Figure 18.7 Technique of cardiac suture repair. Place multiple horizontal mattress sutures 6 mm from the edge of the wound before tying. Close the wound just enough to stop the bleeding. Use Teflon pledgets on the cardiac surface, and pass all surface sutures through these reinforcements. Sutures come from underneath, lie over, then pass back through the pledgets. Closure without pledgets incurs the risk of sutures ripping through the contracting myocardium. Similarly, the use of simple vertical sutures should be discouraged because of the risk for suture dissection through the myocardium. For repairs near a coronary artery, take care to pass the suture under the artery. Note that rectangles of pericardial tissue may be substituted for ready-made Teflon pledgets.

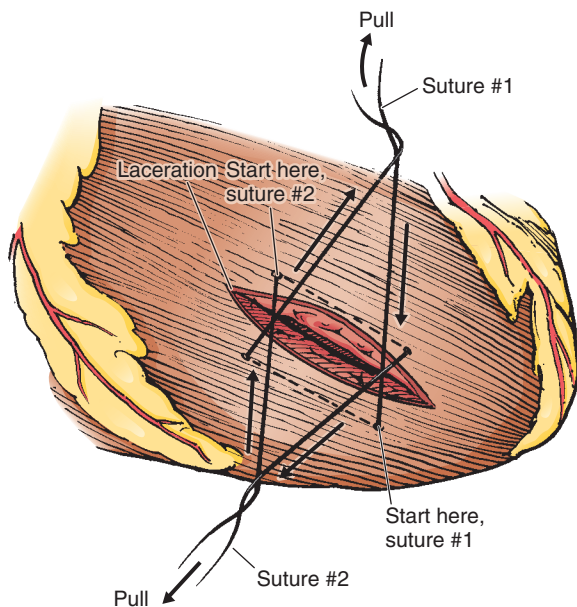

Figure 18.8 Control of hemorrhage with two widely placed incomplete mattress sutures. Ask an assistant to cross two half-horizontal sutures to bring the wound edges into apposition. By controlling the hemorrhage in this manner, the assistant's hands are outside the operative field and the edges of the wound are fully exposed. This facilitates more orderly closure of the wound. After the wound is repaired, the sutures may be either removed or tied to each other.

vena cava between the ring and middle fingers of the left hand to create partial occlusion of inflow. The Sauerbruch grip will interfere only with the repair of wounds involving the right atrium.

Another technique for temporarily controlling hemorrhage is to insert a Foley catheter (20 Fr with a 30-mL balloon) through a wound.⁷¹ After inserting the catheter, inflate the balloon, clamp the catheter to prevent air embolism, and apply

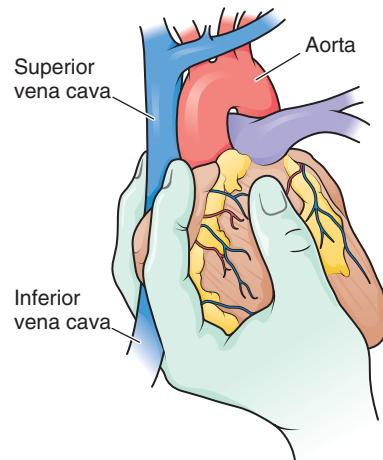

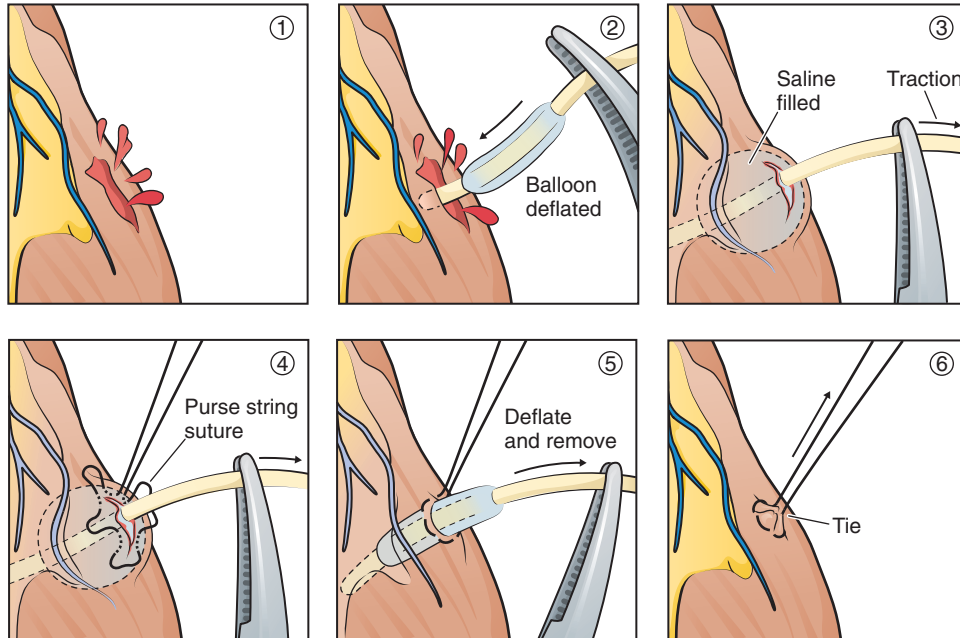

Figure 18.9 The Sauerbruch maneuver is the method of choice for reducing heavy bleeding from cardiac wounds. Occlusion of venous inflow is achieved by using the first and second, or second and third fingers as a clamp.

gentle traction (Fig. 18.10). Apply enough traction to slow the bleeding and provide an acceptable level to visualize and repair the wound. Excessive traction can pull the catheter out and enlarge the wound. The balloon will effectively occlude the wound internally. Use a purse-string suture to close the wound. When repairing the wound be careful with the suture needle because it can easily rupture the balloon. Temporarily pushing the balloon into the ventricular lumen during passage of the needle can be done to avoid this complication. Use normal saline when inflating the balloon because using air could result in air embolism if the suture needle ruptures the balloon.

Foley catheters have several advantages over other methods for controlling cardiac wounds. With the digital method, your fingertip will often slip if there is a strong heartbeat, you cannot visualize the wound during repair, and digital pressure significantly interferes with cardiac massage. Intermittent total venous inflow occlusion is an effective method of controlling bleeding and decompressing the heart, but such control will be at the expense of poor cardiac output. Attempting to elevate the heart for control and repair of posterior cardiac wounds often results in cardiac arrest by reducing both venous and arterial flow. With posterior injuries use of a Foley catheter does not require continued viewing after initial placement. If bleeding can be controlled, repairs in this location should await full-volume expansion or cardiopulmonary bypass.⁷² Regardless of location the most valuable feature of the Foley catheter is that you can control hemorrhage without interfering with cardiac compression. The catheter can also be used for infusion of fluids (see Fig. 18.10B).⁷³

To initially manage wounds of the atria, use partial-occlusion clamps (Fig. 18.11). Because of the thin structure and instability of the atrial wall, you will not be able to effectively stop bleeding with digital pressure. Injuries near the caval-atrial junction are not amenable to clamping; in this location, use a Foley catheter to tamponade the wound.⁷¹ Be careful not to obstruct atrial filling with the inflated balloon. Skin staples may also be used for closure of atrial wounds.⁶⁶

Wounds of the septa, valves, and coronary arteries require definitive repair in the operating suite. Hemorrhage from a coronary artery can generally be controlled with digital pressure. Avoid ligation of a coronary artery whenever possible.

A

B

Figure 18.10 **A**, Serial illustration. Gentle traction on an inflated Foley catheter may control hemorrhage and allow repair. Inflate the balloon with saline while taking care to not rupture the balloon with the suture needle. This technique is particularly useful for injuries to the inferior cavoatrial junction, for posterior wounds, and during cardiac massage. Volume loading can be achieved by infusion of blood or crystalloid solution through the lumen of the catheter. Take care to avoid an air embolus through the lumen of the catheter during placement. **B**, Foley catheter in an atrial stab wound. Keep gentle traction on an inflated balloon and inject saline directly into the heart via the catheter. Note how difficult it is to identify structures in the chest cavity. The heart is collapsed and not beating, which makes even this organ hard to find. The aorta could not be isolated before stopping resuscitation efforts.

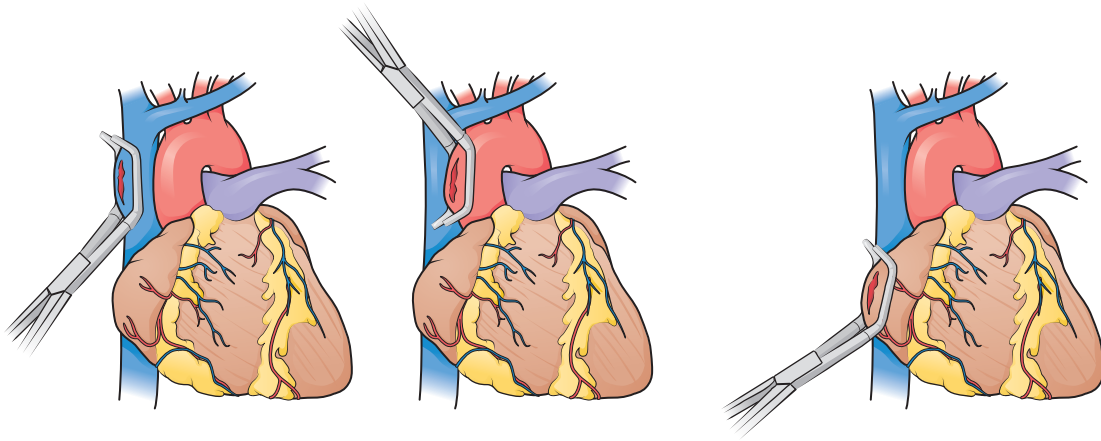

Figure 18.11 Use a partial-occlusion clamp in different locations for control of bleeding and subsequent repair.

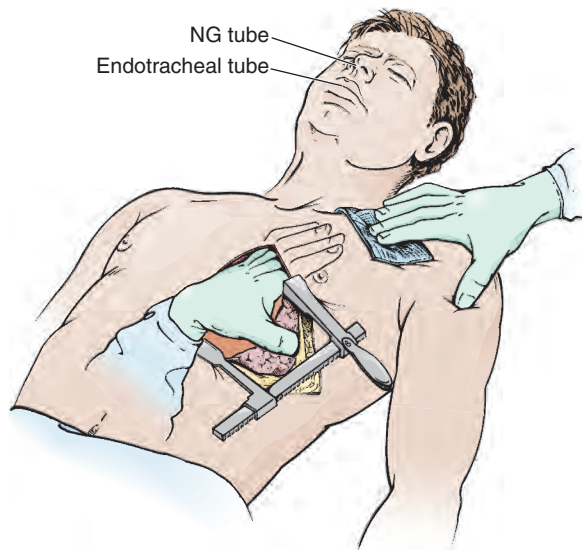

Figure 18.12 Cross-clamping for control of subclavian bleeding is difficult and time-consuming. Compression with laparotomy pads in the apical pleura from below and the supraclavicular fossa from above will control hemorrhage while the patient's condition is stabilized and the patient is transported to the operating room. NG, Nasogastric.

Control of Hemorrhagic Great-Vessel Wounds

Wounds of the great vessels can be controlled with digital pressure or partial-occlusion clamps. If desired, close small aortic wounds with 3-0 Prolene suture.⁷⁴ To prevent exsanguinating hemorrhage from the left subclavian artery, try to cross-clamp the intrathoracic portion of the artery. Cross-clamping of the right subclavian artery is very difficult. For injuries to this vessel, use laparotomy pads for compression in the apex of the pleura from below and the supraclavicular fossa from above (Fig. 18.12) to prevent further bleeding as the patient is stabilized and moved to the operating suite.⁶⁵

Aortic Cross-Clamping

For persistent hypotension (systolic blood pressure <70 mm Hg) after thoracotomy and pericardiotomy, perform temporary

Figure 18.13 Manual cardiac massage and cross-clamping of the aorta can be used to increase coronary and cerebral perfusion selectively.

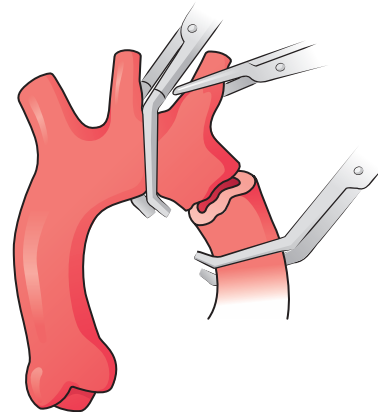

Figure 18.14 Traumatic rupture of the aorta is usually a fatal injury. Three clamps are required for control. Backbleeding will occur if fewer than three clamps are used.

occlusion of the descending thoracic aorta. This maneuver can maintain myocardial and cerebral perfusion (Fig. 18.13; see also Fig. 18.4, step 7), although Kravolich and colleagues⁴⁹ suggested that the benefit of significant improvement in CPP may be overstated. When the aorta has been injured by blunt trauma, selective clamping is necessary (Fig. 18.14). Aortic occlusion has a limited role in controlling hemorrhage below the diaphragm. In patients with a tense abdomen and massive

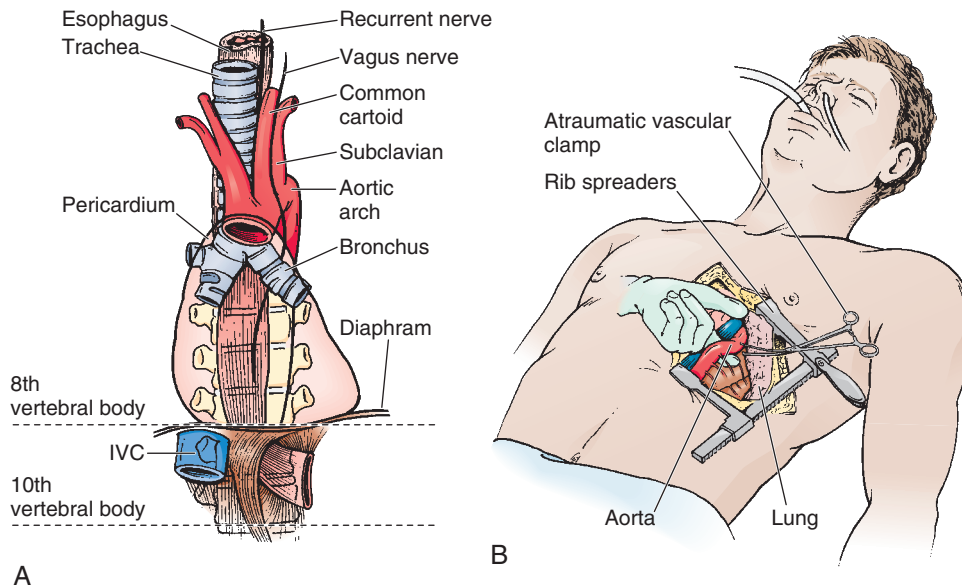

Figure 18.15 **A**, Identification of the aorta is very difficult during emergency department thoracotomy. If possible, first pass a nasogastric tube to help identify the esophagus. The aorta is in the posterior mediastinum, directly anterior to the vertebral bodies. The esophagus is anterior and slightly medial to the aorta. In the lower part of the thorax, both are covered on the anterolateral surface by the mediastinal pleura, which must be dissected before isolating the aorta for cross-clamping. **B**, Aortic cross-clamping. Using blunt dissection, spread the pleura above and below the aorta. Fully mobilize the vessel and clearly separate the esophagus before clamping. The aorta is the more posterior structure and is in contact with the vertebral bodies.

hemoperitoneum, aortic cross-clamping is beneficial when applied just before laparotomy.²⁵

The aorta can be very difficult to identify in an ED, especially when collapsed as a result of exsanguination. It is situated immediately anterior to the vertebrae and actually lies on the vertebral bodies themselves. The esophagus lies anterior and slightly medial to the aorta. Passing a nasogastric tube from above may help in identifying the esophagus. To expose the descending aorta, ask an assistant to retract the left lung in a superomedial direction. To achieve adequate exposure, it is sometimes necessary to divide the inferior pulmonary ligament (be careful not to injure the inferior pulmonary vein). Identify the aorta by advancing the fingers of the left hand along the thoracic cage toward the vertebral column. Open the mediastinal pleura and bluntly dissect the aorta away from the esophagus anteriorly and the prevertebral fascia posteriorly before clamping. To locate the aorta, use a DeBakey aortic clamp or a curved Kelly clamp for blunt dissection, and spread the pleura open above and below the aorta (Fig. 18.15). Alternatively, if excessive hemorrhage limits direct visualization, bluntly dissect with the thumb and fingertips. Separate the aorta from the esophagus, which lies medially and slightly anteriorly. It may be difficult to separate the esophagus from the aorta by feel in a hypotensive or cardiac arrest situation. When the aorta is completely isolated, use the index finger of the left hand to flex around the vessel and apply a large Satinsky or DeBakey vascular clamp with the right hand. Check brachial blood pressure immediately after the occlusion. If systolic pressure is higher than 120 mm Hg, slowly release the clamp and adjust it to maintain a systolic pressure of less than 120 mm Hg.²⁴

Figure 18.16 Use of a Conn aortic compressor is an excellent method for aortic occlusion because it is fast, does not interfere with the operative field, and is associated with minimal risk for injury. Alternatively, direct digital occlusion can be used, but this technique is more awkward.

Given the need for timely intervention, the simplest and most desirable approach to aortic occlusion is to have an assistant digitally compress it or use the aortic tamponade instrument (Fig. 18.16). The aortic tamponade instrument, however, may be applied blindly to the vertebral column and permits safe, quick, and complete aortic occlusion.⁷⁵ This technique may be most prudent when isolation of the aorta is difficult. The instrument's unique shape allows it to remain in place and to provide atraumatic occlusion with little interference in the

operative field when compared with digital compression. The degree of occlusion can be varied by the amount of pressure exerted by the operator.

Potential complications of aortic cross-clamping include ischemia of the spinal cord, liver, bowels, and kidneys. In addition, iatrogenic injury to the aorta and the esophagus may occur. Fortunately, these complications are infrequent. The metabolic penalty of aortic cross-clamping becomes exponential when occlusion time exceeds 30 minutes.⁷⁶ Whenever possible, unclamp the aorta for 30 to 60 seconds every 10 minutes to increase distal perfusion. Perform final release of the aorta gradually.

Management of Air Embolism

In those at risk for air embolism spontaneous ventilation is preferred. It is essential that the source of the air embolism be controlled rapidly. Place the patient immediately in the Trendelenburg (head-down) position to minimize cerebral involvement and direct the air emboli to less critical organs. If the chest injury is unilateral, consider isolating the injured lung by selectively intubating the contralateral lung. If this is unsuccessful, perform a left anterolateral thoracotomy. Flood the exposed thorax with sterile saline and look for bloody froth created during positive pressure ventilation to identify peripheral bronchovenous fistulas. Carry out a quick search for hilar injuries. If the source of the air embolism is not readily apparent, perform a contralateral thoracotomy. Once the bronchovenous communication is controlled, use a needle to aspirate the residual air that commonly remains in the left ventricle and the aorta. If the patient is hypotensive, consider cross-clamping the aorta. Be aware, though, that cross-clamping the aorta before controlling bronchovenous fistulas and removing residual air may result in further dissemination of air to the heart and brain.

Air emboli traverse capillary beds if the blood pressure is high enough. After controlling the bronchovenous fistula, produce a brief period of proximal aortic hypertension by cross-clamping the descending aorta. Maintain systemic arterial pressure with adequate fluid resuscitation. Vasopressors such as dopamine, epinephrine, or norepinephrine may be required to increase systemic pressure and facilitate the passage of air bubbles from left to right.⁷⁷

Maintain left atrial pressure at a high level. Keep the ventilator inspiratory pressure as low as possible, and use 100% oxygen to facilitate diffusion of nitrogen from emboli. Consider high-frequency ventilation, which allows the use of small volumes and has been used successfully in individual patients. The most important adjunctive therapy is hyperbaric oxygen. Although it is best to begin treatment within 6 hours of the traumatic insult, there are cases of success and improvement when hyperbaric oxygen has been started even 36 hours after injury.⁷⁸

INTERPRETATION AND HEMODYNAMIC MONITORING

Use systolic blood pressure after the first 30 minutes of resuscitation as a decision point for further treatment. A report of EDT for blunt and penetrating trauma demonstrated a relationship between blood pressure at 30 minutes and the eventual outcome.⁷⁹ Of the 146 cases reviewed, 45 patients

(31%) were transferred to the operating room after initial resuscitation and aortic cross-clamping when necessary. For patients who survived with full neurologic recovery, the average systolic blood pressure after the first 30 minutes of resuscitation was 110 mm Hg. In those who were long-term survivors but had significant brain damage, the average systolic blood pressure was 85 mm Hg. No survivals were recorded when mean systolic blood pressure was lower than 70 mm Hg. Transfer of these patients to the operating room for definitive repair of these mortal wounds would be futile.

EDT IN CHILDREN

Trauma is the leading cause of death and morbidity in children older than 1 year.¹ Just as with adults, improved transportation of injured children to the hospital has resulted in the survival of more patients who would have been pronounced dead at the scene. Although the role of EDT has been reviewed extensively in the adult population, experience and data in the pediatric population are limited. Overall survival rates in children undergoing EDT are less than that of the adult population with one study showing an overall survival of 3% to 6%.^{80,81} This is likely as a result of a higher proportion of blunt trauma in the pediatric population. Anatomic injury patterns also showed a higher proportion of concomitant head injuries in the pediatric population. Rates of survival below age 15 are very poor. Despite poor survival rates, the general consensus is that EDT is indicated for traumatic pediatric patients with similar indications discussed earlier in this chapter.

COMPLICATIONS

A variety of significant complications occur in patients surviving EDT, but most of them are related to the primary injury rather than the thoracotomy. Techniques to avoid iatrogenic complications include noting the position of the left phrenic nerve and coronary arteries during EDT. Surprisingly, serious infections are uncommon. Patients receiving antibiotics during or immediately after the procedure have a low rate of infectious complications. Standard antibiotic regimens targeting skin flora are recommended, but should not delay the procedure.⁸² As a general rule, excessive attention to antiseptic skin preparation should be avoided because it may delay performance of the procedure.⁸³

Another potentially serious complication of EDT is injury or transmission of disease to health care workers. In an emotionally charged environment in which many clinicians are attempting to perform a lifesaving procedure under difficult conditions, it is easy for a needle, scalpel, or scissors to cause injury. Sharp ribs can cut clinicians quite easily (Fig. 18.17). The seroprevalence of human immunodeficiency virus (HIV) in US EDs is estimated to range from 2% to 6% or 9% in urban areas.⁸⁴ Tardiff and colleagues⁸⁴ noted an HIV-positive rate of 7.2% in a study of trauma patients taken to their urban ED. Occupational exposure to both hepatitis B and hepatitis C virus is also of concern to health care workers. Sloan and associates⁸⁵ found a 3.1% incidence of hepatitis B in trauma patients brought to their inner-city ED. Hepatitis C is now the most common viral hepatitis seen in health care workers since the advent of the hepatitis B vaccine. Approximately 2200 health care workers per year seroconvert after occupational exposure. The risk for

Figure 18.17 Note the sharp edges of this rib (indicated by the circled clamp), which was fractured during unsuccessful emergency department thoracotomy. The incidence of blood-borne diseases (e.g., human immunodeficiency virus, hepatitis) in trauma patients may be high and transmission to a health care worker may occur if sharp bone fragments puncture the gloves and skin.

seroconversion after occupational exposure to HIV is estimated to be 0.3% for needlestick and as high as 4.5% for deep injury.⁸⁶ Hepatitis C seroconversion rates after occupational exposure are estimated to be between 1.8% and 10%.⁸⁶ Keep the risk for exposure to staff in mind, and rigorously follow universal precautions. Although EDT must be performed rapidly to be of value to the patient, excessive haste is not warranted if it threatens the health of members of the medical team.

ACKNOWLEDGMENT

Vascular Techniques and Volume Support

CHAPTER 19

Pediatric Vascular Access and Blood Sampling Techniques

Genevieve Santillanes and Ilene Claudius

Obtaining vascular access and blood samples in an infant or child can challenge and frustrate even the most skilled emergency clinician and can be especially challenging in children who are dehydrated or in shock. Resuscitation of critically ill and injured children should not be delayed for lack of vascular access, and intraosseous (IO) access is the preferred technique if peripheral vascular access cannot be secured rapidly. This chapter reviews the basic principles and techniques of blood sampling and placement of peripheral and central intravenous (IV) and intraarterial catheters in infants and children, including the use of umbilical catheters in neonates. Hydration techniques for dehydrated children are also reviewed. Though very rarely required, emergency cutdown is occasionally useful in obtaining vascular access, and a section of this chapter is devoted to cutdown techniques.

PATIENT PREPARATION AND RESTRAINT

Fear and anticipation of procedural pain can make the hospital experience traumatic for children. Before beginning any painful procedure in a stable child, explain the procedure to the parents, as well as the reasons that it needs to be done. For children capable of understanding, explain the procedure in developmentally appropriate language before starting and before each successive step. Parents should generally be present during emergency department (ED) procedures¹ but should not assist with painful procedures. Parental presence is generally comforting to children, and children with a parent present have been shown to demonstrate less stress during procedures.² Nonpharmacologic techniques such as music, toys, or being held by a parent may further reduce children's distress during attempts at vascular access.³ Many applications for smart phones, including some that produce "bubbles" for the child to "pop" on the screen are excellent and typically available distractions.

The success of blood sampling or obtaining vascular access depends in part on proper positioning and restraint of the patient. In most cases this requires the assistance of at least one other staff person and restraint of the extremity a joint

above and below the intended insertion site. A significant amount of time may be required to perform venipuncture or vessel cannulation in neonates or young infants. Consequently, they may become hypothermic if disrobed and exposed for a prolonged period, especially if perfusion is compromised due to sepsis or hypovolemic shock. Use overhead lights, warm blankets, or other warming modalities to prevent accidental hypothermia in vulnerable patients. Furthermore, there is some evidence that radiant warmth is effective as an analgesic for minor procedures in newborns.⁴

Anesthesia

Many products are available to decrease the pain associated with vascular access. Do not delay IV access in critically ill or injured children to use these medications or devices, but consider using them in stable patients. These medications and products are discussed in more detail in [Chapter 29](#). Options include vapocoolants, topical heat-enhanced anesthetic delivery such as lidocaine-prilocaine, 4% liposomal lidocaine, and injection of lidocaine via a needleless jet injector (J-tip), and vibrating devices. Orally administered sucrose solution has been demonstrated to decrease the pain response in young infants during procedures.^{5,6} Procedural sedation is commonly used during central venous and arterial cannulation in children ([Chapter 33](#)).

BLOOD SAMPLING TECHNIQUES

Capillary Blood Sampling

Indications and Contraindications

Capillary blood sampling is frequently used to obtain blood samples from young infants. In infants, the heel is the most common location for capillary blood sampling, whereas in older children and adults, blood samples are more commonly obtained from the finger tip. This technique is useful when repeated measurements such as blood glucose or serial hemoglobin are needed. It is also an option for obtaining "arterialized" blood for blood gas analysis. If a sufficient volume is obtained, blood from a capillary sample can also be sent for other routine laboratory studies. Heel sticks are more painful than venipuncture but are useful in the event of difficult access or when arterialized samples are needed.⁷

Avoid sampling from an area of local inflammation or hematoma. Avoid repetitive sampling from the same site because it may induce inflammation and subsequent scarring. In general, heel stick sampling is not ideal for blood gas analysis when the infant is hypotensive, the heel is markedly bruised, or there is evidence of peripheral vasoconstriction.

Equipment and Setup

Use a 3-mm lancet (Becton-Dickinson, Rutherford, NJ) or an automated disposable incision device (e.g., Tenderfoot, Tenderfoot, Accrivia Diagnostics, San Diego, CA) to perform this procedure. Perform blood collection with either heparinized capillary tubes or 1-mL Microtainer tubes with a collector attachment (Becton-Dickinson).

Technique

The heel stick method of capillary blood sampling will be described, but capillary blood samples can also be obtained from a finger, toe, or earlobe (Fig. 19.1). Traditional teaching is to puncture only the most medial and lateral portions of the plantar surface of the heel to avoid puncture of the calcaneus.⁸ However, newer research has found that although soft tissue thickness is greater on the medial and lateral portions of the heel, if necessary any site can be safely punctured in term infants, as long as automated lancets are used.⁸ Prewarm the foot by wrapping it in a hot moist towel (microwaved) for 5 minutes to produce hyperemia and enhance blood flow. Immobilize the foot in a dependent position with one hand. First, cleanse the heel with antiseptic solution and allow it to dry. Next, puncture the skin with the lancet. Allow the alcohol to dry to avoid false elevations in the glucose level. Avoid squeezing the foot because it may inhibit capillary filling and actually decrease the flow of blood. Furthermore, squeezing may lead to hemolysis of the sample. If blood does not flow freely, another puncture may be required.

Wipe away the first small drop of blood with gauze and allow a second drop to form. Place a heparinized capillary tube in the drop of blood and invert the proximal end of the tube to allow it to fill by capillary action. Fill the capillary tube until blood reaches the demarcation line on the tube. Over- or underfilling may result in clotting or erroneous test results. If 1-mL Microtainer tubes are used, hold the tube at an angle of 30 to 45 degrees from the surface of the puncture site. Touch the collector end of the tube to the drop of blood and allow the blood to drain into the tube. Gently tap the tube to facilitate flow to the bottom. Once filled, seal the tube with the accompanying cap. After an adequate specimen is obtained, apply a dry dressing to the puncture site.

When a heel stick is performed for an arterialized blood sample, use the same technique, but take care not to introduce ambient air into the sample. Place the tip of the tube as near the puncture site as possible to minimize exposure of the blood to environmental oxygen. Fill the tube as completely as possible and avoid collecting air in the tube. When the tube is full, occlude the free end with a gloved finger to prevent the entry of air, and cap both ends. Excessive squeezing of the foot may artificially lower the partial pressure of oxygen (PO_2).

Complications

When performed properly, heel sticks are associated with a low incidence of complications. Use an automatic incision device to prevent lacerations. Rare complications include infection, scarring, and calcified nodules.

Interpretation

Multiple studies have demonstrated a good correlation between arterial and capillary specimens for determining pH and partial pressure of carbon dioxide (PCO_2) in hemodynamically stable patients.^{9,10} However, determination of PO_2 is not reliable when performed on blood obtained by capillary sampling.

Venipuncture

Indications and Contraindications

Venipuncture is used to obtain larger quantities of blood from infants and children and to obtain blood for culture. When collecting blood for culture, prepare the area of venipuncture with an appropriate antiseptic solution and allow the skin to dry. Wash off the cleanser promptly after blood has been collected because antiseptic solutions can irritate infant skin.

Equipment and Setup

A small-gauge butterfly or straight needle with a syringe are generally preferred for specimen collection in infants and young children because the negative pressure generated by standard specimen collection tubes (e.g., Vacutainer, Becton-Dickinson) may collapse small veins. A 3-mL or 5-mL syringe is less likely than a 10-mL syringe to cause vein collapse. Many providers find that it is easier to control needle position with a butterfly needle rather than a straight needle. If other access is not available, the butterfly needle may also serve as an infusion line after an adequate amount of blood is obtained. A 23-gauge butterfly needle will generally suffice for venipuncture, regardless of patient size.

Technique

As in adults, the usual site for venipuncture in infants and children is the antecubital fossa. However, any reasonably accessible or easily visible peripheral vein that will not be needed for IV cannulation may be used. Veins on the hands, feet, or scalp are frequently visible in young children (Fig. 19.2). Imaging devices (e.g., ultrasound, transillumination, or infrared devices) may also be used to locate and identify veins for venipuncture. These devices are discussed later in this chapter (see section on [Vascular Line Placement: Venous and Arterial](#)).

Assemble all necessary equipment, especially needles, out of sight of the child and have equipment within easy reach before beginning. Ask an assistant to help immobilize the patient when drawing blood from infants and small children. If an extremity vein is to be used, apply a tourniquet proximal to the selected vein. In small infants a rubber band can be used as a tourniquet. Be sure that the tourniquet is not so tight that it impedes arterial filling.

Cleanse the area surrounding the chosen site of skin penetration with antiseptic solution and allow it to dry. Apply slight distal traction to the skin to immobilize the vein. Insert the needle quickly through the skin and advance it slowly into the vein at an angle of approximately 30 degrees with the bevel facing up (Fig. 19.3). Successful vessel penetration is heralded by a flashback, or flow, of blood into the needle hub or butterfly tubing. Apply gentle suction by slowly withdrawing the plunger of the syringe. If the required amount of blood is greater than the capacity of the attached syringe, pinch off the tubing, remove the filled syringe, attach a new syringe, and apply gentle suction again after releasing the pinched tubing. Remove the tourniquet. After the required amount of blood is withdrawn, remove the needle and apply a sterile dressing and direct pressure to the puncture site.

