensors (PASs), screening devices (preliminary breath testers, {PBTs}), breath alcohol ignition interlock devices (BAIIDs), and evidential breath testers (EBTs).<sup>26</sup>

A PAS device may be concealed in a device such as a modified police flashlight and is used to detect alcohol on or in the immediate vicinity of a subject through passive means (ie, with no requirement for subject cooperation). Breath alcohol ignition interlock devices are used to prevent drinking and driving by requiring the driver to blow into a sensor in order to start the ignition of the vehicle. The devices are typically installed on a court order designed to modify drinking and driving behavior in habitual DUI offenders, with the cost of installation typically borne by the offender. A number of mechanisms are employed to prevent substitution of breath samples, including preset patterns of exhalation or humming while blowing into the sampling tube. Additionally, random rolling retests are required, failure of which result in the vehicle's lights flashing or horn blowing. Neither PAS nor BAIID results are useful for quantitative measurement of breath or blood alcohol for prosecution of a *per se* DUI case.

The PBT and EBT devices are the most common breath alcohol-testing devices encountered in cases of DUI arrest. In this setting, PBT results are used in conjunction with observation and field sobriety tests to establish probable cause for DUI arrest. Although a measured BrAC is often provided as a digital readout on a PBT, in most jurisdictions these results are not admissible as evidence for proceedings other than probable cause hearings. Use of PBT devices is also common in nonlegal settings such as hospital emergency departments, alcohol detoxification units, homeless shelters, and workplaces. As with DUI prosecution, these results are generally used for screening for alcohol presence and not for establishing impairment.

In contrast to PBT results, measurements from an EBT device are admissible in court and administrative proceedings and can be used as the basis for establishment of *per se* DUI cases without the necessity of blood collection and analysis. Although mobile EBT devices are available, most often the EBT is maintained in a fixed location such as a police station. For the results to be considered valid and admissible, the operator of the EBT must be trained

and certified, and the operation must be performed using an accepted testing protocol.

Required procedures for the use of EBT devices exist for the subject as well as the instrument. The subject must have a period of alcohol deprivation of at least 15 to 20 minutes during which trained personnel observe him or her to ensure not only that no additional ethanol is consumed but also that no regurgitation, emesis, or eructation occurs, which could result in residual ethanol in the mouth prior to breath alcohol analysis. With respect to the instrument, both blank and control analyses must be performed prior to analysis of the subject sample. A blank analysis, typically done with room air, purges the instrument of contamination from previous samples and demonstrates a lack of environmental contamination. A control analysis is performed on a gaseous ethanol sample of known concentration, usually an ethanol gas canister or wet bath simulator, and demonstrates proper instrument calibration and maintenance. Certification of instrument maintenance of calibration must be documented, demonstrating compliance with applicable rules, regulations, laws, and standards for routine maintenance, troubleshooting, and corrective actions. These documents are then retained for a relevant time period after inspections are complete. Additional documentation for individual cases should include written verification that all steps in the accepted protocol were followed. This documentation also includes automated printouts from the analyzer used, and well as copies of manual checklists.<sup>26</sup>

Beyond the required procedures, additional recommendations include the use of grams/210 L as the reporting units, rather than reporting breath alcohol concentration as a converted blood alcohol concentration of %weight/volume, grams/100 mL, or grams/deciliter. Serial collection and analysis of at least 2 separate sequential breath samples taken 2 to 10 minutes apart should be done in order to demonstrate the absence of residual mouth alcohol, instrument artifacts, frequency interference, and spurious results. Agreement of the serial results must be within prescribed limits (usually, 0.02 g/210 L) to be considered acceptable.<sup>26</sup>

## STANDARDIZED FIELD SOBRIETY TESTS

A driver whose BAC exceeds the established legal standard is considered *per se* intoxicated and often convicted without behavioral evidence of intoxication. However, some objective findings of impairment assists in establishing probable cause to demand chemical testing, initiate a DUI arrest, or prosecute a charge of impairment, without invoking *per se* limits. In these settings, results of a specific group of behavioral tests are of value in discriminating and prosecuting or refuting an impaired driving charge, although submitting to these behavioral tests is typically voluntary. Additionally, an objective measurement of alcohol effect is helpful in assessing alcohol-related impairment in nondriving situations, where it is inappropriate to directly apply *per se* standards.

Under a contract with the NHTSA, a group of 15 candidate sobriety tests were evaluated in a laboratory study.<sup>9</sup> From this original group, the investigators developed a series of 3 specific tests that have subsequently been standardized as a test battery, known as standardized "field sobriety tests" (FSTs), for assessing driver impairment in the United States. The 3 tests comprising the standardized FSTs are the one-leg stand (OLS), walk-and-turn (WAT), and horizontal gaze nystagmus (HGN). Descriptions of these tests are provided in [Table SC11-1](#).

A 1981 study of 297 drinking volunteers with BACs ranging from 0 to 180 mg/dL who were evaluated by trained police officers showed adequate interrater reliability (correlations, 0.6–0.8) and test-retest correlations (0.40–0.75).<sup>59</sup> Using all 3 field sobriety tests, the officers were able to distinguish whether BAC was above or below 100 mg/dL in 81% of participants. Test results were observed to generally correlate with BAC. However, the specificity and sensitivity of each individual test was not evaluated. Field sobriety tests are typically associated with physical, rather than mental, ability other than understanding the instructions for each test. Some aspects of variability in cognitive performance correlate moderately and positively with facets of FSTs, especially those tests evaluating reaction time.<sup>16</sup>

**TABLE SC11-1** Standardized Field Sobriety Tests

Test	Test Description	Test Scoring ("clues")
One-leg stand (OLS)	With the arms at sides, raise one foot at least 6 inches off the ground and stand on the other foot for at least 30 seconds.	4-point scale 1. Putting foot down 2. Hopping 3. Swaying 4. Raising arms Any 2 "clues" is failure.
Walk-and-turn (WAT)	Balance with feet heel-to-toe and listen to test instructions. Walk 9 steps heel-to-toe in a straight line, turn 180 degrees, and walk 9 more steps heel-to-toe, while counting steps, watching feet, and keeping hands at sides.	8-point scale 1. Inability to maintain balance in the starting position 2. Starting too soon (eg, prior to completion of instructions) 3. Stepping off the line 4. Not touching toe to heel 5. Raising arms 6. Improper turn 7. Stopping 8. Wrong number of steps Any 2 "clues" is failure.
Horizontal gaze nystagmus (HGN)	Angle of onset of nystagmus is determined for each eye.	6-point scale (three points for each eye) 1. Lack of smooth pursuit 2. Distinct nystagmus at maximum deviation 3. Onset of nystagmus before 45 degrees Cutoff is 4 "clues."

Adapted with permission from Rubenzer SJ. The standardized field sobriety tests: a review of scientific and legal issues. *Law Hum Behav.* 2008 Aug;32(4):293-313.

In the few studies evaluating the performance of individual FSTs, general correlation between test performance and BAC is observed. Although the correlation magnitudes for the WAT and OLS tests are low, the HGN test showed excellent sensitivity and specificity across a range of BACs.<sup>46</sup> In the control arm (ie, no alcohol ingested and no detectable ethanol in the blood), approximately 50% of the participants were judged to be impaired using the WAT test, whereas in the OLS test, 30% of the participants were rated as impaired. When the BAC was greater than 150 mg/dL, performance on the WAT and OLS tests improved to 78% and 88%, respectively. The rate of false positives (ie, those with a zero BAC who failed the HGN test) was only 3%. As seen with the other FSTs, the sensitivity of the HGN test increased with increasing BAC, being 81% for those with a BAC between 100 and 149 mg/dL and 100% for those with a BAC greater than 150 mg/dL. The presence of horizontal gaze nystagmus, even in alcohol-tolerant drinkers, gives this test an advantage over the WAT and OLS tests in detecting the presence of alcohol.<sup>10</sup> It is noteworthy that balance and coordination can be affected by factors unrelated to alcohol consumption, such as physical disability, age, and nervousness about potential arrest; however, chronic drinkers with substantial alcohol tolerance are reportedly able to complete balance tests with few errors, even with moderate to high BACs.<sup>9</sup>

The 3 tests utilized for field sobriety assessment have some advantages, in that they are standardized and are easily understood by test takers. In addition, personnel administering the tests can be trained in a matter of hours.<sup>39</sup> However, because the test results are only approximately correlated with BAC, their use is limited by the threshold BAC they are able to detect. Predictably, various scientific and legal challenges to the use of the FSTs have also been made. For example, the tests were designed and validated at a time when the *per se* DUI limit in most of the United States was 100 mg/dL; however, that threshold is now 80 mg/dL in every state (and 20–50 mg/dL in many European countries).<sup>39</sup> Because of the variability of psychomotor

effects of alcohol as a result of individual tolerance, FST assessments are generally not allowed as a means of estimating BAC in court proceedings. The effects of fear, fatigue, rehearsal of test performance, the arresting officer's knowledge of estimated BAC prior to administering the standardized FSTs, and various medical conditions have not been fully addressed. It has further been argued that the studies most strongly supporting use of standardized FSTs are those conducted by NHTSA-affiliated investigators and reported in non-peer-reviewed government publications. So contentious has the debate been that some have charged that "the United States Department of Transportation indulged in deliberate fraud in order to mislead the law enforcement and legal communities into believing the test (HGN) was scientifically meritorious and overvaluing its worth in the context of criminal evidence." A comprehensive review detailing this, and other, legal and scientific issues surrounding standardized FSTs was published in 2008.<sup>50</sup> The author concluded that FSTs are not useful in predicting BAC, and that further research is needed to determine whether improvements can be made to the current battery of tests included in FST assessments. Despite arguments of FSTs having limitations, these assessments are still commonly used in arrest and prosecution of alcohol-impaired driving cases.

### ESTIMATING THE AMOUNT OF ALCOHOL INGESTED

The kinetic profile of ethanol in the blood has been extensively studied. In general, it is known that when blood ethanol concentration is greater than 20 mg/dL, it follows a zero-order elimination profile and then converts to first-order elimination when the concentration drops below this threshold.<sup>30</sup> In the zero-order portion of the curve, typical elimination rates range from 10 to 20 mg/dL/h in social drinkers. In one study of adult patients in an urban hospital emergency department, nonchronic users of alcohol (n = 9) demonstrated a mean elimination rate of 18.7 mg/dL/h (range, 16.1–21.4), whereas chronic users (n = 15; defined as more than 2 drinks per day, history of delirium tremens, or prior detoxification) had a significantly greater mean elimination rate of 20.3 mg/dL/h (range, 16.1–24.6).<sup>6</sup> Other studies report elimination rates of 30 to 50 mg/dL/h in chronic heavy drinkers due, at least in part, to metabolic enzyme induction.<sup>6,7</sup> Pharmacokinetic calculations in healthy persons often employ a range of elimination rates of 10 to 20 mg/dL/h in order to best bracket individual differences.<sup>7</sup>

The estimation of the number of drinks ingested in order to achieve a given BAC has been extensively studied and is predicated on knowing several case-specific pieces of information. According to the US Department of Agriculture, a standard drink consists of 12 ounces of beer (5% v/v), 5 ounces of wine (12% v/v), or 1.5 ounces of 80-proof spirits (40% v/v); each of these drinks contains approximately 14 g of ethanol.<sup>7,63</sup> The time period over which the ingestion occurred, the time of the last drink, and time of blood alcohol specimen collection must be known. It is helpful to know whether the subject was fasting or had a full stomach at the time of drinking because the presence of food in the stomach slows ethanol absorption.<sup>34,65</sup> Finally, the gender, age, height, and weight of the individual should be known and considered.<sup>7</sup>