Although peripheral sites for venous blood sampling are preferable in infants, the external jugular and femoral veins may also be used for venipuncture during resuscitation or when peripheral sites are inadequate. The external jugular vein lies in a line from the angle of the jaw to the middle of the clavicle

Capillary Blood Sampling

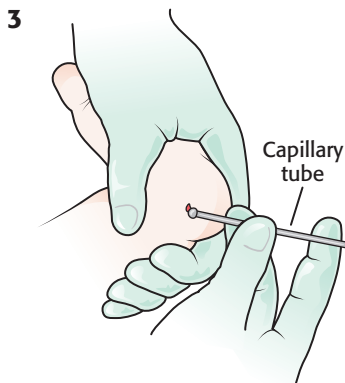

1 Obtain the blood sample from the medial or lateral portions of the plantar surface of the heel.

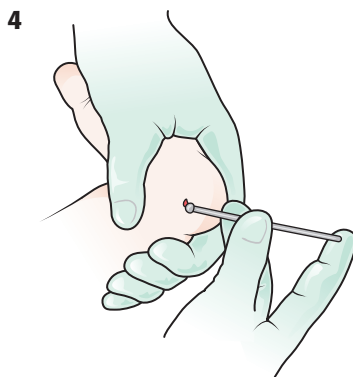

2 Prewarm the foot for 5 minutes to enhance blood flow. Immobilize the foot in a dependent position, cleanse with antiseptic, and allow to dry.

Puncture the skin with the lancet.

Capillary Tube Method

3 Wipe away the first drop of blood with gauze and allow a second drop to form. Place a heparinized capillary tube in the drop of blood and allow it to fill by capillary action.

4 Fill the tube until the blood reaches the demarcation line on the tube. Maintain the blood in the capillary tube using your index finger to maintain capillary tension on the end of the tube.

5 Seal both ends

After the sample has been collected, seal both ends of the tube with the caps provided or with wax or clay.

Microtainer Tube Method

6 If using a Microtainer tube, touch the collector end to the drop of blood and allow the blood to flow down the wall of the tube to the bottom.

Do not squeeze foot

Figure 19.1 Capillary blood sampling: capillary tube and Microtainer tube methods.

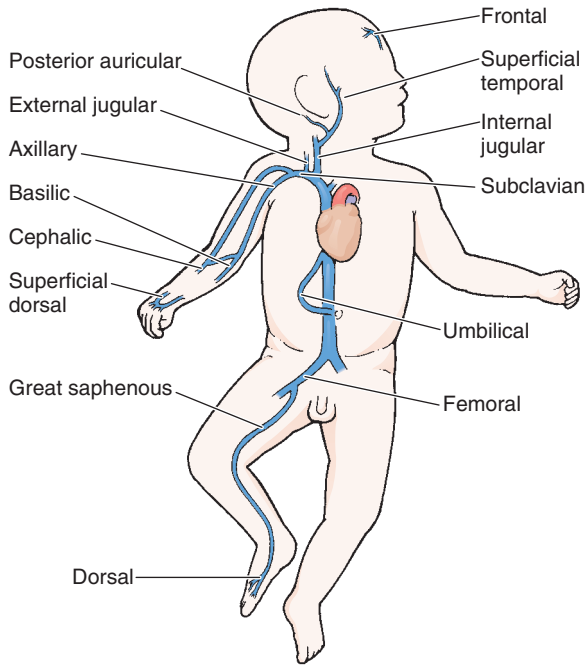

Figure 19.2 Venous access sites in neonates and young infants. If venous access is unavailable, arterial blood may be used for most laboratory tests, including blood cultures.

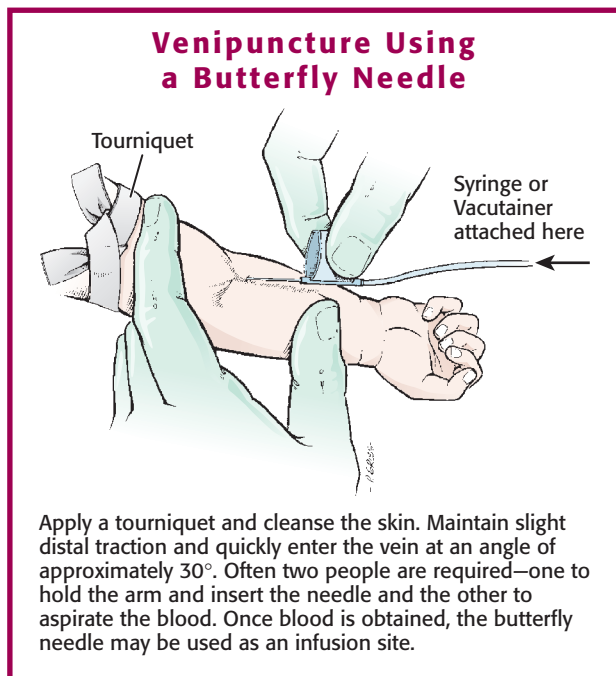

Figure 19.3 Venipuncture using a butterfly needle.

and is usually visible on the surface of the skin (Fig. 19.4). When the infant is crying, this vein is more prominent. Ask an assistant to restrain the infant in a supine position with the head and neck extended over the edge of the bed. Alternatively, place a towel roll or pillow under the child's shoulders. Turn the head approximately 40 to 70 degrees from the midline. Cleanse the skin surrounding the area to be punctured with alcohol or another antiseptic solution. Apply finger pressure just above the clavicle to help distend the jugular vein. Use a

21- to 25-gauge straight needle or a 21- to 25-gauge butterfly needle attached to a syringe. Puncture the skin and then advance the needle slowly until the jugular vein is entered and a flashback of blood is observed. Keep the syringe connected to the needle at all times to maintain constant negative pressure and avoid air embolism. After the appropriate amount of blood is obtained, withdraw the needle and apply slight pressure to the vessel. Place the child in an upright position if possible after the needle is removed, and hold pressure over the puncture site for 3 to 5 minutes. Observe the puncture site closely afterward to identify persistent bleeding.

In most patients, the femoral vein lies medial to the femoral artery and inferior to the inguinal ligament (Fig. 19.5A). Ask an assistant to position the patient's hips in mild abduction and extension while you palpate the artery. Identify its location by placing a mark on the skin just superior to the femoral triangle. If available, use ultrasound to assess the position of the femoral vessels. Prepare the femoral triangle with alcohol or another antiseptic agent. Use a povidone-iodine or chlorhexidine scrub when obtaining blood for culture. Puncture the skin and then direct the needle or catheter toward the umbilicus at a 30- to 45-degree angle to the skin and just medial to the pulsation of the femoral artery (see Fig. 19.5B). Apply slight negative pressure constantly throughout insertion. After the needle enters the femoral vein, withdraw the desired blood samples. Afterward, remove the needle or catheter unless an IV catheter for venous access is desired in this location. Apply pressure over the puncture site in the femoral triangle for a minimum of 5 minutes. Observe closely for recurrent bleeding.

Scalp veins can be very useful for venous sampling in small infants when other options are not possible or readily available. The anatomic considerations and technique are discussed later (see sections on [Peripheral Venous Catheterization: Percutaneous](#) and [Peripheral Venous Catheterization: Venous Cutdown](#)).

Complications

Complications of venipuncture include hematoma formation, arterial puncture, local infection, injury to adjacent structures, and phlebitis. Serious complications are uncommon. Use special care when attempting to puncture the external jugular or femoral vein. Inadvertent deep puncture in the neck can injure the carotid artery, vagus nerve, phrenic nerve, or apex of the lung. The femoral artery or nerve can be injured during puncture of the area around the femoral triangle. Fortunately, these injuries are unlikely when proper technique is used.

Arterial Blood Sampling

Indications and Contraindications

Arterial blood sampling is most often indicated to obtain an arterial blood gas (ABG) analysis. Consider sending venous blood for blood gas analysis because all parameters except PO₂ may be clinically useful. Arterial blood may be drawn for routine laboratory analysis or blood culture if venous blood is difficult to obtain. Avoid puncture of an artery if the overlying skin is infected, burned, or otherwise damaged. In addition, consider the presence of adequate collateral circulation and any potential coagulation disorders.

Equipment and Setup

For arterial puncture in infants and children, a small-gauge butterfly needle is preferable to a needle and syringe. A 23-gauge butterfly needle is used most often, although a 25-gauge

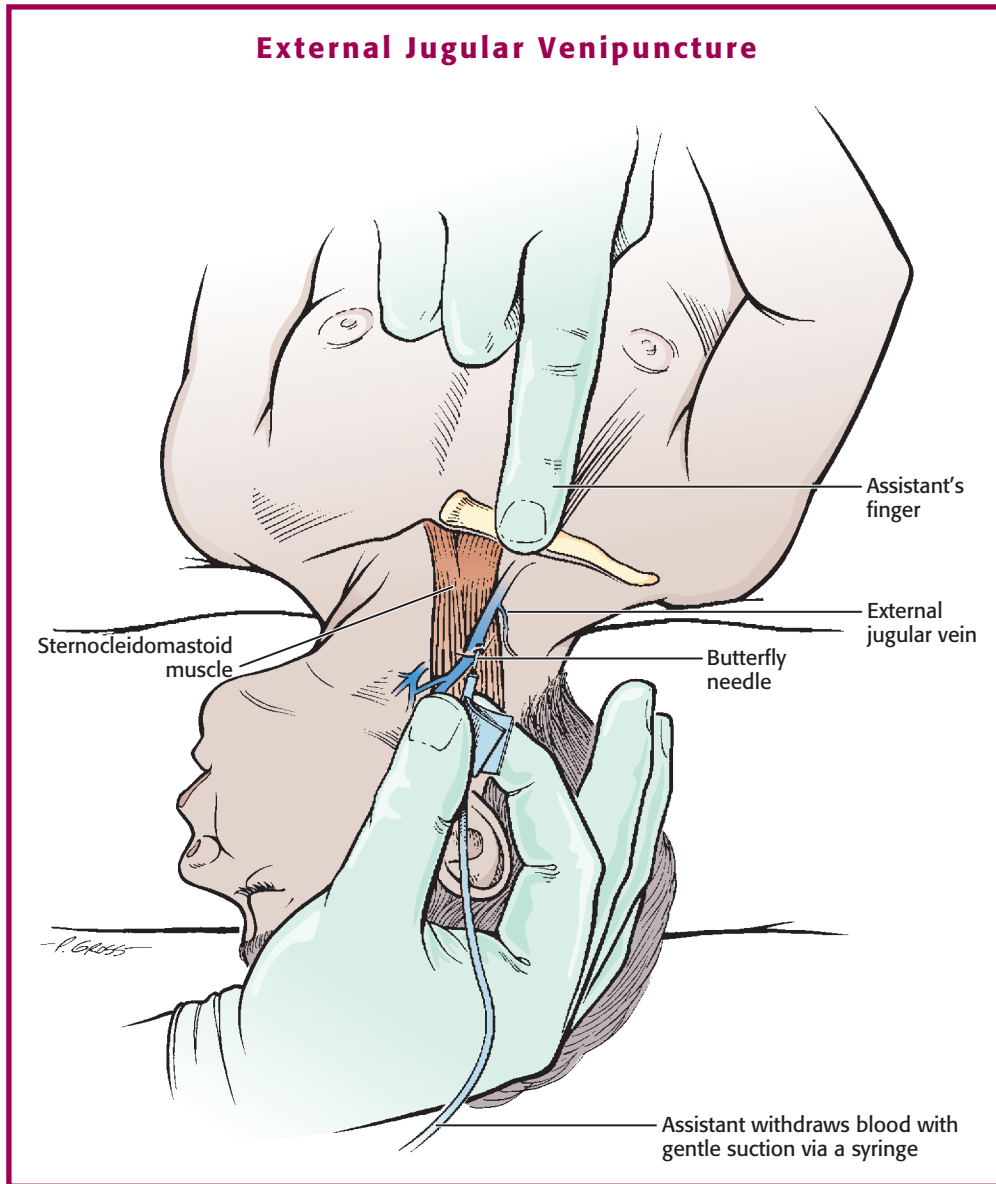

Figure 19.4 External jugular venipuncture. A syringe or a butterfly needle may be used. Venous distention is aided when an assistant's finger occludes the vein or when the infant cries. The neck is extended, either over the side of the bed or by placing a rolled towel under the shoulders. This procedure requires two people.

butterfly needle may be preferable in newborns. Some clinicians prefer to use a 25-gauge needle connected to a syringe, but a butterfly allows better control of the needle while an assistant aspirates the syringe. This technique may also permit a larger volume of blood to be withdrawn.

Technique

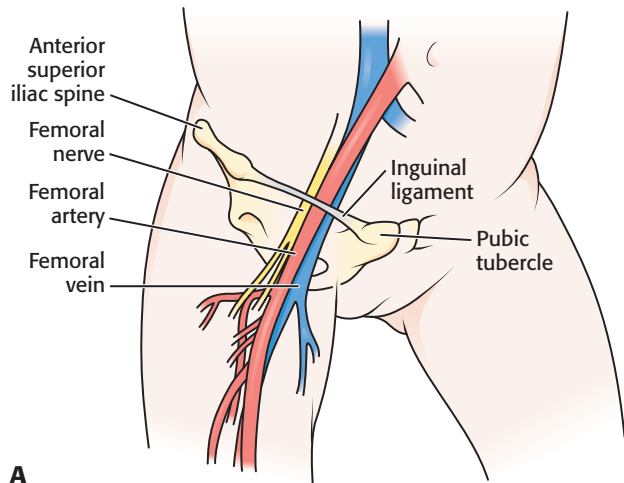

Potential sites for arterial blood sampling include the radial, brachial, dorsalis pedis, and posterior tibial arteries. In newborn infants the umbilical arteries are also available. The radial artery has several advantages that make it the most commonly used artery for blood sampling. First, its location makes it easy to palpate and puncture (Fig. 19.6A). The ulnar artery is more difficult to locate. Second, no vein or nerve is immediately adjacent to the radial artery, minimizing the risk of obtaining

venous blood or damaging a nerve. Another advantage of the radial artery is the presence of good collateral circulation from the ulnar artery. The brachial artery has little collateral circulation and should be avoided unless an arterial sample is absolutely necessary and no other options are available. Limit use of the ulnar artery to preserve collateral circulation to the hand. As a general rule, do not use the femoral artery for obtaining routine blood samples.

Because the radial artery is used most frequently to obtain percutaneous arterial blood samples, the technique for radial artery puncture will be described. (See Chapter 20 for a discussion of the Allen test and the effect of heparin on arterial blood sampling.)

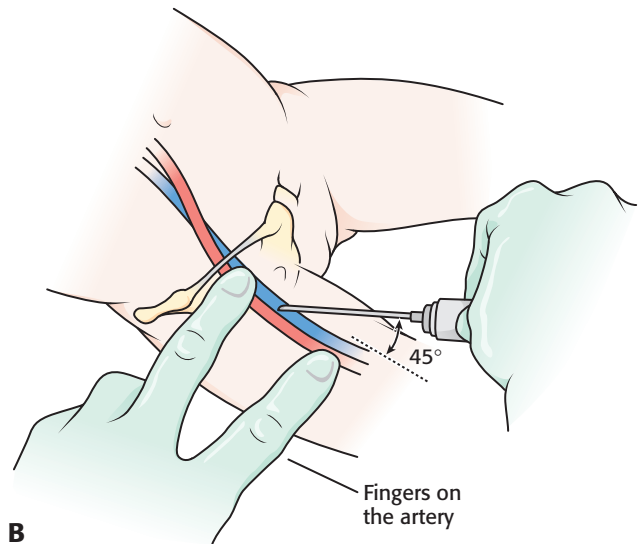

Hold the infant's wrist and hand in your nondominant hand (see Fig. 19.6B). Hold the hand fully supinated with the wrist

Femoral Venipuncture

A

The femoral vein lies medial (in most patients) to the femoral artery and inferior to the inguinal ligament.

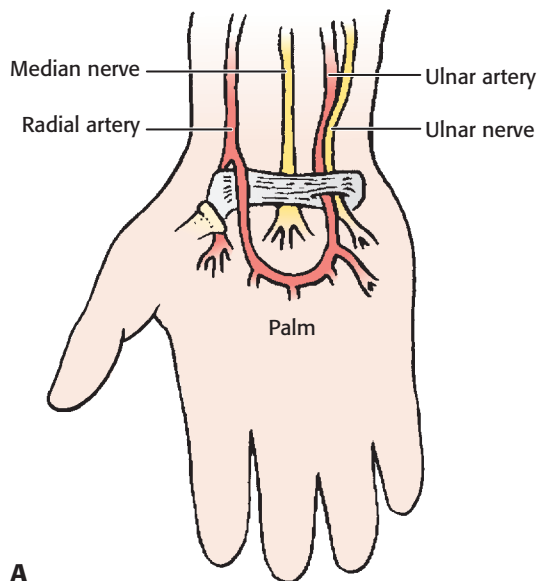

B

Position the hips in mild abduction and extension. Palpate the artery just superior to the femoral triangle. Puncture the skin and direct the needle toward the umbilicus at a 30° to 45° angle to the skin while remaining just medial to the femoral artery pulsation. Maintain slight constant negative pressure throughout the insertion. Apply pressure for a minimum of 5 minutes after the procedure and monitor for bleeding.

Figure 19.5 Femoral venipuncture. **A**, Anatomy. **B**, Technique.

Radial Arterial Blood Sampling

A

The radial artery is preferred for sampling procedures. Its superficial location is easy to palpate and puncture, and there are no immediately adjacent nerves or veins that may be injured or accidentally punctured.

Hold the wrist in a position of supination and slight extension. Insert the needle at a 30° to 45° angle while applying continuous, gentle suction with the plunger. Advance the needle until the radial artery is punctured and blood is returned or until resistance is met (see Fig. 19.7).

Figure 19.6 Radial arterial blood sampling. **A**, Anatomy. **B**, Technique.

Figure 19.7 Resistance met during passage of the blood gas needle usually indicates contact with bone. The needle should be withdrawn slowly. If the needle has traversed both walls of the artery, blood will be obtained as the needle is slowly withdrawn into the arterial lumen.

slightly extended (i.e., dorsiflexed). Palpate the arterial pulsation just proximal to the transverse wrist creases. Do not overextend the wrist because this can cause loss of the arterial pulse during palpation. Make a small indentation in the skin with a fingernail to mark the insertion site. Cleanse the area with antiseptic and allow the skin to dry. The topical anesthetic options discussed previously may be used if the clinical situation permits. Penetrate the skin at a 30- to 45-degree angle. As the plunger of the syringe is gently withdrawn by an assistant, advance the needle slowly until the radial artery is punctured or resistance (bone) is met (Fig. 19.7). In contrast to performing the procedure in adults, provide continuous, but gentle suction with the plunger of the syringe in infants. Pulsating or rapidly flowing blood that appears in the hub of the needle is a good indication that the radial artery has been punctured. Some clinicians prefer to attach the syringe to the butterfly needle only after blood return is noted. Suction can be applied afterward.

If resistance is met while pushing the needle deeper, withdraw the needle slowly because both walls of the artery may have been punctured, but the tip may reenter the lumen on withdrawal. If no blood returns, withdraw the needle slowly to the point at which only the distal tip of the needle remains beneath the skin. Repeat the procedure after checking the location of the pulse and reorienting the needle. After the desired amount of blood is obtained, remove the needle and apply pressure for 5 minutes or longer to prevent hematoma formation.

Complications

Complications of radial artery puncture include infection, hematoma, arterial spasm, tendon injury, and nerve damage. With proper technique, however, the complication rate is extremely low. If the infant starts to cry before blood is obtained, the PO₂ and PCO₂ values may not reflect the infant's true steady state.

VASCULAR LINE PLACEMENT: VENOUS AND ARTERIAL

Intravascular lines are indicated when ongoing access to the venous or arterial circulation is necessary. Remember to consider

using local anesthetics or procedural sedation if the clinical situation permits.

Peripheral Venous Catheterization: Percutaneous

Indications and Contraindications

In general, peripheral IV lines are indicated when the patient is unable to attain medical and nutritional goals with enteral therapy. These lines are used to provide fluids for resuscitation and maintenance needs and for the administration of medications.

Equipment and Setup

Over-the-needle catheters such as the Angiocath, JELCO I.V. (Smiths Medical, Dublin, OH) are the mainstay of peripheral venous catheterization. These thin-walled, flexible catheters range in size from 14 to 24 gauge. Select the appropriate gauge and length of the catheter based on the size of the child and the clinical situation. Larger-diameter catheters allow more rapid administration of fluids in emergency situations but may decrease the success of cannulation in young children with small veins. In general, use the smallest-gauge catheter that is appropriate for the clinical situation. For infants, a 22- to 24-gauge catheter is generally appropriate.

Attach T-connector extension tubing to the catheter after insertion to facilitate blood collection. This device makes flushing the catheter easier, especially while taping and securing the IV line. It also allows dressing changes without disturbing the IV insertion site.

Use either a homemade or commercially available device to protect the IV site from a child's attempts to remove the line. An arm or leg board appropriate for the size of the child provides stabilization of the extremity after insertion. Macrodrip tubing and liter bags are inappropriate for use in infants because they can result in the inadvertent infusion of large amounts of fluid. An infusion pump is an ideal way of limiting fluid infusion while keeping the vein open.

Vein Imaging Devices

A variety of imaging modalities, including ultrasound, transillumination, and infrared technologies, can be used to help locate peripheral veins for cannulation. In adults, data support the use of ultrasound to facilitate peripheral vein cannulation in those with difficult access.^{11,12} The data is more limited in children. Several small pediatric studies demonstrated a modest benefit of ultrasound, especially in patients with difficult access¹³⁻¹⁵ and other studies have shown no benefit.¹⁶

Transillumination has been shown to facilitate peripheral venous cannulation in infants and small children.¹⁷ These devices work by projecting a high-intensity light into the patient's subcutaneous tissue, causing the veins to contrast with surrounding tissue, and making them easier to locate. Newer vein imaging technology, available as VeinViewer (Christie Medical Holdings, Memphis, TN), AccuVein (Cold Spring Harbor, NY), Vein-Eye (Newmaw Medical Ltd, Liverpool, United Kingdom), Veinsite (VueTek Scientific, Gray, ME), Vasculuminator (De Koningh Medical Group, Arnhem, the Netherlands) and others, uses near-infrared technology to project an enhanced image of the subcutaneous veins onto the patient's skin. Theoretically, knowledge of the location of the venous valves and the course of the vessel can assist the clinician in selecting the best area to be cannulated. However, multiple

studies have not demonstrated improved overall success rates in obtaining IV access.^{18–25}

Technique

Fig. 19.2 shows sites available for placement of a peripheral IV line. The most common sites chosen for IV insertion in infants and children are the superficial veins of the dorsum of the hand, the antecubital fossa, the dorsum of the foot, and the scalp (in newborns and small infants) (Video 19.1). The veins on the dorsum of the hand are relatively straight and are easily stabilized because they lie flat on the metacarpals. If the hand is chosen, take the child's hand preference into consideration and avoid the dominant hand or hand used for thumb sucking whenever possible. Veins in the antecubital fossa (cephalic and basilic veins) are easily accessible; however, the angulation across the fossa makes advancement of the catheter difficult. These veins may be palpable even if they are not easily visible. Tributaries of the dorsal venous arch on the dorsum of the foot, like those on the dorsum of the hand, are relatively straight, and the extremity is easily immobilized after insertion. Because indwelling catheters in this location prevent mobility, consider using this site only in preambulatory patients or after attempts at other sites have been unsuccessful. The scalp veins are easy to cannulate, but their use is primarily limited to small infants. The particular site is a matter of preference, so choose the vein that appears to be the easiest to cannulate. When possible select the most distal vein that is large enough to accommodate the catheter and leave the larger, more proximal veins in case the initial attempts are unsuccessful or prolonged IV therapy is needed. If peripherally inserted central venous catheter (PICC) placement may be required during the hospitalization, do not use PICC insertion sites if possible.

With few exceptions, the same techniques used for IV insertion in adults may be used in infants and children, especially in the veins of the distal ends of the extremities. If an extremity location is chosen, place a tourniquet proximal to the planned site of insertion. Warm the extremity to induce vasodilation in the surface veins. Flush the tubing of the T-extension set before venipuncture with a sterile IV solution, such as normal saline (NS), to prevent air embolism. Direct the IV catheter through the skin at a 10- to 20-degree angle and slowly advance it until blood return is noted (Fig. 19.8, *step 1*). Next, advance the catheter over the needle and into the vein. Retract the needle and connect the IV line to the hub of the catheter by means of a T-extension set (see Fig. 19.8, *step 2*). After 1 mL of saline has been flushed through the line, inspect the site for swelling, which may indicate infiltration. If an artery is entered during placement of the needle and fluid is infused, blanching will occur in the area. If this happens, remove the IV catheter, maintain slight pressure for 5 minutes, and repeat the procedure at another site.

Secure the catheter to the skin with a 0.5-inch piece of tape passed over the catheter hub and skin. Place a second piece of tape adhesive side up and slip it under the catheter hub. Cross it over the catheter hub in a V shape (see Fig. 19.8, *step 2*). After securing the catheter with tape, cover the entire area with a transparent sterile dressing such as Tegaderm (3M, St. Paul, MN) or OP Site (Smith and Nephew Medical, Massillon, OH). Loop back the tubing of the T-extension set, place a piece of tape midway over the tubing, and secure it to the skin. This ensures that the IV tubing will not be accidentally dislodged if it is suddenly pulled. Securely tape the hand and forearm to an arm board for immobilization (see Fig. 19.8,

step 3). Occasionally, the flow rate of the infusion may depend on the position of the catheter, especially if the catheter spans a joint or the tip abuts a venous valve. Adjust the hand position or catheter with strategically placed sterile gauze or withdraw the catheter slightly to remedy the problem.

Obtain blood specimens just after IV insertion. If the IV line has been flushed, the initial blood draw will be diluted. To prevent dilution, withdraw 5 mL of blood from the catheter before collecting the samples. This 5 mL of “waste” can be either discarded or reinstalled into the patient. Next, remove the syringe. Connect the T-extension tubing to the IV infusion tubing, and set the infusion pump at the desired rate. Send blood for culture only if the skin was cleaned with an appropriate antiseptic before insertion of the IV catheter.

If a butterfly infusion set is used, grasp the wings of the butterfly between the thumb and forefinger and introduce the needle beneath the skin approximately 0.5 cm distal to the anticipated site of vein entrance (Fig. 19.9, *step 1*). Advance the needle slowly toward the vessel until blood appears in the tubing, which indicates that the vessel has been entered. Next, remove the tourniquet if one was used. Flush the needle with 0.5 to 2 mL of IV fluid, such as NS, to ensure that the needle is properly in place within the vein. If infiltration occurs, as noted by a subcutaneous bump, remove the IV line and repeat the process at another site.

After the wings are secured, tape the tubing of the butterfly set in a loop so that it is not pulled inadvertently. Place a wisp of cotton under the wings of the butterfly if the flow rate of the infusion is affected by the position of the catheter. Tape a small medication cup over the wings and the needle to protect the IV line (see Fig. 19.9, *step 2*). Connect the tubing of the butterfly set to the tubing from the IV system. It is generally preferable to use standard over-the-needle IV catheters whenever possible, whether for extremity or scalp IV lines, because they are less likely to infiltrate and will last longer. However, a small butterfly needle that can be inserted temporarily until achievement of additional access is sometimes the only option short of IO access.

External Jugular Venous Catheterization

The external jugular vein is superficial and easily visible. It can be used when other attempts at peripheral IV access have been unsuccessful but can be difficult to access if airway or other procedures are occurring simultaneously. The procedure should be discussed with parents because laypersons may have fears about a needle being placed in their child's neck.

Technique. The external jugular vein is most often entered with a standard over-the-needle IV catheter. The vein lies in a line from the angle of the jaw to the middle of the clavicle and is usually visible on the surface of the skin. It is more prominent when the child is crying or in Trendelenburg position. Ask an assistant to restrain the patient in a supine position with the head and neck extended and a towel roll placed under the shoulders. Turn the head approximately 40 to 70 degrees from the midline and away from the side to be punctured (see Fig. 19.4). Cleanse the skin surrounding the area to be punctured with alcohol (or another antiseptic solution). If time allows, infiltrate the overlying skin with 1% lidocaine. Place a finger just above the clavicle to distend the jugular vein.

Puncture the skin approximately one-half to two-thirds of the distance from the angle of the jaw to the clavicle. Advance the needle slowly until the jugular vein is entered. Once there is a flash in the needle hub, advance the catheter into the vein.

Peripheral Intravenous Catheterization

1 Direct the catheter at a 10° to 20° angle toward the insertion site and advance until blood return is seen in the catheter and hub. Advance the catheter over the needle and into the vein.

2 Remove the needle, and attach the T-extension set to the catheter hub. Flush with saline, and secure the catheter to the skin with tape.

3 Secure the hand and forearm to an arm board.

4 Cover the insertion site with the plastic wrapper from the extension set for additional protection.

Figure 19.8 Pediatric peripheral intravenous catheterization. (See Fig. 21.6 for additional details on proper intravenous technique.)

Attach preflushed extension tubing or a syringe and obtain blood samples. Take particular care to avoid introducing air to prevent air embolism. Secure the catheter in place and apply a sterile occlusive dressing.

Complications

Serious complications of peripheral IV lines and IV fluid therapy are rare. Complications include infection, phlebitis, inadvertent arterial puncture, injection of sclerosing agents into the subcutaneous space with resultant necrosis of the skin (especially in small infants), pneumothorax, air embolism, and administration of inappropriate volumes of fluid. Puncture of the apex of the lung leading to pneumothorax is possible with external jugular puncture if the needle is inserted too far. Attention to antiseptic procedures during insertion and maintenance of the IV system decreases the risk of infection.

Peripheral Venous Catheterization: Venous Cutdown (See also Chapter 23)

Indications and Contraindications

Peripheral venous cutdown is rarely performed in the ED because IO access is rapid and safe. Even in experienced hands, a saphenous vein cutdown may take more than 10 minutes and is associated with a higher rate of infection than other routes of vascular access.²⁶ Nevertheless, if peripheral venous, central venous, or IO access cannot be obtained, venous cutdown may provide an alternative means of emergency venous access. Contraindications to peripheral venous cutdown are major trauma to the extremity, vascular injury of the extremity proximal to the intended site of cutdown, or soft tissue infection of the intended incision site.²⁷ A coagulation disorder is a relative contraindication.

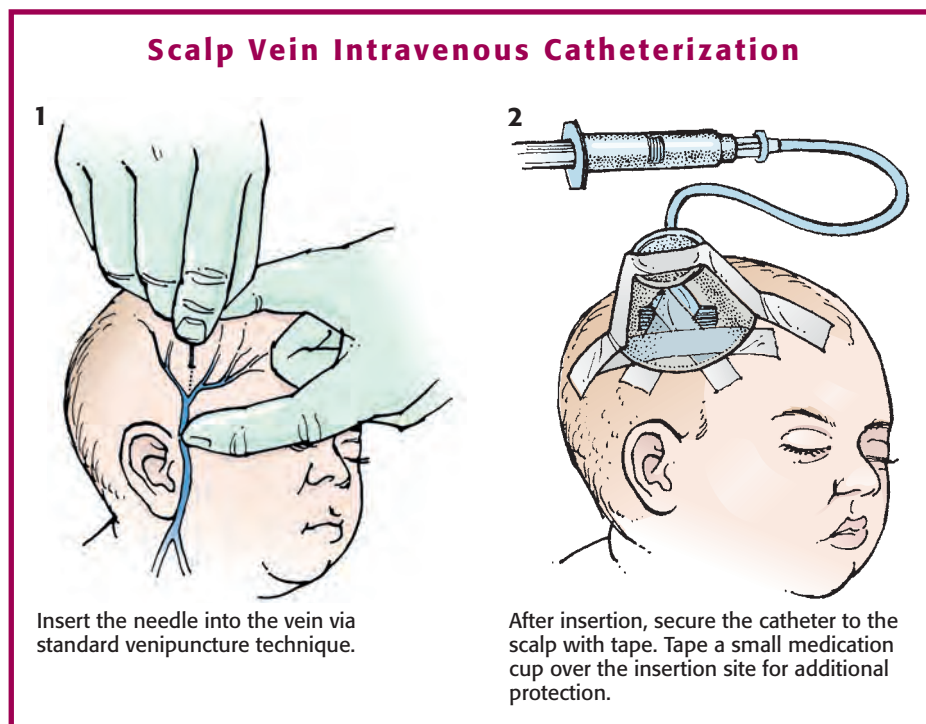

Fig 19.9 Scalp vein intravenous catheterization using a butterfly needle.

Equipment and Setup

Successful venous catheterization via cutdown in infants and small children requires an assistant, good lighting, and a selection of standard IV catheters or silastic catheters prefilled with NS. Sterile instruments may be available in a “cutdown tray” or can be individually assembled. Assemble regular and mosquito hemostats, fine forceps, a vein dilator, a vein lifter, silk suture, a needle driver, and fine scissors or a scalpel.

Technique

For the purpose of illustration, exposure and cannulation of the saphenous vein will be discussed (Fig. 19.10). The same principles apply when cutdown is performed on most peripheral veins. Begin with complete immobilization of the thigh, leg, ankle, and foot by taping them to a padded leg board. Attach this board in turn to the table or bed where the procedure is being performed (see Fig. 19.10, step 1). Prepare the area around the medial malleolus with antiseptic solution and drape it with sterile towels. Infiltrate 1% lidocaine in an area approximately 1 cm proximal and 1 cm anterior to the medial malleolus. No major nerves or tendons accompany the saphenous vein in this location.

Place a tourniquet proximally on the leg and make a transverse skin incision (usually approximately 2 cm in length) in the anesthetized area. Insert a small mosquito hemostat into the wound with the concavity of the clamp upward. Using the tip of the hemostat, “scoop up” all tissue lying against the bone (see Fig. 19.10, step 2). This will invariably lift the vein out of the wound along with the surrounding tissue. Use fine forceps or a mosquito hemostat to separate and remove all nonvenous structures so that only the saphenous vein is left tented over the hemostat (see Fig. 19.10, step 3). To avoid injury to the vein during dissection, spread the ends of the hemostat parallel to the direction of the vein, never transversely.

Pass two 4-0 silk sutures under the vein. Place one distally to stabilize the vein, and place the other proximal to the intended site of venipuncture. The distal suture may be tied, but if left untied it can still be used for stabilization of the vein and to occlude blood flow by applying gentle traction. Removing the untied distal suture after cannulation of the vein may allow subsequent recannulation after eventual catheter removal. Once the vein is isolated, either place a catheter surgically through a venotomy or cannulate the vein directly with a standard IV catheter. If venotomy is chosen, use fine scissors or a scalpel blade to make an oblique or V-shaped incision in the anterior wall of the vein between the sutures (see Fig. 19.10, step 4). Grasp the silastic catheter (prefilled with saline solution) with forceps and advance it into the vein for a distance of 2 to 3 cm (see Fig. 19.10, steps 5 and 6). This is usually the most difficult and time-consuming portion of the procedure. Use a vein dilator, an L-shaped lifter, or a forceps to hold the venotomy incision open (see Fig. 19.10, steps 7 and 8). Pull downward on the distal tie to provide countertraction and stabilize the vein during advancement of the catheter. Remove the tourniquet and tie the proximal suture around the vein with the catheter inside. Take care to avoid tying the suture so tightly that it occludes the catheter. If the distal suture was tied, tie the free ends of the suture around the catheter to provide additional stability. If the distal suture was not tied, remove it at this point. Tie the proximal suture to secure the catheter, but leave the ends long enough so that the suture can later be removed. This allows recannulation once the catheter is removed.

Alternatively, direct cannulation of the vein may be achieved more rapidly and, unlike venotomy, may preserve the vein for future cannulation. If direct cannulation is chosen, isolate and immobilize the vein, using a standard IV catheter to directly cannulate the vein. Essentially a percutaneous catheter insertion technique is used to catheterize a directly visualized vein (Fig. 19.11).

Venous Cutdown

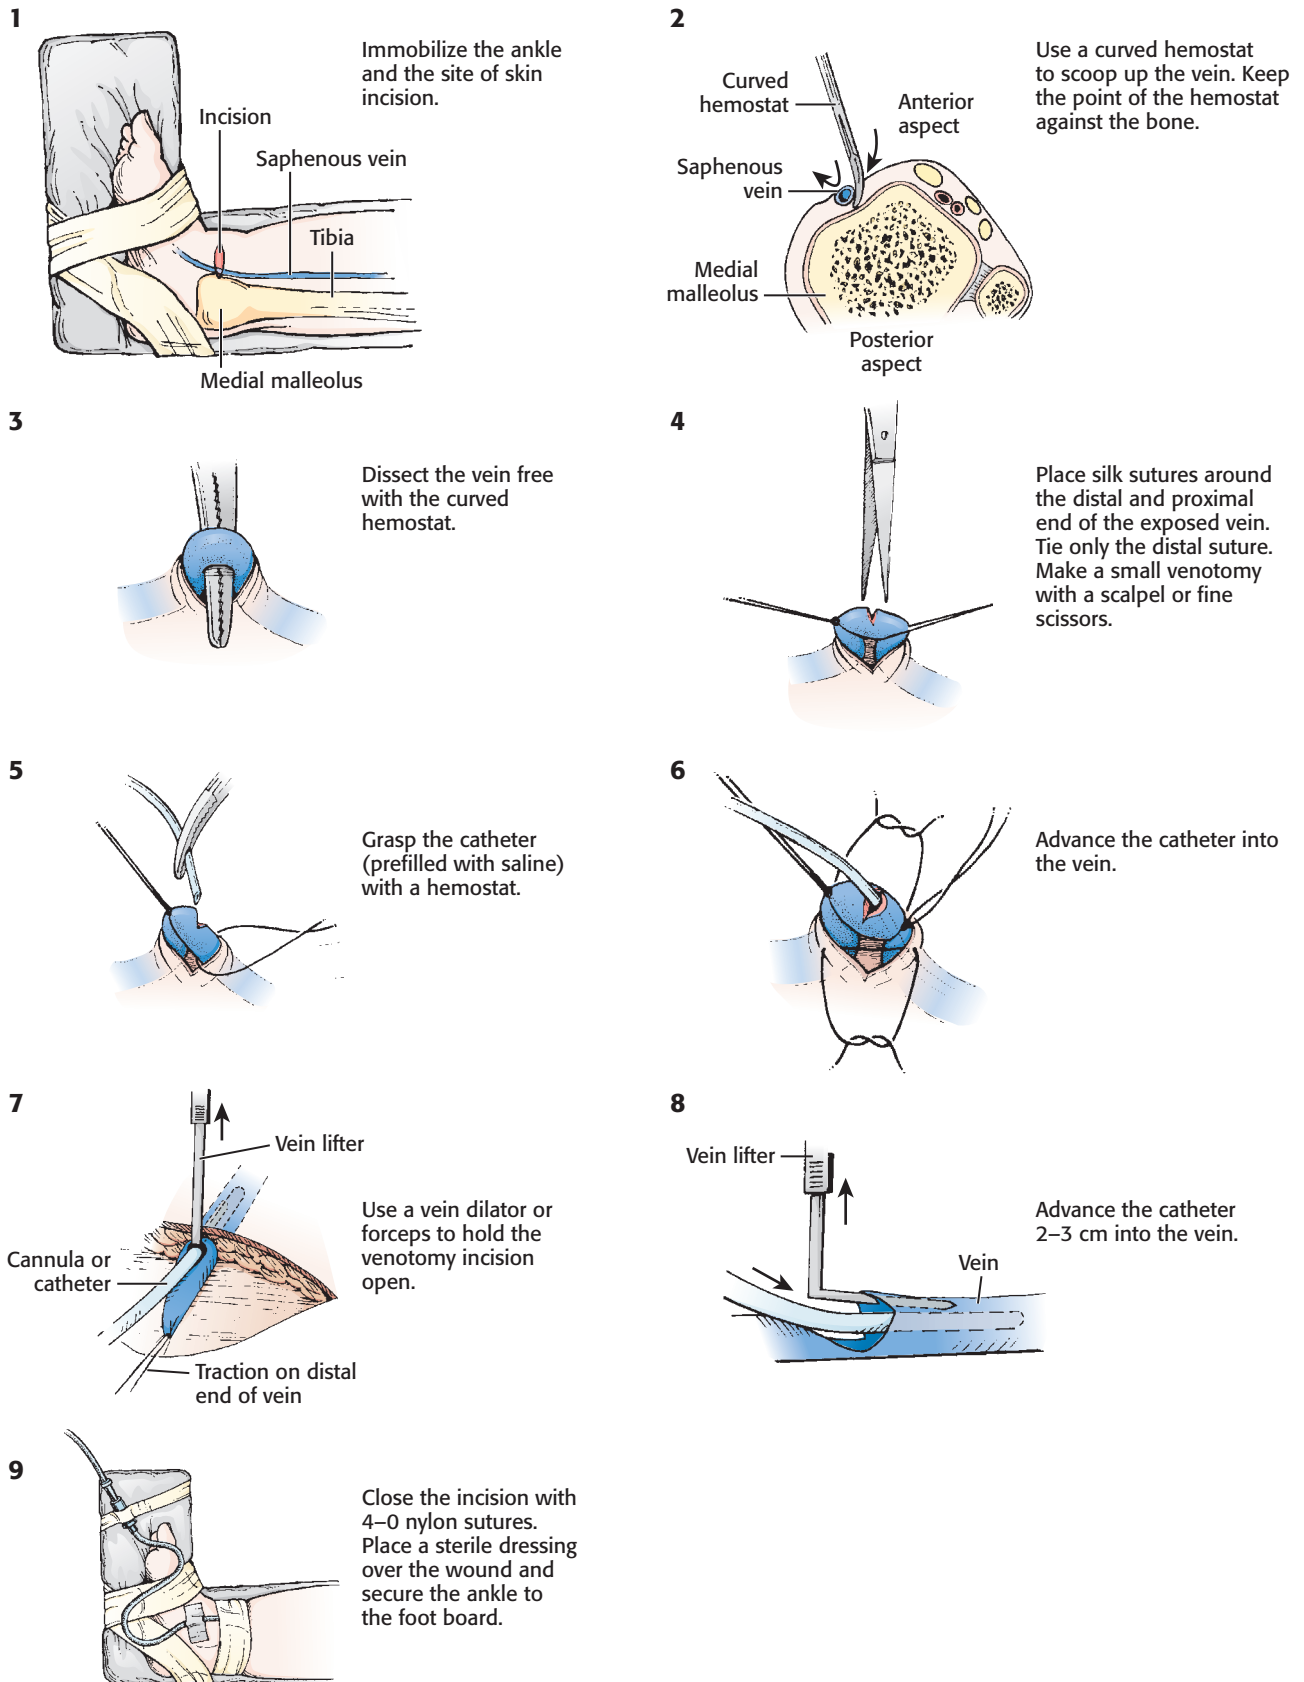

Figure 19.10 Venous cutdown (saphenous vein). (From Suratt PM, Gibson RS: *Manual of medical procedures*, St. Louis, 1982, Mosby. Reproduced by permission.)

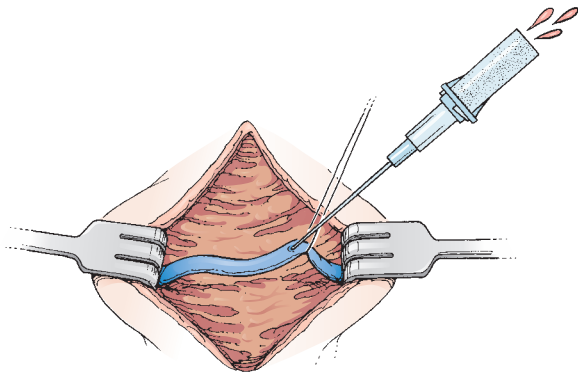

Figure 19.11 The “mini-cutdown” procedure using a standard intravenous catheter-over-the-needle system is technically easier than a full cutdown and may be preferred in an emergency.

Continued infusion of saline through the catheter from an attached syringe will ensure patency. Orient the catheter into one corner of the incision and close the incision with interrupted 4-0 nylon suture. Wrap the skin suture nearest the catheter around it and tie it to hold the catheter in place. Control bleeding with direct pressure. Place antibiotic ointment over the wound and apply a sterile occlusive dressing. Connect the IV tubing and tape it securely to the foot board to prevent inadvertent removal of the catheter (see Fig. 19.10, step 9).

Change the dressing carefully every day with sterile technique and reapply antibiotic ointment. When cared for properly catheters can remain in place for as long as 7 to 10 days, but generally it is best to replace the catheter and insert it into another site after 3 to 4 days. At the first sign of infiltration or infection, remove the catheter. See Chapter 23 for more information on venous cutdown techniques.

Complications

In addition to the problems with percutaneous catheter placement that were discussed previously, venous cutdown can result in wound infection and thromboembolism. Adjacent structures may be injured during the incision and subsequent blunt dissection. Extravasation of infusate may result if the vein is not ligated. Light pressure on the closed wound will generally prevent continued extravasation.

Central Venous Catheterization: Percutaneous

Indications and Contraindications

Central venous cannulation is indicated in the ED when peripheral venous access is limited or impossible. In young children central line placement can almost always be delayed until after initial stabilization. Central venous lines have traditionally been used for hemodynamic monitoring but the use of point-of-care ultrasound in the ED may decrease this need. Ultrasound evaluation of the inferior vena cava (IVC) can be used to estimate intravascular volume status.²⁸ Central venous access is preferred for infusion of vasoactive and sclerosing medications. Nevertheless, 2007 pediatric sepsis guidelines state that vasoactive infusions, including epinephrine, can be started via IO or peripheral venous lines, so placement of a central venous line is not required prior to starting vasopressors.²⁹

TABLE 19.1 Pediatric Central Line Sizes

AGE (YEARS)	WEIGHT (kg)	CATHETER SIZE (Fr)
<1	<10	3.0
1–5	10–20	4.0
6–10	20–32	5.0
11 +	32 +	6.0

Contraindications to percutaneous placement of central venous catheters include local infection or burns at the insertion site; vascular insufficiency of an extremity; or obstruction or compression of the access veins by tumor, abnormal vessels, hematoma, or thrombus. Caution should be used in patients with uncorrected coagulopathies or with malformations or deformations distorting vascular anatomy. Attempts at central venous access should not result in a delay in medication and fluid administration during resuscitation efforts, but if a central line is in place, medications should be given centrally rather than peripherally.³⁰

Equipment and Setup

Commercially available kits are convenient because they contain most of the items needed for the procedure. The catheters in these kits are typically made of a silicone elastomer, polyvinyl chloride, or polyethylene; some are available with an antimicrobial coating, which may reduce infection rates. Catheter length is variable and one- to three-lumen catheters are available. Rapid volume replacement, as in the case of severe dehydration or acute blood loss from trauma, is best achieved by inserting a short, large-bore catheter for the initial resuscitation and stabilization. Table 19.1 lists appropriate central line sizes by age and weight.

Other necessary equipment includes antiseptic solution, gauze pads, sterile drapes, gowns, sterile gloves, caps, masks, syringes (3, 5, and 10 mL), sterile transparent skin coverings, Luer-Lok three-way stopcocks, 0.25% to 1.0% lidocaine, flush solution (1 to 2 Units heparin/mL NS), and IV tubing with a T-connector extension. Depending on the vein to be accessed, restraint of the extremity, pelvis, or head may require a padded support, an assistant, or both.

Technique

Young patients should ideally be sedated, or if that is not possible, well restrained, to minimize movement during the procedure. Local anesthesia should be administered prior to central line placement. Equipment should be placed in an easily accessible location to minimize the need to reach or move while inserting the catheter. All catheter lumens should be preflushed and clamped before beginning the procedure.

Strict sterile precautions with cap, gown, mask, and sterile drapes should be used when placing all but the most emergent central lines to decrease the risk of catheter-associated bloodstream infections. The skin should be cleaned with chlorhexidine in preparation for the procedure unless there is a specific contraindication to chlorhexidine.^{31,32} In this case, betadine may be used.

Percutaneous placement of central venous catheters can be accomplished with either a guidewire (Seldinger) technique or an over-the-needle catheter. It can be difficult to thread a

guidewire in young children; one technique to maximize the chance of placing a usable catheter is to use a modified Seldinger technique. Use the over-the-needle catheter from the central line kit to place a catheter. The catheter can be left in place for initial resuscitation or the guidewire can immediately be advanced through the catheter. If the guidewire can be threaded into the vein, the catheter can then be removed, the skin dilated, and the longer central catheter can be placed over the wire. If the guidewire cannot be advanced sufficiently through the catheter, remove the guidewire and leave the catheter in place for venous access. The catheter-over-the-needle technique can be used in the femoral, subclavian, or internal jugular veins.

Ultrasound guidance for internal jugular, subclavian, and femoral line placement has been shown to improve safety in adult patients^{33,34} and the Agency for Healthcare Research and Quality has identified the use of ultrasound guidance for placement of central venous catheters as an important patient safety practice.³⁵ Although there is less literature on the use of ultrasound for placement of central lines in children, ultrasound-guided central line placement has been associated

with decreased numbers of punctures, complications, and increased procedural success in pediatric patients.³⁶⁻³⁸

Femoral Catheterization

Femoral venous catheterization is the central venous access route most commonly used in infants and children in emergency situations (Fig. 19.12). The anatomy is fairly straightforward and the femoral arterial pulse provides a good landmark for femoral venous catheterization. The femoral site is advantageous because the risk of mechanical complications is low. In the event of inadvertent arterial puncture or venous laceration, hemostasis can be achieved by the application of direct pressure. Femoral vein catheterization does not carry any risk for hemothorax or pneumothorax. Studies in children have found that when controlling for other factors, such as number of days the catheter is left in place, use of the femoral location does not pose a higher risk of catheter-associated bloodstream infection when compared to subclavian or internal jugular vein locations.^{39,40} Another advantage is that placement of a femoral catheter is less likely to interfere with other resuscitative

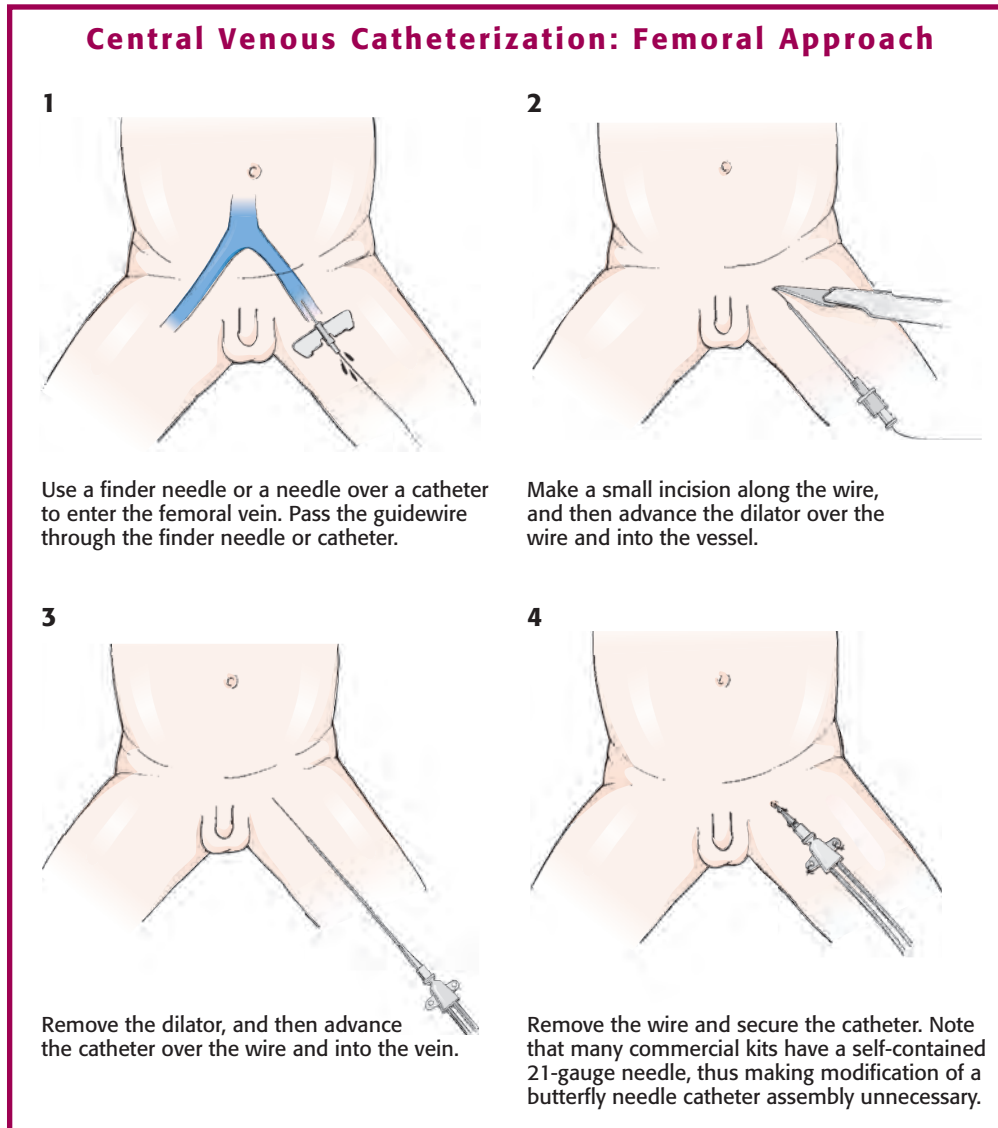

Figure 19.12 Central venous catheterization: femoral approach.

procedures than placement of a subclavian or internal jugular catheter.

Technique. Restrain the child adequately to permit exposure of the inguinal region. Use an introducer needle with or without a syringe to enter the femoral vein. If using landmarks rather than ultrasound to locate the vein, palpate the femoral artery with one finger, and puncture the skin just medial to the artery. Enter the skin at a 30- to 45-degree angle approximately 1 cm below the inguinal ligament. Direct the needle in a line toward the umbilicus. If using a finder needle with a syringe, apply continuous, gentle suction while inserting the needle. Gently pass the wire through the needle into the proximal end of the vein when blood return is noted. The wire should not meet resistance when introduced gently. Make sure that the proximal end is always visibly protruding from the hub of the needle. If resistance to passage of the wire is encountered, remove it to assess the needle's position within the vessel. If resistance to removal of the wire is encountered, withdraw the needle and the wire together to prevent shearing off the end of the wire.

An alternative method is to use the catheter over the needle that is supplied in the central line kit to enter the vein and advance the catheter into place. Once the catheter is placed, remove the needle and advance the wire through the catheter. If the wire threads completely, leave the wire in place and remove the catheter. If the wire cannot be threaded into the vein, remove the wire, leaving the catheter in place, and secure the catheter to be used for access until alternative access is obtained. Always occlude the hub of the open finder needle or catheter with a sterile gloved finger when the wire is not in place to prevent excessive blood loss or air embolism.

Once the wire is in place and the catheter or needle removed, make a small incision (1 to 2 mm) with a No. 11 scalpel blade in the skin at the wire's entry point to allow passage of the dilator (see Fig. 19.12, step 2) and the catheter itself. When making the incision, point the sharp edge of the blade away from the wire. Advance the dilator gently over the wire and then remove the dilator. Advance the catheter over the wire and into the vein (see Fig. 19.12, step 3). Remove the wire. Withdraw blood from the catheter ports and then flush them with a sterile saline solution. Secure the catheter to the skin with silk or nylon sutures (see Fig. 19.12, step 4). Place a sterile, transparent, and impermeable dressing over the exit site.

Note that during cardiopulmonary resuscitation (CPR), palpable pulsations or Doppler tones in the femoral vein may be detected. Hence, if the vein is not found medial to the pulsations, consider catheterization of the pulsating vessel during CPR as a last resort when other options for vascular access or drug delivery are unavailable. Alternatively, ultrasound can be used to locate the femoral vein.

Internal Jugular Venous Catheterization

The internal jugular veins lie within the carotid sheath along with the carotid artery and vagus nerve. The lower part of the vein lies within the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and then becomes more lateral and anterior to the artery as it joins the subclavian vein. The right internal jugular vein is preferred over the left because the internal jugular, the innominate vein, and the superior vena cava form a nearly straight line into the right atrium and complication rates appear to be lower.⁴¹ Placement of internal jugular venous access may not be possible when

other critical procedures are occurring and it is not possible if the patient is in a cervical spine immobilization device.

Technique. Three approaches to internal jugular catheterization are possible (including the anterior, median or central, and posterior approaches, as discussed in Chapter 22). The median or central approach is described here. Use of ultrasound to guide cannulation of the internal jugular vein appears to improve success rates (see Chapters 22 and 66).⁴² Position the child in the same fashion as described for external jugular venous catheterization. The Trendelenburg position will distend the vein. For the medial or central approach, use the apex of the angle formed by the sternal and clavicular heads of the sternocleidomastoid muscle as the puncture site. If a line were drawn from the mastoid process to the sternal notch, the apex of the angle formed by the two muscular heads would fall approximately along the middle third of that line. Introduce a needle attached to a syringe at the apex of the triangle at an angle of 30 degrees downward and toward the ipsilateral nipple (Fig. 19.13). Advance the needle slowly until the jugular vein is entered. Keep the syringe connected to the needle at all times to maintain constant negative pressure and avoid air embolism. After blood flow is obtained, remove the syringe and place a finger over the hub of the needle. Insert a guidewire during a positive pressure breath or exhalation. Remove the needle and introduce a catheter via the Seldinger technique. Pass the catheter far enough to reach the junction of the superior vena cava and right atrium. Check the catheter for blood return, secure the line with sutures, and apply a sterile occlusive dressing. Confirm proper location of the catheter and rule out pneumothorax with a chest radiograph.

Subclavian Venous Catheterization

The subclavian vein is used less frequently for central venous access in children than in adults (see Fig. 19.13). The technique is more difficult in pediatric patients because of the smaller size of the vessel, as well as a more cephalad location under the clavicles. Placement of subclavian venous access may not be possible when other critical procedures are occurring or if the patient cannot be properly positioned due to cervical spine immobilization.

Technique. The approach to the vein is more lateral in children than in adults. The infraclavicular approach is described hereafter. Turn the patient's head away from the side to be punctured and place a towel roll under the shoulders. The right side is preferred because the dome of the lung is more cephalad on the left side. The needle insertion site is at the distal third of the clavicle in the depression created between the deltoid and the pectoralis major muscles.

Introduce the finder needle bevel up and advance it slowly while applying negative pressure with the attached syringe. Keep the syringe and needle parallel to the frontal plane. Direct the needle medially and slightly cephalad, beneath the clavicle toward the posterior aspect of the sternal end of the clavicle (i.e., toward a fingertip placed in the sternal notch). Advance the needle until blood return is obtained. Turn the syringe so that the bevel of the needle points caudad to direct the guidewire to the superior vena cava. Remove the syringe from the needle and insert the wire during a positive pressure breath or natural exhalation. Remove the needle and introduce the catheter over the wire via the Seldinger technique, as previously described for femoral catheterization. The cardiac monitor may show a

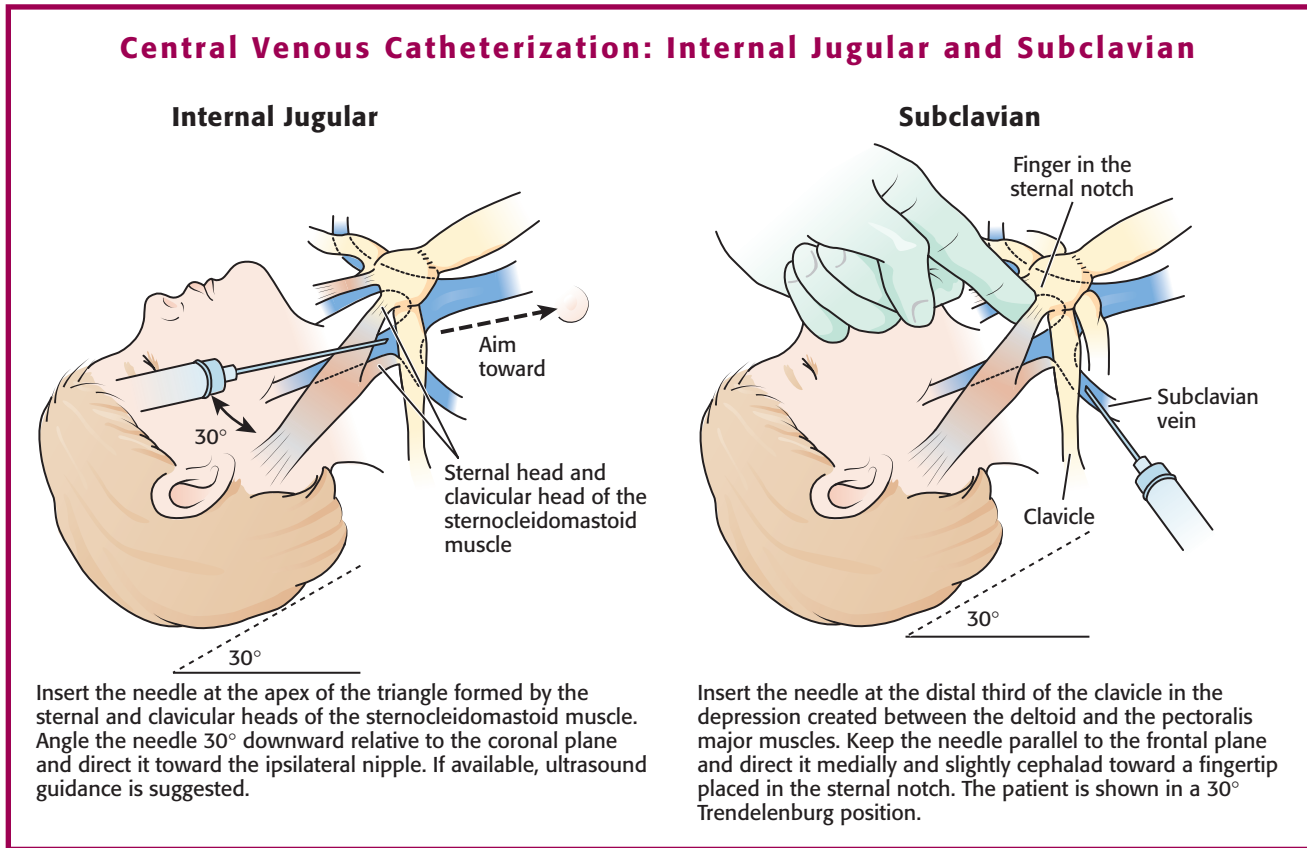

Figure 19.13 Central venous catheterization: internal jugular and subclavian approaches.

rhythm disturbance if the wire is advanced too far. Secure the catheter in place with sutures and apply a sterile, occlusive dressing. Perform auscultation of bilateral breath sounds and obtain a chest radiograph to confirm proper positioning of the catheter in the superior vena cava and to rule out procedural complications such as pneumothorax or hemothorax.

Complications

Infection, thrombosis, and arterial puncture are the major risks associated with central venous catheters. The risk of pneumothorax and hemothorax is approximately 2% and 1%, respectively, with subclavian catheter placement.³² Pneumothorax is a less frequent complication of internal jugular catheter insertion. Other complications include accidental displacement, phlebitis, hemorrhage, hematoma, dysrhythmia, air embolism, vascular obstruction or perforation, right atrial perforation, and localized edema. Sterile technique must be used when accessing indwelling central lines for blood draws or medication and fluid administration to minimize risk of catheter-associated bloodstream infections. Remove catheters as soon as they are no longer needed to minimize the risk for complications.

Emergency Vascular Access

Vascular access is a key component of any resuscitation to allow the administration of fluid and medications and to obtain blood samples. However, achieving venous access during pediatric resuscitation can challenge even the most seasoned clinician, not infrequently requiring 10 or more minutes. Children who are successfully resuscitated have vascular access

achieved significantly sooner than those not resuscitated. Emergency IV access is most prolonged in children younger than 2 years, the age group in which the majority of cardiopulmonary arrests occur.

For these reasons, clinicians should obtain IO access in critical patients if IV access is not established quickly, rather than delay treatment with attempts to place peripheral or central venous catheters (see [Chapter 25](#)).³⁰ IO lines are easily and rapidly placed, can accept any drug given parenterally in similar doses, and are likely underused in many EDs.⁴³ If no IV or IO line is available, give certain drugs via the endotracheal tube (see [Chapter 26](#)) while attempts at venous access are initiated. However, endotracheal drug administration has been shown to be less efficacious than IV administration in adults, and this route of administration should be used only when no alternatives are available. Placement of an internal jugular, subclavian, or femoral line can prove time-consuming⁴⁴ and is thus discouraged in the unstable patient. Umbilical and IO lines are effective alternatives.

Umbilical Vein Catheterization

Indications and Contraindications

The major indication for umbilical vein catheterization is the need to access the vascular system for emergency resuscitation and stabilization of neonates. It may also be used for exchange transfusions and short-term central venous access in newborns. The umbilical vein may remain patent for up to 2 weeks after birth. In neonates who require emergency access in the ED,

a peripheral vein would be preferable, but attempting to cannulate one of the umbilical vessels could be lifesaving. Omphalitis, omphalocele, gastroschisis, and peritonitis are all contraindications to access of the umbilical artery or vein.

Equipment and Setup

Place the infant beneath a radiant warmer because keeping the infant warm during the procedure is critical. Restrain the extremities. Wear a mask, cap, gown, and sterile gloves. Assess the length of catheter needed before the procedure. Methods to estimate the best length for both umbilical vein and artery lines are discussed hereafter.

Technique

Hold the umbilical stump upright and scrub the cord with a bactericidal solution. Avoid pooling of liquid at the infant's side because this may be associated with blistering of the skin under a radiant warmer. Drape the umbilical area in sterile fashion with the infant's head left exposed for observation (Video 19.2).

Place a loop of umbilical tape or a purse-string suture at the junction of the skin and the cord to provide hemostasis and to anchor the line after placement (Fig. 19.14, step 1). Cut the cord with a scalpel approximately 1 cm from the skin (often less in infants who are not newly born), and identify the vessels. There are two arteries and one vein in the umbilicus. The vein is usually located at 12 o'clock and has a thin wall and large lumen. It may continue to bleed after cutting. The two arteries have thicker walls and smaller lumens. Constriction reduces bleeding after the arterial vessels are cut. Occasionally, a persistent urachus may be mistaken for the umbilical vein, but the presence of urine in the urachus may help correctly identify that structure.