Using this information, an estimation of the number of drinks is possible. The original work in which the prediction of ethanol concentrations from known doses was performed by Widmark in 1932 using 20 healthy volunteer moderate drinkers (10 of each gender).<sup>67</sup> This work was translated into English from the original German by Baselt in 1981.<sup>68</sup> The basis of Widmark's work was that the BAC was directly proportional to the administered amount of alcohol ("dose"); the body weight of the subject; and a unitless scaling factor that Widmark referred to as "ρ" (rho), which corrected the subject's body weight for water content. Of note, in present-day pharmacokinetics, Widmark's ρ effectively represents the volume of distribution of ethanol. Because of the differences in body water content between sexes, ρ was determined to be approximately 0.6 in women and 0.7 in men. The original Widmark equation is therefore written as

$$A = C \times \rho \times p$$

where A represents the total amount of ethanol equilibrated in all fluids and tissues at the time of sampling (ie, total dose ingested), C is blood ethanol

concentration in grams/kilogram,  $\rho$  is the previously described Widmark  $\rho$  factor, and  $p$  is subject body weight in kilograms. Although the calculation has served well as an estimating tool for more than 80 years, it does have some limitations, principally in the  $\rho$  factor. As a result, refinement of Widmark's original  $\rho$  was undertaken by others.<sup>7,66</sup> One method for the estimation of total body water (TBW), which takes into account not only gender but also individual age, weight, and height (abbreviated  $\Sigma V_d$ ) for men aged 17 to 86 years yields the following equation:

$$\Sigma V_d = 2.44 - (0.09516 \times \text{age}) + [0.1074 \times (\text{height} \times 2.54)] + [0.3362 \times (\text{weight}/2.2045)]$$

For women aged 17 to 84 years, the TBW equation is:

$$\Sigma V_d = -2.097 + [0.1069 \times (\text{height} \times 2.54)] + [0.2466 \times (\text{weight}/2.2045)]$$

In all persons, the height is measured in inches and the weight is measured in pounds. Note that the equation for men includes a mathematical term derived from age, and the equation for women does not.<sup>66</sup> The significance of this calculation is its ability to be tailored to a specific person, rather than the broad extrapolation of the relatively few subjects in the original study. Inclusion of such individual information improves the accuracy of such calculations.<sup>54</sup>

The need for a more standardized approach to calculations involving alcohol in forensic medicine has been known for decades. One author summarized 20 of the most commonly used alcohol-related calculations.<sup>7</sup> As an example, the following equation is derived to calculate the estimated dose of ethanol necessary to achieve a specific blood alcohol concentration:

$$g \text{ EtOH} = \text{BAC}_{\text{target}} + [(\beta_{1-n} \times (t_s + t_p)) \times \Sigma V_d / Bl_{\text{H}_2\text{O}}$$

where  $g \text{ EtOH}$  is the ingested dose of ethanol in grams;  $\text{BAC}_{\text{target}}$  is the observed blood alcohol concentration in mg/dL;  $\beta_{1-n}$  is a range of alcohol elimination rates (typically, 10–20 mg/dL/h);  $t_s$  is the time from the start of drinking to the last drink;  $t_p$  is the range of times from the last drink to the peak BAC (typically, 30–90 minutes);  $\Sigma V_d$  is the Watson TBW, which is the volume of distribution based on age, weight, height and gender; and  $Bl_{\text{H}_2\text{O}}$  is the approximate percentage of water in whole blood (80.65%).<sup>7</sup> Noting the inherent variability in terms such as  $\beta_{1-n}$  and absent specific kinetic data from the individual in question, it can be seen that results of such equations are most reasonably presented as a range, rather than a single discrete calculated value.

Some legal arguments have quite incorrectly suggested that ethanol is odorless. Ethanol has a characteristic pleasant smell, with an odor threshold of approximately 50 ppm.<sup>14</sup> The presence or absence of breath alcohol odor is often used by police officers in the decision to proceed further with sobriety testing. In one study, 20 experienced police officers assessed alcohol odor on 14 subjects with BACs ranging from 0 to 130 mg/dL after drinking beer, wine, bourbon, or vodka.<sup>42</sup> Assessments were initiated 30 minutes after cessation of drinking. The strength of breath alcohol odor was determined to be an unreliable indicator of BAC. Correct detection of the presence of alcohol was 85% for BACs at or above 80 mg/dL but declined with decreasing BAC or the presence of food. The authors also noted that there were only small differences in odor intensity as a function of beverage type, meaning fusel oils and other constituents of alcoholic drinks are not the primary determinant of detectable odor after absorption of the beverage.

## DRAM SHOP

Liquor liability or “dram shop” laws hold the server of alcoholic beverages liable for damages or injuries caused by an individual who was provided alcohol when such service should have been refused. For example, if a an individual who was already intoxicated, or any minor, is served alcohol and crashes his or her vehicle, the person and/or establishment who served the alcohol may be liable for damages or injuries sustained in the crash.

Interestingly, US dram shop laws were first enacted in the mid-1800s, although they were rarely used. The initial intent of these laws was to provide financial support to the families of persons who had become “habitual

drunkards” through their patronage of a drinking establishment.<sup>52</sup> Repeal of Prohibition in the United States in 1933 shifted laws governing alcohol sales from federal to state control, resulting in state-to-state variability in alcohol availability, criminal and administrative laws, and liquor liability. There was also a move from public focus on habitual drunkenness to the damage caused by impaired drivers, as well as a paradigm shift in the standard for irresponsible service away from serving a “drunkard” to serving an individual who was “visibly intoxicated.”<sup>52</sup> The purpose of liquor liability laws has also changed over time. In the 19th century, laws were enacted to punish tavern owners who contributed to the downfall of patrons. By contrast, current application of the laws is typically as a means to compensate innocent victims injured by an intoxicated patron. This action on behalf of the innocent victim is why liquor liability law is sometimes referred to as “third party” liability.

Beginning in the late 1970s and early 1980s, political activists began to take note of dram shop laws as an effective means for prevention of impaired driving (or DWI). Outreach began to bring attention to irresponsible commercial and social service of alcohol. Various drunk-driving prevention strategies emerged, including “server intervention” (ie, the practice of bar or restaurant workers intervening to prevent an intoxicated patron from driving). Interestingly, although the goal of keeping intoxicated patrons from “getting behind the wheel” is certainly praiseworthy, these programs put notably less emphasis on preventing intoxication in the first place. The 1983 Presidential Commission on Drunk Driving recommended dram shop liability and server intervention as drunk-driving prevention strategies, and federal grant funds for state impaired-driving initiatives also listed such programs as qualifying criteria.<sup>1</sup>

Alcoholic Beverage Control agencies in the various states are responsible for reviewing and approving liquor licenses of commercial establishments, collecting taxes, and enforcing criminal and administrative laws prohibiting service to minors and intoxicated persons. Largely as a tool to improve public perception of the industry, the alcoholic beverage producers have largely been responsible for the development of training programs for servers in the retail community. Numerous programs offering Responsible Beverage Service (RBS) training for servers are administered at the state or regional level, or sometimes even sponsored by the server's employer. Calls for greater organization and standardization of RBS programs in the United States have been answered, at least in part, by the Responsible Hospitality Council, whose work has focused on developing minimum standards for legitimate RBS training.<sup>52</sup> Although such standards are often welcomed by regulators, some restaurant associations and owners have expressed concern over cost and compliance standards associated with RBS mandates. Nonetheless, the US legal climate seems to dictate that alcoholic beverages be served in a “responsible” manner and that liability for “overservice” falls on the serving establishment. It is also noteworthy that cases placing liability on individuals serving alcohol socially in their home have been successfully argued.

Direct comparison of the efficacy of dram shop liability laws between states is difficult as liability laws and insurance vary widely. Historically, different states and regions emphasized different areas of alcohol service liability, and it was noted that research played only a minor role in determining server training, with the majority of policy formation arising from political influence.<sup>52</sup> However, even data collected in the 1980s suggested that dram shop laws did result in a statistically significant decline in mortality rates not only for motor vehicle collisions, but also for other alcohol-related causes.<sup>55</sup> A more recent study concluded that dram shop liability and RBS laws were associated with significant reduction in *per capita* beer consumption and fatal crash ratios in drivers under age 21.<sup>53</sup> This begged the question of whether enhanced enforcement of dram shop laws would result in a decrease in excessive alcohol consumption and related consequences. An evaluation of 11 studies concluded that while dram shop laws were effective in reducing alcohol-related harms, the data supporting the efficacy of enhanced enforcement on reduction of alcohol-related harms were mixed and ultimately judged insufficient.<sup>47</sup>

Specific study of alcohol service liability on younger and underage drinkers has also been investigated. Reduction of the legal age for alcohol purchasing from 20 to 18 in New Zealand in December of 1999 resulted in a

statistically significant increase in traffic injuries attributable to male drivers aged 15 to 19 years.<sup>33</sup> Review of annual fatal motor vehicle collision data from the United States showed that the most effective interventions for the prevention of underage alcohol-related fatal crashes were those associated with reducing teen drinking, rather than those restricting teen driving.<sup>49</sup> An evaluation of 20 minimum legal drinking age 21 (MLDA-21) laws in order to assess which had an effect on fatal underage drinking and driving traffic crashes.<sup>18</sup> Nine of the laws were associated with a decrease in fatal crash ratios: fake identification support for retailers (-11.9%), use alcohol and lose your driver's license (-7.9%), possession of alcohol (-7.1%), purchase of alcohol (-4.2%), age of the bartender greater than or equal to 21 (-4.1%), responsible beverage service program (-3.8%), zero tolerance 0.02 BAC limits for underage drivers (-2.9%), state dram shop liability (-2.5%), and social host civil liability (-1.7%). Interestingly, 2 laws were associated with a significant increase in fatal underage crash ratios (registration of beer kegs [+9.6%], and prohibition of furnishing alcohol to minors [+7.2%]). The authors concluded that 9 effective MLDA-21 laws were responsible for saving an estimated 1,135 lives annually, though only 5 states have adopted all 9 of these laws.

### INTOXICATION AND ESTIMATION OF BLOOD ALCOHOL CONCENTRATION

Neither the characteristic odor of ethanol nor the measurement of various markers of alcohol exposure (eg, ethyl glucuronide, ethyl sulfate, carbohydrate deficient transferrin, and so on) are useful in estimating BAC or degree of intoxication. The ability of an individual to accurately estimate his or her own BAC is poor.<sup>35,51</sup> Drivers who underestimate their own BAC are more impulsive and riskier drivers than those who overestimate their BAC.<sup>36</sup> A lack of accuracy in estimating BAC is also observed in trained medical providers and police officers.<sup>4,13</sup> A large confounding factor in these observations is tolerance. Greater tolerance, as occurs in heavy drinkers and alcoholics, imparts greater difficulty in detecting the clinical effects associated with alcohol intoxication.

Tolerance involves a central adaptation to the intoxicating effects of alcohol. As such, persons with significant tolerance to the effects of ethanol may not manifest signs of intoxication despite having a high BAC. Multiple case reports and case series in the medical literature describe alcoholic individuals with heavy alcohol consumption who have very high BACs but muted or absent clinical effects.<sup>15,24,29,38,48,58</sup> As a result of tolerance in the chronic heavy drinking population, it is often difficult to detect clinical intoxication even though an individual has a high BAC. Critically, this circumstance does not suggest that, even in the clinically sober chronic drinker, driving abilities are unaffected or that the individual is necessarily capable of safely operating a motor vehicle.<sup>4</sup> Furthermore, tolerance has no bearing on the potential prosecution of a DUI case on a *per se* BAC or BrAC basis.

The circumstance is slightly more straightforward in the social drinker. The intensity of the effects of alcohol on the central nervous system (CNS) is generally proportional to the concentration of alcohol in the blood. Dubowski tabulated the stages and effects of acute alcohol intoxication, and these tables are often used in educational programs and some legal proceedings.

However, though useful as a pedagogic tool for explaining the continuum of alcohol intoxication, the table must be used with care as the effects are defined only over a population, thereby making assignment of a specific effect or degree of effect in an individual impossible. The inherent individual variability in the table is apparent in the fact that the BAC ranges for the various stages of alcoholic influence overlap. Furthermore, the population and methods used to compile the table are not described, and the table itself has not been subjected to peer review.

The CNS effects of alcohol intoxication are typically more pronounced on the ascending portion of the blood alcohol kinetic curve than on the descending side due to acute tolerance.<sup>21</sup> In other words, the clinical effect of intoxication is greater during the absorptive arm of the kinetic curve than on the elimination arm, even though the same blood alcohol concentration is measured in both kinetic phases. This principle is known as acute tolerance, or the Mellanby effect.