Flush the catheter (3.5 Fr [preterm infants] to 5.0 Fr [term infants]) with heparinized saline and attach it to a three-way stopcock. Place the catheter into the lumen of the umbilical vein and advance it gently (see Fig. 19.14, step 2). An umbilical vein line can be placed in a fashion that is intended either for emergency use or for more chronic use. In an emergency case, advance the catheter only 1 to 2 cm beyond the point at which good blood return is obtained. This is usually only 4 to 5 cm in a term-sized infant. Beyond this distance, the umbilical vein branches. Therefore the catheter may enter a branch of the portal vein within the liver (as evidenced by resistance at 5 to 10 cm). Infusion of medications into a catheter in the portal vein can result in liver necrosis. In an emergent case, a line placed no greater than 5 cm into the patient can be used without confirmatory radiographs.

If the patient does not require emergent access and a more enduring line is desired for blood draws, monitoring central venous pressure or infusion of medications, high concentrations of glucose (>10%), IV fluids, and hyperalimentation solutions, then the line is instead inserted 10 to 12 cm in a term-sized infant to reach the IVC. Because of the potential for placement into the portal vein and resultant complications, radiographs are required prior to usage to confirm placement into the IVC. Note that an umbilical venous catheter will proceed directly cephalad (without making a downward loop) until it passes through the ductus venosus (Fig. 19.15).

Some practitioners use standardized graphs to estimate the length of insertion. Such graphs are based on the shoulder-to-umbilicus length (Fig. 19.16A). Shoulder-to-umbilicus length is the perpendicular line measured from the tip of the shoulder to the horizontal level of the umbilicus. If the graph is not available, the shoulder-to-umbilicus length multiplied by 0.6 gives an approximate insertion length that will result in the

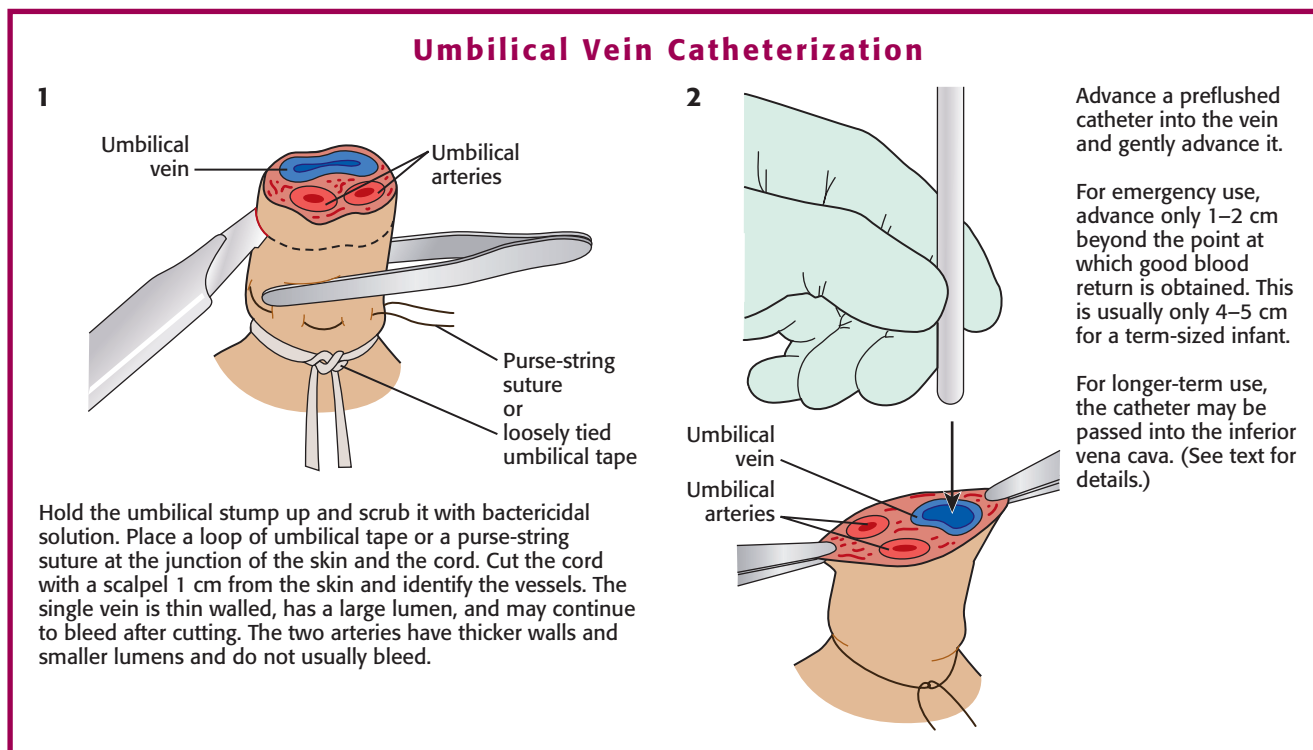

Figure 19.14 Umbilical vein catheterization. (From Zaoutis L, Chiang V: *Comprehensive pediatric hospital medicine*, Philadelphia, 2007, Elsevier.)

tip of the catheter being above the diaphragm but below the right atrium in the IVC.⁴⁵ Formulas based on birth weight, such as $(1.5 \times \text{birth weight in kg}) + 5.5 \text{ cm}$, can further guide placement.⁴⁶

Air embolism may occur at the time of catheter removal if the infant generates sufficient negative intrathoracic pressure

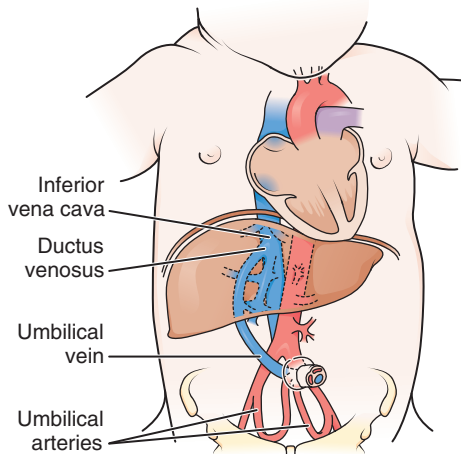

Figure 19.15 An umbilical venous catheter will proceed directly cephalad (without making a downward loop) until it passes through the ductus venosus.

(as during crying) and causes air to be drawn into the patent umbilical vein. Therefore caution must be used during removal of the catheter to ensure that the vein is promptly occluded (by tightening a purse-string suture or applying pressure on or just cephalad to the umbilicus).

An alternative method has been described. In this method, maintain the clamp on the umbilical cord, then make a cut proximally in the amniotic membrane over the umbilical vein and bluntly dissect through Wharton's jelly down to the vein. At this point, place a catheter into the umbilical vein through this site. The remainder of the procedure is identical to the standard technique. This option may be attractive in situations where transecting the cord proximal to the site of the clamp is not possible or not desired.⁴⁷ Similarly, use of a 14-gauge angiocatheter with the needle removed has been described, and may be an option if an umbilical line or feeding tube is not readily available.⁴⁸

Complications

Complications of umbilical venous catheters include hemorrhage, infection, injection of sclerosing substances into the liver (resulting in hepatic necrosis), air embolism, catheter tip embolism and resultant ischemia (including myocardial infarction), liver hematoma, arrhythmias, effusions, malplacement, and vessel perforation.⁴⁹⁻⁵¹ Although careful technique during insertion and maintenance should be maintained to minimize complications, studies suggest that the overall complication rate of umbilical venous catheters is lower than femoral catheters, predominantly due to a lower thrombosis rate.⁵²

Figure 19.16 A, After measuring the shoulder-to-umbilicus length, a standardized graph can be used to determine the appropriate length of the umbilical venous catheter, or B, the umbilical arterial catheter. The venous catheter should be inserted into the inferior vena cava below the level of the right atrium. The appropriate length of the arterial catheter depends on whether a “high” or “low” line is desired (see text for explanation). (A and B, From The Johns Hopkins Hospital, Nechyba C, Gunn VL: *The Harriet Lane Handbook: A Manual for Pediatric Home Officers*, ed 16, St. Louis, 2002, Mosby.)

Umbilical Artery Catheterization

Indications and Contraindications

Umbilical artery catheterization is a useful procedure in the care of newborn infants who require frequent monitoring of ABGs and arterial blood pressure, fluid and medication administration, and exchange transfusions. Either one of the two umbilical arteries may be cannulated for resuscitation purposes, but an umbilical vein is generally technically easier to cannulate and may be preferred in an emergency. These arteries can typically be accessed up to 7 days after birth.⁵³ Contraindications include those described in umbilical venous access, as well as necrotizing enterocolitis.

Equipment and Setup

The equipment required for umbilical artery catheterization is identical to that used for umbilical venous catheterization.

Additional equipment needed for continuous arterial pressure monitoring and infusion should be readily available. Estimate the catheter length needed before starting the procedure. Do this by using a standard graph (see Fig. 19.16B) or a birth weight regression formula.

Technique

The technique of umbilical artery catheterization is similar to that described for umbilical vein catheterization in the preceding section. After the umbilical arteries have been located (Fig. 19.17, *step 1*), grasp the cord with a curved hemostat near the selected artery. Ask an assistant to use two hemostats to grasp each side of the cord and slightly evert the edges to aid in exposure of the arteries. Using curved iris forceps without teeth, gently dilate the artery (see Fig. 19.17, *step 2*). Sometimes, repeated passes of the forceps are required because the umbilical artery can spasm and make the procedure difficult. Attach a

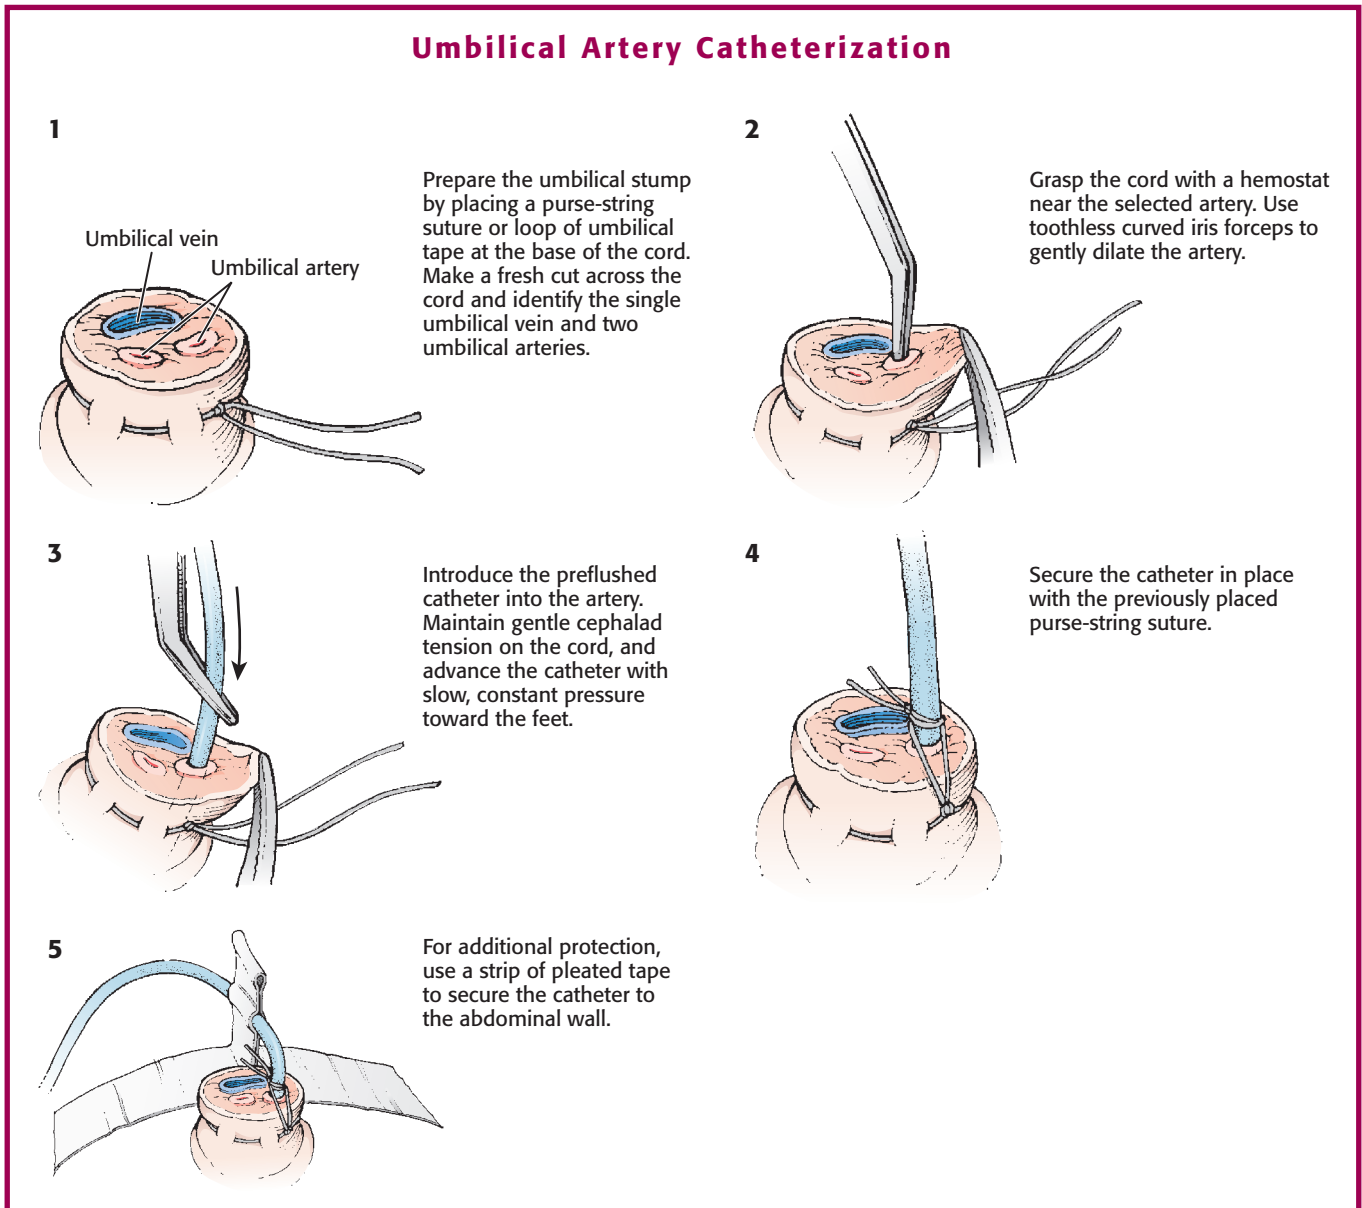

Figure 19.17 Umbilical artery catheterization.

3.5-Fr to 5-Fr catheter to a three-way stopcock and flush it with a sterile heparinized solution. Introduce the catheter into the dilated artery (see Fig. 19.17, step 3). Use a 3.5-Fr to 4-Fr catheter for infants weighing less than 2 kg and a 5-Fr catheter for those weighing 2 kg or more.

When the catheter is being inserted, place gentle tension on the cord in a cephalad direction, and advance the catheter with slow, constant pressure toward the feet. Resistance is occasionally felt at 1 to 2 cm. Overcome this with gentle, sustained pressure. On the other hand, if the catheter passes 4 to 5 cm and then meets resistance, this generally indicates that a “false passage” through the vessel wall has occurred, with the catheter curving caudad. Occasionally, one may bypass the perforation by reattempting catheterization with a larger catheter.

Acceptable positions of umbilical artery catheters are between T6 and T9 (“high line”) and between L3 and L5, just above the aortic bifurcation (“low line”). High lines are associated with a lower incidence of thrombotic complications.⁵⁴ Use graphs and formulas to estimate the proper catheter length for insertion at both the high and low positions (see Fig. 19.16B), but confirm placement with a radiograph. These formulas may not be as accurate in babies at the extremes of weight. A new formula, developed by Wright ($[4 \times \text{birth weight in kg}] + 7 \text{ cm}$), accurately predicts high-line location 83% of the time.⁵⁵ Once sterile technique is broken, do not advance the line. It is therefore preferable to position the catheter too high and to withdraw it as necessary according to postinsertion radiographs. This will show the catheter proceeding from the umbilicus down toward the pelvis, making an acute turn into the internal iliac artery, continuing toward the head into the bifurcation of the aorta, and then moving up the aorta slightly to the left of the vertebral column (Fig. 19.18). After it has been properly positioned, tie the catheter with the previously placed suture and tape it to the abdominal wall (see Fig. 19.17, steps 4 and 5).

Complications

Complications of umbilical artery catheterization include hemorrhage, infection, thromboembolic phenomena (especially

involving the kidneys, gastrointestinal tract, and lower extremities), aortic thrombosis, aortic aneurysm, vasospasm, air embolism, vessel perforation, peritoneal perforation, nerve lesions, and hypertension from renal artery obstruction.

If the catheter becomes plugged or fails to function properly, or if there is blanching or discoloration of the buttocks, heels, or toes, remove the catheter at once. Umbilical arteries are most easily cannulated in the first few hours of life but may provide a viable vascular route as late as 5 to 7 days after birth.

IO Catheterization (See also Chapter 25)

Compared to other forms of access, the IO line is rapid, cost-effective, and has a high success rate.⁵⁶ In the simulation setting, IO lines were placed an average of 46 seconds more quickly than umbilical lines without a significant difference in adverse events for neonatal resuscitations.⁵⁷ This delivery system makes use of the venous sinusoids in the medullary cavity of the long bones to infuse fluids, medications, and blood products into the venous system. Potential sites include the flat portion of the proximal tibia (1 cm medial and 1 fingerbreadth below the tibial tuberosity), distal femur, medial malleolus (2 cm above), humeral head, distal radius, and ulna. The sternum is a potential IO site; however, its use is not recommended with most modern drill sets. In growing children, care must be taken to avoid the growth plate.⁵³

Indications and Contraindications

IO access is recommended when peripheral access cannot be obtained safely at a pace that matches the illness of the child. Because the fluid can extravasate into the surrounding tissue causing a compartment syndrome, IO access should be avoided in a bone that is fractured or in which an IO line has been attempted within the previous 24 hours.⁵⁸ A proximal vascular injury, bony or overlying infection, and osteogenesis imperfecta are also contraindications. Typically, the duration of use of an IO line is limited to 24 hours.⁵⁹

Equipment and Setup

IO access can be achieved with the use of manual or mechanical puncture. The mechanical options include spring-loaded devices and reusable drills. In infants and children, both are successful, with more time required for manual insertion.⁶⁰ If a reusable drill is used, different sized needles are available depending on the weight and habitus of the patient. Needle options for the EZ-IO (Teleflex, Morrisville, NC) include pink 15-mm (3 to 39 kg), blue 25-mm (>40 kg), and yellow 45-mm (>40 kg with excess subcutaneous tissue) needles. Typically, the pink needles are used for pediatric patients receiving tibial IO lines; however, consideration should be given to use of a longer needle if the line penetrates more soft tissue (e.g., femoral IO).

Technique

All IO lines should be performed with sterile technique. The proximal tibia is preferred in children. After sterile preparation, the needle is held at a 90-degree angle to the bone and inserted. If a manual IO needle is used, a rotary motion will ease passage through the bone, whereas the drills are held stationary. A slight “give” or “pop” signifies that the needle is through the first cortex and into the medullary space. It is imperative to stop at that point to prevent penetration out of the bone into the soft tissue. The needle should stand unassisted if it is firmly

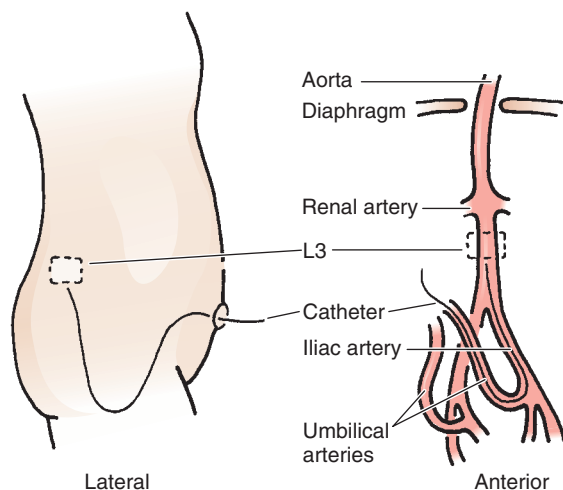

Figure 19.18 The umbilical artery catheter makes a loop downward before heading cephalad (schematic drawing of a radiograph interpretation).

Figure 19.19 Intraosseous line protected by a paper cup.

implanted in the bone. Often, bone marrow can be aspirated to confirm placement, and to send for laboratory analysis (excluding a complete blood count). Catheters are provided with some of the needles. The line should be flushed with 5 to 10 mL of saline while the provider's hand is on the patient's calf to confirm that fluid is not extravasating into the soft tissue.

In an awake patient, infusion of preservative-free lidocaine (typically, lidocaine intended for IV use in arrhythmias is available and appropriate for IO use) prior to the initiation of fluid can mitigate the pain associated with distension of the medullary cavity. The maximum dose is 20 mg to 50 mg, and children receive 0.5 mg/kg. Maximum gravity flow rates of 20 mL/min and pressure-driven rates of 40 mL/min are achievable, and standard resuscitation medications, including vasopressors, glucose, and blood products can be infused.⁵³ Pushing fluid via a syringe or the use of a pressure bag may be necessary to allow an acceptable rate of delivery in a critically ill patient. Securing an IO line is difficult, but a simple solution is to surround the needle and proximal tubing with a small inverted paper cup with the bottom removed and the cup taped to the leg (Fig. 19.19) if a device to secure the line is not included with the device.

Complications

Complications of IO access are rare,⁶¹ and include cellulitis, osteomyelitis, bony fracture, fat or bone marrow embolism, and extravasation of fluid into the extraosseous tissue leading to compartment syndrome.⁴⁶ If both cortices of a bone have been penetrated and fluid extravasates, a new bone must be selected. Clearly, use of the sternum may be associated with additional risks, due to the potential for trauma if both cortices of the sternum are penetrated.

Percutaneous Arterial Catheterization

Indications and Contraindications

Despite the growing use of noninvasive devices for monitoring transcutaneous oxygen and carbon dioxide, percutaneous peripheral artery catheterization may be indicated when there is a need for frequent blood gas sampling, continuous monitoring of arterial blood pressure, or both. However, mounting

evidence supports minimizing the frequency of ABG sampling; therefore this is not an intervention that should be considered mandatory in the intubated intensive care unit patient.^{62–65} Arteries used for peripheral catheters in infants and children include the radial, ulnar, femoral, dorsalis pedis, and posterior tibial arteries. If preductal blood gas values are required, the right radial artery is used. This procedure is rarely performed in the ED.

Peripheral arterial catheterization is contraindicated when: (1) adequate peripheral artery samples can be obtained by percutaneous puncture, (2) the circulation of the extremity to be catheterized is compromised, (3) occlusion of the vessel to be catheterized compromises perfusion of the extremity, (4) there is an ongoing bleeding diathesis, (5) localized infection or inflammation overlies the artery to be cannulated, (6) intensive monitoring of line function is not available, or (7) vascular grafts are present in the extremity.

Equipment and Setup

The equipment needed for arterial catheterization is essentially the same as that required for percutaneous peripheral venous catheterization. Some centers use commercially available arterial line kits, which come with all the necessary supplies and equipment. Alternatively, standard 22- or 24-gauge over-the-needle IV catheters, a T-piece connector, and a three-way stopcock can be used. Connect the T-piece and the stopcock and then fill them with NS solution. Prepare an infusion pump with heparinized saline.

Technique

Perform the procedure with good lighting and an adequate work area and monitor the infant's heart rate and respiratory rate closely. Palpate the radial artery proximal to the transverse wrist crease on the palmar surface of the wrist, medial to the styloid process of the radius. Before the procedure, compress the artery and observe the hand and fingers for change in color. If blanching or cyanosis is noted (indicating poor collateral circulation), do not perform catheterization. If locating the artery by palpation is difficult, a transillumination device, Doppler probe, or ultrasound may be helpful. Use of ultrasound improves success rate over Doppler alone.⁶⁶

Secure the infant's or child's hand and lower part of the forearm to an arm board, with the wrist dorsiflexed 45 to 60 degrees by placing a roll of gauze underneath it. Take care to leave the fingers exposed to allow assessment of the peripheral circulation. Palpate the radial artery at the point of maximal impulse and mark it by making a gentle indentation with a gloved fingernail. Prepare the area over the radial artery with povidone-iodine or another antiseptic solution and wash it with alcohol. Use a topical or local anesthetic (such as 1% lidocaine without epinephrine), or both, at the planned insertion site. Insert the catheter with the needle through the skin just proximal to the transverse wrist crease at a 10- to 20-degree angle (Fig. 19.20A). With the bevel of the needle facing proximally, advance the catheter slowly until blood appears in the catheter hub, which signifies puncture of the anterior arterial wall. Slowly advance the catheter until blood appears in the needle and then carefully lower the angle of the needle to approximately 10 degrees. Slowly advance the catheter over the needle and into the lumen of the artery. Remove the needle. Attach the stopcock and T-piece connector to the catheter hub. Open the stopcock to the syringe to confirm return of pulsatile blood. Flush it with 0.5 mL of heparinized solution

Radial Artery Catheterization

A
Introduce the catheter assembly into the radial artery through the skin at a 10° to 20° angle. This is a smaller angle than that used for simple arterial puncture.

B
One technique of taping the arterial catheter. The arm board should be well padded and secured.

Figure 19.20 Radial artery catheterization. (See Fig. 20.5 for additional details on this technique.)

very gently to clear the catheter and observe the fingers and the hand for evidence of blanching or cyanosis.

Kits are available to allow placement of an arterial line using the Seldinger technique. With this method, after the artery is accessed with the needle, insert a guidewire and remove the needle over the guidewire. Make a small incision in the skin at the base of the guidewire and then insert the catheter over the guidewire to the hub. Remove the guidewire. If there is resistance when the guidewire is inserted, remove the guidewire and attempt an alternate site. Sterile preparation and care of the catheter mirrors standard technique.

Fix the catheter to the skin with a thin piece of tape. With the adhesive side up, place the tape under the catheter hub and cross it over the catheter in a V shape. Pass a second piece of tape around and over the catheter hub to fix it to the wrist (see Fig. 19.20B). Add a transparent sterile dressing such as Tegaderm (3M) or OP Site (Smith and Nephew Medical) for an additional layer of security and protection. Use a small piece of tape to attach the T-piece connector to the wrist area or to the splint. Be sure that the fingers are easily visible.

Use only heparinized NS or half NS for infusion. Do not infuse medications, blood, blood products, amino acid solutions, IV fat solutions, or hypertonic solutions through the catheter. Remove the catheter if there is evidence of blanching or cyanosis, if it is impossible to withdraw blood from the catheter, or if it becomes difficult to flush the catheter.

Complications

Complications, which have been reported with every type of arterial catheter, include hemorrhage, thrombosis, spasm, infection, scars, air embolism, retrograde blood flow, transient elevation in blood pressure with rapid (<1 second) infusion, arteriovenous fistula formation, and nerve or tendon sheath damage. There is the potential for loss of digits, an entire extremity, or large areas of skin, and perfusion must be carefully

monitored. Additionally, concerns regarding the type of flush used in the arterial line and the impact on results of blood samples drawn from that line must not be underestimated. Normoglycemic patients have received insulin therapy based on falsely elevated glucose readings in samples taken from an arterial line flushed with dextrose-containing fluid.^{67,68} When decannulating the artery, apply pressure over the site for 3 to 5 minutes following removal to minimize bleeding.

REHYDRATION TECHNIQUES IN INFANTS AND CHILDREN

Approach to Dehydration

The literature on clinical assessment of the degree of dehydration in children with acute gastroenteritis is inconsistent. Physician gestalt alone typically performs poorly, with a reported sensitivity of 42%.⁶⁹ Parental report of symptoms associated with dehydration (emesis, diarrhea, poor fluid intake, decreased urine output, weak cry, sunken fontanelle, sunken eyes, decreased tears, dry mouth, and cool extremities) is sensitive, but not specific. Table 19.2 presents a more thorough list of the signs, symptoms, and definitions of mild, moderate, and severe dehydration. Different dehydration scales exist to improve assessment, with a wide range of accuracy. A 2015 paper suggests a simpler model in which sunken eyes, decreased skin elasticity, weak radial pulse, and general appearance are used, with two factors being predictive of at least 5% dehydration and three or four factors predictive of 10% dehydration.⁷⁰ A popular assessment tool, the Clinical Dehydration Scale, also uses four features for assessment: general appearance, eyes, mucous membranes, and tears. Point-of-care ultrasound demonstrating an IVC to aortic diameter ratio of 0.8 or less can also be predictive of dehydration.⁷¹

TABLE 19.2 Estimating Dehydration

DEHYDRATION	SYMPTOMS	SIGNS	FLUID LOST IN INFANTS	FLUID LOST IN OLDER CHILDREN	TREATMENT
Mild	Thirsty	Slightly dry mucous membranes	50 mL/kg	3–5% total fluid	ORS, 50–100 mL/kg over a 2- to 4-hr period Consider other methods if not tolerated No laboratory studies
Moderate	Decreased urine output Absent tears	Tachycardia Capillary refill >2 sec Dry mucous membranes Weak pulse Abnormal respirations Sunken eyes	100 mL/kg	6–9% total fluid	ORS, 50–100 mL/kg over a 2- to 4-hr period Consider other methods if not tolerated No laboratory studies
Severe	Abnormal mental status, lethargy	Abnormal skin turgor Sunken fontanelle Hypotension	150 mL/kg	>9% total fluid	20–60 mL/kg of NS by IV bolus Serum chemistries

IV, Intravenous; NS, normal saline; ORS, oral rehydration solution.

Oral Rehydration

Oral rehydration therapy (ORT) has been shown to be equivalent to IV therapy in children with acute gastroenteritis in terms of rehydration, subsequent diarrheal episodes, and the development of sodium abnormalities.⁷² Failure rates are 4.9% as compared with 1.3% for IV therapy, and use of ORT can avoid the need for IV hydration in 24 of every 25 patients.⁷³ This is the modality of choice for rehydration of a mildly to moderately dehydrated infant or child aged 1 month or older. Oral rehydration solutions (ORSs) come in a number of commercial forms (World Health Organization rehydration salts, Enfalyte [Mead Johnson Nutrition, Chicago, IL], Pedialyte [Abbott, Abbott Park, IL], Rehydralyte [Abbott], CeraLyte [Cera Products, Hilton Head, SC]). The ideal composition is 50 mEq/L of sodium, 25 g/L of dextrose, and 30 mEq/L of bicarbonate,⁷⁴ and a solution can be made at home with five cups of water, eight teaspoons of sugar, and one teaspoon of salt. A JAMA paper came out this year showing that rehydration of mildly dehydrated patients with dilute apple juice instead of oral rehydration solution resulted in fewer treatment failures, and that is another option.^{74a} The target volume is 50 to 100 mL/kg over a period of 2 to 4 hours. Typically, this is started with a spoon, cup, or syringe delivering 5 mL to children younger than 2 years and 10 mL to children older than 2 years every 5 minutes and then increasing volumes slowly as tolerated (Fig. 19.21). Vomiting is not a contraindication to attempting ORT because children can typically tolerate these small volumes. Some practitioners fear accompanying electrolyte abnormalities; however, hypernatremic dehydration responds well to ORT.

Oral rehydration can be facilitated with the use of an antiemetic. Ondansetron has been shown to decrease ED vomiting (number needed to treat [NNT] = 5), decrease the need for IV hydration (NNT = 5), and possibly decrease the need for admission (NNT = 14).⁷⁵ Ondansetron is administered at a dose of 0.15 mg/kg in the form of syrup or oral dissolving tablets. An alternative, simplified dosing regimen is to give 2 mg for children 8 to 15 kg, 4 mg for children 15 to 30 kg,

Figure 19.21 Oral rehydration with a syringe. The parent is instructed on the technique in the emergency department.

and 8 mg for children greater than 30 kg. Oral rehydration should be initiated 15 to 30 minutes after administration of ondansetron.⁷⁶ Most oral ondansetron studies include children 6 months and older, but several studies using IV ondansetron have included infants as young as 1 month. Concern regarding the possibility of ondansetron delaying the identification of more pathologic diagnoses is unfounded. A metaanalysis has shown no difference in return visit rates in those who do not receive antiemetic therapy, and it has been shown that antiemetic therapy does not mask alternative diagnoses.⁷⁷ Outpatient prescriptions for ondansetron do not affect recidivism or readmission rates. Ondansetron has received attention for its ability to prolong the QT interval. In children, it lengthens

the duration of the QT interval by 10 to 17 msec, and is unlikely to induce torsades de pointes in an otherwise healthy child.⁷⁸ It may contribute to mild and self-limited diarrhea.⁷⁶ Other antiemetics and antimotility agents are not recommended by the American Academy of Pediatrics for use in children younger than 5 years, and they have a high incidence of side effects. There is a Food and Drug Administration “boxed warning” against the use of promethazine in children younger than 2 years and a strong recommendation against its use even in older children. For patients with diarrhea, the antisecretory agent racecadotril is used in several European countries in conjunction with ORS, with a favorable treatment and adverse event profile.⁷⁹

Laboratory Tests

The American Academy of Pediatrics recommends electrolyte testing in patients with severe dehydration, those who need IV rehydration, or children with moderate dehydration and findings on the history or physical examination inconsistent with straightforward diarrheal episodes. A prospective study of patients 2 months to 9 years of age, in whom parenteral rehydration was deemed required on clinical grounds, demonstrated a 48% rate of laboratory abnormalities, 10.4% of which changed treatment management. More than 9% of their patients had hypoglycemia, so it is recommended to obtain a glucose level urgently, as well as electrolytes when feasible, in patients who require IV rehydration.⁸⁰ It is difficult to provide recommendations regarding the management of low bicarbonate because the level has been found to correlate poorly with the need for admission and unscheduled revisit rate in some studies,⁸¹ whereas it correlates well in others.⁸² Urine specific gravity tends to lag behind the child’s hydration status and is particularly unreliable in infants younger than 1 year. Blood urea nitrogen levels are also poorly sensitive in young children,⁷⁴ but significant elevations in these levels and in creatinine may be specific.⁸³ Serum ketones have been shown in one study to correlate with clinical dehydration scores.⁸⁴

Parenteral Rehydration

Obtaining IV access is covered elsewhere in this section. If parenteral administration of fluids is deemed appropriate, standard therapy involves 20-mL/kg boluses of NS or lactated Ringer’s solution infused over a 60-minute period each until normalization of pulse, perfusion, and mental status occurs. Recent literature has demonstrated comparable efficacy of rapid rehydration protocols involving the administration of 50 to 60 mL/kg over a 60-minute period in otherwise healthy children,^{85–88} though it may paradoxically lengthen time to discharge. Adverse events were minimal in the studies; however, they were not entirely powered to ensure safety.⁸⁹ A handful of small studies have looked at bolusing with dextrose-containing fluids. This practice seemed safe and decreased ketone levels, but did not significantly decrease the admission rate.⁹⁰

Children who have received parenteral fluids and subsequently tolerated oral fluids can typically be discharged home from the ED, although an unscheduled revisit rate of 16% has been reported.⁹¹ If the child requires admission for continuance of maintenance fluids, isotonic saline is recommended because of a documented 17% to 45% risk for hyponatremia with the use of hypotonic fluid.^{92–94} The amount of maintenance fluid is calculated as 100 mL/kg for the first 10 kg of body

weight, 50 mL/kg for 10 to 20 kg of body weight, and 20 mL/kg for the remaining body weight in a 24-hour period. For example, a 50-kg child would require (100 mL × 10 kg) + (50 mL × 10 kg) + (20 mL × 30 kg) divided evenly over 24 hours.

Nasogastric Tube Rehydration

Nasogastric (NG) rehydration is a potentially effective, safe, and cost-effective alternative to parenteral rehydration in children who refuse to take fluids orally in the quantity required for rehydration. In developing nations, NG hydration has been shown to be effective for severe dehydration as well.⁹⁵ NG rehydration is accomplished by placement of an NG tube, with a 5-Fr feeding tube typically being adequate for children younger than 3 years. For comfort, the use of topical anesthetic or nebulized lidocaine (5 mg/kg diluted in NS) before insertion is recommended. A bolus of 50 mL/kg of electrolyte solution (e.g., Pedialyte [Abbott]) is administered by continuous infusion via an enteral feeding pump over a 3-hour period. Twenty-four-hour rehydration regimens (50 to 100 mL/kg for the first 10 kg of body weight and then 25 to 50 mL/kg for the remaining body weight) have also been proposed but seem to have equivalent outcomes to more rapid rehydration protocols.⁹⁶ Unscheduled revisit rates are not significantly different compared with patients who have received IV rehydration. Additionally, NG hydration has been used for infants with bronchiolitis with hospital lengths of stay comparable to those receiving IV hydration, and also with better placement success.⁹⁷ No study has evaluated the use of frequent, small boluses; however, experience with ORT would indicate that 5- to 10-mL parent-administered syringe boluses to equal 50 mL/kg would be an option in the event that a pump for continuous administration is unavailable.

Subcutaneous Rehydration

Subcutaneous rehydration therapy, also known as hypodermoclysis, is an option in children with mild to moderate dehydration in whom IV or IO access is not available or feasible. Its utility as a bridge to facilitating commencement of IV hydration in severely dehydrated children has been postulated, but not studied. Although the potential has been recognized since the early 1900s, the hyaluronan-containing intercellular matrix of subcutaneous tissue prevents easy delivery and absorption of large quantities of fluid, and the previous preparations of hyaluronidase (enzymes that hydrolyze hyaluronan) were animal based and allergenic. More recently, a recombinant formulation of human hyaluronidase, HuPH20 (Hylenex), has become available, thus making this technique more accessible. Its primary utility has been in geriatric and hospice patients requiring hydration, but several studies have substantiated its safety and efficacy in pediatric patients as young as 2 months, with a mean ED volumes deliverable comparable to IV hydration. In assessing recidivism, pediatric patients treated with subcutaneous hydration and discharged from the ED had an unscheduled revisit rate comparable to those receiving IV hydration.⁹⁸ The cost-effectiveness profile is advantageous when compared with equivalent IV therapy, with children below 3 years of age representing the most difficult cases for IV access and, thus, the greatest cost savings.⁹⁹

After sterile preparation, a 22- or 24-gauge angiocatheter or 25-gauge butterfly needle is inserted at a 30- to 45-degree

Figure 19.22 Subcutaneous rehydration with normal swelling 5 minutes after beginning the infusion. (Courtesy Dr. Corburn Allen; reproduced with permission from Pediatrics.)

angle to the hub into subcutaneous tissue. After placement of a small piece of gauze under the hub of the catheter to maintain the angle, it is secured with a sterile occlusive dressing. Although the interscapular area is often used, the thigh, abdomen (left iliac fossa), chest, and upper part of the arm are also options.¹⁰⁰ If possible, an area with a pinchable fat fold of 1 inch should be selected. The catheter should be aspirated for absence of blood return. A 150-unit dose of hyaluronidase is injected through the catheter, and the fluid infusion is started. Typically, isotonic fluids such as 0.9% NS are used. Mean fluid infusion rates are highly variable in adults and range in children from 18.9 mL/kg over the first hour to 38.4 mL/kg for a 4-hour infusion.¹⁰¹ An eventual infusion rate of approximately 20 mL/kg per hour should be selected and titrated down if the infusion pump indicates occlusion. Because the hyaluronidase requires approximately 15 minutes to take full effect, some providers prefer to start more slowly and titrate upward.¹⁰² Initially, an erythematous swelling may appear at the infusion site (Fig. 19.22), but it will decrease in size after 5 minutes and disappear 1 to 2 hours after cessation of the fluid infusion. Some pain may occur at the infusion site. Suggestions for troubleshooting subcutaneous infusion problems can be found in Table 19.3. Maximal diffusion of fluid into the IV compartment occurs in 1 hour. An injection of hyaluronidase allows subcutaneous infiltration for 48 hours, and maintenance fluids, including those containing dextrose and potassium, can be infused through

TABLE 19.3 Troubleshooting Subcutaneous Rehydration Complications

The catheter becomes dislodged	Restart in the same area without an additional dose of hyaluronidase ¹⁰⁰
The infusion pump indicates occlusion	Slow the infusion rate by 10 mL/hr
The area becomes firm, indurated, and painful	Administer an additional dose of hyaluronidase
The child fails outpatient therapy	Continue infusion of fluid through the catheter for 48 hours as maintenance

the catheter after the bolus if required. No special care is required following removal of the catheter.

Subcutaneous rehydration is not recommended in patients with signs of shock, coagulation deficits, gross edema, significant electrolyte abnormalities (sodium >150 mEq/L or <130 mEq/L), or no intact skin sites (e.g., massive burns). The most common adverse events reported are redness, swelling, or bruising at the infusion site. Allergic reactions have not been reported with the newer formulation of hyaluronidase, and skin infections are rare.

Discharge

Commonly held beliefs include avoidance of dairy products, need for formula change or overdilution of formula with water, gut rest for 24 hours or longer, and the BRAT diet (bananas, rice, applesauce, toast). These beliefs are not supported by the literature in most cases. Once rehydration has been achieved, returning to a normal diet is suggested as soon as possible, with continued replacement of ongoing losses with an ORS or potentially dilute juice.

Most children seen in the ED with acute dehydration will be corrected and discharged home. Admission criteria include inadequate care at home or inability to follow return precautions, inability to take or failure of rehydration with ORT, concern for more serious pathology, severe dehydration, and neonatal dehydration. Probiotics can help reduce the duration of diarrhea in children with gastroenteritis.¹⁰³

Arterial Puncture and Cannulation

Erick Eiting and Hyung T. Kim

Arterial puncture is the most accurate blood sampling technique for true arterial blood gas (ABG) and acid-base determination. The absence of arterial blood pressure defines cardiac arrest and serves as a definitive end point for resuscitative efforts. Intraarterial cannulation with continuous blood pressure measurement remains an accepted standard in critically ill patients. Intraarterial monitoring of blood pressure better reflects the force of systemic perfusion and is one of the most important determinants of cardiac work. In recent years, noninvasive technologies have achieved an accuracy that is nearly equal to that of invasive monitoring, but these techniques

also have limitations. Invasive modalities require specific expertise and support to perform.

INDICATIONS AND CONTRAINDICATIONS

Indications for and contraindications to arterial puncture and cannulation are listed in [Review Box 20.1](#). The use of arterial lines for continuous monitoring is generally reserved for the intensive care setting; however, arterial cannulation may be initiated in the emergency department (ED). The indications for placement of an arterial catheter fall into two major categories^{1,2}:

1. *Repetitive and direct arterial blood sampling.* Catheter access removes the need for multiple arterial punctures and allows either repeated sampling or placement of sensors for continuous monitoring of blood gas and other chemistry values.
2. *Continuous real-time monitoring of blood pressure.* Catheter access allows superior monitoring and moment-to-moment detection of changes. Intraoperative and intensive care unit (ICU) management is often facilitated by placement of an arterial line. Some patients, such as those with severe burns, dialysis grafts or shunts, or morbid obesity, may need ongoing monitoring of perfusion, which can best be accomplished by arterial catheterization.

Arterial Puncture And Cannulation

Indications

- Blood gas sampling
- Continuous pressure monitoring
- Need for frequent blood sampling
- Major surgery involving fluid shifts/blood loss
- Hypothermia (induced or environmental)
- Diagnostic angiography
- Therapeutic embolization

Contraindications

<i>Strict</i>	<i>Relative</i>
Inadequate circulation	Previous surgery in the area
Raynaud's syndrome	Anticoagulation/coagulopathy
Buerger's disease	Skin infection at the site
Full-thickness burns	Atherosclerosis
	Inadequate collateral flow
	Partial-thickness burns

Complications

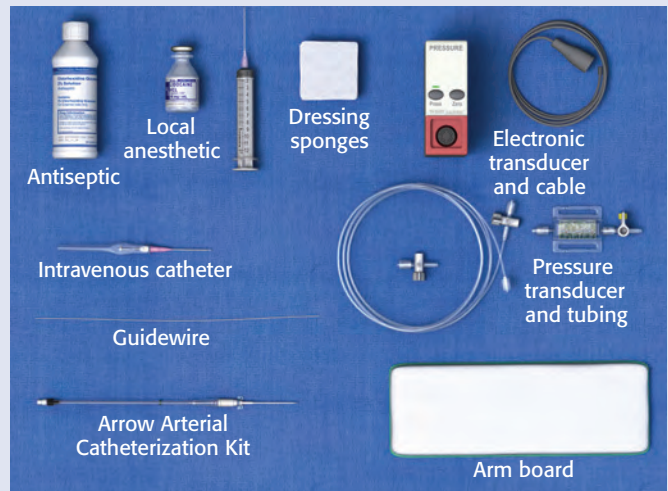

- Hematoma formation
- Infection
- Bleeding
- Ischemia
- Thrombosis/embolism
- Arteriovenous fistula formation
- Pseudoaneurysm formation

Equipment

Arterial Puncture

Arterial Cannulation

(Not shown: bag of normal saline, pressure infuser)

Although acute respiratory decompensation and metabolic emergencies are the most common reasons for ABG sampling, all blood tests performed on venous blood are also possible on an arterial sample. Cultures performed on blood obtained from an indwelling arterial line have a sensitivity and specificity similar to that of cultures performed on blood obtained from a venipuncture site.^{3,4} Patients with moderate respiratory decompensation may be managed without arterial puncture by using continuous, noninvasive pulse oximetry, end-tidal or transcutaneous carbon dioxide monitoring, carboxyhemoglobin and methemoglobin monitoring, or any combination thereof.⁵ Nonetheless, a role still exists for arterial blood sampling. The initial correlation between noninvasive values and acid-base status via arterial sampling is often important in critical illness to set a baseline or verify a trend. Some authors use ABG sampling in the initial evaluation of critically ill trauma patients.⁶ Vasoactive drugs (e.g., nitroprusside and norepinephrine) are best administered with continuous monitoring of arterial pressure to guide titration. The response of trauma and post-cardiac arrest patients to acute resuscitative efforts may also be more easily monitored with the use of arterial catheterization.

Few contraindications to arterial puncture exist; none are absolute. For example, after thrombolysis, arterial cannulation should be performed only if it will provide essential data that cannot be obtained by any other method. If absolutely necessary, a single arterial puncture of the readily compressible radial artery is preferred. Arterial puncture can be performed safely in patients who are anticoagulated or who have other coagulopathies, but it should be undertaken with extreme caution in patients with severe disseminated coagulopathies.

There are reports of patients with bleeding complications who require transfusion. Some patients have suffered compression neuropathies secondary to hematomas at the puncture site.⁷ Repeated arterial sampling in such patients should be accomplished by insertion of an indwelling cannula to minimize trauma to the arterial wall.

The presence of severe arteriosclerosis, with or without diminution in flow, is a relative contraindication to arterial puncture. In hemodynamically unstable patients with advanced cardiovascular disease, the benefits of invasive monitoring may nonetheless outweigh its risks.² Consider an alternative site if an isolated, decreased palpable pulse or bruit is felt over the site selected. Additionally, consider an alternative site if there is evidence of decreased or absent collateral flow in areas where flow normally exists, such as in Raynaud's syndrome or an abnormal result on the modified Allen test (discussed later in the section on [Techniques](#)). Avoid puncturing a specific arterial site when infection, burn, or other damage to cutaneous defenses exists in the overlying skin or through or distal to a surgical shunt.

Arterial Versus Venous Analysis

Arterial sampling has been the traditional approach to evaluating acid-base abnormalities in critically ill patients, especially those being maintained on a ventilator. In most ED settings, however, venous blood gas analysis will suffice. Studies have demonstrated that analysis of venous blood (especially central venous blood) for pH, bicarbonate, lactate, base excess, and carbon dioxide pressure (PCO₂) are within 95% limits of agreement with arterial sampling and can safely supplant it.⁸⁻¹⁰ On the other hand,

arterial blood sampling is still required for accurate analysis of oxygen pressure (PO₂).¹¹⁻¹³

EQUIPMENT: ARTERIAL PUNCTURE

Arterial Puncture With a Needle/Syringe

To obtain a single sample of arterial blood by the percutaneous method, attach a 3-mL syringe (preferred and most common) to a needle. Select the needle size based on puncture location and patient size and age. For an adult, use a 20-gauge, 2.5-inch needle for a femoral sample and a 22-gauge, 1.25-inch needle for a radial artery puncture. For pediatric arterial sampling, use a needle with a slightly shorter length in the range of 22- to 24-gauge at the same sites as in adults.

Precoated blood gas plastic syringes (with dry lithium heparin) are commonly used and allow a longer shelf life and ready use ([Fig. 20.1](#)). Such devices are designed to minimize sampling error as a result of heparin.¹⁴ If necessary, prepare a regular syringe with 1 or 2 mL of a heparinized saline solution (1000 International Units [IU]/mL) drawn into the syringe to coat the barrel and needle. Fully eject the heparin through the needle immediately before skin puncture to minimize heparin-related errors. Although the syringe may appear devoid of heparin, enough heparin remains in the needle and syringe to provide anticoagulation. Even dry heparin may produce abnormalities in ABG results because of a heparin-induced dilutional effect.

The latest blood gas and chemistry analyzers require only 0.2 mL of whole blood for accuracy, and some point-of-care devices can perform analyses on single drops of blood. However, sample sizes of less than 1.0 mL of blood aspirated into heparin-coated syringes may result in a heparin-related error on ABG values.

Stored heparin solution has higher PO₂ and lower PCO₂ values than blood does.¹⁵ A dilutional effect from heparin would mean that the addition of 0.4 mL of heparin solution to a 2-mL sample of blood (dilution of 20%) will lower PCO₂ by 16%.¹⁴ Proper technique with dry lithium heparin-prefilled syringes or full ejection of excess heparin will prevent such problems if more than 2 mL of blood is collected. A falsely

Figure 20.1 Arterial blood gas syringe. This device is precoated with dry lithium heparin. Additionally, the plunger is vented, which allows air in the syringe to escape through the plunger as the sample is collected. To use this type of syringe, pull back the plunger to the desired volume before arterial puncture. When the needle enters the artery, blood will fill the syringe spontaneously—there is no need to pull back on the plunger.

low PCO_2 is the most clinically significant change caused by excess heparin.^{14,15} Neither PO_2 nor pH levels are significantly altered by the addition of heparin in most instances, although a slight increase in PO_2 and a minimal decrease in pH may occur if high concentrations of heparin (25,000 IU/mL) are used.¹⁶ If 2 to 3 mL of blood is collected, heparin-related effects are likely to be clinically inconsequential.

Continuous Monitoring via Arterial Catheter

The fluid-filled recording systems used with arterial cannulation have a great influence on the accuracy of pressure measurements. The frequency responses of tubing, transducers, and other components of the monitoring system influence the accuracy of systolic and diastolic pressure measurement. Failure to recognize recording system artifacts will lead to errors in interpretation of the pressure.

Various catheter types have demonstrated similar frequency-response characteristics, but some studies have found different complication rates. Teflon catheters may carry an increased rate of thrombosis.^{17,18} Another contributing element leading to thrombosis is catheter diameter; the incidence of thrombosis is inversely related to the ratio of vessel lumen to catheter diameter.^{19,20} Thus the risk for thrombosis increases as the diameter of the catheter decreases. The incidence of thrombosis also increases with increased duration of catheter placement. In contrast, a higher risk for thrombosis was seen in the femoral artery than in the radial artery in a study involving a pediatric population.²¹ Catheters coated with a combination of chlorhexidine and silver sulfadiazine have produced lower infection rates.²²

Preparation for Arterial Cannulation

Box 20.1 lists the usual equipment for arterial cannulation, although the majority of prepackaged kits contain the supplies most needed (see also Review Box 20.1). Shorter catheters are ideal for peripheral artery cannulation, whereas use of a longer catheter and the Seldinger technique is preferable for the femoral artery.

For arterial cannulation in adults, use a 16- to 18-gauge catheter for the femoral artery and a 20-gauge catheter for the radial artery (Fig. 20.2). Small children and infants require a 22- to 24-gauge catheter, which may need to be inserted percutaneously via the Seldinger technique or through a femoral cutdown. Based on patient size, older pediatric patients usually require 20- to 22-gauge catheters.

The tubing that connects the catheter to the pressure transducer has a significant effect on accuracy of the monitoring system. The higher the frequency response of the entire system, the more accurate the determination of systolic and diastolic pressure; however, artifact also becomes more of a problem.^{1,23} Use stiff, low-capacitance plastic tubing for arterial catheterization and monitoring. Place the electronic pressure transducer connection as close as possible to the patient and zero it appropriately because the frequency response of a tube is inversely related to its length.^{24,25}

The pressure wave produced with each contraction is transmitted from the artery through the catheter and connecting tubing to a measuring device. The arterial fluid wave is received by an electromechanical transducer that changes the mechanical pressure wave into an electrical signal that can be displayed on the monitor. The most basic technique for obtaining blood

BOX 20.1 Equipment for Insertion and Maintenance of an Indwelling Arterial Cannula

Antiseptic solution

1% lidocaine (without epinephrine); usually 2 to 3 mL delivered by a 25- to 27-gauge needle is required for adequate anesthesia of the cannulation site

10- × 10-cm dressing sponges

Arm board for brachial, radial, or ulnar cannulation

Appropriately sized intravenous catheters

Syringes (3 and 5 mL for anesthesia, 5 mL for aspiration)

Pressure tubing

Two three-way stopcocks

Pressure transducer

Connecting wire

Monitor display

500- to 1000-mL bag of normal saline

Pressure blood infuser set up with a continuous flush device

ADDITIONAL EQUIPMENT REQUIRED FOR THE CUTDOWN INSERTION TECHNIQUE

Scalpel blade (No. 11)

Tissue spreader, self-retaining

Two hemostats

2-0 silk ties, multiple

2-0 silk suture with a straight needle

Needle driver with a 2-0 nylon skin needle

Figure 20.2 Catheters for arterial cannulation. **A**, Standard intravenous catheter. Use 20 gauge for the radial artery and 16 or 18 gauge for the femoral artery. **B**, Arrow Arterial Catheterization Kit. This device has a self-enclosed guidewire that is advanced into the artery by moving the actuating lever forward. When the lever reaches the reference mark on the barrel of the device, the tip of the guidewire is at the opening of the needle lumen. (Arrow International, Reading, PA.)

pressure values involves the use of a simple manometer.²⁶ This system can be assembled quickly if the material is available.

A continuous method of flushing the pressure tubing is required to maintain patency of the catheter lumen during intraarterial pressure monitoring. A three-way stopcock through which the tubing is intermittently flushed with saline (a minimum of every 15 to 30 minutes) is a simple, effective method. Continuous flush devices push a set amount of fluid

Figure 20.3 Arterial pressure monitoring systems. **A**, System for continuous flushing. A 1-L bag of normal saline is pressurized to 250–300 mm Hg with a metered blood pump (not shown). The continuous flush device is set to deliver 3 mL/hr of saline. A mechanical pressure transducer is depicted. The transducer device is a sterile, inexpensive, fully assembled monitor that can be used during patient transfer. Alternatively, the electronic transducer depicted in **B** may be used. **B**, System for manual flush. A saline flush solution can be injected manually through a syringe at the proximal or distal port. The transducer dome should be maintained at the level of the patient's heart. (From Beal JM, editor: *Critical care for surgical patients*, New York, 1982, Macmillan. Reproduced by permission.)

(usually 2 to 3 mL/hr) through the line.¹⁶ A typical monitoring system that includes this device is shown in Fig. 20.3. The pressure transducer must be mounted at the level of the patient's heart. Current pressure-monitoring setups include not only built-in stopcocks but also in-line flushing plungers to facilitate clearance of blood after sampling.

Intravascular transducers were initially seen as an improvement over the external electromechanical transducers in use since the mid-1970s. Many of the numerous brands are fragile, temperature sensitive, of variable quality, and much more difficult to place in vessels than catheters are. Despite anecdotal reports of fibrin deposition on these devices, no increased incidence of thrombus formation has been noted. The most important advantages of intravascular transducers are the ability to continuously monitor ABG values and to eliminate potential errors induced by catheters, stopcocks, and connecting tubing.^{27,28}

SITE SELECTION

The radial, brachial, and femoral arteries are the sites usually punctured for blood gas sampling in adults (Video 20.1).

TABLE 20.1 Parameters That Affect Interpretation of Arterial Blood Gases

PARAMETER	HEPARIN ^a	AIR BUBBLE IN SAMPLE	DELAYED ANALYSIS ^b
PO ₂	No significant change ^c	Elevated	Variable ^b
PCO ₂	Lowered ^d	No significant changes ^c	Elevated ^f
pH	Unchanged ^d	No significant changes ^c	Lowered ^f

^aUse only a 1000-IU/mL concentration. Fill the dead space of the needle and syringe only and collect 3 mL of blood.

^bChanges unpredictable at 20 minutes regardless of the storage method.

^cThere are reports of slight increases in Po₂ with excessive heparin.

^dThe falsely lowered Pco₂ that occurs with added heparin is the most clinically significant change noted. pH may be decreased if a large volume of concentrated heparin (25,000 IU/mL) is used.

^eIf stored at 4°C for 20 minutes. Anaerobic storage at room temperature for 20 minutes results in no significant change.

^fMinimal changes up to 2 hours if stored at 4°C.

Pediatric sites commonly used for arterial puncture include arteries in the foot and the umbilical artery in newborns.

When an artery is cannulated for longer-term use, there is a risk of complete loss of blood flow through a vessel as a result of intraluminal thrombosis. This is important when choosing a site for arterial puncture. Because the most frequent complication of arterial catheterization is bleeding, the ability to control hemorrhage must also be considered. For these reasons, the radial and femoral arteries are favored because of their good collateral blood flow and ease of compression in case of hemorrhage. Patient comfort and nursing care concerns should also be considered during selection of the site.

TECHNIQUES

Arterial Puncture

Palpate the arterial pulse to ascertain the location of the vessel and prepare the overlying skin with an antiseptic solution (Fig. 20.4, step 1). Anesthetize the patient's skin with a wheal of local anesthetic (e.g., 1% lidocaine without epinephrine) through a small needle (25- or 27-gauge) (see Fig. 20.4, step 2). If local anesthesia is to be given, take care to use only a small amount of local anesthetic because a large wheal may obscure the pulse. One study found no significant alterations in PCO₂ or pH from the pain or anxiety of an unanesthetized arterial puncture (Table 20.1).²⁹ If the patient is in extremis or unresponsive to pain in the area to be punctured, anesthetic infiltration may be omitted.

Isolate the arterial pulsation with the index and middle fingers of the gloved, nondominant hand and identify the course of the vessel. Puncture the skin through the anesthetic wheal, immediately distal to the palpated pulse under the index finger (see Fig. 20.4, step 3). The older technique of placing the needle between the index and middle finger risks self-puncture and is no longer advised. Hold the syringe like a dart with the bevel up and the syringe kept in view so that blood flow can be seen immediately. Advance the needle slowly toward the

Arterial Puncture (Radial Artery)

1 Position the wrist in slight dorsiflexion, cleanse the skin with antiseptic solution, and palpate the radial pulse.

2 Optionally, place a small wheal of local anesthetic (e.g., 1% lidocaine without epinephrine) over the entry site. Avoid placing too large of a wheal, which may obscure the artery.

3 Hold the syringe in your hand like a dart, with the bevel up. Palpate the artery with the index and middle fingers of your other hand. Puncture the skin distal to your finger, and slowly advance the needle at a 30° angle toward the pulsating vessel.

4 As soon as blood flows, stop advancing the needle. Allow the syringe to fill on its own. If bone is encountered, withdraw slowly because both vessel walls may have been penetrated and the lumen may be entered as the needle is withdrawn.

5 Remove the needle from the artery after the syringe has filled. Apply a bandage and firm pressure to the puncture site for a minimum of 3 to 5 minutes.

6 Remove all air from the syringe by holding it upward, gently tapping it, and depressing the plunger. Attach the end cap to the syringe to maintain anaerobic conditions, and submit the sample to the laboratory.

Figure 20.4 Arterial puncture (radial artery).

pulsating vessel at an approximately 30-degree angle. A larger angle is required to puncture the deeper femoral artery. Once the needle enters the arterial lumen, allow the syringe plunger to rise with the arterial pressure on its own to discriminate between arterial and venous sampling (see Fig. 20.4, step 4). As soon as blood flows, stop advancing the needle and allow the syringe to fill. If no blood flow is obtained or if bone has been hit, withdraw the needle slowly because both walls of the vessel may have been punctured and the lumen may be entered as the needle is withdrawn. Redirect the needle only when the needle has been retracted to a location just deep to the dermis. After at least 1 to 2 mL of blood has been obtained, remove the needle from the artery. Apply firm pressure at the puncture site for a minimum of 3 to 5 minutes (see Fig. 20.4, step 5). If the patient is anticoagulated or has a coagulopathy, 10 to 15 minutes of pressure is required (Videos 20.2, 20.3, and 20.4).

Use of ultrasound is rapidly becoming a standard in procedures involving central vascular access. The same ultrasound-guided techniques are also being applied to arterial cannulation (Ultrasound Box 20.1.) Shiloh and colleagues reported 71% improvement in the likelihood of success at the first attempt when using ultrasound guidance.³⁰ Vascular Doppler can also be used to improve success rates. Hold the probe over the

artery just proximal to the puncture site. An important indication of vessel identification is the loss of audible pulsations with compression.

Proper handling of the sample and rapid analysis are very important. When the needle is withdrawn, expel any air bubbles present in the syringe to avoid a false elevation in PO_2 .³¹ Remove the air neatly and easily by tapping the inverted syringe (needle pointing upward) to force any air to the top; then carefully and slowly depress the syringe plunger to push out the remaining air (see Fig. 20.4, step 6). A gauze pad or alcohol wipe may be used to collect any excess blood expelled with the syringe held upright and the plunger side down. Remove the needle and cap the syringe to ensure anaerobic conditions. Alternatively, many of the commercially available ABG kits come with an air bubble removal device (Filter-Pro [Smiths Medical, St. Paul, MN]) that allows the clinician to expel air bubbles from the sample and reduce potential exposure from the blood product.

Air in the sample will significantly increase PO_2 (mean increase, 11 mm Hg) after 20 minutes of storage, even if kept at 4°C. pH and PCO_2 are not significantly altered by air bubbles if the blood is stored at 4°C for 20 minutes and no significant deterioration has occurred.^{16,31} If blood is stored at room temperature for longer than 20 minutes, PCO_2 will increase

ULTRASOUND BOX 20.1: Arterial Puncture

by Christine Butts, MD

Ultrasound can be used with great success in the placement of peripheral and central intravenous lines, and it can also be used for the placement of arterial catheters.

First, identify the target vessel with ultrasound. Use a high-frequency transducer (10 to 12 MHz) to ensure proper resolution. The target vessel is typically easiest to identify in the transverse plane (with the indicator pointing toward the patient's right side) (Fig. 20.US1). Arteries usually appear as rounded structures with thick walls, as opposed to veins which are ovoid. Depending on the size of the vessel, pulsations may be noted in the arteries. Application of color flow Doppler to a suspected artery will frequently demonstrate a pattern of pulsatile flow (Fig. 20.US2). Although arteries are usually thought to resist collapse from outside pressure (such as from applying pressure to the overlying transducer), smaller arteries in the periphery may show a degree of collapse. When seeking to identify

the target vessel, multiple means of identification should be used before an attempt at cannulation.

Once the vessel has been identified, ultrasound can also be used to directly guide cannulation. Sterile technique should be maintained, particularly when accessing central arteries such as the femoral artery. A full description of the technique of ultrasound-guided venous access can be found in both the general ultrasound chapter (Chapter 66) and the central venous access chapter (Chapter 22) in this textbook. The principles of these procedures also apply to arterial cannulation, although a few points should be emphasized. When guiding access to the radial artery, a transverse approach is typically used because the vessel is small and difficult to visualize in the longitudinal approach. Additionally, it may be difficult to keep the image of the longitudinal vessel centered on the screen, especially when one physician is directing both the ultrasound and the needle.

Figure 20.US1 Placement of the transducer over the distal end of the arm in the transverse plane to localize the radial artery.

Figure 20.US2 Image of the radial artery with color flow. Applying color flow will enable the operator to correctly identify the artery.

and the pH will decrease, probably as a result of leukocyte metabolism. In a stored sample, PO₂ varies to such an extent that the change is unpredictable for chemical interpretation at 30 minutes, regardless of the storage method. High leukocyte or platelet counts, such as those seen in leukemic patients, may shorten acceptable storage intervals.^{32,33}

Thus, ABG samples should always be kept on ice and analyzed within 15 to 20 minutes. Samples that cannot be analyzed within this time frame should be considered unreliable.

PERCUTANEOUS TECHNIQUE FOR ARTERIAL CANNULATION

Direct Over-the-Needle Catheter Cannulation

Placement of an angiocatheter directly into an arterial lumen in a manner similar to placement of an intravenous catheter is the most practiced and simplest method, but it is not always successful because of technical difficulties. The only routine site for this technique is the radial artery. Use of a catheter over a guidewire as per the Seldinger technique is strongly advised at most other sites.

Take time to ensure proper alignment of the desired site. Delays, complications, and inability to successfully cannulate an artery often occur as a result of failure to properly prepare the desired site and involved limb. An important preparatory step is to ensure that the target limb is secured flat and not rotated; any rotation could result in the desired artery being shifted from the expected anatomic position and making it more difficult to cannulate. For example, to adequately prepare the radial artery, immobilize the wrist and hand in mild dorsiflexion with some padding for support underneath the wrist (Fig. 20.5, step 1). Prepare the skin with sterile technique. Inject local anesthetic with a 25-gauge or smaller needle to achieve sufficient infiltration and to ensure a painless procedure. Subcutaneous infiltration of lidocaine or a similar anesthetic may also reduce vessel spasm at the time of arterial puncture.