In a dram shop case, the ultimate question often becomes, what is the typical BAC at which it is more likely than not that the average nontolerant individual will exhibit signs of intoxication (eg, the odor of alcohol on the breath, clumsiness, difficulty walking or maintaining balance, slurred speech, inappropriate behavior) that are apparent to a bystander or untrained casual observer? A 1986 report by the Council on Scientific Affairs of the AMA reviewed 7 studies spanning 50 years that included more than 6,500 participants for identification of BACs at which individuals appeared "drunk" (ie, clinically intoxicated).<sup>2</sup> BACs were stratified by increments of 50 mg/dL, beginning at 0.0 to 50 mg/dL and extending to 401 mg/dL. In the lowest BAC group (0.0–50 mg/dL), observer perceptions of subject drunkenness ranged from 0% to 10%, with an average of 4%. The percentage of individuals determined by observers to be drunk increased steadily from a mean of 32% (range, 14%–68%) at a BAC of 51 to 100 mg/dL to a mean of 62% (range, 47%–93%) at a BAC of 101 to 150 mg/dL. In this latter range, 4 of the 7 studies indicated a perception of drunkenness by less than or equal to 50% of observers. However, in the next BAC increment of 151 to 200 mg/dL, observers judged a mean of 89% (range, 83%–97%) of the drinkers to be drunk. In each of the subsequent higher increments, the mean percentage of persons classified as drunk ranged from 95% to 100% with no individual study value less than 90%. Therefore, it can be reasonably concluded that in a nontolerant individual, a BAC of 151 to 200 mg/dL will more likely than not result in observable signs of drunkenness to a casual observer.

Study of the effects of alcohol on driving performance has been the subject of decades of research. Driving simulators are often used in laboratory studies of impaired driving and have the benefit of easy replication and control of experimental conditions. A number of simulation devices have also been developed including "fatal vision goggles," which provide visual distortion to the wearer in order to simulate the effects of alcohol on visual perception.<sup>41</sup> Additionally, simulators and simulation devices allow study of the effects of impairing substances in populations in which actual drinking is legally or ethically unacceptable (eg, underage precicensed drivers). However, it is known that driving performance evaluated in a simulator is less sensitive to the effects of alcohol than actual on-the-road driving.<sup>32</sup> Additionally, despite frequent use, many driving simulator tests lack validation and head-to-head comparison with naturalistic driving.<sup>32</sup>

The validity of a police officer detecting intoxication in drivers involved in motor vehicle crashes also increases with increasing BAC. One report examined a total of 1336 subjects over age 15 who were admitted or died at a level 1 trauma center in Seattle during a 5-year period from 1986 to 1993 and in whom both a recorded BAC and a police assessment of sobriety were conducted.<sup>23</sup> The blood alcohol measurement was conducted in the hospital, and it is not expressly stated if the analytical matrix used was whole blood, serum, or plasma. Four categories of sobriety assessment were used by police: (a) had not been drinking, (b) had been drinking—not impaired, (c) had been drinking—sobriety unknown, and (d) had been drinking—impaired. Officers used a battery of specific criteria to judge whether a driver was intoxicated, including odor on the breath, slurred speech, chemosis, poor coordination of motor function, and the ability to simultaneously perform multiple tasks. The greatest number of drivers were in the 2 extreme categories: had not been drinking (n = 746) and had been drinking—impaired (n = 568). A direct correlation between measured BAC and police officer assessment of sobriety was observed. The mean BAC associated with the "had been drinking—impaired" group was 190 mg/dL with a 95% confidence interval (CI) of 180 to 200 mg/dL. Those in the "had been drinking—sobriety unknown" group had a mean BAC of 130 mg/dL (95% CI, 110–150). Among all drivers, police field assessment of sobriety had a positive predictive value of 85% with sensitivity and specificity of 91% and 90%, respectively, demonstrating recognition of drunk driving by police with a high degree of accuracy, especially in the group with the highest BAC.

Another study designed to determine the ability of police officers, who have more training than the average lay person, to make assessments about alcohol intoxication in drinking target subjects without the aid of special testing normally available to them (eg, standardized field sobriety

tests or the ability to smell the odor of alcohol on the subject's breath).<sup>8</sup> This study involved 39 police officers who viewed a series of videotaped interviews with 6 volunteer moderate drinkers having targeted BACs in 3 concentration ranges: low (80–90 mg/dL), medium (110–130 mg/dL), and high (150–160 mg/dL). Based on their observations of the taped interviews, the officers answered 3 questions:

1. Has the person been drinking?
2. Was it OK to serve that person one additional drink?
3. Was the person able to drive a car?

Each of the 3 questions could be answered “yes,” “no,” or “not sure.” A fourth question assessed the officers' confidence in their answers as “not sure,” “little uncertain,” or “positive.” Question 2 was to be answered from the perspective of a social host or bartender, not a police officer. None of the police officers had any formal training in the management or service of alcohol to intoxicated people, such as that offered by commercial seller/server training programs like Techniques of Alcohol Management (TAM) or Training for Intervention Procedures (TIPS). With respect to their answers, the police officers were fairly certain that the subjects had been drinking only in the target groups with the highest BAC (150–160 mg/dL). Officers also answered in the affirmative to question 2 (ie, that it was OK to serve the target subject another drink) the majority of the time in the low- and medium-BAC target groups but not in the high BAC target group. The percentage of officers answering affirmatively to this question was 55%, 75%, and 41% for the low, medium, and high target groups, respectively.

Multiple studies have examined the likelihood of on-premise (bars and restaurants) and off-premise (liquor stores, grocery stores, and convenience stores), as well as outdoor events like festivals, to sell alcohol to obviously intoxicated persons (typically, paid professional actors pretending to be drunk).<sup>19,37,60-62</sup> The results are fairly uniform in that the majority of the time the alcohol was sold or served to the individual. Additionally, it was noted that male servers/clerks who appeared younger than age 31 were more likely to make such sales and the sales were more likely to occur in off-premise establishments.<sup>19</sup>

In a typical study, the authors employed 19 actors who were specifically hired based on their ability to feign intoxication. All actors were male and ranged in age from 31 to 59 years, with a mean of 42 years.<sup>61</sup> The actors used a standardized script to attempt to purchase either a single vodka drink after asking what beers were available on tap (on-premise) or a 6-pack of beer (off-premise). Prior to entering the establishment, the actor received specific instructions to demonstrate multiple signs of intoxication, including disheveled hair and clothing, smelling of alcohol, lack of coordination, stumbling, fumbling with money, slurring words, repeating questions, appearing forgetful, and laughing inappropriately. If the actor was asked if he was driving, he responded “no” and if he was asked if he had been drinking, he responded, “I've had a few beers.” Attempts at alcohol purchase were made at 223 on-premise and 132 off-premise establishments.

Of the 355 attempts, actors were able to successfully make the alcohol purchase in 280 instances (79%). On-premise establishments served the actors 76% of the time, whereas off-premise establishments allowed the sale 83% of the time. Actors and a nondrinking observer also watched for clues that the server/clerk indicated an awareness or suspicion that the buyer was obviously intoxicated. Verbal indications, including asking the buyer to leave, suggesting a nonalcoholic drink, offering to call a cab, and so on, as well as nonverbal indications, such as staring or rolling of eyes, were recorded. A similar series of observations were made of security staff, other staff/bartenders/cashiers, and other customers. In 51% of the attempted purchases, there was an indication from the server of the recognition of the intoxication of the buyer. Even within the group that recognized signs of apparent intoxication, the alcohol was sold 61% of the time. When the server made no indication of the apparent intoxication, alcohol sales were completed 97% of the time. In 45% of purchase attempts, another staff member or customer made an indication that they believed the buyer was intoxicated. Still, alcohol purchases were completed in 66% of these cases. When no other staff member

or customer indicating an awareness of the buyer's behavior, the actor was served 89% of the time. Details of responsible beverage service (RBS) training for individual servers were not provided, though the authors did comment that such training is an important tool in preventing illegal alcohol sales, especially in younger servers. The authors concluded that sales of alcohol to obviously intoxicated individuals in some US communities is very high and recommended additional study to identify effective training and tools to mitigate such illegal sales.

## SUMMARY

- Impaired driving charges may be prosecuted based on BAC and application of a *per se* statute, as well as on observations of impairment such as standardized field sobriety tests (FSTs).
- Analytical techniques capable of accurately measuring alcohol concentration in a variety of biological matrices have been available for decades.
- The ability to accurately predict a BAC after drinking is poor, not only for the drinking individual but also for trained personnel such as police officers and medical professionals.
- Casual observers begin to reliably detect signs of alcohol intoxication in nontolerant persons at a BAC of 150 mg/dL.
- Clinically apparent signs of alcohol intoxication are difficult to detect in individuals with significant tolerance, increasing the probability of driving when BAC exceeds a *per se* value, or “overservice” in a bar or restaurant. Tolerance also seriously limits the applicability of tables correlating BAC with specific clinical effects in an individual case.
- The use of standardized FSTs is the norm for prosecution of impaired driving cases, though this battery of tests has also received significant legal and scientific criticism.
- Of the 3 routinely used FSTs, horizontal gaze nystagmus (HGN) has the best correlation with BAC.

### CASE

A newly hired train conductor sustains irreversible brain injury due to a large subdural hematoma from a train crash. Surgical intervention is deemed futile. After 4 days in the hospital, he is declared dead by neurologic criteria (ie, “brain dead”) and removed from life support. An autopsy confirms the brain injury. Postmortem toxicologic samples are obtained from the femoral vein and reveal oxycodone and oxycodone metabolites. As a toxicologist, you are asked to interpret the findings. How do you proceed?

### INTRODUCTION

Postmortem toxicology is the study of the identification, distribution, and quantification of xenobiotics after death. This information is used to account for physiologic effects of a xenobiotic at the time of death through its quantification and possible redistribution in the body at the time of autopsy. Several variables cause changes in xenobiotic concentrations during the interval between (1) the time of death and subsequent autopsy and (2) the storage interval between the time of sampling and the time of testing. Toxicologists and forensic experts are frequently asked to interpret postmortem xenobiotic concentrations and decide whether the reported values are meaningful and whether these xenobiotics were incidental or contributory to the cause of death.

The development of the field of forensic toxicology and the improvement of laboratory technology now permit more refined identification and quantification of xenobiotics. The interpretation of postmortem xenobiotic concentrations and their significance, however, continues to evolve.

This chapter reviews factors that affect xenobiotic concentrations identified at autopsy and discusses an approach for interpreting postmortem toxicologic reports as they relate to the cause and manner of death.<sup>39,40,43,45,52-54,61,86,105</sup>

### HISTORY AND ROLE OF MEDICAL EXAMINERS

The relationship between antemortem xenobiotic exposures and death has been a subject of investigation for centuries. In 12th-century England, an appointee of the royal court, eventually named the *coroner*, was designated to record and identify causes of death.<sup>78</sup> In suspicious circumstances, coroners investigated poisonings, but scientific methods were primitive, and conclusions regarding such deaths were conjecture at best.

By the mid-19th century, however, techniques for detecting certain xenobiotics in postmortem tissue were developed and focused generally on identifying heavy metals as a cause of death in homicides.<sup>46,78,83,102,108</sup> At that time, coroners were still elected or appointed individuals with little or no medical training. However, with better laboratory techniques and autopsies being performed by trained pathologists, the specialty of forensic medicine continued to develop. In Massachusetts during the late 19th century, these forensically trained pathologists, referred to as *medical examiners*, ultimately replaced the coroner system and were eventually empowered by the state to investigate and determine the cause and manner of death in certain types of unusual or suspicious cases and the medicolegal autopsies became their primary tools.<sup>78</sup> Cause and manner of death are defined below.

Currently, a death may prompt a medicolegal investigation if it serves the interests of the state through either the criminal justice or public health systems.<sup>89</sup> Information from the circumstances of the death are integrated with laboratory data and a medicolegal autopsy when human remains are available. In the United States, the requirements for performing a medicolegal autopsy vary substantially by jurisdiction.<sup>4,50</sup>

Some US jurisdictions use elected or appointed personnel with variable or no medical training to determine the cause and manner of death. These

are usually termed coroner systems. The coroner is usually not a physician but may have other qualifications. Other jurisdictions require that physicians or other medically trained personnel determine the cause and manner of death and perform a medicolegal autopsy if they deem it necessary. These providers are medical examiners, and their training requirements also vary by jurisdiction. The strictest and most robust regulations specify that autopsies are performed exclusively by forensic pathologists. These are physicians with board certification in forensic pathology. The specific training and performance standards of forensic pathologists are well described elsewhere.<sup>1,89</sup>

As of 2016 in the United States, death investigations are the responsibility of a coroner in 14 states, a medical examiner in 20 states, or some combination of coroner and medical examiner in the remainder.<sup>4</sup> For the purposes of this chapter, the person performing the medicolegal autopsy will be referred to broadly as the medical examiner.

The purpose of the death investigation is to determine the *cause* and *manner* of death. The *cause of death* is the etiologically specific pathophysiologic aberration that is ultimately responsible for death to occur (Table 140–1). For example, the presence of cyanide in the toxicologic evaluation is sufficient to establish cardiorespiratory arrest from cyanide poisoning. The *manner of death* is an explanation of how the death occurred, or the circumstances surrounding the terminal events. It broadly distinguishes natural from nonnatural (or violent) deaths. Nonnatural deaths, depending on the jurisdiction, can be divided into several categories (Table 140–2). With the identification of cyanide, the manner of death cannot be considered natural because a poisoning is a “chemically traumatic” (violent) event. The medical examiner must make the best determination of the manner of death based on the available evidence.<sup>108,115</sup> An unintentional exposure can be classified as an *accident* (a legal term for some unintentional nonnatural deaths), and intentional self-injury can be classified as a *suicide*. If the circumstances indicate an exposure due to the acts of another person, the manner of death can be classified as a *homicide*.

Determination of the manner of death has important consequences. Homicide necessitates involvement of law enforcement officials for further investigation. Cases deemed suicide not only impact survivors psychologically but also can nullify some life insurance payments. Conversely, a case deemed an “accident” can invoke a double-indemnity insurance clause. Assignment of financial responsibility for workplace deaths can be similarly affected when xenobiotics are identified in the postmortem specimens of involved workers.

Recognition of xenobiotic-related deaths also has significant public health consequences. The findings may identify fatal drug reactions, preventable errors, or rapidly fatal epidemics associated with illicit xenobiotic use or malicious intent activities. In cases of occupational and environmental xenobiotic-related fatalities, interventions can be implemented to prevent subsequent morbidity and mortality. In addition, the gross and microscopic autopsy findings can elucidate mechanisms of xenobiotic toxicity.

\*A legal term described in the text.

Postmortem toxicologic techniques can be used in other types of investigations as well. For example, if carboxyhemoglobin is identified in burned human remains from an airplane crash, a cabin fire before descent is more probable than deaths due to a fire on impact. This type of postmortem analysis is useful in the reconstruction of events leading to the crash.<sup>10,57,66,106</sup>

### THE TOXICOLOGIC INVESTIGATION

Ordinarily, toxicologic samples are collected as part of an autopsy. In the hospital, when a death is assumed to be from natural causes, the hospital pathologist can perform an autopsy with the consent of the family. In a medicolegal investigation, however, the medical examiner determines the need for an autopsy and has statutory authority to act on that determination independent of familial consent or wishes. A “complete autopsy” is one that “completely” answers the questions needed to determine cause and manner of death; and usually includes gross external and internal inspection of the body and organs and often includes microscopical analyses as well as tissue and fluid sampling for microbiologic and toxicologic testing. Occasionally, only fluid samples are obtained along with an external inspection of the body if a complete autopsy is either unnecessary or the family has valid legal or religious grounds for objecting to an internal examination.

The precise list of xenobiotics screened in postmortem samples varies greatly by jurisdiction and by individual preference of the medical examiner, and is often case specific. Investigations in large cities routinely screen for hundreds of illicit, therapeutic, and environmental xenobiotics. Occasionally, the suspicions of the medical examiner or death scene investigator warrant specific assays that are performed only upon special request.

The sampling of fluid and tissue can be obtained minutes to years after death. The *postmortem interval*, defined as the time between death and autopsy, is important, but many other factors will influence the extent of bodily decomposition. Some of these factors include environmental conditions such as ambient temperature, humidity, aerobic versus anaerobic surroundings, immersion in water,<sup>67</sup> type of local flora and fauna, and the body habitus and metabolic state immediately prior to death. Samples for testing can be collected from a body during advanced stages of decomposition, after exhumation from graves, or even after embalming.<sup>10,39,40,47,85</sup> Knowing the condition of the body at the time of sampling assists in interpreting the toxicologic findings. These postmortem changes are reviewed below.

### DECOMPOSITION AND POSTMORTEM BIOCHEMICAL CHANGES

The first stage of decomposition is autolysis, during which endogenous enzymes are released and normal mechanisms maintaining cellular integrity fail.<sup>60</sup> Chemicals move across compromised and leaky cellular membranes down relative concentration gradients. Glycolysis continues in the red blood cells until intracellular glucose is depleted and lactate is produced. Ultimately, intracellular ions and proteins are released into the blood, and tissue and blood acidemia develops leading to the biochemical changes described in [Table 140–3](#).<sup>108</sup>

The next stage of decomposition in most normal environments is putrefaction. This stage involves digestion of tissue by bacterial organisms, which typically colonize the bowel or respiratory system. Later, additional organisms can be introduced by insects or other external sources. As the

**TABLE 140–3** Postmortem Biochemical Changes Over the First 3 Days<sup>a</sup>

Increased	Decreased	Stable <sup>b</sup>	Variable
Amino acids	Cl <sup>-</sup>	BUN/Cr (vitreous)	Lipids
Ammonia	Glucose	Cholinesterases	T <sub>3</sub>

Epinephrine	pH	Proteins (serum)	
Aspartate aminotransferases	T <sub>4</sub>	Sulfates	
Insulin (especially right heart blood)			

<sup>a</sup>In refrigerated bodies. <sup>b</sup>Whole blood is typically utilized unless otherwise reported.

BUN = blood urea nitrogen; Cr = creatinine; T<sub>3</sub> = triiodothyronine; T<sub>4</sub> = thyroxine.

putrefactive process advances, the colors of the skin and organs change; epithelial blebs may form and separate from the underlying dermis; and gases accumulate, resulting in foul odors and bloating.<sup>108</sup>

If death occurs in a very warm, dry climate, such as a desert or comparably arid environment, the body can desiccate so rapidly that putrefactive changes do not occur. This results in mummification and produces a lightweight cadaver with a tight, dry skin enveloping a prominent bony skeleton.<sup>108</sup>

If the environment is very cold and devoid of oxygen, such as at great depths under water, putrefaction will be slowed. Anoxic decomposition of fatty tissues occurs, forming a white, cheesy material known as adipocere.

Another phase of decomposition, anthropophagia, occurs in unprotected environments where insects or large animals feed on the remains.<sup>108</sup>

Because most postmortem changes result from chemical reactions that are temperature dependent, increased temperatures will accelerate the process and cooler temperatures will retard it. In general, morgue refrigerators achieve low enough temperatures (40°F {4°C}) to prevent further gross decomposition and many of its associated postmortem changes.

Another means of altering natural decomposition is embalming, a process of chemically preserving tissues that can be performed in a variety of ways.<sup>48,49</sup> Typically, blood is drained through large vessel pumps, and embalming fluid is injected intravascularly to perfuse and preserve the face or other tissues. Intracavitary spaces can be injected with the preserving substances, and solid organs are sometimes removed. Some authorities regulate the contents of the embalming fluid specifically to avoid confounding postmortem analysis. Most embalming fluid in the United States consists of formaldehyde, sodium borate, sodium nitrate, glycerin, water, and colorants.

### SAMPLES USED FOR TOXICOLOGIC ANALYSIS

Unless the medical examiner has other suspicions about a death, only standard autopsy samples will be obtained from an otherwise intact body.<sup>26,39,40,55,62,90</sup> These typically include samples of blood, gastric contents, bile, urine, and occasionally solid organs such as the liver or brain. Less commonly, vitreous humor and/or cerebrospinal fluid is obtained for analysis ([Table 140–4](#)). Antemortem specimens, if available, can be used for evaluation and comparison. These specimen analyses are reviewed in greater detail below.

**TABLE 140–4** Sampling Sites<sup>18,23,27,39,53,100</sup>

Routine	Infrequent	Uncommon
Bile	Antemortem blood	Casket fluid
Blood	Cerebrospinal fluid	Extravasated fluid
Brain	Fat	Extravasated blood
Gastric contents	Hair	Insect larvae
Liver	Kidneys	Pupae casings
	Muscle, nails, skin	
	Vitreous humor	

## Blood

Postmortem cell lysis limits the concept of plasma concentrations, and “blood” concentrations are reported instead. Most commonly, a single site such as femoral or subclavian blood is sampled unless an unusual xenobiotic with nonuniform distribution is suspected of causing the death. In patients with a prolonged postmortem interval and in cases where intravascular blood is coagulated, right heart blood can serve as an alternative sample.

Other sources of blood are sometimes available. These frequently include antemortem samples often from time of hospital admission and occasionally extravasated blood, which is unlikely to undergo extensive metabolism. Intracranial clots, in particular, serve as useful comparative samples in patients with a prolonged survival period after exposure to a xenobiotic.<sup>68</sup>

In advanced states of decomposition, blood from the abdominal or thoracic cavities is less useful for some testing because it can be contaminated by bacteria or other substances that can affect xenobiotic metabolism, recovery, or analysis.

## Vitreous Humor

Because of the relatively avascular and acellular nature of the fluid, the vitreous humor is well protected from the early decompositional changes that typically occur in blood.<sup>18,21–24,27</sup> When bodies are immediately refrigerated, creatinine, blood urea nitrogen, and sodium can be reliably approximated from vitreous humor samples for up to 3 or 4 days. Potassium concentrations are less reliable because cell lysis causes intracellular release. When vitreous glucose is elevated, hyperglycemia at the time of death can be assumed. A low vitreous glucose concentration, however, is a less reliable indicator of the antemortem serum glucose concentration, because a low vitreous glucose concentration can be attributable to either antemortem hypoglycemia or postmortem glycolysis even in the relatively avascular vitreous.

The aqueous content of the vitreous is normally higher than that of blood and can affect the partitioning of certain water-soluble xenobiotics, such as ethanol.

## Urine

Urine may be available during the autopsy and can reveal renally eliminated xenobiotics or their metabolites. Because the bladder serves as a reservoir in which metabolism is unlikely to occur, the concentrations of xenobiotics obtained during the autopsy reflect antemortem urine concentrations. An isolated urine sample is of limited quantitative value but can be useful when compared with other sample sites.

## Gastric Contents

The contents of the stomach are measured and grossly inspected for color, odor, and the presence or absence of pill fragments, food particles, activated charcoal, and other foreign materials.<sup>105</sup> Typically, gastric concentrations of xenobiotics are reported as milligrams of substance per gram of total gastric contents. Xenobiotic-induced pylorospasm, diminished intestinal motility, or decreased splanchnic blood flow may all decrease gastric emptying and affect the quantitative values obtained from sampling different parts of the gastrointestinal tract. Pills and pill fragments from modified release drugs are sometimes identified on autopsy after oral overdose in some cases after surviving several days postingestion.<sup>75</sup>

## Solid Organs and Other Sources

Xenobiotic concentrations in solid organs, such as the liver and brain, are usually reported as milligrams of substance per kilogram of tissue. Other tissue samples, including hair and nails, are used for thiol-avid xenobiotics such as metals. Rarely, tracheal aspirates of gases can be analyzed to confirm inhalational exposures when circumstances warrant testing. Pleural fluid analysis of postmortem xenobiotics typically yields qualitative results in decomposed bodies because redistribution of xenobiotics from the stomach and intestines can occur.<sup>34,97</sup> Cerebrospinal fluid (CSF) is inconsistently collected at autopsy and is not relevant in most cases. The ratios of CSF to heart blood are described for a number of xenobiotics, but data are limited antemortem because of the lack of published information, cause of death, or time of last exposure.