Check the catheter assembly for proper movement and function. Alternatively, a 3-mL syringe with the plunger removed can be used as a blood reservoir. Advance the catheter toward the palpated artery at a comfortable angle for the operator, generally 30 to 45 degrees from the skin (see Fig. 20.5, step 2). Make a small incision with a No. 11 scalpel blade or a larger-bore needle to eliminate the problem of damage to the catheter from kinking on the skin. The tip of the needle is often perceived to pierce the artery, but successful puncture is confirmed by identifying a “flash” of arterial blood flow into the needle hub and reservoir. As the needle-catheter assembly advances through the skin toward the artery, the initial flash of arterial blood is obtained by the needle alone, which protrudes beyond the catheter. For this reason, the needle-catheter assembly should be lowered and advanced 2 mm forward to ensure that the tip of the catheter has cannulated the vessel, along with the needle (see Fig. 20.5, step 3). The position of the catheter within the vessel lumen is confirmed by continuous return of arterial blood. The catheter alone can now be advanced with care over the needle and into the artery (see Fig. 20.5, step 4). If the catheter fails to thread, it has not properly entered the vessel lumen and should not be forced to advance without confirmation of placement by active blood return.

When successful blood flow into the needle-catheter assembly has ceased, it may have pierced the backside of the arterial wall and may no longer be in the artery. This double-puncture method is useful for cannulating small vessels, yet it is not recommended as a routine procedure for inexperienced clinicians. If double puncture has occurred and blood has ceased to flow into the collection reservoir, do not remove the entire needle-catheter assembly. Instead, simply retract the needle slightly to determine whether blood flow into the catheter can be reestablished. If blood flow occurs, gently advance the catheter. If not, slowly withdraw the catheter until pulsatile blood flow reappears and then advance the catheter into the artery. It is important for the clinician to be aware of whether the tip of the needle or the catheter is the leading edge within the vessel.¹

Once the catheter is fully advanced into the vessel lumen, maintain occlusive pressure on the proximal end of the artery to limit blood loss, and then remove the needle (see Fig. 20.5, step 5). Next attach narrow-bore, low-compliance pressure tubing to the catheter (see Fig. 20.5, step 6). Securely suture the apparatus to the wrist, and then apply an appropriate sterile dressing. Occasionally, difficulty will be encountered advancing the catheter into the lumen. The “liquid stylet” method may aid further passage of the catheter.³⁴ Fill a 10-mL syringe with approximately 5 mL of sterile normal saline. Attach the syringe to the catheter hub, and aspirate 1 to 2 mL of blood to confirm intraluminal position. Then slowly inject the fluid from the syringe and advance the catheter behind the fluid wave.

Ultrasound guidance is now routinely used for both peripheral and central venous access and can also assist with arterial cannulation (see [Ultrasound Box 20.1](#)). Ultrasound-guided radial artery cannulation is associated with an increased first attempt success rate, fewer attempts prior to success, and a lower incidence of hematoma formation compared to the traditional method of palpation.³⁵

With B-mode ultrasound, visualize the targeted artery in real-time by using a 7.5- to 10-MHz linear-array transducer. Differentiate the target artery from the adjacent vein by its pulsatility and noncompressibility under mild pressure by the transducer. Use color Doppler to further distinguish between arteries and veins. Either transverse or longitudinal views can be applied during arterial cannulation, but the transverse view is often more useful in smaller arteries. Once the catheter has entered the artery and it is confirmed by blood flow, place the ultrasound transducer on the field to free up the nondominant hand.^{36,37}

The number of attempts and additional arterial punctures increases the size of the developing hematoma and the real risk for vessel wall damage, thrombosis, and even loss of arterial flow through the vessel. Despite the added trauma, there is no reported increase in complications when both walls, rather than one, are punctured in a single cannulation attempt.³⁸⁻⁴⁰

Guidewire Techniques for Arterial Cannulation

A modified Seldinger technique can often rescue a failed direct cannulation attempt with an over-the-needle catheter (Fig. 20.6). If the catheter has been placed in the arterial lumen with successful blood return, pass a properly sized guidewire through the catheter and into the artery. Advance the catheter over the guidewire and fully into the vessel. Be careful because stiffer guidewires, unlike most prepackaged ones, do not have a softer, more flexible end tip and the vessel wall may be

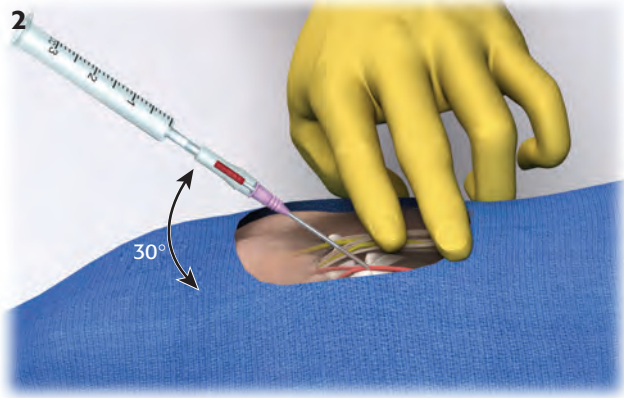

Arterial Cannulation: Over-the-Needle Catheter Technique

1

Immobilize the hand and wrist in mild dorsiflexion on a padded arm board. Prepare the skin with antiseptic, anesthetize, and apply a sterile drape.

2

Advance the needle into the artery at a 30° to 45° angle to the skin. Confirm arterial puncture by observing a flash into the needle hub.

3

Lower the angiocatheter and advance it 2 mm forward to ensure that the tip has cannulated the vessel. Confirm proper placement by observing continuous arterial blood return.

4

Carefully advance the catheter over the needle and into the artery. Do not force the catheter; if it fails to easily thread, it has not properly entered the vessel lumen. (See text for troubleshooting tips.)

5

Tamponade over the artery proximal to the tip of the catheter (to prevent blood loss), and remove the needle.

6

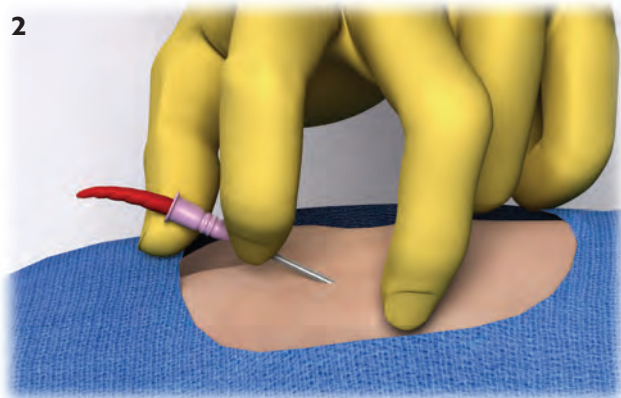

Attach the tubing from the pressure transducer to the catheter. Suture the catheter hub to the skin and cover with a sterile dressing, such as Tegaderm.

Figure 20.5 Arterial cannulation: over-the-needle catheter technique. Note that in this example the angiocatheter *does not have a safety mechanism* such as a retracting needle. This allows a syringe to be attached to the back of the hub as a blood reservoir. Such angiocatheters may be difficult to find in some institutions.

Arterial Cannulation: Guidewire Technique

1 Prepare the wrist and insert the needle as described in Fig. 20.5. Look for pulsatile blood return in the flash chamber.

2 Hold the catheter in place and remove the needle. Pulsatile blood should flow from the catheter. If not present, slowly back the catheter out, and observe for blood return.

3 Insert the guidewire through the catheter. It should advance freely and easily into the vessel. Do not force it.

4 Advance the catheter over the wire and into the artery. Remove the wire, attach the catheter hub to the transducer tubing, and secure it to the skin.

Figure 20.6 Arterial cannulation: guidewire technique.

damaged or even perforated with excessive force. Alternatively, catheter sets are available with an attachable, catheter-contained, wire stylet that permits a modified Seldinger technique for placement of the catheter. The over-the-needle catheter follows the self-contained guidewire during cannulation. Numerous commercially available sets feature styles of guidewire and reservoir attachments that are different from an over-the-needle catheter assembly. Most resemble the Arrow Arterial Catheterization Kit (Arrow International, Inc., Reading, PA) (Fig. 20.7; see also Fig. 20.2). These kits are extremely practical for smaller vessels, especially the radial, brachial, and axillary arteries, and have excellent success rates for first-time placement. Although some authors have suggested that guidewire-based techniques will improve arterial cannulation success rates in certain patients,⁴¹ it appears that success is more a function of operator experience and personal preference.⁴²

Seldinger Technique

The Seldinger technique for venipuncture is described in detail in Chapter 22. Overall success rates with the Seldinger,

guidewire-directed technique are superior to those with direct arterial cannulation.⁴² A few available kits are designed specifically for cannulation of larger arteries, but single-lumen venous catheters with guidewires may be used if catheter size and length are appropriate for specific arteries (see the following section for guidelines). The guidewire technique should be used initially for critical patients.

Place the needle percutaneously into the arterial lumen, as described previously. Then place a guidewire through the needle into the vessel lumen, and remove the needle. Thread the catheter over the wire, and pull the wire out. Although most kits have vessel dilators, especially with larger catheter sizes, caution is advised. Dilate the tract only and not the artery to avoid unnecessary blood loss and excessive arterial injury.

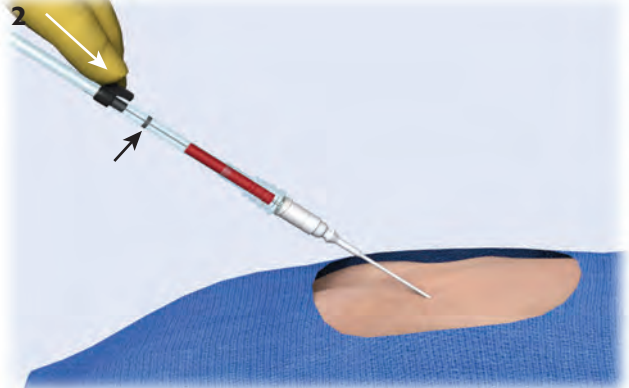

Cutdown Technique for Arterial Cannulation

The cutdown technique is rarely used, but in certain circumstances it may be performed to obtain arterial access. With the increasing use of ultrasound-assisted catheter placement, this technique should seldom be required. Perform cannulation

Arterial Cannulation: Arrow Arterial Catheterization Kit

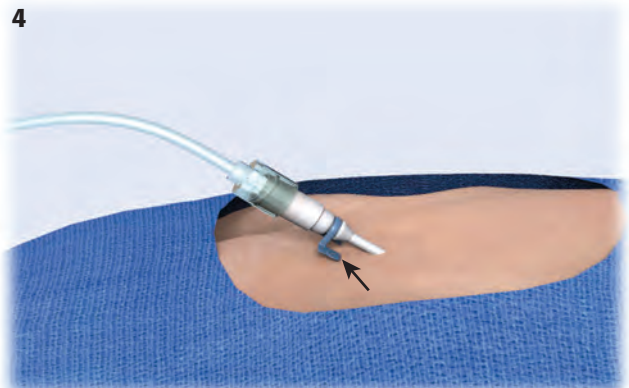

1 Ensure that the actuating lever is fully retracted, and then insert the needle into the artery. Monitor for blood flashback in the hub of the needle to confirm intraarterial placement.

2 Stabilize the needle and advance the guidewire into the vessel by using the actuating lever. When the lever reaches the reference mark (*black arrow*) on the device, the wire begins to exit the needle.

3 After the wire is fully inserted, advance the entire assembly 1–2 mm farther into the vessel. Firmly hold the needle in position, and advance the catheter over the wire and into the vessel. A slight rotating motion may be helpful.

4 Remove the needle and guidewire assembly and attach the transducer tubing to the catheter hub. Use the wing clip (*arrow*) to suture the catheter to the skin, and then cover with a sterile dressing.

Figure 20.7 Arterial cannulation: Arrow Arterial Catheterization Kit.

after direct visualization of the vessel. A cutdown can be performed on any artery but is most commonly reserved for distal lower limb arteries and, rarely, the brachial artery. After a site has been selected, prepare the overlying skin with an antiseptic solution. Using sterile technique, inject local anesthetic solution subcutaneously in a horizontal line 2 to 3 cm long and perpendicular to the artery. Omit this step if the patient is unconscious or otherwise anesthetized at the cutdown site.

Use a No. 10 or 15 scalpel blade to incise the skin along the anesthetic wheal. Spread the underlying tissues parallel to the artery with a mosquito hemostat. Palpate the pulse repeatedly throughout the procedure to ensure proper positioning. Once the surrounding soft tissue has been retracted and after exposing approximately 1 cm of the artery, isolate the artery by passing two silk sutures underneath it with the hemostat. Strip away only enough perivascular tissue to expose the artery. Perivascular tissue will help limit bleeding at the time of catheter removal. Introduce an over-the-needle catheter device, such

as the kind used in the percutaneous method, and introduce it through the skin just distal to the incision. Advance it into the surgical site ([Fig. 20.8](#)).³⁴ Alternatively, use a modified Seldinger guidewire setup to catheterize the artery. Puncture the arterial wall with the tip of the needle, and thread the catheter into the vessel lumen. When this has been accomplished, remove the two silk sutures, which have only been used to control the vessel, and close the skin incision. Do not tie off the artery the way that a vein is tied off during a venous cutdown. Apply firm pressure over the cutdown site, as used after arterial puncture. If pressure is not applied, separation of the soft tissues during the procedure may allow considerable hemorrhage into the tissue.

Local Puncture Site and Catheter Care

Once the catheter has been placed successfully, advance it until the hub is in contact with the skin. Secure the catheter by fastening it to the skin with suture material. Silk (2-0) or nylon

Figure 20.8 Placement of an arterial line using the cutdown technique. Note that the catheter enters the surgical wound percutaneously to minimize entry of bacteria into the healing wound and permit better stabilization of the catheter. Entry of the catheter into the vessel is more parallel to the vessel than illustrated. Ligatures are only used to temporarily isolate the artery and to control bleeding. *The artery should not be tied off.* The catheter is secured by suturing the hub to the skin.

Figure 20.9 A technique for securing a vascular catheter to adjacent skin.

(4-0) sutures provide the best anchoring. To accomplish this, take a moderate bite of skin with the needle, and tie a knot in the suture while leaving both tails of the suture long. Avoid pinching the skin too tightly. Tie the loose ends of the suture around the catheter at its hub. Then, after laying two ties, place a second set of knots on the back portion without occluding the lumen by constriction (Fig. 20.9).

Another option to secure these lines is to apply commercially available sutureless securement devices. According to one study, sutured lines are associated with a 10% rate of catheter-related bloodstream infection. In comparison, lines that were secured with a sutureless method had an infection rate of less than 1% and eliminated the potential for accidental needlestick from suturing.⁴³

After tying the catheter in place, apply a drop of antibiotic ointment to the puncture site⁴⁴ and a self-adhesive dressing over the area. Certain transparent dressings containing chlorhexadine gluconate can retard the colonization of bacteria.⁴⁵ Further secure the catheter and its connecting tubing with sterile sponges and adhesive tape. Make sure that all tubing connections are tight and secure. If the tubing becomes disconnected inadvertently, the patient can exsanguinate rapidly.

Fluid-Pressurized Systems

When successful arterial cannulation has been performed, attach the catheter to a pressurized fluid-filled system. A three-way stopcock can be interposed between the patient and the transducer for blood gas sampling and to allow flushing of the system. Flushing can be periodic or continuous at a rate of 3 to 4 mL/hr through a continuous-flow device. Most institutions use normal saline in place of heparinized solution

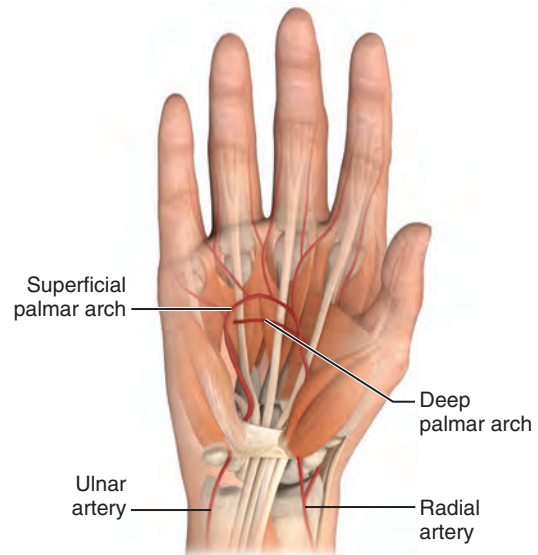

Figure 20.10 Arterial anatomy of the hand and wrist.

to maintain patency. Use of a heparinized flush solution in pressurized arterial lines may result in greater long-term accuracy of pressure monitoring, but no real difference in catheter blockage has been reported, and this approach avoids heparin-related complications such as drug incompatibility, thrombosis, local tissue damage, and hemorrhage.⁴⁶⁻⁵⁰ For short-term setups as in the ED, saline is sufficient.

Blood samples are obtained easily from the arterial catheter system. Attach a syringe to the three-way stopcock and aspirate and discard the blood to clear the line. Studies examining the necessary discard volume of flushed blood solution have found considerable variation, depending on the volume of the system.^{51,52} Short lengths of tubing between the catheter and the aspiration port minimize the necessary discard volume. For a tubing length of 91 cm (36 inches), aspirate 4 to 5 mL⁵²; for a tubing length of 213 cm (84 inches), aspirate 8 mL.⁵¹ Attach a second syringe that has been heparinized, and aspirate 3 mL of blood to send for ABG analysis. If the blood is to be used for other tests, the second syringe does not need to be heparinized. Self-contained, nondetachable, blood sample withdrawing systems allow less blood wasting for sampling. Flush the stopcock and line to avoid clotting.

SELECTION OF ARTERIES FOR CANNULATION

Radial and Ulnar Arteries

The radial artery is most frequently used for prolonged cannulation. Widespread collateral flow is present in the wrist because of two major palmar anastomoses known as arches (Fig. 20.10). The superficial palmar arch lies between the aponeurosis palmaris and the tendons of the flexor digitorum sublimis. The arch is formed mainly by the terminal ulnar artery and the superficial palmar branch of the radial artery. The other major communication of these two vessels, the deep palmar arch, is formed by connections of the terminal radial artery with the deep palmar branches of the ulnar artery.⁵³ Some collateral flow is almost always present at the wrist, with the deep arch alone being complete in 97% of 650 hand

dissections at autopsy.⁵⁴ Despite these findings, Friedman⁵⁵ noted the absence of palpable ulnar pulses in 10 of 290 (3.4%) healthy children and young adults. Interestingly, this was always a bilateral finding. Radial pulses were present in all subjects, however.

Before attempting radial artery cannulation, the adequacy of collateral flow to the hand may be assessed by performing a bedside examination called the Allen test. This examination was originally described by E. V. Allen in 1929⁵⁶ and is used to assess arterial stenosis in the hands of patients with thromboangiitis obliterans. This test identifies patients at increased risk for ischemic complications from radial artery catheterization. The procedure has undergone many modifications^{57,58} since originally being described in a cooperative patient. The modified Allen test is performed as follows: occlude both the radial and ulnar arteries with digital pressure and then ask the patient to tightly clench the fist repeatedly to exsanguinate the hand. Then open the hand and release the occlusion of the ulnar artery only (Fig. 20.11). After 2 minutes, repeat the test in the same manner with release of the radial artery only. Rubor should return rapidly to the hand following the release of pressure from either vessel.

An abnormal (positive) Allen test result, suggestive of inadequate collateralization, is defined as the continued presence of pallor 5 to 15 seconds after release of the radial artery.^{6,19,58,59} If return of color takes longer than 5 to 10 seconds, do not perform radial artery puncture. Be careful to avoid overextension of the hand with wide separation of the digits, which may compress the palmar arches between fascial planes and yield a false-positive result.⁶⁰ Time permitting, performance of some variation of the Allen test is desirable before ulnar or radial puncture, especially for prolonged cannulation. This test is not considered mandatory or standard for one-time radial artery

puncture for blood gas sampling. Moreover, the utility of the Allen test is still questioned because of numerous reports of permanent ischemic sequelae after cannulation even after a normal Allen test result.^{58,61,62} Notably, other studies have found no ischemic complications following radial artery catheterization and abnormal results on the Allen test.^{39,63} Although there are no guarantees against digital ischemia after radial artery cannulation,⁶⁴ the finding of an abnormal Allen test result should be documented and lead one to search for an alternative site for the procedure.

At the wrist, the radial artery rests on the flexor digitorum superficialis muscle, the flexor pollicis longus muscle, the pronator quadratus muscle, and the radius bone.⁵⁴ Isolate the pulsation of the artery on the palmar surface of the wrist. The radial artery is more superficial as it moves closer to the wrist. In this location, it provides a more consistent site for cannulation because of its fixation and decreased mobility. Dorsiflexing the wrist at approximately a 45-degree angle over a towel or sandbag and fixing the wrist to an arm board will also help isolate the artery.⁶⁵ This degree of preparation should be considered standard when time for setup permits (see Fig. 20.5, step 1).^{38,39}

Antegrade radial artery cannulation may be accomplished in infants and children when the radial arteries are obstructed and retrograde blood flow is observed during a failed cutdown attempt at standard retrograde arterial cannulation.⁶⁶ In addition, displacement of perivascular interstitial fluid in neonates and bright light make the course of the artery visible. Then, under direct vision, cannulation of the artery becomes as easy as venous cannulation.⁶⁷ Doppler ultrasound on selected patients with poor peripheral pulses may also facilitate percutaneous radial artery cannulation and minimize the number of punctures needed for placement.⁶⁸

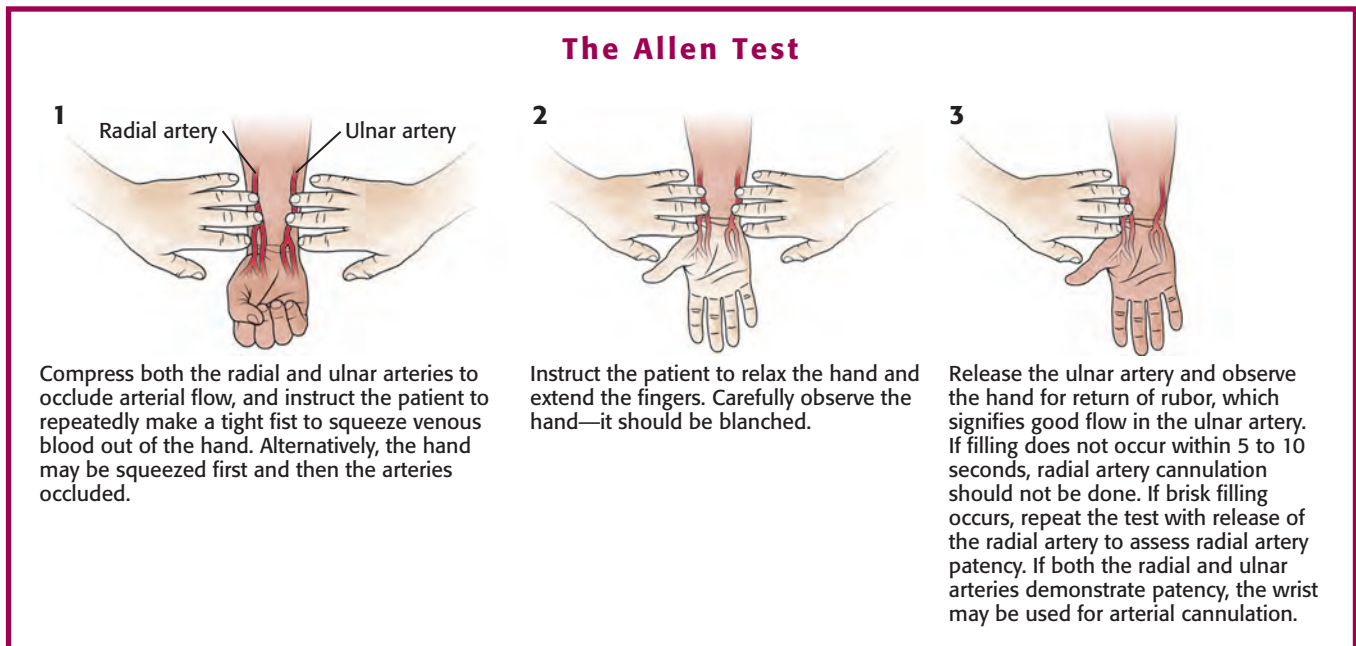

Figure 20.11 Allen test. Before puncturing the radial artery for cannulation, it is important to identify a competent ulnar artery should injury to the radial artery occur. This is not generally required, nor standard, for a single arterial puncture. (Adapted from Schwartz GR, editor: *Principles and practice of emergency medicine*, Philadelphia, 1978, Saunders, p 354. Reproduced by permission.)

The ulnar artery is seldom used because its smaller size makes it more difficult to puncture than the radial artery. At the wrist, the ulnar artery runs along the palmar margin of the flexor carpi ulnaris in the space between it and the flexor digitorum sublimis.⁵⁴ Use caution because the artery runs next to the ulnar nerve as both pass into the hand just radial to the pisiform bone. Minimize any potential injury by approaching the ulnar artery from the radial side.⁶⁹ Make the ulnar artery more accessible with dorsiflexion of the wrist.

Brachial Artery

Although it appears safe for arterial puncture, the brachial artery does not have the anatomic benefit of the collateral circulation that is found in the wrist. The brachial artery begins as the continuation of the axillary artery and ends at the head of the radius, where it splits into the ulnar and radial arteries. The preferred puncture site of the brachial artery is in or just proximal to the antecubital fossa. In this region, the artery lies on top of the brachialis muscle and enters the fossa underneath the bicipital aponeurosis with the median nerve, and on the medial side of the artery (Fig. 20.12). Both the radial and the axillary arteries are preferred over the brachial artery in the upper extremity. With the brachial artery, there is increased risk for ischemic complications from the reduction in collateral circulation, as well as the need to maintain the arm in extension for puncture and prolonged cannulation. Nonetheless, safe cannulation of the brachial artery has been demonstrated by some investigators.⁷⁰ Bazaraal and coworkers⁷¹ found only one minor thrombotic occurrence in a study of more than 3000 brachial artery catheterizations over a 3-year period in cardiac surgery patients. A longer catheter (10 cm) is required for the brachial artery so that sufficient length is available to traverse the elbow joint.

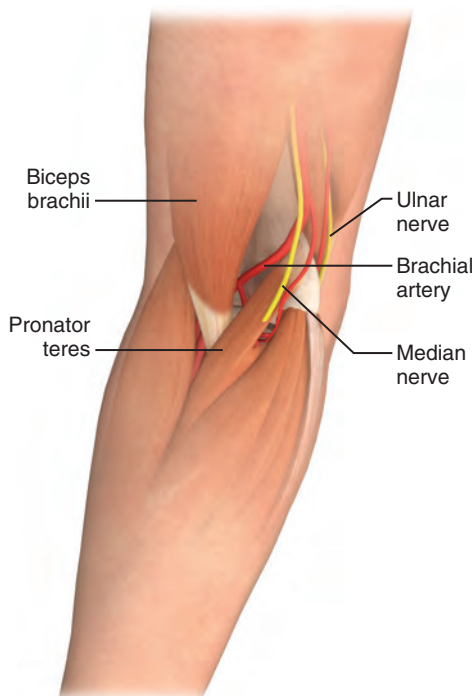

Figure 20.12 Brachial artery anatomy.

Dorsalis Pedis Artery

The dorsalis pedis artery continues from the anterior tibial artery and runs from approximately midway between the malleoli to the posterior end of the first metatarsal space, where it forms the dorsal metatarsal and deep plantar arteries. The lateral plantar artery, a branch of the posterior tibial artery, passes obliquely across the foot to the base of the fifth metatarsal. The plantar arch is completed at the point where the lateral plantar artery joins the deep plantar artery between the first and second metatarsals. On the dorsum of the foot, the dorsalis pedis artery lies in the subcutaneous tissue parallel to the extensor hallucis longus tendon and between it and the extensor digitorum longus (Fig. 20.13).⁷²

Cannulate the artery in the midfoot region. Although this vessel is amenable to cutdown, the vascular anatomy of the foot is quite variable. This is of no consequence if a pulse can be palpated, but Huber,⁷³ in his dissection of 200 feet, noted that the dorsalis pedis artery was absent in 12% of patients. In 16% of patients the dorsalis pedis artery provided the main blood supply to the toes.⁷⁴ Although the dorsal pedis and posterior tibial arteries form similar collateral foot circulation as in the hand, the nature of advancing vascular disease makes this a more difficult cannulation, with higher complication rates than in the wrist. This site has its major utility in pediatric monitoring cases. Attempts to predetermine collateral flow with a modified Allen test using the posterior tibial and dorsalis pedis arteries is not as easily performed in the foot as in the hand, nor are there good data to prove its validity. Monitoring problems also exist with this artery. The pressure wave obtained with an electronic transducer attached to the dorsalis pedis artery will be 5 to 20 mm Hg higher than that of the radial artery and, in addition, will be delayed by 0.1 to 0.2 second.⁷²

Femoral Artery

The femoral artery is the second most commonly used vessel for arterial cannulation. Based on its ease of cannulation and

Figure 20.13 Dorsalis pedis artery anatomy.

low record of complications, it has been called the vessel of choice for arterial access.⁷⁵⁻⁷⁷ Along with the axillary artery, the femoral artery more closely resembles aortic pressure waveforms than those from any other peripheral site. The femoral artery is the direct continuation of the iliac artery and enters the thigh after passing below the inguinal ligament. Arterial puncture must always occur distal to the ligament to prevent uncontrolled hemorrhage into the pelvis or peritoneum.⁷⁸ The artery may be palpable easily midway between the pubic symphysis and the anterior superior iliac spine. The advantage of cannulating the artery at a site just distal to the inguinal ligament is that the artery can be compressed against the femoral head. Cannulation becomes more difficult the more distal the puncture site is from the inguinal ligament because the femoral artery splits into the superficial femoral and the deep femoral arteries. These arteries, especially the deep femoral, can be challenging to compress if bleeding needs to be controlled. One method of locating an appropriate arterial puncture site is to place the thumb and fifth finger on the pubis symphysis and the anterior iliac spine and locate the artery underneath the middle knuckle. When puncturing this vessel, be careful to avoid the femoral nerve and vein, which form the lateral and medial borders, respectively (Fig. 20.14).

A longer, larger-diameter catheter is required for accurate monitoring of the femoral artery because of its size and the relatively greater depth at which it lies. Only the Seldinger technique is recommended for this site, which enables placement of a 15- to 20-cm plastic catheter for prolonged monitoring. Avoid using catheter-through-the-needle or over-the-needle devices because of the vessel's distance beneath the skin. Leakage around the catheter can occur with these devices as a result of the high arterial pressure and the loose fit of the cannula in the hole in the vessel wall. Regardless of the device used,

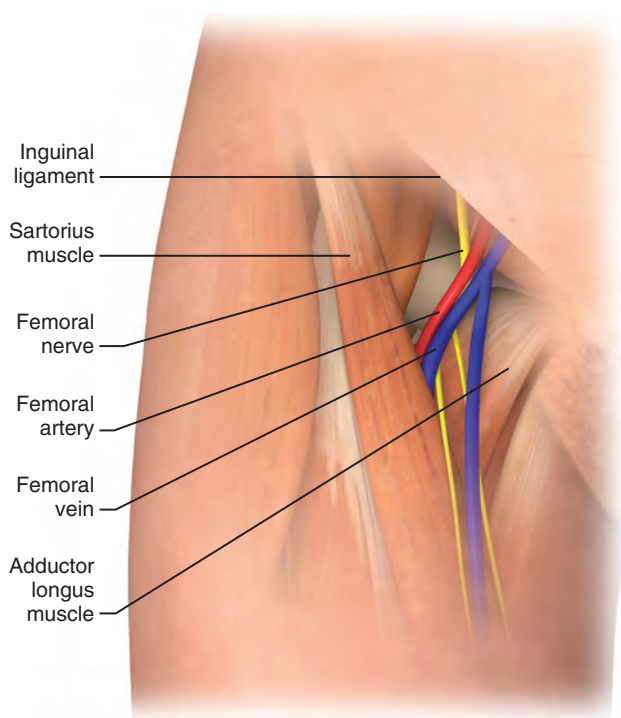

Figure 20.14 Femoral artery anatomy.

enter the skin with the needle at an angle of approximately 45 degrees instead of the usual 15 to 20 degrees.

The extremely large ratio of arterial diameter to catheter diameter is thought to reduce the incidence of thrombosis, particularly total occlusion. However, occlusion has been reported with femoral cannulation for monitoring purposes.⁷⁹ A commonly perceived disadvantage of this site is the increased possibility of bacterial contamination because of its proximity to the warm, moist groin and perineum; however, no studies have confirmed this hypothesis.⁸⁰ The femoral area is inconvenient for any patient who is awake and mobile or for a patient who is able to sit in a chair. If the patient is that mobile, reconsider the risk-benefit ratio of invasive monitoring. Despite theoretical difficulties, some hospitals use femoral arterial lines almost exclusively, and the ICU nursing staff is often more comfortable caring for these lines than those at other sites.