## OTHER SAMPLING SOURCES

In an embalmed body, either the organs or tissues that remain relatively unembalmed, such as deep leg muscle,<sup>70</sup> or the embalming fluid itself can be used for analysis. When a body is disinterred, soil samples are usually obtained from above and below the coffin to validate identification of xenobiotics that leached into, or out from the body.<sup>85</sup>

On rare occasions, cremated remains, often referred to as *cremains*, are the only source of sampling available. Most battery-containing metallic implants, such as pacemakers, are removed before cremation to prevent explosions or environmental hazards.<sup>107</sup> Other metallic implants such as joint prostheses are removed in whole or in part after cremation depending on the particular alloy. Only dental remains, particulate matter, and occasionally calcified blood vessels are available for analysis.<sup>5,114</sup> In most cremations performed in the United States, the incineration process is followed by mechanical grinding to yield a fine particulate matter.<sup>114</sup> The ability to extract xenobiotics from cremains is markedly limited at best, and little published data are available on the subject. A technique to identify heavy metals such as lead from cremains was described, but is not routinely used.<sup>5,114</sup>

## ENTOMOTOXICOLOGY

A variety of anthropophagic insect species can demonstrate the presence of xenobiotics.<sup>2,44,64,65</sup> This process of analysis is termed *entomotoxicology*. In putrefied bodies or bodies that have undergone anthropophagy, fluids and even insect parts can be analyzed. Forensic entomologists collect samples of these insects from the remains. After considering the stage of insect life, environmental conditions, and the season, the approximate time of death can be extrapolated. The family of flies Calliphoridae, such as the common blow fly, is attracted to unprotected remains by a very fine scent that develops in the cadaver within hours of death. The adult fly lays eggs on mucosal surfaces or in open wounds. After the eggs hatch, the larvae feed on the decomposing tissue. Larval samples can then be examined for the presence of xenobiotics. To achieve accurate analysis, these samples must be preserved immediately after collection because living larvae can continue to metabolize certain xenobiotics. In the next phase of their life cycle, the larvae undergo pupation, secreting a substance that encloses them into pupal casings until they hatch as adults. These pupal casings are often found in the soil beneath the body or in the body cavities. Some xenobiotics are identified in the pupal casings long after the adult fly has emerged and flown away (Table 140–5).<sup>91</sup>

## INTERPRETATION OF POSTMORTEM TOXICOLOGY RESULTS

After fluid and tissue samples are collected and analyzed for the presence of xenobiotics, the process of interpreting these results begins. This complex task attempts to account for the clinical effects of a xenobiotic at the time of death by integrating medical history, autopsy, death-scene findings, and toxicologic reports. Multiple confounding variables can affect the final concentrations of xenobiotics from the time of death to the time of testing after the autopsy. Variables include the nature, metabolism, and distribution of the xenobiotic; the body habitus and state of health of the decedent prior to death; physical and environmental variables during the postmortem

interval; the techniques of sampling and analysis; and other variables of the autopsy (Tables 140–6 and 140–7).

**Variables Relating to the Xenobiotic**  
**Postmortem Redistribution**

The xenobiotic concentration in blood can be higher during the time of sampling at autopsy than at the actual time death occurred if significant postmortem redistribution occurs.<sup>56,88,113-120</sup> Redistribution typically occurs with xenobiotics that have large volumes of distribution and when postmortem changes result in release of intracellular xenobiotic into the extracellular compartment.<sup>94</sup> For example, amitriptyline can be released from tissue stores into the blood as autolysis progresses, resulting in a significantly higher blood concentration at the autopsy than at the actual time of death.

If postmortem redistribution is not considered, xenobiotic concentrations obtained during the autopsy can be misinterpreted as being supratherapeutic or even toxic, and the cause of death can be inappropriately attributed to this xenobiotic.

**Postmortem Metabolism**

Less commonly, xenobiotic concentration can decrease secondary to postmortem metabolism. For example, cocaine continues to be degraded after death by endogenous enzymes such as cholinesterases in the blood, which continue to function in postmortem tissue and in vitro. Unless blood is collected immediately after death and placed in tubes containing enzyme inhibitors such as sodium fluoride, the concentration of cocaine will decrease, and the analysis will not accurately reflect the concentration of the drug at the time of death.<sup>51,76,106,111</sup> All available information regarding postmortem redistribution or metabolism of a specific xenobiotic must be evaluated for the proper interpretation of the toxicologic results.

Strychnine	

**State of Absorption and Distribution**

Both in the living and deceased, the state of absorption, distribution, and other toxicokinetic principles affect the apparent concentration of a sampled xenobiotic. For a xenobiotic with minimal postmortem metabolism or redistribution, the phase of absorption is suggested by the relative quantity of the xenobiotic in different fluids and solid organs. For example, a high concentration of xenobiotic in the gastric contents, with progressively lower concentrations in the liver, blood, vitreous, and brain, suggests an early phase of absorption at the time of death. When a xenobiotic is orally administered and the tissue concentration is highest in the liver, the relationship suggests a postabsorption phase but a redistribution concentration. A concentration found to be highest in the urine suggests that the xenobiotic was in an elimination phase at the time of death. Although this approach has limitations, it is important for correlating the state of absorption and the expected clinical course of the xenobiotic. Unfortunately, multiple samples are not always available at the time of autopsy or the interpretation of reports, and opportunities for subsequent sampling are often limited.

**Xenobiotic Properties**

Xenobiotic chemical composition affects partitioning into fat or water compartments and total body burden is poorly captured when sampling the blood compartment. The significance of this and partitioning of blood to serum is uncertain.<sup>74</sup> Xenobiotic stability refers to the ability of a xenobiotic to maintain its molecular integrity despite postmortem changes such as decomposition of the body, adverse storage conditions, or the lack of preservatives.<sup>7,15,17,58,59,64,74,100,109,116-119</sup>

Postmortem xenobiotic stability was assessed in homogenized liver tissue infused with various concentrations of xenobiotics.<sup>109</sup> The samples were allowed to putrefy outdoors, and sequential sampling of xenobiotic concentrations was performed. The xenobiotics that decreased in concentration as putrefaction progressed were considered labile, and samples with a constant concentration were considered stable. The authors proposed that the

chemical characteristics of a xenobiotic determine its stability. For example, labile xenobiotics share the molecular configuration of an oxygen–nitrogen bond, thiono groups, or aminophenols. Conversely, chemical structures that enhance stability include single-bonded sulfur groups, carbon–oxygen and carbon–nitrogen bonds, and sulfur–oxygen and hydrogen–nitrogen bonds. Although not explicitly studied in otherwise intact but putrefying bodies, logically, a less stable xenobiotic can be recovered in a lower concentration than the actual concentration at the time of death. This must be considered when information regarding stability is available and the body of a decedent is in an advanced stage of decomposition.

### Xenobiotic Chemical Reactions

An artifact can result from a chemical reaction with a xenobiotic added during the postmortem interval, such as embalming fluid.<sup>41</sup> In a study of xenobiotic-spiked blood and formalin in test tubes, amitriptyline was formed by the methylation of nortriptyline.<sup>29,119</sup> Identification of amitriptyline, which was not present at the time of death, could confuse the interpretation of toxicologic analyses.

### Expected Clinical Effects of the Xenobiotic

For a fatality to be attributed to a xenobiotic, the expected clinical course from the exposure should be consistent with the autopsy findings. For example, what are the implications of a person found dead minutes after ingesting pills, if a large concentration of acetaminophen (APAP) is identified in both the gastric contents and blood but not in other tissues at autopsy?<sup>99</sup> Although suicidal intent can be supported by this finding, the onset of death within minutes is inconsistent with a fatality due to an APAP overdose. Thus, another cause of death must be sought. Interpretation of postmortem toxicology must also incorporate clinically relevant consequences of xenobiotic interactions. For example, the combined ingestion of phenobarbital and ethanol can cause fatal respiratory depression. Although neither are necessarily fatal alone, their additive effects must be acknowledged during toxicologic interpretation.

## Variables Related to the Decedent

### Comorbid Conditions

The clinical response to a xenobiotic can be affected by acquired and inherited physiologic conditions that are not always identified or identifiable on autopsy. A thorough medical history is important and can assist in interpreting the clinical effects of a xenobiotic exposure. Similarly, certain clinical conditions can produce substances that interfere with postmortem laboratory assays. For example, an individual with a critical illness can produce digoxinlike immunoreactive substances (DLIS), which may cross-react with the postmortem digoxin assay.<sup>8</sup> Without knowledge of DLIS production, the results can confound toxicologic analysis (Chap. 62).

### Tolerance

Tolerance is an acquired condition in which increasingly higher xenobiotic concentrations are required to produce a given clinical effect. It is an important consideration for deaths in the presence of opioids, ethanol, and sedative–hypnotics. For example, respiratory depression and death from methadone is easily diagnosed in an opioid-naïve individual with a history of methadone exposure and methadone-positive postmortem samples. However, the same methadone concentrations in a patient on chronic methadone maintenance therapy will not produce the same outcome. Unfortunately, no autopsy markers are available to indicate tolerance, and no biochemical or histologic markers are available during autopsy that can be used to predict clinically dangerous xenobiotic concentrations in a tolerant individual.<sup>30</sup> Complex postmortem assays analyzing opioid receptors are not routinely used.<sup>38</sup> Postmortem assessment of tolerance ultimately depends on knowledge of the patient, pharmacokinetics of the xenobiotic, and the best judgment of the investigator.

### Pharmacogenetics

There is genetic variability in the expression of certain metabolic enzymes. For example, pharmacogenetic differences in metabolic enzymes such as

CYP2D6 can affect the metabolism of codeine to morphine. Individuals with duplicate alleles for CYP2D6 may be ultra-rapid metabolizers, rendering them susceptible to morphine toxicity despite generally acceptable dosing of the parent compound codeine. Deaths in young children are reported from bioaccumulation of morphine. In such cases, postmortem blood analysis can reveal an elevated concentration of morphine, the codeine metabolite, and raise suspicion for a malicious overdose. Postmortem genotyping can provide an alternate explanation. Such distinctions are not routinely identifiable on autopsy.<sup>19,31,32</sup> Postmortem evaluation of frozen tissue or blood can also identify genetic predisposition of long-QT syndromes that can be consequential in both the diagnosis of sudden death that can be considered along with toxicologic data, but such testing is not routine across jurisdictions.<sup>71</sup>

## Variables Relating to the Autopsy

### State of Decomposition

In bodies with advanced stages of decomposition, xenobiotics diffuse from depot compartments such as the stomach urinary or gall bladders into adjacent tissues and blood vessels and secondarily affect sample concentrations near sites of origin of diffusion.<sup>25,39,68,81,82,93-95</sup>

During putrefaction, bacteria cause fermentation of endogenous carbohydrates, resulting in ethanol formation. In decedents without gross evidence of putrefaction, especially those in cool, dry environments, endogenous ethanol production is minimal.<sup>24,30,84</sup> With a longer postmortem interval or in an environment that is more conducive to ethanol production, the distinction between endogenous and exogenous sources of ethanol becomes more difficult. Sampling from multiple sites is often useful in making the distinction, but not definitive.<sup>110</sup> The pattern of ethanol detected in the blood and absent from the urine and vitreous samples is more suggestive of postmortem ethanol production. However, postmortem ethanol production may occur in the vitreous in decedents with hyperglycemia at the time of death and significant putrefaction at autopsy. A comprehensive review of interpreting postmortem ethanol concentrations is available elsewhere.<sup>68,84</sup>

### Handling of the Body or Samples

Inappropriate handling of the body can result in artifacts.<sup>99,101</sup> In one reported case, methanol was detected in the vitreous humor of a decedent after embalming.<sup>14</sup> The methanol was subsequently traced to a spray cleanser that likely settled on the surface of open eyes during washing of the body.

In addition, inappropriate handling of samples can affect xenobiotic concentrations. In one study, autopsy blood was obtained from a diabetic man who died of bronchopneumonia. The samples were stored at 40°F (4°C) and tested at 2 and 5 days postmortem. The blood ethanol increased from 0.4 to 3.5 g/L due to an inadequate addition of fluoride preservative to the samples. The combination of inadequate preservation, hyperglycemia (vitreous glucose of 996 mg/dL), and bacterial sepsis created an ideal environment for ethanol production by fermentation.<sup>68</sup>

In the United States, heavy metals are currently banned for use in embalming because they can contaminate subsequent evaluation for metal poisoning. Formalin can also affect stability or quantitative identification of some xenobiotics. When necessary, an analysis of the embalming fluid used in the body or soil samples from around disinterred bodies may facilitate the toxicologic investigation.<sup>21,36,116,118,119</sup>

### Autopsy Findings

In many xenobiotic-related deaths, the anatomic findings are nonspecific,<sup>116</sup> but in some cases, the autopsy does reveal confirmatory or supportive findings. A large quantity of undigested pills in the stomach is consistent with an intentional overdose, and suicide should be considered as the manner of death. Centrilobular hepatic necrosis can be found in decedents with a history of acetaminophen overdose. The autopsy can also reveal other findings such as coronary artery narrowing, chronic hypertensive changes, renal abnormalities, or a clinically silent myocardial injury. Such information is useful to assess the potential effects of a xenobiotic in a patient with previously undiagnosed conditions. In other cases, the absence of a chronic condition can be strongly suggestive of a xenobiotic-related death. For example,

a decedent with an autopsy finding of aortic dissection in the absence of chronic hypertensive findings or other predisposing conditions suggests a xenobiotic-induced hypertensive crisis as can occur from the use of cocaine or other sympathomimetics.

### Artifacts Related to Sampling Sites

Site-specific differences in postmortem xenobiotic blood concentrations are common.<sup>37</sup> For example, blood obtained from femoral vessels can have low glucose concentrations because of postmortem glycolysis, but the blood glucose concentration removed from the right heart chambers can be high as a result of perimortem release of liver glycogen stores. Concentrations between heart, femoral, and subclavian samples vary significantly.<sup>80</sup> As noted above, hyperglycemic conditions are more reliably assessed from sampling the vitreous humor because it is an acellular fluid and in an environment that is relatively protected from diffusion artifacts in the early postmortem interval. An elevated vitreous glucose concentration strongly suggests antemortem hyperglycemia. The individual interpreting the toxicologic report must know the exact site from which the sample was taken.<sup>22,62</sup>

Ideally, samples from more than one site would be available for comparison; fortunately, multiple site sampling is now a standard procedure required for accreditation. In decedents with minimal putrefaction or decomposition, comparison of concentrations from different sites can reveal important information regarding the extent of xenobiotic absorption at the time of death and acute versus chronic exposure.<sup>11-13,28,32,52-54,77,87,90,93,96-98,103,110,112</sup>

### Other Considerations

Published therapeutic, toxic, and fatal xenobiotic concentrations from autopsy samples as well as postmortem redistribution data are available to aid in the interpretation of these specimens.<sup>6,73</sup> However, the conditions associated with reported concentrations (“average” range) do not necessarily permit comparisons with the concentrations of the particular case under investigation. Thus, these resources although valuable, should not be accepted as absolute values that specifically define either toxic or therapeutic concentrations. Similarly, formulas available for assessing xenobiotic doses or concentrations in the living are not usually applicable when analyzing postmortem samples.

### Other Limitations

Although there are generalized standards of practice in forensic investigations, specimen collection and laboratory methodologies may vary.<sup>3,6</sup> Some xenobiotic concentrations may be falsely elevated or depressed depending on the chosen methodology.<sup>33,77</sup> Descriptions of specific toxicology laboratory techniques are beyond the scope of this chapter, but these variables must also be considered in the interpretations of results. Other limitations may include a lack of information relating to the circumstances of death, or the possible compromise in specimen handling to maintain proper chain-of-custody for evidence that is often of paramount importance in medicolegal autopsies.<sup>39,40</sup>

### Case Discussion

Interpreting the oxycodone concentrations obtained from postmortem femoral samples requires information about the medical and behavioral health of the decedent before death, medication history, interviews with family, coworkers, scene investigation, and thorough review of all medications administered during the hospital stay. A subsequent evaluation revealed a previously undisclosed history of opioid misuse syndrome and recent discharge from an opioid rehabilitation program. A review of hospital records revealed that no oxycodone was administered in the hospital. The scene investigation and evaluation of the train and rails revealed no clear mechanical failure. The concern is for illicit oxycodone use. Samples of blood from the subdural hematoma revealed high concentrations of oxycodone. Although there may be postmortem drug redistribution, extravasated blood is generally protected from these changes and likely more closely related to antemortem concentrations. Ideally, a sample of blood from admission or recovered from the blood bank should be sent for forensic toxicologic studies. A family member subsequently came forward, having found a bottle of pills with

the markings of oxycodone in the decedent’s home. The family member remarked that he seemed unusually drowsy prior to leaving for work and they were suspicious for relapsed opioid misuse. A coworker confirmed that he seemed lethargic and asked if he was “okay.” An analysis of the tablets revealed that the pills were oxycodone. The cause of death was deemed traumatic brain injury due to blunt force injury while intoxicated by oxycodone. The manner of death was deemed an accident, the legal term for a nonnatural, unintentional death.

### SUMMARY

- Accurate interpretation of postmortem toxicology reports requires an understanding of the potential biochemical changes that affect these samples.
- It is exceptionally difficult to make an absolute correlation between the xenobiotic concentrations of postmortem blood and tissue to the concentrations in comparable samples from the actual time of death.
- Postmortem toxicology is an evolving discipline that permits identification of the most likely cause and manner of xenobiotic-related deaths.
- Progress in this field will depend on the continued collaboration between the treating physicians, medical and forensic toxicologists, and medical examiners.

# ORGAN PROCUREMENT FROM POISONED PATIENTS

Rama B. Rao

Xenobiotics cause brain death as a result of the unique vulnerabilities of the central nervous system. With supportive care, however, many such patients are suitable candidates for organ donation.<sup>11,12,38,47</sup>

Early identification of potential donors is critical because the viability of transplantable tissue diminishes as duration from the time of brain or cardiac death prolongs.<sup>30</sup>

Donor identification by clinicians is one barrier. Among a group of toxicologists given scenarios of brain death from poisoning due to cocaine or carbon monoxide, toxicologists had variable perceptions of donor and organ suitability.<sup>45</sup> Such inconsistency can affect the potential pool of donors in patients with clinical signs of brain death.

Some xenobiotic poisonings can confound clinical assessments of brain stem function and mimic brain death (Table SC12-1). Published brain death protocols require exclusion of poisoning,<sup>12,43,49</sup> but limited guidance is provided.<sup>44</sup> Obtaining and interpreting xenobiotic concentrations is complex and, in many circumstances, not feasible. Few xenobiotics have timely and readily available assays. This is further complicated when the exposure history is unknown. Determining brain death from novel psychoactive substances (NPS) and illicit synthetic opioids is especially challenging. Routine testing for many NPS is often unavailable or uninterpretable, further complicating decisions regarding donor suitability.

Other methods of establishing brain death are utilized such as cerebral blood flow. The effects of xenobiotics on these studies are not well described.<sup>34</sup>

Once brain death is established, organ procurement personnel assist in obtaining familial consent, deciding which organs are most suitable for transplant, and maximizing physiological support and perfusion until organ procurement occurs.<sup>47</sup> The protocols following controlled or uncontrolled donation after cardiac arrest are socially complicated and practiced extensively in Europe.<sup>42</sup>

Successful transplantation of organs is reported from poisoned donors associated with a variety of xenobiotics (Tables SC12-2 and SC12-3).<sup>2,3,6,8,11,12,18,26,29,36,38-41,46</sup> Although some xenobiotics are highly toxic, such as cyanide and carbon monoxide (CO), transfer of clinical poisoning to the organ recipient is not reported. This is likely caused by several factors, including xenobiotic metabolism, tissue redistribution or binding prior to procurement, as well as the means of handling organs during the transplantation process. For example, some xenobiotic clearance occurs

in the myocardium during organ rinsing and cardiopulmonary bypass.<sup>35</sup> Furthermore, individual organs do not uniformly manifest toxicity following specific xenobiotic insults. For example, the heart of a CO-poisoned donor was examined after a transplantation failed for technical reasons. The myocardium did not demonstrate histologic signs of CO poisoning.<sup>41</sup> A comprehensive review with organ-specific procurement recommendations post-CO poisoning is presented elsewhere.<sup>4</sup>

Probably more critical to transplantation success is adequate tissue perfusion and well-maintained cellular morphology. For example, patients suffering brain death from acetaminophen poisoning are not suitable liver donors given the hepatotoxicity. Alternatively, xenobiotics considered toxic to organ function by impairing enzymes resulted in successful transplantation if the cellular structure is otherwise maintained. For example, a death from cardioactive steroid poisoning did not preclude successful heart transplantation even when the donor had a bradydysrhythmia, an elevated serum digoxin concentration, and required cardiopulmonary resuscitation.<sup>41</sup> Similarly, the liver of a patient poisoned with brodifacoum was transplanted after administration of fresh-frozen plasma and vitamin K<sub>1</sub>. The recipient's international normalized ratio (INR) post-transplant was 2 and corrected rapidly with supportive care. Recipient concentrations of brodifacoum were not reported and not clearly causative of the elevated INR.<sup>35</sup> In both examples, the target of toxicity was enzymatic and the tissue morphology was otherwise minimally affected. Organs from a patient who suffered hypoxic brain death after malathion poisoning were procured and successfully transplanted 2 weeks after the exposure, at which time no further evidence

**TABLE SC12-2** Organs Transplanted After Donor Poisonings

Organ	Xenobiotics Identified in Donors
Cornea <sup>a,2,27,29,30,35</sup>	Brodifacoum, cyanide
Heart <sup>9,16,29,32</sup>	Acetaminophen, β-adrenergic antagonists, alkylphosphate, benzodiazepines, brodifacoum, carbamazepine, carbon monoxide, chlormethiazole, cyanide, digitalis, digoxin, ethanol, glibenclamide, insulin, meprobamate, methanol, propoxyphene, thiocyanate
Kidney <sup>a,3,5,7,12,29,30</sup>	Acetaminophen, brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, insulin, malathion, methanol, cyclic antidepressants
Liver <sup>5,7,8,12,16</sup>	Brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, insulin, malathion, methanol, methaqualone, cyclic antidepressants
Lung <sup>6,8,16,29,31,35</sup>	Brodifacoum, carbon monoxide, methanol
Pancreas <sup>7,8,12,29</sup>	Acetaminophen, brodifacoum, carbon monoxide, <i>Conium maculatum</i> , cyanide, ethylene glycol, methanol, cyclic antidepressants
Skin <sup>8,31</sup>	Cyanide, methanol

<sup>a</sup>Can be cadaveric procurement.

**TABLE SC12-3 Xenobiotic-Related Deaths With Successful Organ Donation**

β-Adrenergic antagonists	Ethanol
Alkylphosphate	Ethylene glycol
Barbiturates	Glibenclamide
Benzodiazepines	Ibuprofen
Brodifacoum	Insulin
Carbamazepine	Malathion
Carbon monoxide	Methaqualone
Cardioactive steroids	Meprobamate
Chlormethiazole	Methanol
<i>Conium maculatum</i>	Nicotine
Cyanide	Opioids
Cyclic antidepressants	Propoxyphene

of acute cholinergic toxicity was present.<sup>6</sup> Most transplant failures from poisoned donors are due to rejection, sepsis, or technical reasons. The one-year survival in recipients from poisoned donors approximates that from nonpoisoned donors. One series reported at 75% survival.<sup>15</sup> In another review, 5-year survival rates were between 33% and 100%, with heart transplant recipients the lowest.<sup>17</sup>

In the United States, the waitlist for organs exceeds 100,000.<sup>10</sup> Since 2003, the percentage of organ donors due to drug overdose increased 350%, largely due to the opioid epidemic.<sup>10</sup> Despite concerns about infectious disease transmission from these donors, the risk of dying while on the waitlist is substantially higher. Finding consensus on the ethics of procuring organs from this vulnerable population is challenging.