Umbilical and Temporal Arteries

In neonates, arterial access can be accomplished for a short time through the umbilical artery (see Chapter 19). After this artery closes, the temporal artery provides a safe alternative. Prian described the use of the temporal artery and noted its accessibility and lack of clinical sequelae if it undergoes thrombosis.⁸¹ Use the cutdown method with a 22-gauge catheter after the artery's course has been traced with an ultrasonic flow detector. Because of the increasing accuracy of ear oximeters and the use of capillary blood gas samples for determination of pH, prolonged arterial cannulation will become less frequent during infant care.

COMPLICATIONS OF ARTERIAL CANNULATION

Arterial cannulation is safe if care is taken to avoid complications. Most can be avoided by adhering to a few simple principles. Reported clinical sequelae of arterial puncture and cannulation range from simple hematomas to life-threatening infections and exsanguination. In addition, ischemia, arteriovenous fistula, and pseudoaneurysm formation are possible. The incidence of complications varies with the site selected, the method of cannulation, and the clinician's level of skill and experience. Early detection of complications is greatly aided by enhanced vigilance.

It is difficult to compare complication rates at various sites because most published studies have primarily used only the radial artery. No studies have compared the approach and complication rates of arterial catheters in the ED with those placed in the ICU or operating room. In a large study spanning 24 months, 2119 ICU patients had arterial catheters placed at admission: 52% at the radial site and 45% at the femoral site. The most common complication was vascular insufficiency (4%), followed by bleeding (2.1%), and infection (0.6%). No difference was reported in infection rates at femoral versus radial sites.⁸² There are reports of complications from arterial puncture for procedures unrelated to cannulation, such as arteriography or simple puncture for blood sampling as routinely performed in the ED. In a study of 2400 consecutive cardiac catheterizations over a 12-month period, complications occurred in 1.6% of patients, including 17 needing vascular repair and 28 requiring transfusion.⁸³

Figure 20.15 Right groin hemorrhage with resulting hematoma. The injury resulted from a failed attempt to place a right femoral artery catheter via the Seldinger technique. Inadequate pressure after the procedure resulted in bleeding from the artery. A large femoral hematoma is pictured here 3 days after iatrogenic injury.

Hematoma formation at the puncture site is common. Zorab reported this complication in 50% of all catheterizations.⁸⁴ Bruising was of minimal clinical significance in this report, but leakage can be dangerous when it occurs around the catheter or from the puncture site after the catheter is removed (Fig. 20.15). Compression neuropathies requiring surgical decompression have been reported after arterial puncture secondary to hematoma formation.^{7,85,86} The large amount of soft tissue surrounding the femoral artery makes bleeding in this area difficult to control. Large hematomas are not uncommon after femoral artery catheterization; indeed, Soderstrom and colleagues⁷⁶ reported two cases of bleeding that required transfusion after femoral puncture. Though uncommon, a clinician should be aware of the potential development of a retroperitoneal hematoma, a morbid complication, following femoral artery cannulation. Suspect this complication in patients in whom hypovolemic shock with a falling hematocrit develops following the procedure.^{87,88} Another serious complication is the formation of a pseudoaneurysm as the walls of the punctured artery fail to seal properly. Although most pseudoaneurysms can be managed conservatively, they are susceptible to both rupture and infection. Several treatment options are now available, and identification of a pseudoaneurysm should prompt referral to a vascular surgeon.^{89,90} More commonly, hematomas are painful, slow to resolve, and prone to infection. Multiple-site punctures and inadequate pressure applied for insufficient time account for most hematomas. Multiple punctures can be avoided in most instances by experienced operators and the use of ultrasound-aided techniques.

Thrombotic occlusion after radial arterial cannulation occurs in nearly 50% of infants and small children; however, ischemia from occlusion is rare because of collateral blood supply from the ulnar artery.⁹¹ Insertion sites closest to the bend of the wrist increase the chance of maintaining patency. Nonpatency is four times more likely with insertion at sites 3 cm or more proximal to the bend in the wrist.⁹² Slogoff and associates⁶³ described 1700 cardiovascular surgery patients who underwent

radial artery cannulation without any long-term ischemic complications despite evidence of radial artery occlusion after decannulation in more than 25% of the patients. Serious complications after radial artery cannulation are extremely rare in the absence of contributing factors such as preexisting vasospastic arterial disease, previous arterial injury, protracted shock, high-dose vasopressor administration, prolonged cannulation, or infection.^{62,93}

Prevention of bleeding complications can be accomplished with frequent careful inspection of the puncture site and the use of prolonged compression after removal of the catheter or needle. Maintain firm pressure for 10 minutes or longer after removing a peripheral artery catheter and longer after femoral cannulation or if the patient has received anticoagulants. Five minutes of pressure is sufficient after puncture for a blood gas sample in an individual with normal coagulation. Exsanguination may occur if the arterial line apparatus becomes disconnected. This is more common in an obtunded or combative patient, and restraints are often required for patients with indwelling arterial cannulas. Exsanguination should not occur if tight connections are maintained throughout the system and if frequent, careful inspections of both the circuit and the patient are made.

Meticulous attention to aseptic technique is necessary during insertion and catheter maintenance to minimize the risk for catheter-related infections.^{94,95} Serious infections rarely complicate arterial cannulation. Simple interventions can reduce the risk for serious catheter-related infection. Evidence supports the use of full-barrier precautions during catheter insertion, specialized nursing care, and newer-generation catheters with antiseptic hubs or antimicrobial agent-impregnated catheters.⁹⁴ The incidence of catheter-related infections increases with prolonged cannulation.⁸⁰ Catheters placed via sterile technique have an extremely low rate of infection in the first 96 hours after placement. Catheters changed over a guidewire every 96 hours have an infection rate of approximately 10% at the radial and femoral sites.⁷⁷

Most infections begin locally at the puncture site and remain localized, although systemic sepsis has been reported.⁹³ The radial and femoral sites have a similar incidence of complications, but axillary cannulation seems to have a much higher incidence of infection (although no large studies of cannulation at this site exist).^{81,96} Arterial cannulas are more prone to infectious complications than other vascular catheters. Many mechanisms have been proposed for this increased incidence.^{95,97} The arterial pressure-monitoring system usually consists of a long column of fairly stagnant fluid and is subject to frequent manipulation. Stamm and coworkers⁹⁶ found that patients were at greater risk for systemic infection if they had an arterial line and required frequent blood gas determinations than if they had the cannula alone. The sampling stopcock is a site of frequent bacterial contamination.

The risk for infection also increases as the duration of cannulation is prolonged. Older studies recommend that catheters be changed after 4 days if continued monitoring is necessary.^{96,97} In addition, Makai and Hassemer⁹⁷ recommended changing the entire fluid-filled system, including the transducer chamber domes and continuous flow devices, every 48 hours. However, the risk for noninfectious complications increases with more frequent catheter and site changes. Therefore daily evaluation of the site is advised, and catheter change should not be mandatory until 7 to 8 days if the site remains clean.

Shinozaki and colleagues⁹⁸ demonstrated a marked reduction in equipment contamination when the continuous flush device was located just distal to the transducer, as opposed to closer to the three-way stopcock used for sampling. This setup reduces the length of the static column of fluid between the sampling stopcock and the transducer. As mentioned previously, a drop of iodophor or antibiotic ointment applied to the puncture site decreases the incidence of local wound infection.⁴⁶ This technique has drawn a great deal of criticism, however. The current standard is a clean, nonocclusive, dry dressing. An antibiotic- or silver-impregnated catheter is recommended for long-term placement.

Thrombosis of the vessel in which the cannula is placed is another frequently encountered problem. The incidence of thrombosis varies with the method used to determine the presence of clots. Bedford and Wollman¹⁸ found a greater than 40% occlusion rate when radial artery catheters were left in place for longer than 20 hours. All these occluded vessels eventually recanalized. Angiographic studies show deposition of fibrin on 100% of catheters left in place for longer than 1 day, although clinical evidence of ischemia secondary to occlusion by such thrombi is seen in less than 1% of cases in most studies.⁹⁹ Most reports of nonangiographic catheterization involve the radial artery. Therefore it is difficult to compare the incidence of thrombosis at other sites, although during the 176 femoral catheterizations reported by Soderstrom and colleagues⁷⁶ and Ersoz and associates,¹⁰⁰ dorsalis pedis pulses were decreased in only two patients and no clinical signs of ischemia were noted. Larger catheter sizes, trauma during cannulation, and the presence of atherosclerosis have all been postulated to increase the incidence of thrombosis; however, conflicting studies abound.

Arterial spasm after puncture (usually following multiple attempts) can predispose to thrombus formation and can even lead to ischemic changes without fibrin deposition. Successful reversal of spasm with intraarterial lidocaine, reserpine, and phentolamine has been reported, but no reliable studies of their efficacy in this clinical situation have been published.¹⁰¹

Thrombosis can be minimized by decreasing the duration of catheterization and proper flushing. Surgical embolectomy or thrombectomy is rarely required because the smaller vessels that are most likely to occlude usually have good collateral circulation. The larger femoral artery, which has poor collateralization, rarely occludes with catheterization when used for monitoring purposes.

Thrombosis can result in occlusion of the catheter. Time until occlusion of radial and femoral artery catheters has been compared. Radial cannulas became occluded at an average of 3.8 days, whereas femoral cannulas became occluded after 7.3 days.⁷⁷ The importance of this comparison is minimal if the clinician follows infection prophylaxis guidelines and changes arterial catheters after 4 days.

A few less common complications are easily prevented. One that occurs only with the percutaneous catheter-through-the-needle method is catheter embolization. Once the catheter has been placed through the needle, it should never be pulled back because the end of the catheter may be sheared off by the sharp needle bevel. If this complication occurs, surgical removal of the tip of the catheter is necessary.

Skin necrosis is a complication of radial artery cannulation that involves an area of the volar surface of the forearm proximal to the cannula.^{102,103} Wyatt and colleagues¹⁰⁴ believed this to be

secondary to the poor blood supply in this area and thought that proper technique would decrease the incidence of necrosis.

One feared complication of indwelling radial and brachial arterial catheters is the occurrence of a cerebrovascular accident secondary to embolization from flushing of the catheters.^{20,102} As little as 3 to 12 mL of flush solution has been shown to reflux to the junction of the subclavian and vertebral arteries.⁷⁶ A fatality caused by air embolism from a radial artery catheter has been reported and was re-created in a primate model.¹⁰⁵ Although these animals were much smaller (7 kg) than an adult human, as little as 2.5 mL of air introduced at a relatively low flush rate was found to embolize in retrograde fashion to the brain. Cerebral embolization can be prevented with the use of continuous flush systems (3 mL/hr) and by ensuring the integrity of the tubing and transducer systems to prevent entry of air. In addition, small volumes (<2 mL) of intermittent flush solution should be used.

Complication rates also vary according to the method of arterial cannulation. Mortensen¹⁰⁶ studied the three main techniques (discussed earlier in the section on **Techniques**), but unfortunately, most of his arterial cannulations were for angiographic purposes. The complications associated with prolonged cannulation time are therefore underrepresented. In Mortensen's series, cutdown arteriotomy exhibited the lowest incidence of complications (7.7%), whereas the Seldinger technique had a 17.7% incidence of complications. The complication rate with percutaneous cannulation was 11.3%. False passage of the guidewire, the catheter, or both was associated with increased intimal damage and complications. It is imperative that the wire or catheter be advanced only if no resistance is met.

Once the monitoring system is set up, manipulate it as little as possible. Perform any handling with aseptic technique. Change the tubing and other fluid-filled devices every 48 hours, and insert catheters into a vessel that provides the largest vessel-to-catheter ratio as possible.

If these principles are followed and the patient and system are carefully inspected at frequent intervals, complications of arterial puncture and cannulation can be minimized.

INTERPRETATION

An indwelling arterial catheter provides continuous blood pressure monitoring. The trend of a patient's pressure facilitates assessment of the effect of various therapeutic interventions. The absolute systolic and diastolic pressure measured will vary at different catheter sites, with higher peak systolic pressures measured at the periphery. The pressure will also be higher when measured at the distal end of the lower limb.^{23,76} A wide variance between direct arterial pressure and the pressure measured with a standard pneumatic cuff will always exist in some patients. Oscillometric blood pressure measurement can significantly underestimate arterial blood pressure.¹⁰⁷ For this reason, regularly compare a cuff pressure with that obtained via invasive monitoring. Moreover, a change in their relationship may be the first indication of difficulty with the direct measuring system.

Waveform analysis may also provide an early indication of thrombosis in the arterial catheter. Many variables affect the waveform, including cardiac valvular disease and arteriosclerosis.¹⁰⁸ Waveforms may vary tremendously among patients, but after an adequate monitoring system has been established,

a change in an individual's pressure wave is usually indicative of thrombosis or a malfunction in the monitoring system. A change in waveform may also indicate a change in the patient's cardiovascular status, such as a papillary muscle rupture. Before making a therapeutic decision based on an electronically generated number, recheck the patient's blood pressure with a pneumatic cuff. This device is less fallible than the electro-mechanical system.

Radial systolic arterial pressure poorly estimates the actual ascending aortic pressure, with more than 50% of cases reporting a difference in values of 10 to 35 mm Hg. Mean arterial pressure and diastolic pressure, in contrast, are highly accurate with greater than 90% of the values being within 3 mm Hg of aortic values.¹⁰⁹ Longer catheters have also been used successfully from radial sites to more accurately reflect central aortic pressure for cardiac surgery patients.¹¹⁰

An indwelling arterial cannula can provide valuable information about the hemodynamic status of a patient (through continuous pressure monitoring) and about the patient's respiratory and metabolic status (through intermittent sampling for ABG analysis and other blood tests). The PCO_2 and pH of the blood can be used to define four major groups of metabolic derangement: respiratory acidosis or alkalosis and metabolic acidosis or alkalosis. Rarely will a disorder be strictly classified into one of these groups; however, a simple chart such as that provided in the Appendix helps determine the relative effects of metabolic and respiratory influence on blood pH (see also discussion in the Appendix).

Adequacy of blood oxygenation can be determined from the measured PO_2 of arterial blood and the known concentration of oxygen that the patient is inspiring. To avoid iatrogenic complications of intensive care, one must be absolutely certain that the data are from an arterial sample that has been properly analyzed before basing one's treatment decisions on the numbers obtained. Not uncommonly, a venous sample is interpreted as though it were arterial. Furthermore, false readings may result if the sample is not free of air bubbles, not promptly chilled, or not analyzed within 20 to 30 minutes. Though still controversial, blood gas values that are not corrected for body temperature appear to be more appropriate for guiding therapy in hypothermic patients.^{111,112}

CONCLUSION

As intensive care knowledge and technology grow and develop, cannulation of the arterial system may decrease in frequency. Oximeters can determine the quality of blood oxygenation transcutaneously and are becoming more accurate and sophisticated. Electronic sphygmomanometers are being refined for continuous indirect blood pressure monitoring. As these devices improve and noninvasive sampling methods for clinically relevant electrolytes and physiologic markers are refined, the indwelling arterial cannula may in time become considered overly invasive. Despite improvements in noninvasive monitoring devices, the current need for frequent blood sampling for chemical and hematologic analysis remains an indication for its use in selected critically ill patients. Overzealous blood gas analysis may lead to iatrogenic anemia in the ICU. Multiple reports have documented the advantages of limiting frequent blood sampling.¹¹³⁻¹¹⁵

Arterial puncture and cannulation are invaluable aids to the emergency and critical care clinician. Long-term catheterization is a safe procedure when the catheter is placed, maintained, and removed with care. The radial artery is the most favored location for puncture, but as more experience is gained and reported with femoral artery catheterization, the latter may become a more frequently used site. Selection of either site is associated with a low complication rate and should be determined by the skill of the clinician, the nursing team, and the relative convenience and comfort of the patient. Ultrasound guidance for arterial catheter placement is becoming the standard and should be considered in every instance to reduce the need for multiple puncture attempts.

Peripheral Intravenous Access

Bonnie L. Kaplan, Shan W. Liu, and Richard D. Zane

INTRODUCTION

▶ Intravenous (IV) access is a mainstay of modern medicine. IV cannulation is a procedure (Videos 21.1 and 21.2) performed by a wide array of health care professionals, including physicians, nurses, physician assistants, phlebotomists, and emergency medical technicians. In the emergency department (ED), uncomplicated peripheral venous access is usually secured by a nurse or technician. In the United States, more than 25 million patients have peripheral IV catheters placed each year as vascular access for the administration of medications and fluids and the sampling of blood for analysis. IV access can usually be accomplished in less than 5 minutes.¹⁻⁴ Despite their growing number, dedicated IV teams are very costly and not always cost effective.^{5,6} Moreover, in the ED setting, multiple providers may be called on to obtain IV access, thus making it an essential skill for both emergency physicians and nurses to master. Subtleties in technique are important and can be improved with practice; newer technologies such as ultrasound can assist providers in placing IV lines in even the most challenging situations.

HISTORICAL PERSPECTIVE

Bloodletting, or bleeding, dates to the time of Hippocrates. The ancient technique consisted of tying a bandage around the arm to distend the forearm veins, opening a vein with a sharp knife, and collecting the blood into a basin. In the Middle Ages, this was performed by barber-surgeons. In 1656, Sir Christopher Wren injected opium into dogs intravenously with a quill and bladder, thereby becoming the father of modern IV therapy.⁷ Blood transfusions also date back to the mid-1600s. The French physician Jean Denis is credited with the first successful transfusion by giving lamb's blood to a 15-year-old boy.^{8,9}

Originally, 16- to 18-gauge indwelling steel needles were used for IV infusions. In the 1950s the Rochester needle was introduced, which was a resinous catheter on the outside of a steel introducer needle. Because of increased comfort and mobility, plastic catheters have replaced indwelling metal needles and are now almost universal.^{7,10}

INDICATIONS AND CONTRAINDICATIONS

Obtaining timely and adequate vascular access is a major priority during any resuscitation. In patients with normal perfusion, differences in delivery times for injections centrally versus peripherally are minimal, within seconds.¹¹ During cardiopulmonary resuscitation (CPR), however, medications have been shown to reach the central circulation faster with central access than with peripheral venous access.¹² A change in outcome, though, has not been demonstrated with the central administration of advanced cardiac life support drugs; hence,

Peripheral Intravenous Access

Indications

- Venous blood sampling
- Intravenous fluid infusion
- Intravenous medication infusion
- Blood transfusion
- Intravenous contrast infusion

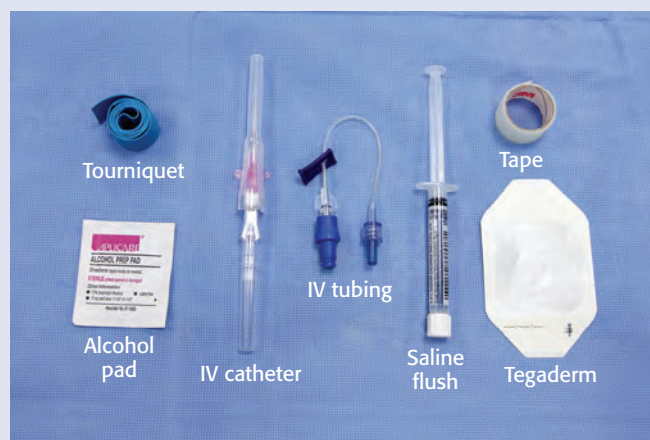

Contraindications

- Extremity with significant edema, burns, sclerosis, phlebitis, or thrombosis
- Ipsilateral radical mastectomy or fistula
- Overlying cellulitis

Complications

Early	Late
Bruising	Phlebitis
Infiltration	Infection
Air embolism	Nerve damage
	Thrombosis

Equipment

Review Box 21.1 Peripheral intravenous access: indications, contraindications, complications, and equipment.

peripheral IV cannulation is the procedure of choice even during CPR because of the speed, ease, and safety with which it can be accomplished. In less critically ill patients, the role of IV therapy is more often debated and access is ultimately unnecessary in a large proportion of patients in whom it is obtained.¹³ In broad terms, IV access or therapy is needed in patients for whom IV medications are required or when oral therapy is inadequate (e.g., severe shock states), contraindicated (e.g., surgical emergencies), or impossible (e.g., intractable vomiting).

Saline or heparin locks are preferable when IV medications are needed and there are limited foreseeable fluid requirements. Saline locks cost less than a full IV fluid and tubing assembly and are especially helpful when vascular access is needed suddenly.^{14,15} Access to the catheter requires irrigation with a separate syringe and flush.

A peripheral IV central catheter (PICC) shares the attributes of both central and peripheral venous IV lines (see [Chapter 24](#)). A PICC is composed of a thin tube of biocompatible material with an attachment hub. It is inserted percutaneously, under ultrasound guidance by a dedicated PICC team, into a peripheral vein and then advanced into a large central vein, followed by radiographic confirmation of placement. PICCs are suitable for long-term vascular access for blood sampling, infusion of antibiotics and hyperosmolar solutions such as total parenteral nutrition, and infusion of certain chemotherapeutic agents. Insert a PICC line as soon as long-term access is anticipated.³

Peripheral IV lines should not be placed in extremities with massive edema, burns, sclerosis, phlebitis, or thrombosis due to risk for extravasation or suboptimal volume flow. When practical, avoid placing an IV line in extremities on the same side as radical mastectomies, though they can be used when an urgent condition exists and other peripheral access is not possible. When feasible, cannulation at infected sites, such as through an area of cellulitis, and extremities with shunts or fistulas should be avoided because it may cause bacteremia or thrombosis. If possible, do not cannulate a vein over or distal to a recent fracture site on an extremity ([Fig. 21.1](#)). Veins that drain from an area affected by trauma or major vascular disruption (e.g., distal to a ruptured aorta) are also suboptimal because

Figure 21.1 Do not place peripheral intravenous (IV) access (*long arrow*) near or distal to a fracture in an extremity (*short arrow*). In this case an IV line for pain medication was placed before obtaining the radiograph. The scaphoid fracture was not suspected and the opposite arm had difficult access.

fluid or medications may not be delivered to the circulatory system.

Blood samples for laboratory analysis are usually drawn before IV cannulation to avoid contamination with IV fluid or medication. However, studies have shown that accurate basic electrolyte and hematologic values can be obtained with peripheral IV lines when infusions are shut off for at least 2 minutes, at least 5 mL of blood is wasted, and all tubes are completely filled to avoid inaccurate bicarbonate readings.¹⁶⁻¹⁸ By adopting these techniques, one can reduce the number of peripheral needlesticks, minimize trauma or sclerosis of the vein, and improve patient satisfaction.

ULTRASOUND GUIDANCE AND TRANSILLUMINATION

Though more commonly used with central venous access, ultrasound can also assist in the placement of peripheral lines. For IV placements that have been designated “difficult” after a certain number of attempts by nursing staff, use of ultrasound guidance increases the success rate and decreases the number of attempts necessary for successful cannulation in both adult and pediatric patients.¹⁹⁻²² One 2016 randomized controlled trial showed that ultrasound guidance is particularly helpful in patients with perceived difficult access. However, this same trial noted that patients with perceived easy access had more success with landmarks alone.²³ The caliber of the vein identified on ultrasound is predictive of its ability to be cannulated. If no vessel is identified, cannulation is not usually possible.^{24,25} An additional issue with ultrasound-guided peripheral IV lines is their longevity. One study highlighted the high premature failure rate of ultrasound-guided peripheral lines.²⁶ Ongoing studies are evaluating this concern. It is likely related to the depth of the veins being cannulated, the length and type of catheter used, and the angle of the catheter through soft tissue.

Other devices transilluminate the veins to increase their visibility. This appears to be especially helpful in infants, though little evidence exists evaluating their utility. One 2012 study showed an increase in successful first attempt rates in pediatric patients with difficult peripheral access.²⁷ As emergency providers have become more comfortable with these advancing technologies, ultrasound-guided and illumination-assisted insertion of peripheral lines have increased.

ANATOMY

The success of cannulation depends on familiarity with the vascular anatomy of the extremities. In the upper extremity, the veins of the hands are drained by the metacarpal and dorsal veins, which connect to form the dorsal venous arch ([Fig. 21.2](#)). These sites are excellent for IV therapy and comfortably accommodate 22- and 20-gauge catheters. The venous supply of the wrist and forearm consists of the basilic vein, which courses along the ulnar portion of the posterior aspect of the forearm. It is often ignored because of its location but can easily be accessed if the patient’s forearm is flexed and the clinician stands at the head of the patient.²⁸ On the radial side of the forearm, the cephalic vein is commonly known as the *intern vein*. Readily accessible, this vein can accommodate 22- to 16-gauge catheters. The median veins of the forearm course through the middle of the forearm, and the accessory cephalic

Figure 21.2 Anatomy of extremity veins for peripheral intravenous cannulation.

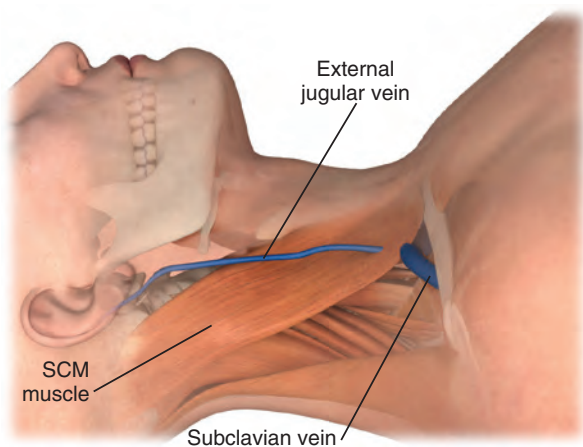

Figure 21.3 External jugular anatomy. SCM, Sternocleidomastoid.

veins on the radial aspect of the forearm are easily stabilized and accessible.

The antecubital veins consist of the medial cubital, basilic, and cephalic veins; these are often selected for catheters or blood drawing. IV placement here is easy, but mobility of the arm is restricted once the catheter is in place. The larger veins above the antecubital space, the cephalic and basilic veins, are often more difficult to see but can be accessed without difficulty if necessary.

The relevant lower extremity venous anatomy starts with the dorsal digital veins, which become the dorsal metatarsal veins and form the dorsal venous arch. The arch ultimately splits into the great saphenous vein, which travels up the medial aspect of the ankle, and the small saphenous vein, which courses laterally up the opposite side. These are the vascular structures most easily accessible for IV therapy.

The external jugular vein is formed below the ear and behind the angle of the mandible (Fig. 21.3). It then passes downward and obliquely across the sternocleidomastoid and under the middle of the clavicle to join the subclavian vein. It is important to note the presence of valves in the external jugular, usually approximately 4 cm above the clavicle, because they can significantly impede IV function.²⁹

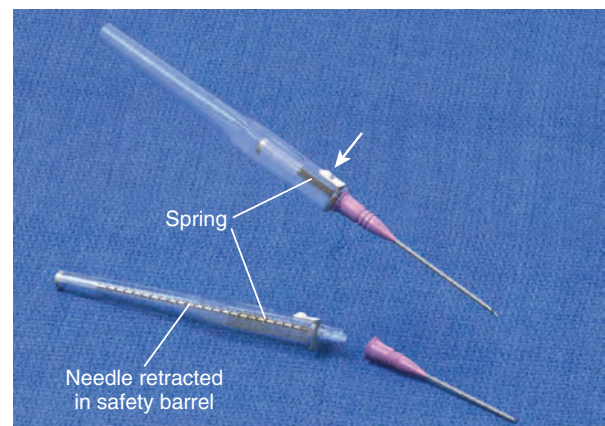

Figure 21.4 Intravenous catheter safety device. When the activation button is depressed (arrow), the spring is released and the needle is retracted into the safety barrel.

PREPARATION

Safety

Universal precautions must be applied to all patients, especially in emergency care settings, in which the risk for exposure to blood is increased and the infection status of patients is largely unknown.³⁰ One study showed that 11% of all hospital IV catheter injuries to health care workers occurred in the ED.³¹ Newer catheter devices have emerged that prevent inadvertent needle injuries (Fig. 21.4). The Protectiv IV Catheter Safety System (Smiths Medical, Minneapolis, MN) has a protective sleeve that encases the sharp stylet as it is retracted from the catheter. The needle of the Insyte Autoguard Shielded IV Catheter (Becton, Dickinson and Company, Franklin Lakes, NJ) is instantly encased inside a tamper-resistant safety barrel by pressing an activation button. The Saf-T-Intima IV catheter (Becton, Dickinson and Company), Punctur-Guard Safety Winged Set (Gaven Medical, Grand Island, NY), Vacutainer Safety-Lok (Becton, Dickinson and Company), Shamrock safety winged needle (Smiths Medical, Dublin, OH), and Angel Wing Safety Needle systems (Medtronic, Minneapolis, MN) are all

Figure 21.5 Various gauges of intravenous catheters. Needles are sized according to gauge, from large to small (14 to 24 gauge).

types of winged safety devices with shields that advance over the needle to prevent its exposure.⁷

Choosing the Catheter Gauge

The specific gauge of catheter to use depends on the clinical scenario (Fig. 21.5). The narrowest catheter typically used in adults is a 22 gauge, which is sufficient for the routine administration of maintenance fluids and antibiotics. A 20 or 18 gauge is necessary for the administration of blood products, and a 16-gauge needle is preferred in resuscitation settings when large amounts of fluid must be given quickly.²⁸ A second IV line at a different location allows additional IV therapy and also acts as a backup line in critical resuscitations. An 18-gauge catheter in the antecubital fossa is the standard device for IV contrast-enhanced computed tomography (CT) studies such as pulmonary CT angiogram.

Appropriate Site

Site selection depends largely on the expected duration of IV therapy, the patient's activity level, and the condition of the extremities. When choosing a location to initiate IV access, the best place to start is the hand and then advance cephalad as necessary. Hand veins are appropriate for 22-gauge catheters. Cephalic, accessory, or basilic veins are ideal for larger-bore IV lines. Avoid veins that are not resilient and feel hard or cordlike because they are often thrombosed.⁷ Deep, percutaneous antecubital venipuncture and external jugular vein cannulation are also options in patients with difficult veins or those who may need IV access quickly.⁷ The lower extremity veins can also be useful locations, especially in pediatric patients. In patients who have undergone radical mastectomy, avoid the arm on the same side as the surgery because IVs may impair circulation, affect flow, or lead to edema and other complications.^{7,22} Scalp veins are commonly used in neonates.^{3,32}

Adjuncts for Finding a Vein

Patients often have nonvisible and nonpalpable veins. A common method of increasing venous distention is to ask patients to open and close their fist. Lowering the arm below the level of the heart can also increase venous distention. Light tapping can likewise be effective, although heavy tapping may cause the vein

to spasm. If these methods are inadequate, heat packs can be applied for 10 to 20 minutes to increase venous engorgement. This is particularly useful in the pediatric population.⁷

Nitroglycerin ointment applied to the hands of patients with small-caliber veins has been shown to increase the diameter of the vein by two to six times and increase the rate of successful first-attempt cannulation. Once the tourniquet is applied to the wrist, apply a quarter inch of 2% nitroglycerin to a 2.5-cm² area, leave it on for 2 minutes, and then rub it off.³³ Nitroglycerin alone can have adverse effects in neonates and premature babies, however. The combination of topical nitroglycerin with local anesthetics has been shown to increase success and decrease the pain of cannulation in children 1 to 11 years old.³⁴ This technique is contraindicated in hypotensive patients.

In the late 1980s, several small studies demonstrated the potential use of a venous distention device, a cardboard mailing tube that was placed over the forearm with a sealed bulb at one end that caused a vacuum within the tube. Of the patients predetermined to be difficult to access, 90% were cannulated when this device was used. Reported complications were few and included petechiae and discomfort.^{35,36}

Anesthesia

Though somewhat time-consuming, local anesthesia at the site should be considered part of routine care. Local anesthesia significantly decreases pain before cannulation.^{37–39} Anesthetics such as lidocaine or bupivacaine may be instilled just beneath the skin at the site of planned cannulation through a tuberculin (1-mL) syringe equipped with a 27- or smaller-gauge needle. Adding bicarbonate (e.g., buffered lidocaine), warming the solution to room temperature, instilling the solution slowly, and distracting the patient during injection all contribute to reducing pain.⁴⁰ In the pediatric population, 2.5 g of EMLA (eutectic mixture of local anesthetics) can be applied topically over the site.^{7,41} Its main disadvantage is slow onset, with as long as an hour needed for induction of anesthesia before cannulation.⁴² Other options include ethyl chloride topical spray,⁴³ which temporarily numbs the skin, and oral sucrose in infants.⁴⁴

IV Assembly

Review Box 21.1 itemizes the materials necessary for IV cannulation. The procedure is detailed in Fig. 21.6. The first step is to prepare the IV fluids and tubing. Remove the cap from the IV tubing and the tab from the IV bag. Clamp the IV tubing shut and insert the spiked end into the IV fluid bag. Pinch the drip chamber and fill it halfway. Open the clamp slightly to flush the IV tubing. If saline locks are being used, flush them similarly before cannulation. To do this, attach the lock to a saline-filled syringe and push saline through it.