Ideally, a comprehensive international registry of transplants from poisoned donors will be established to improve understanding of transplants from such patients. Patients who suffer brain death from poisoning are potentially suitable donors when cellular infrastructure is preserved.<sup>22,24-26,28,38,47</sup> Consideration for organ procurement should not be defined or limited by the xenobiotic.

## SUMMARY

- Organ procurement from poisoned donors often reaches success rates similar to nonpoisoned donors when carefully selected.
- Clinically significant xenobiotic concentrations are not reported in organ recipients.
- Adequate tissue perfusion is important for the viability of a transplanted organ, regardless of the primary toxicologic insult.

## Normal Vital Signs by Age<sup>a</sup>

Age	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Pulse (beats/min)	Respirations (breaths/min) <sup>b</sup>
Adult	120	80	50–90	16–24
16 years	120	< 80	80	16–30
12 years	119	76	85	16–30
10 years	115	74	90	16–30
6 years	107	69	100	20–30
4 years	104	65	110	20–30
2 years	102	58	120	25–30
1 year	100	55	120	25–30
6 months	90	55	120	30
4 months	90	50	145	30–35
2 months	85	50	145	30–35
Newborn	65	50	145	35–40

<sup>a</sup>The normal rectal temperature is defined as 96.8° to 100.4°F (35°–38°C) for all ages. For children ≤ 1 year, these values are the mean values for the 50th percentile. For children > 1 year, these values represent the 90th percentile at a specific age for the 50th percentile of weight in that age group. <sup>b</sup>These respiration values were determined in the emergency department and are likely environment and situation dependent.

## Common Equations

$^{\circ}\text{C} = (^{\circ}\text{F} - 32) \times 5/9$ $^{\circ}\text{F} = (^{\circ}\text{C} \times 9/5) + 32$	$\text{lb} = \text{kg} \times 2.204$ $\text{kg} = \text{lb} \times 0.454$	$\text{Anion Gap (mEq/L)} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$	$\text{Calculated Osmolarity (mOsm/L)} = 2[\text{Na}^+] + \frac{[\text{BUN}]}{2.8} + \frac{[\text{Glucose}]}{18} + \frac{[\text{EtOH}]}{4.6}$	$\text{SI Units from Conventional}$ $\text{mmol} = \text{mg} \div \text{MW}$ $\text{mEq} = \text{mmol} \times \text{valence}$
$C_0 = \frac{S \times F \times \text{Dose}}{\{V_d (\text{L/kg}) \times \text{Wt} (\text{kg})\}}$	$t_{1/2} = \frac{0.693}{K_e}$	$\text{where } K_e = \frac{(\ln C_1 - \ln C_2)}{t_1 - t_2} = \frac{\text{Cl}}{V_d}$		$\text{A-a Gradient (on room air)} = 150 - \text{PO}_2 - (1.25 \times \text{PCO}_2)$
$\text{Body Mass Index (BMI) (kg/m}^2\text{)} = \frac{\text{Wt (lbs)} \times 703}{\text{Ht (in)}^2} \text{ or } \frac{\text{Wt (kg)}}{\text{Ht (m)}^2}$	$\text{Body Surface Area (m}^2\text{)} = \sqrt{\frac{\text{Ht (in)} \times \text{Wt (lb)}}{3131}} \text{ or } \sqrt{\frac{\text{Ht (cm)} \times \text{Wt (kg)}}{3600}}$		$\text{Creatinine Clearance (mL/min)} = \left( \frac{(140 - \text{age}) \times \text{Ideal Body Wt (kg)}}{72 \times [\text{Cr}]_{\text{serum}}} \right) \times (0.85 \text{ for women})$	

## Toxic Syndromes

Group	Vital Signs				Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
	BP	P	R	T					
Antimuscarinics	–/↑	↑	±	↑	Delirium	↑	↓	↓	Dry mucous membranes, skin flush, urinary retention
Cholinergics (nicotinic and muscarinic)	±	±	±	–	Normal to depressed	±	↑	↑	Salivation, lacrimation, urination, diarrhea, bronchorrhea, fasciculations, paralysis
Ethanol or sedative–hypnotics	↓	↓	↓	–/↓	Depressed	±	↓	–	Hyporeflexia, ataxia, nystagmus
Opioids	↓	↓	↓	↓	Depressed	↓	↓	–	Hyporeflexia
Serotonin toxicity	↑	↑	–/↑	–/↑	Normal to agitated delirium	–/↑	↑	↑	Clonus, tremor, seizures
Sympathomimetics	↑	↑	↑	↑	Agitated, disoriented, hallucinations	↑	–/↑	↑	Tremor, seizures Diaphoresis
Withdrawal from ethanol or sedative–hypnotics	↑	↑	↑	↑	Agitated, disoriented, hallucinations	↑	↑	↑	Tremor, seizures Diaphoresis
Withdrawal from opioids (abstinence related; antagonist precipitated withdrawal may mimic sympathomimetics)	–/↑	–/↑	–	–	Normal, anxious	↑	↑	↑	Vomiting, rhinorrhea, piloerection, diarrhea, yawning

– = change unlikely; ↑ = increase; ↓ = decrease; ± = variable; BP = blood pressure; P = pulse; R = respirations; T = temperature.

**Selected Emergency Antidotes With Common Initial Doses<sup>a</sup>**

<i>Antidote</i>	<i>Indication and Dose</i>	<i>Page</i>
N-Acetylcysteine	<b>Acetaminophen:</b> <i>Adults IV:</i> 150 mg/kg in 200 mL D <sub>5</sub> W infused over 60 min followed by 50 mg/kg in 500 mL of D <sub>5</sub> W over 4 h; then 100 mg/kg in 1,000 mL D <sub>5</sub> W over 16 h. <i>Oral:</i> 140 mg/kg followed by 70 mg/kg every 4 h for 17 doses. <b>NOTE:</b> Special IV dilution required for children: www.acetadote.com/dosecalc.php.	492
Atropine	<b>Cholinesterase inhibitors:</b> <i>Adults:</i> 1–2 mg (mild) or 3–5 mg (severe) IV, doubled every 3–5 min until bronchorrhea resolves. <i>Children:</i> 20 mcg/kg up to adult dose IV, doubled as for adults. Also for other cholinergics in similar dosing.	1503
L-Carnitine	<b>Valproic acid–induced hyperammonemia or valproic acid–induced elevated AST/ALT:</b> <i>Clinically ill:</i> 100 mg/kg (up to 6 g) infused IV over 30 min, followed by 15 mg/kg infused over 30 min every 6 h. <i>Clinically well:</i> 100 mg/kg/day given orally in divided dose every 8 h up to 3 g/day.	732
Deferoxamine	<b>Iron:</b> Begin continuous IV infusion at 5 mg/kg/h; titrate to 15 mg/kg/h as tolerated with a total dose of 6–8 g/for no more than 24 h	676
Digoxin-specific antibody fragments (Fab)	<b>Digoxin:</b> Known concentration: # of vials = Weight (kg) × Concentration (ng/mL)/100 rounded up to nearest vial. Empiric dosing: Acute: 10–20 vials. Chronic: <i>Adults:</i> 3–6 vials; <i>Children:</i> 1–2 vials. Usually given as IV infusion over 30 min. An IV bolus is acceptable for cardiac arrest. <b>NOTE:</b> For nondigoxin cardioactive steroids, use empiric dose.	977
Dimercaprol (BAL)	<b>Lead encephalopathy:</b> 75 mg/m <sup>2</sup> (–4 mg/kg) deep IM every 4 h. First dose to precede edetate calcium disodium (CaNa <sub>2</sub> EDTA) by 4 h. Contraindicated if peanut allergy.	1251
Edetate calcium disodium (CaNa <sub>2</sub> EDTA)	<b>Lead encephalopathy:</b> 1500 mg/m <sup>2</sup> /day (~50–75 mg/kg/day) as a continuous IV infusion (≤0.5% solution); maximum dose, 3 g/day; reduce dose if impaired kidney function. <b>NOTE:</b> Dimercaprol should be administered 4 h before starting this dose.	1315
Fomepizole	<b>Methanol or ethylene glycol:</b> 15 mg/kg diluted in 100 mL 0.9% NaCl or D <sub>5</sub> W infused IV over 30 min; after 12 h, give next 4 doses at 10 mg/kg every 12 h; additional doses at 15 mg/kg every 12 h if needed. Adjust dose during hemodialysis.	1435
Glucagon	<b>β-Adrenergic antagonists or calcium channel blockers:</b> IV infusion over 3–10 min. <i>Adults and Children:</i> 50 mcg/kg. Repeat in 10 min for 1–2 doses as needed. Dose up to 10 mg are reasonable in an adult. Follow with a continuous infusion at 2–10 mg/h based on response. Emesis should be expected with higher doses and rates of administration.	941
Hydroxocobalamin	<b>Cyanide:</b> <i>Adults:</i> 5 g reconstituted with 200 mL 0.9% NaCl (invert for 60 sec) and infuse IV over 15 min. <i>Children:</i> 70 mg/kg up to 5 g. Repeat second dose as needed.	1694
Insulin (High-dose insulin [HDI])	<b>Calcium channel blockers or β-adrenergic antagonists:</b> 1 unit/kg IV bolus regular human insulin. Follow with infusion of 1 unit/kg/h. Use 10 units/mL insulin concentration. Titrate to 2 units/kg/h if no improvement in 15 min and titrate up to 10 units/kg/h as needed. If glucose <300 mg/dL, give 0.5 g/kg D <sub>50</sub> W bolus. Start 0.5 g/kg/h dextrose infusion. If glucose >300 mg/dL, hold glucose. Monitor glucose every 15–30 min until stable; then every 1–2 h. Maintain glucose 100–250 mg/dL. Monitor K <sup>+</sup> frequently to maintain K <sup>+</sup> in the “mildly hypokalemic” range (2.8–3.2 mEq/L).	953
Leucovorin (folinic acid)	<b>Methotrexate:</b> 100 mg/m <sup>2</sup> infused IV over 15–30 min every 3–6 h for several days or until serum methotrexate concentration <0.01 × 10 <sup>-6</sup> mol/L in the absence of bone marrow toxicity.	775
Lipid emulsion	<b>Cardiac arrest from lipid soluble xenobiotic (CCB, CA, local anesthetics):</b> Lipid emulsion 20% 1.5 mL/kg IV over 1 min. Follow with infusion at a rate of 0.25 mL/kg/min (15 mL/kg/h) over 30–60 min while continuing chest compressions. Repeat bolus for severe persistent symptoms.	1004
Methylene blue	<b>Methemoglobinemia:</b> 1 mg/kg (0.1 mL/kg) of 1% methylene blue IV over 5 min followed by a 30-mL fluid flush of 0.9% sodium chloride.	1713
Naloxone	<b>Opioid-induced respiratory depression:</b> <i>Adults:</i> 40–50 mcg (0.04–0.05 mg) IV titrated upward to reversal. Avoid opioid withdrawal and provide manual ventilation. <i>Children:</i> not receiving chronic opioids 0.1 mg/kg IV titrated as for adults.	538
Nitrites and sodium thiosulfate	<b>Cyanide:</b> <i>Adults:</i> (1) Sodium nitrite: 300 mg (10 mL of a 3% concentration) infused IV over 2–5 min. (2) Sodium thiosulfate: 12.5 g (50 mL of a 25% solution) infused IV over 10–30 min or as a bolus. <i>Children:</i> (1) Sodium nitrite: 6–8 mL/m <sup>2</sup> (0.2 mL/kg) of a 3% conc (maximum, 300 mg) infused IV over 2–5 min. (2) Sodium thiosulfate: 7 g/m <sup>2</sup> (0.5 g/kg) (maximum, 12.5 g) infused over 10–30 min or as a bolus. <b>NOTE:</b> In both adults and children, avoid sodium nitrite when carboxyhemoglobin is expected to be elevated.	1698
Octreotide	<b>Sulfonylurea-induced hypoglycemia:</b> <i>Adults:</i> 50 mcg SC every 6 h. <i>Children:</i> 1.25 mcg/kg (maximum, 50 mcg) SC every 6 h.	713
Physostigmine	<b>Anticholinergic syndrome:</b> IV infusion over 5 min. <i>Adults:</i> 1–2 mg. <i>Children:</i> 20 mcg/kg (maximum, 0.5 mg). Repeat the dose in 5–10 min if an adequate response is not achieved and cholinergic effects are not noted.	755
Pralidoxime	<b>Cholinesterase inhibitors:</b> <i>Adults:</i> 30 mg/kg (up to 2 g) over 15–30 min followed by a maintenance infusion of 8–10 mg/kg/h (up to 650 mg/h) for sickest patients. <i>Children:</i> 30 mg/kg (maximum, 2 g) infused IV over 15–30 min and then 10–20 mg/kg/h (maximum, 650 mg/h).	1508
Pyridoxine	<b>Isoniazid:</b> 1 g for each gram of isoniazid up to 70 mg/kg (maximum, 5 g) infused IV at 0.5 g/min until seizures stop, with the remainder infused IV over 4–6 h. Empiric dose: <i>Adults:</i> 5 g. <i>Children:</i> 70 mg/kg (maximum, 5 g) at specific dosing rate. Repeat dose 1–2 times if needed for the treatment of seizures or persistent depressed level of consciousness. Comparable therapy should be used following gyromitrin poisoning.	862
Succimer	<b>Lead poisoning:</b> <i>Adults and Children &gt;5 years old:</i> 10 mg/kg orally every 8 h for 5 days followed by 10 mg/kg orally every 12 h for 14 days. <i>Children &lt;5 years old:</i> 350 mg/m <sup>2</sup> orally as for adults.	1309

<sup>a</sup>Consult pages listed for complete information regarding dose, route, duration of therapy, adverse effects, safety issues, contraindications, and other considerations. For up-to-date information, contact your regional poison center at 800-222-1222 or a medical toxicologist.

CCB = calcium channel blocker; D<sub>5</sub>W = dextrose 5% in water; D<sub>50</sub>W = dextrose 50% in water; IM = intramuscular; IV = intravenous; SC = subcutaneous; TCA, tricyclic antidepressant.

### Common Toxicology Laboratory Concentrations (serum unless otherwise noted)

	Conventional	SI		Conventional	SI
Acetaminophen*	10–30 mcg/mL	66–199 µmol/L	Lithium*	0.6–1.2 mEq/L	0.6–1.2 mmol/L
Arsenic (blood)	<5 mcg/L	<0.0665 µmol/L	Mercury (blood)	<10 mcg/L	<50 nmol/L
Arsenic (urine)	<50 mcg/L	<0.665 µmol/L	Mercury (urine)	<20 mcg/L	<100 nmol/L
Caffeine	1–10 mcg/mL	5.2–51 µmol/L	Methanol <sup>c</sup>	<25 mg/dL	<7.8 mmol/L
Carbamazepine	4–12 mg/L	17–51 µmol/L	Methemoglobin	<3%	<3%
Carboxyhemoglobin (blood)	<2%	<2%	Phenobarbital*	15–40 mg/L	65–172 µmol/L
Cyanide (blood)	<1 mcg/mL	<38.5 µmol/L	Phenytoin*	10–20 mg/L	40–79 µmol/L
Digoxin <sup>a</sup> *	0.8–2 ng/mL	1.1–2.6 nmol/L	Salicylates <sup>c</sup> *	15–30 mg/dL	1.1–2.2 mmol/L
Ethanol <sup>b</sup>	80 mg/dL	17.4 mmol/L	Thallium (blood)	<2.0 mcg/L	<9.78 nmol/L
Ethylene glycol <sup>c</sup>	<25 mg/dL	<4 mmol/L	Thallium (urine)	<5.0 mcg/L	<24.5 nmol/L
Iron*	80–180 mcg/dL	14–32 µmol/L	Theophylline*	5–15 mg/mL	27.8–83 µmol/L
Lead (blood)	<10 mcg/dL	<0.48 µmol/L	Thiocyanate	<30 mcg/mL	<100 µmol/L
Lidocaine*	1.5–5 mcg/mL	6.4–21.4 µmol/L	Valproic acid*	50–120 mg/L	347–832 µmol/L

\*Therapeutic, generally accepted normal or nonaction concentrations (no symbol) are listed. Please see the appropriate chapter for details regarding specific situations. Normal ranges vary by laboratory.

<sup>a</sup>The therapeutic concentration of digoxin for heart failure is 0.5 to 0.9 ng/mL, but toxicity is usually present only when the concentration is >2 ng/mL. <sup>b</sup>This value is the “per se” concentration for ethanol above which motor vehicle operators are considered legally impaired in the United States. <sup>c</sup>Concentration must be interpreted with respect to the serum pH and clinical status.

<sup>d</sup>See acetaminophen nomogram (page 477).

### Common Standard Blood/Serum Laboratory Concentrations

	Conventional	SI		Conventional	SI
Ammonia	10–80 mcg/dL	6–47 µmol/L	Glucose	60–99 mg/dL	3.3–6.1 mmol/L
Alanine aminotransferase (ALT, SGPT)	7–41 U/L	0.12–0.70 µkat/L	Lactate	<18 mg/dL	<2 mmol/L
Aspartate aminotransferase (AST, SGOT)	12–38 U/L	0.20–0.65 µkat/L	Magnesium	1.3–2.1 mEq/L	0.65–1.05 mmol/L
Bicarbonate	18–24 mEq/L	18–24 mmol/L	PCO <sub>2</sub> (art)	35–45 mm Hg	4.7–6.0 kPa
Blood urea nitrogen	7–18 mg/dL	2.5–6.4 mmol/L	PCO <sub>2</sub> (ven)	45–55 mm Hg	6.0–7.33 kPa
Calcium	8.4–10.2 mg/dL	2.10–2.55 mmol/L	pH (art)	7.35–7.45	7.35–7.45
Chloride	98–106 mEq/L	98–106 mmol/L	pH (ven)	7.33–7.40	7.33–7.40
Creatinine	0.6–1.2 mg/dL	0.053–0.106 mmol/L	PO <sub>2</sub> (art)	90–100 mm Hg	12–13.3 kPa
Creatine kinase (total)			PO <sub>2</sub> (ven)	30–50 mm Hg	4.0–6.67 kPa
Females	39–238 U/L	0.66–4.0 µkat/L	Phosphorus	3–4.5 mg/L	1–1.4 mmol/L
Males	51–294 U/L	0.87–5.0 µkat/L	Potassium	3.5–5.2 mEq/L	3.5–5 mmol/L
			Sodium	135–145 mEq/L	135–145 mmol/L

art = arterial; ven = venous.

### Clinical and Laboratory Findings in Poisoning and Overdoses

Agitation	Antimuscarinics, <sup>a</sup> ethanol and sedative–hypnotic withdrawal, hypoglycemia, lithium, phencyclidine, sympathomimetics, <sup>b</sup> synthetic cannabinoids
Alopecia	Alkylating agents, radiation, selenium, strontium, thallium
Ataxia	Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycemia, lithium, mercury, nitrous oxide, phenytoin
Blindness or decreased visual acuity	Caustics (direct), cocaine, cisplatin, mercury, methanol, quinine, thallium
Blue skin	Amiodarone, FD&C #1 dye, methemoglobin, silver, sulfhemoglobin
Constipation	Antimuscarinics, <sup>a</sup> botulism, lead, opioids, thallium (severe)
Deafness, tinnitus	Aminoglycosides, carbon disulfide, cisplatin, loop diuretics, macrolides, metals, opioids, quinine, salicylates
Diaphoresis	Amphetamines, cholinergics, <sup>c</sup> ethanol and sedative–hypnotic withdrawal, hypoglycemia, opioid withdrawal, salicylates, serotonin toxicity, sympathomimetics <sup>b</sup>
Diarrhea	Arsenic and other metals/metalloids, boric acid (blue–green), botanical irritants, cathartics, cholinergics, <sup>c</sup> colchicine, iron, lithium, opioid withdrawal, radiation
Dysesthesias, paresthesias	Acrylamide, arsenic, ciguatera, cocaine, colchicine, <i>n</i> -hexane, thallium
Gum discoloration	Arsenic, bismuth, hypervitaminosis A, lead, mercury

(Continued)

## Clinical and Laboratory Findings in Poisoning and Overdoses (Continued)

Hallucinations	Antimuscarinics, <sup>a</sup> dopamine agonists, ergot alkaloids, ethanol, ethanol and sedative-hypnotic withdrawal, lysergic acid diethylamide (LSD), phencyclidine, sympathomimetics, <sup>b</sup> tryptamines
Headache	Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor–food interaction (hypertensive crisis), nitrites, serotonin toxicity
Metabolic acidosis (elevated anion gap)	Cyanide, ethylene glycol, ketoacidosis (diabetic, starvation, alcoholic), iron, isoniazid, metformin, methanol, paraldehyde, phenformin, protease inhibitors, salicylates, toluene, uremia
Miosis	Cholinergics, <sup>c</sup> clonidine, opioids, phencyclidine, phenothiazines
Mydriasis	Antimuscarinics, <sup>a</sup> botulism, methanol, opioid withdrawal, sympathomimetics <sup>b</sup>
Nystagmus	Barbiturates, carbamazepine, carbon monoxide, dextromethorphan, ethanol, lithium, monoamine oxidase inhibitors, phencyclidine, phenytoin, quinine
Purpura	Anticoagulant rodenticides, corticosteroids, heparins, pit viper venom, quinine, salicylates, warfarin and other antithrombotics
Radiopaque ingestions	Arsenic, “body packer,” chloral hydrate, enteric coated tablets (variable), halogenated hydrocarbons, iodinated compounds metals (eg, iron, lead)
Red skin	Antimuscarinics, <sup>a</sup> boric acid, disulfiram-ethanol interaction, hydroxocobalamin, scombroid, vancomycin
Rhabdomyolysis	Carbon monoxide, doxylamine, HMG CoA reductase inhibitors, sympathomimetics, <sup>b</sup> <i>Tricholoma</i> mushrooms
Salivation	Arsenic, caustics, cholinergics, <sup>c</sup> clozapine, ketamine, mercury, olanzapine phencyclidine
Seizures	Bupropion, camphor, carbon monoxide, cyclic antidepressants, ethanol and sedative-hypnotic withdrawal, <i>Gyromitra</i> mushrooms, hypoglycemia, isoniazid, theophylline, tramadol
Tremor	Antipsychotics, arsenic, carbon monoxide, cholinergics, <sup>c</sup> clozapine, ethanol, lithium, mercury, methyl bromide, sympathomimetics, <sup>b</sup> thyroid hormones
Weakness	Botulism, corticosteroids, diuretics, magnesium, neuromuscular blockers, paralytic shellfish, toluene
Yellow skin (jaundice)	Acetaminophen (late), <i>Amanita</i> mushrooms, β-carotene, dinitrophenol, pyrrolizidine alkaloids

<sup>a</sup>Antimuscarinics: eg, antihistamines, atropine, cyclic antidepressants, scopolamine. <sup>b</sup>Sympathomimetics: eg, amphetamines, β-adrenergic agonists, cocaine, ephedrine, methylxanthines. <sup>c</sup>Cholinergics: eg, muscarinic mushrooms, organic phosphorus compounds, and carbamates, including Alzheimer drugs and physostigmine and pilocarpine and other direct-acting cholinergics.

## Periodic Table of the Elements

Alkali metals I/IA		Alkaline earth metals 2/IIA										Transition metals										13/IIIA	14/IVA	15/VA	16/VIA	17/VIIA	18/O
1 H 1.01												29 Cu 63.55 ← Atomic number ← Atomic weight										5 B 10.81	6 C 12.01	7 N 14.01	8 O 15.99	9 F 18.99	10 Ne 20.18