Inspection and Positioning

After collecting and preparing the equipment and supplies, palpate the veins. Position the patient comfortably on a flat surface. Place a 1-inch-wide tourniquet on the upper part of the patient's arm or forearm and pull it sufficiently tight to impede venous flow but not tight enough to compromise arterial flow. Place the tourniquet under the arm. Fold both ends of it above the arm and cross the ends. Pull the overlying end taut and tuck the middle portion below the underlying end to

Peripheral Intravenous Access

1 Apply tourniquet to arm.

2 Prepare the insertion site with an alcohol pad.

3 Insert the IV catheter with the bevel facing upward.

4 Advance the needle until a flash of blood is seen.

5 Advance the catheter over the needle until flush with the skin.

6 Attach the preflushed saline lock.

7 Cover the insertion site with Tegaderm (or similar) dressing.

8 Attach IV tubing to the saline lock for IV fluid administration.

Figure 21.6 Peripheral intravenous (IV) access. IV lines placed in the dorsum of the hand are associated with the lowest infection rates from venous cannulation.

create a loop. After placement of the tourniquet, palpate the veins with the index and middle finger of one's nondominant hand. The veins are soft, elastic, resilient, and pulseless.²⁸

Cannulation

Wash your hands, don gloves (nonsterile is adequate), and clean the injection site with iodine, alcohol, or both. Iodine is a better antiseptic than alcohol and results in fewer infections.⁴⁵ If using alcohol, allow it to dry on the surface of the skin. Stabilize the vein without contaminating the prepared site. One method is to position one's thumb alongside the vein and pull down while the index finger is positioned more cephalad and pulls upward. Take the angi catheter between the thumb and forefinger of the dominant hand. With the bevel up, angle the angi catheter 10 to 30 degrees between the catheter and the vein and parallel to the vein. Puncture the vein. Once a flash of blood is seen, advance the catheter several millimeters more to ensure that the catheter has entered the vein and not just the wall. Avoid advancing too far and puncturing the posterior wall. Loosen the stylet and advance only the catheter. Use the fingers that were anchoring the vein to occlude the vein at the tip of the catheter to prevent extravasation of blood from the angi catheter. Remove the needle; connect the saline lock, IV lining, or syringe for phlebotomy; and release the tourniquet.²⁸

Cannulation of the external jugular vein deserves a special note (Fig. 21.7). In patients with otherwise limited peripheral access, it can be cannulated as follows. Place patient in the Trendelenburg position to fill the external jugular vein. Rotate the head to the opposite side and prepare the area as described earlier. Take the cannula and align it in the direction of the vein with the point aiming toward the ipsilateral shoulder. Puncture midway between the angle of the jaw and the midclavicular line while lightly compressing the vein with the free finger above the clavicle. Proceed as described previously for cannulation.

Anchoring the Device

After the IV cannula has been connected to the saline lock or IV tubing, anchor the device (see Fig. 21.6). Use a half-inch-wide strip of tape, adhesive side up, under the hub of the catheter and fold it over in a bow-shaped manner. This will secure the catheter and prevent lateral movement. Clear polyurethane dressings can also be used with or instead of tape. Saline locks can be connected to needless hubs to prevent accidental needle injury. Then secure the loose saline lock or IV tubing with tape to prevent accidental dislodgement. Connect the IV tubing to the angi catheter and anchor it. Alternatively, use a commercially available securing device. Sign and date the dressings to ensure timely dressing changes.⁷ As an option, topical antibiotics or iodophor ointment may be applied to the insertion site to prevent infection, though the efficacy of doing so is unproven.⁴⁶

Maintaining Patency

An important component of IV care is maintaining patency with frequent flushing. Until recently, heparin solutions were used to flush catheters and maintain patency, but heparin can cause problems such as hemorrhage. Saline flushes are as effective as heparin in maintaining patency and preventing

Figure 21.7 External jugular vein cannulation. **A**, Note that traction on the vein is applied with the thumb of the nondominant hand while the index finger tamponades the vessel (*arrow*) (essentially serving as a tourniquet) near the clavicle. Flow is dependent on neck position. **B**, Intravenous catheters may be sutured in place for stability. The Trendelenburg position and a Valsalva maneuver can facilitate cannulation.

phlebitis but do not carry the risks of bleeding or heparin-induced thrombocytopenia.^{47–49}

Dressing

It is not cost effective to continually redress peripheral venous catheters at periodic intervals. Sterile gauze or transparent, semipermeable, polyurethane dressings can be left in place until removal of the catheter without increasing infection rates, as long as the site is regularly evaluated.⁵⁰ Securing techniques that use proprietary devices, such as the StatLock IV (Bard Access Systems, Inc., Salt Lake City, UT), a sterile, adhesive-backed anchor, and distal male Luer-tip extensions, may reduce complications by decreasing mobility and risk of dislodgement.⁵¹ Commonly used topical antimicrobial ointments have not been consistently proved to reduce the rate of peripheral catheter-related infection but have been associated with increased rates of antimicrobial resistance and *Candida* colonization. Such ointments are not harmful in the ED, but their routine use is not supported.

Percutaneous Brachial Vein Cannulation

Brachial vein cannulation is an option when attempts at peripheral IV access have failed or are contraindicated and may obviate the need for central venous access or surgical cutdown. Complications include brachial artery puncture, hematoma, and transitory paresthesias.

To cannulate the brachial vein, palpate the brachial artery in the antecubital fossa. Prepare the site in the usual manner and apply a tourniquet above the antecubital space. At a point immediately medial or lateral to the pulse, insert an angiocatheter with an attached syringe and advance it at a 45-degree angle while maintaining suction on the syringe. After entrance into the vein, continue 2 to 3 mm further to ensure cannulation. Advance the catheter and remove the needle as usual.^{26,43}

COMPLICATIONS

Although IV placement is a common procedure, it is not without complications. Fortunately, morbidity is rarely severe. Phlebitis, infiltration, infection, nerve damage, air embolism, bruising, and thrombosis are the most common complications and rarely cause significant morbidity or fatality.

Phlebitis is a common complication after IV cannulation and is described as the presence of a palpable cord accompanied by warmth, erythema, tenderness, and induration over the involved vein (Fig. 21.8). Phlebitis necessitates removal of the catheter and replacement on another extremity. Avoiding IV placement in the lower extremities (where there is more often stagnant blood flow) and across joints (where motion traumatizes the venous wall) minimizes the incidence of IV catheter-related phlebitis.⁷ Other causes of phlebitis include IV infusion of potassium chloride, certain antibiotics (vancomycin, erythromycin), many cytotoxic chemotherapy agents, phenytoin, and any hyperosmolar solution (e.g., 50% dextrose solution).^{52,53} The role of in-line filters to prevent phlebitis is controversial. Particulates from reconstituted medications, degradation products, precipitates, glass from vials, and other foreign debris may all play a part in postinfusion phlebitis. In-line filters may therefore play a role in preventing phlebitis, but given their cost, risk of clogging, and paucity of evidence that they improve outcomes, these filters have not become routine.⁵⁴

Even with the most pristine technique, there is approximately a 0.5% incidence of catheter-related bloodstream infection with peripheral IV catheters. IV devices facilitate infection by damaging epithelial barriers and thereby providing microorganisms direct access to the bloodstream.⁵⁵ The risk for infection with peripheral venous catheters is higher in the lower extremity than in the upper extremity and higher in the wrist or upper part of the arm than in the hand. The most common infectious

complication of peripheral IV access is self-limited cellulitis.⁵⁶ The safety of maintaining peripheral IV lines for up to 72 hours before they are relocated has been established in a large, prospective study.⁵⁰ With rates of clinically significant bacteremia lower than 0.5%, some argue that routine replacement of catheters is now no longer needed.⁵⁷ Nonetheless, infection can be a costly and potentially devastating complication of IV therapy. Suppurative thrombophlebitis is extremely rare. It most frequently occurs in patients with thermal injury and long-term or lower extremity cannulation.⁵⁵ Local signs of inflammation or suppuration are often absent and can occur 2 to 10 days after removal of the catheter.⁵⁸ Treatment is immediate surgical excision of the entire length of the involved vein and tributaries. Though rare with peripheral IV catheters, intravascular device-related bloodstream infection may be an unrecognized cause of nosocomial infection. Peripheral IV catheters are most often associated with staphylococcal and candidal species.⁵⁹ Infectious complications can be reduced significantly by hand washing, wearing gloves, preparing the site with iodine, and monitoring the site for signs of infection.⁷

Bruising is a common complication of IV therapy. Contrary to popular belief, flexing of the elbow after venipuncture does not prevent bruising in the antecubital site.⁶⁰ Applying direct pressure immediately after decannulation is the most useful technique to prevent bruising.

Tissue or interstitial infiltration occurs when the catheter is dislodged from the vein during infusion. It is a common and usually relatively minor complication of IV therapy. Extravasation of certain infusions, such as hypertonic solutions, vasopressors, or chemotherapeutic agents, however, poses a significant risk for necrosis and skin sloughing when infiltration and extravasation occur. In extreme cases, skin grafting may be required.⁷ For extravasation of dopamine or epinephrine, local injection of antidotes such as phentolamine may be used to reverse the tissue damage.⁶¹

Nerve injury is rare after IV cannulation. Any peripheral nerve is potentially vulnerable to a needle-induced injury, and sequelae can range from a minor motor or sensory abnormality to complete paralysis. Nerve damage may be due to direct injury by the needle, intraneural microvascular damage from hematomas, or toxic effects of the agent injected.⁶² The first symptoms are usually pain, numbness, or paresthesia. Pain may persist for years and can be debilitating. Fortunately, most simple procedures do not result in nerve injury because nerves tend to roll or slide away from a needle. Like all procedures, knowledge of the relevant anatomy is essential. Should a patient complain of numbness or severe pain after a needle puncture, stop the injection immediately.^{63,64}

Thrombosis and subsequent pulmonary embolism (PE) are commonly associated with centrally placed IV catheters.⁷ Though rare, thrombosis followed by clinically significant PE may occur in patients with peripheral IV lines if saline locks are not flushed or IV fluids run dry. Should this occur, aspirate the line. If the return fluid appears bloody, discard the syringe and then gently flush the saline lock and resume the infusion. If there is no bloody aspirate, use 2 to 3 mL of saline to gently flush the line. If resistance is encountered, stop flushing immediately because there is a risk for development of an embolism. Attempt IV insertion at another site.⁶⁵

Venous air embolism is another significant, though exceedingly rare complication of peripheral IV access. Symptoms include chest pain, shortness of breath, sudden vascular collapse, cyanosis, and hypotension. If air embolism is suspected, place

Figure 21.8 A, Suppurative phlebitis from a peripheral intravenous line. B, After incising and cleaning the infected subcutaneous tract, a gauze pack was placed for 24 hours and oral antibiotics were given with good results.

the patient in the left lateral decubitus Trendelenburg position. Invasive maneuvers include aspiration of air through a central venous catheter and even thoracotomy with direct aspiration from the heart (see Chapter 18). This complication can be prevented by eliminating air from the IV tubing before initiating therapy and not allowing IV lines to run dry.⁷ If air bubbles are present in an IV line, tap the tubing while holding it taut to allow the air to escape to the top. Similarly, curl the tubing around a pen or syringe to accomplish the same goal. If the air is near a Y-connector, one can use a needle and syringe to directly remove it. If all else fails and there is air between the Y-connector and the patient, disconnect the tubing and flush it.⁶⁶

Recommendations of the Centers for Disease Control and Prevention for IV catheter care to prevent complications are as follows:

1. Record and date the time of catheter insertion in an obvious location near the insertion site.
2. Do not palpate the insertion site after the skin has been cleansed with antiseptic.
3. Palpate the insertion site for tenderness daily through an intact dressing.
4. Visually inspect the site if the patient reports tenderness.
5. Wash hands before and after palpating, inserting, replacing, or dressing any intravascular access site.
6. Replace dressings when they are damp, loose, or soiled.⁵⁶

EXTRAVASATION OF MEDICATIONS AND VASOPRESSORS

Usually, infiltration of a vein is a relatively minor and common complication of IV therapy if only sterile fluid extravasates, even in large amounts. This often occurs when the catheter is dislodged from the vein during infusion. However, if the infusions consist of hypertonic substances, vasopressors, or chemotherapeutics, there is a significant risk for skin sloughing if infiltration and extravasation occur (Box 21.1). Pain at the infusion site or the alarm sounding on an infusion pump device requires inspection of the infusion site for extravasation. In extreme cases, grafting may be required for skin sloughing (Fig. 21.9).⁵ If dopamine, phenylephrine (Neo-Synephrine, Hospira, Inc., Lake Forest, IL), or norepinephrine extravasate, phentolamine may be used as an antidote to prevent ischemia locally; its use is encouraged as soon as extravasation is identified. Reversal of ischemia with phentolamine is a common technique, but its ability to totally reverse or prevent skin sloughing is not guaranteed. However, if infiltration of these vasopressors occurs, the authors suggest that it be used routinely. There are few downsides to this intervention, although hypotension is a theoretical side effect because phentolamine is an α -adrenergic antagonist. To inject phentolamine, place 5 mg in a vial and dilute with equal parts of saline (final form: 5 mg in 2 mL). For large areas, use two vials with the contents of each vial injected 10 minutes apart through a 25- to 27-gauge needle or a tuberculin syringe. If the IV line is still in place, inject approximately 1 mL of phentolamine through the catheter before it is removed; however, the IV line is often removed before this can be done. The entire area of skin blanching, or suspected area of extravasation, is injected with multiple small aliquots of the solution, approximately 0.25 to 0.5 mL each. The procedure may be repeated in 2 to 4 hours. Hyaluronidase is probably benign and has been suggested in the past to ameliorate some effects of extravasation of other solutions.

Though it has been a common suggestion, its efficacy has not been well established, and the product is not readily available. Ice and heat have varying effects in counteracting fluid extravasation. Extravasation of IV contrast material is discussed in Chapter 36.

BOX 21.1 Medications and Solutions That May Cause Tissue Injury When Extravasation Occurs in a Peripheral Vein^a

Aminophylline	Mithramycin
Calcium chloride 10%	Mitomycin
Carmustine	Nafcillin
Chlordiazepoxide	Neo-Synephrine (Hospira, Inc., Lake Forest, IL)
Colchicine	Nitroglycerin
Crystalline amino acids 4.25%/dextrose 10%	Norepinephrine
Crystalline amino acids 4.25%/dextrose 25%	Parenteral nutrition solutions
Dactinomycin	Phenytoin ^b
Daunorubicin	Potassium solutions
Dextrose 10%	Propylene glycol
Dextrose 50% in water	Renografin-60 (Bracco Diagnostics Inc., Monroe Township, NJ)
Diazepam	Sodium bicarbonate 8.4%
Dobutamine	Sodium thiopental
Dopamine	Tetracycline
Doxorubicin	Vasopressin
Epinephrine	Vinblastine
Ethyl alcohol	Vincristine
Mechlorethamine	Vindesine
Metaraminol	

^aMany medications and intravenous solutions will cause pain and occasionally skin sloughing if significant amounts extravasate into soft tissues. Thus, any complaint of pain during infusion or signs of tissue swelling should prompt an investigation for extravasation. Most extravasations have no specific therapy, so prevention is the only option. Phentolamine, injected subcutaneously to reverse vasoconstriction, is the most common technique, but its efficacy has not been well studied.

^bUse a maximum concentration of 2 mg/mL of saline or fosphenytoin solution to minimize this risk.

Figure 21.9 **A**, Infiltration of calcium chloride in an infant. Once this occurs, there is no treatment except débridement and possible skin grafting. Calcium gluconate will not cause such a reaction. Extravasation of hypertonic dextrose, phenytoin, and vasoconstrictors or vasopressors will cause similar necrosis. **B**, Full-thickness tissue injury from doxorubicin extravasation, not obvious until 7 to 10 days after the infusion.

Extravasation of chemotherapy solutions is particularly common and can produce full-thickness tissue sloughing. The patient may complain of pain and burning at the time of infusion, but skin sloughing may be delayed for many days. **Table 21.1** lists possible antidotes and dosages for chemotherapy-induced extravasation injury. Results of these interventions vary.

Injury from extravasation of phenytoin can be minimized or avoided by using dilute solutions, no more than a 2-mg/mL concentration (1 g in 500 mL saline), or by using fosphenytoin instead of phenytoin. When possible, use calcium gluconate, not calcium chloride, in a peripheral IV line.

The bottom line is that most extravasated chemotherapy and other agents have no specific antidote or reversal agents

TABLE 21.1 Possible Antidotes for Extravasated Chemotherapeutic Agents^a

CHEMOTHERAPEUTIC AGENT	ANTIDOTE	DOSE
Anthracycline	Dexrazoxane hydrochloride ^b	First dose, inject the equivalent of 500 mg dexrazoxane intravenously over 1–2 hr, second dose at 24 hr, and third dose at 48 hr.
Mechlorethamine	Sodium thiosulfate	Multiple subcutaneous injections in and around the area of extravasation with a 25-gauge needle: 4 mL of 10% sodium thiosulfate + 6 mL water.
Vinca alkaloids (vincristine, vinblastine, and vinorelbine)	Hyaluronidase	Inject subcutaneously in and around the area of extravasation with a 25-gauge needle: 150 units (1 mL). For vinca alkaloids, apply local hot compresses.
Doxorubicin	Granulocyte-macrophage colony-stimulating factor ^c	Inject subcutaneously in and around the area of extravasation with a 25-gauge needle.
Doxorubicin, daunorubicin, and mitomycin	Dimethyl sulfoxide (free radical scavenger)	Apply a 50%–70% solution topically qid for 14 days. Leave uncovered.
Mitomycin	Pyridoxine ^c	Inject subcutaneously in and around the area of extravasation with a 25-gauge needle.
Nonspecific	Saline	Inject subcutaneously in and around the area of extravasation with a 25-gauge needle.
Nonspecific	Corticosteroids ^d	Inject subcutaneously in and around the area of extravasation with a 25-gauge needle: hydrocortisone, 500 mg diluted in 500 mL saline.

^aMany of these interventions are anecdotal and none are guaranteed to reverse or ameliorate tissue injury. Controversy surrounds the actual benefit, and no randomized prospective trials have been conducted for many of the suggested regimens. Also consider elevation and surgical débridement when necessary.

^bApproved by US Food and Drug Administration for this indication.

^cNot well studied, theoretical benefit.

^dResults are variable; injury is not an inflammatory reaction.

ULTRASOUND BOX 21.1: Peripheral Intravenous Access

by Christine Butts, MD

Ultrasound-guided access is indicated when standard placement is difficult. This may include patients with no palpable or visible peripheral veins, history of intravenous drug use or multiple previous peripheral lines causing scarring or thrombosis, obesity, or previous surgeries causing distortion of the anatomy. Use of ultrasound to achieve peripheral intravenous access has been found to increase the rate of success, decrease both the time to placement and the number of attempts, and increase overall patient satisfaction.¹ Nursing use of ultrasound to guide peripheral intravenous access has also shown promise in improving success and decreasing complications.²

There are two methods by which the ultrasound may be used to access peripheral veins. In the first method, ultrasound is used to simply evaluate the underlying anatomy. Frequently, veins are present

superficially but cannot be seen or palpated from the surface of the skin. Apply the transducer to rapidly locate an ideal vein and cannulate it “blindly” in the typical fashion. The second method calls for ultrasound to be used to directly guide venous access. This method may be most practical when the veins are deeper within the tissues or adjacent to other more important structures.

Use a high-frequency (7.5- to 10-mHz) transducer to obtain the necessary resolution for evaluating the anatomy. Typically, for peripheral venous access, a sterile field is not necessary. However, it is important to clean the area with alcohol or chlorhexidine solution before the procedure. Use universal precautions. Apply a tourniquet when appropriate to assist in distending the veins and to make them easier to identify.

ULTRASOUND BOX 21.1: Peripheral Intravenous Access—cont'd

Figure 21.US1 Ultrasound image of the basilic vein (*arrow*).

Figure 21.US3 Ultrasound image of the deep brachial vein (*large arrow*). Another smaller vein can be seen more superficially to the right of the image (*small arrow*).

Figure 21.US2 Ultrasound image of the median cubital vein (*arrow*).

Multiple peripheral vessels are available for ultrasound-guided access. The basilic vein lies on the ulnar aspect of the forearm and the cephalic vein can be found on the radial aspect (Fig. 21.US1). The larger median cubital vein represents the junction of these two veins and lies in the antecubital fossa (Fig. 21.US2). The deep brachial vein is found on the median aspect of the distal end of the arm in the bicipital groove (Fig. 21.US3). The external jugular vein is found superficially in the neck and runs diagonally across the sternocleidomastoid muscle.

Distinguishing the artery from the vein may prove more challenging than with central vessels. Peripheral veins and arteries are smaller, and even arteries may collapse with pressure. Evaluate the veins before application of the tourniquet. Veins should collapse easily and in fact may collapse from only the pressure of applying the transducer to the skin. Placing the heel of the operator's hand on the patient's arm and then applying the transducer may decrease this effect. Arteries can be further identified by evaluating the Doppler flow pattern of the vessel. Even small arteries will have a biphasic, pulsatile flow pattern versus the steady low-amplitude venous pattern. Finally, venous augmentation can be used for confirmation. Color flow imaging is used over the vessel in question. Squeezing the arm distal to the area should cause

Figure 21.US4 Demonstration of venous augmentation. **A**, Ultrasound view of a suspected vein (*arrow*). **B**, Once the wrist is lightly squeezed, adding color Doppler flow to the area will demonstrate a “flush” of color within the vessel (*arrow*).

a temporary flush of flow in the vein (Fig. 21.US4). The artery should not show any change in its typical pulsatile flow.

Once a location for cannulation has been chosen, scan the relevant area to locate the desired vessel. Once the vein has been identified, the cannulation procedure is identical for all peripheral veins. A transverse, or short-axis, approach is universally used because of the small size of the peripheral veins. Center the transducer over the target vessel. The depth of the image on-screen should be

ULTRASOUND BOX 21.1: Peripheral Intravenous Access—cont'd

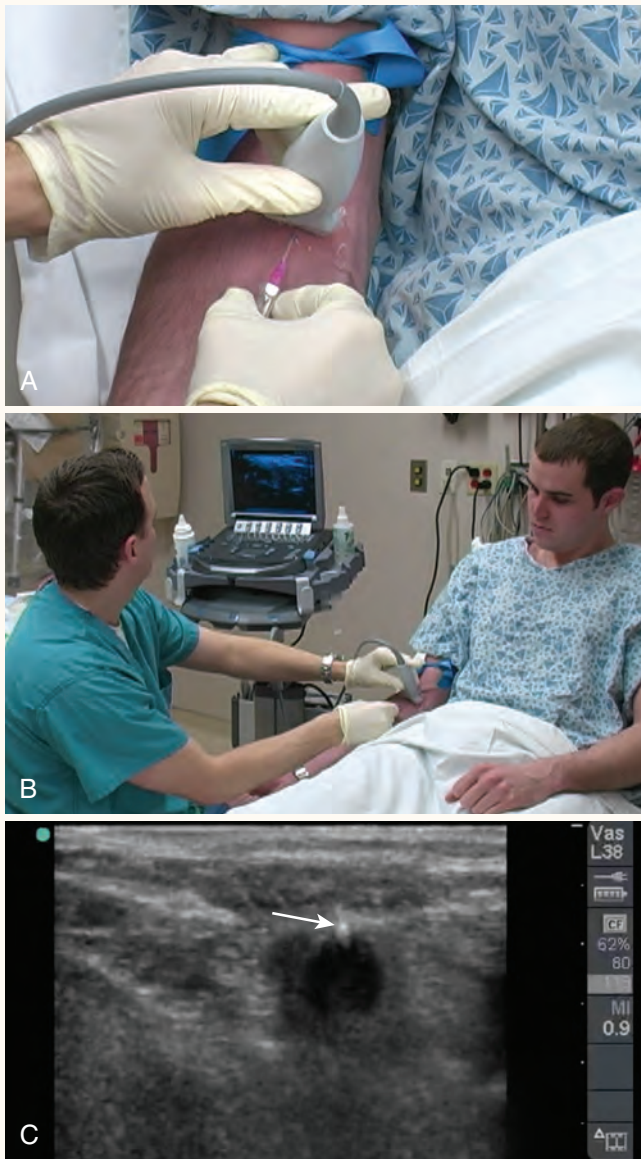

Figure 21.US5 **A**, Introduce the needle at a 45-degree angle, slightly back from the transducer. **B**, Identify the tip of the needle on-screen. **C**, Advance the tip of the needle (*arrow*) toward the vessel.

decreased as much as possible so the best possible image is obtained. A blunt object (e.g., a fingertip) is applied over the center of the transducer to ensure that the vessel in question is centered. Then introduce the needle at a 45-degree angle slightly back from the transducer (Fig. 21.US5). Once the tip of the needle is identified on-screen, advance it toward the vessel. Watch the catheter closely for a flash of blood. Once the flash is obtained, set the ultrasound aside and continue the procedure in the typical fashion.

A pitfall that may frustrate the sonographer is kinking or difficulty threading or advancing the catheter once a flash has been obtained. This frequently occurs in deeper vessels, such as the deep brachial. Using a longer, stiffer catheter [e.g., 1.75-inch Arrow twin catheter (Teleflex, Morrisville, NC) or the longer catheter from the Arrow arterial line kit] may help reduce this problem.

to alter the final outcome. At most extravasation sites it may be best to avoid the empirical use of suggested treatments such as sodium bicarbonate, sodium thiosulfate, heparin, calcium gluconate, magnesium sulfate, lidocaine, cimetidine, diphenhydramine, and other chemical substances that are believed to

inactivate drugs and reduce toxic effects on cells. In some experimental settings, these substances have made the necrosis and ulceration worse.^{54–57}

Central Venous Catheterization and Central Venous Pressure Monitoring

Salim R. Rezaie, E.C. Coffey, and Christopher R. McNeil

Central venous access remains a cornerstone of resuscitation and critical care in both the emergency department (ED) and intensive care unit. Advanced hemodynamic monitoring, rapid infusion of fluid, placement of transvenous pacemakers, and administration of selected medications all require reliable central venous access. Central venous catheterization has also gained acceptance in the resuscitation and treatment of critically ill children (see [Chapter 19](#)). Traditionally, the subclavian vein (SV), internal jugular (IJ) vein, and femoral vein have provided reliable and easily obtainable vascular access through the use of identifiable anatomic landmarks. Over the past decade the increased availability of, and training and provider competence in bedside ultrasonography have had a significant impact on the standard approach to both peripheral and central venous catheterization. Ultrasound-guided central venous catheterization has improved success rates, reduced complication rates, decreased the time required to perform the procedure, and resulted in overall cost savings.

The various techniques described in this chapter each have inherent advantages and disadvantages, but all have a place in the practice of emergency medicine. Frequently, a clinician's previous experience with a particular technique determines the preferred approach, but clinicians responsible for acute resuscitation of the ill and injured should master several of these techniques (Videos 22.1-22.8).

HISTORICAL PERSPECTIVE

In 1667, Lower placed the first known central venous catheter (CVC) into a human IJ vein for a blood transfusion from the carotid artery of a sheep.¹ Modern central venous catheterization heralds back to at least 1928 when Werner Forssmann, a 25-year-old German surgeon, performed a venous cutdown on his own left antecubital vein, inserted a ureteral catheter to a distance of 65 cm, and then climbed several flights of stairs to the radiology suite to confirm that it terminated in the right atrium. Although the hospital fired Dr. Forssmann for not obtaining permission, he went on to win the 1956 Nobel Prize for his pioneering efforts.^{1,2}

Duffy reported a large series of femoral, jugular, and antecubital vein catheterizations in 1949.³ Aubaniac developed subclavian venipuncture while working on French Army casualties between 1942 and 1952.⁴ His infraclavicular SV approach was refined by Keeri-Szanto in 1956, and the supraclavicular approach to the vein was first described by Yoffa in 1965.^{5,6} Aside from Duffy's earlier work, Hermosura (1966) and English (1969) are generally credited with the scientific development of the percutaneous IJ approach.⁷

The most important advancement in modern CVC came in 1953 when the Swedish radiologist Sven Seldinger had the idea of advancing large catheters over a flexible wire that was inserted through a percutaneous needle.^{8,9} The role of central venous pressure (CVP) monitoring in the maintenance of optimal blood volume helped popularize central catheterization in the United States.¹⁰ This was accelerated by the advent of the pulmonary artery catheter, which was developed by Jeremy Swan and William Ganz in 1968.¹¹ Swan, who was inspired by his observations of a sailing boat during a picnic with his children, developed a flow-directed balloon that allowed measurement of pulmonary artery pressure.¹²

ANATOMY

SV System

The SV begins as a continuation of the axillary vein at the outer edge of the first rib. It joins the IJ vein to become the innominate (sometimes referred to as the brachiocephalic) vein 3 to 4 cm proximally. The SV has a diameter of 10 to 20 mm, is approximately 3 to 4 cm long, and is valveless. After crossing over the first rib, the vein lies posterior to the medial third of the clavicle. It is only in this area that there is an intimate association between the clavicle and the SV. The costoclavicular ligament lies anterior and inferior to the SV, and the fascia contiguous to this ligament invests the vessel. Posterior to the vein and separating it from the subclavian artery is the anterior scalene muscle, which has a thickness of 10 to 15 mm. The phrenic nerve passes over the anterior surface of the scalene muscle laterally and runs immediately behind the junction of the SV and the IJ vein. The larger thoracic duct (on the left) and the smaller lymphatic duct (on the right) pass over the anterior scalene muscle and enter the SV near its junction with the IJ vein. Superior and posterior to the subclavian artery lies the brachial plexus. The dome of the left lung may extend above the first rib, but the right lung rarely extends this high ([Fig. 22.1](#)).

IJ Vein

The IJ vein begins just medial to the mastoid process in the jugular foramen at the base of the skull and is formed by the inferior petrosal sinus and the sigmoid sinus. It runs inferiorly and passes under the sternal end of the clavicle to join the SV and form the innominate or brachiocephalic vein. At the level of the thyroid cartilage, the IJ vein, the internal carotid artery, and the vagus nerve course together in the carotid sheath just deep to the sternocleidomastoid (SCM) muscle. Within the carotid sheath, the IJ vein typically occupies the anterior lateral position and the carotid artery lies medial and slightly posterior to the vein. This relationship is relatively constant, but studies have found that the carotid artery may overlap the IJ vein. Note that normally the IJ vein migrates medially as it nears the clavicle, where it may lie directly over the carotid artery. When using the most common (central) approach, the IJ vein tends to be more lateral than expected.^{13,14} Furthermore, in 5.5% of those studied, the IJ vein may even be medial to the carotid artery.¹⁴⁻¹⁷ The relationship between the IJ vein and the carotid artery also depends on head position. Excessive head rotation can cause the carotid artery to rotate over the IJ vein.^{18,19}

Central Venous Catheterization

Indications

Central venous pressure monitoring
 High-volume/flow resuscitation
 Emergency venous access
 Inability to obtain peripheral venous access
 Repetitive blood sampling
 Administering hyperalimentation, caustic agents, or other concentrated fluids
 Insertion of transvenous cardiac pacemakers
 Hemodialysis or plasmapheresis
 Insertion of pulmonary artery catheters

Contraindications

Infection over the placement site
 Distortion of landmarks by trauma or congenital anomalies
 Coagulopathies, including anticoagulation and thrombolytic therapy
 Pathologic conditions, including superior vena cava syndrome
 Current venous thrombosis in the target vessel
 Prior vessel injury or procedures
 Morbid obesity
 Uncooperative patients

Complications

Arterial puncture and hematoma
 Pneumothorax (subclavian and internal jugular approach)
 Hemothorax (subclavian and internal jugular approach)
 Vessel injury
 Air embolism
 Cardiac dysrhythmia
 Nerve injury
 Infection
 Thrombosis
 Catheter misplacement

Equipment (contents of a typical central venous catheterization kit)

Review Box 22.1 Central venous catheterization: indications, contraindications, complications, and equipment.

Figure 22.1 Subclavian vein anatomy. The subclavian vein runs parallel to the clavicle and anterior to the subclavian artery. The cupula of the lung lies just caudad to these structures. If the introducer needle is kept almost parallel to the clavicle, the artery and lung should not be encountered.

Anatomic landmarks for locating the vein include the sternal notch, the medial third of the clavicle, and the SCM. The two heads of the SCM and the clavicle form a triangle that is key to understanding the underlying vascular anatomy. The IJ vein can be located at the apex of the triangle as it courses along the medial head of the SCM and occupies a position in the middle of the triangle at the level of the clavicle before it joins the SV and forms the innominate vein. At the level of the thyroid cartilage, the IJ vein can be found just deep to the SCM.

Generally, the right IJ vein is bigger than the left IJ vein because of its connection to the SV and the right atrium. The IJ vein can be pulsatile, but in contrast to the aorta, these pulsations are not palpable. When visualized, however, the presence of venous pulsations can give an indication of patency of the IJ vein to the right atrium. The IJ vein also changes size with respiration. Because of the negative intrathoracic pressure at end-inspiration, blood in the IJ vein is actually drawn into the right atrium and the diameter of the IJ vein shrinks. In contrast, at end-expiration the increased intrathoracic pressure will limit return of blood to the right atrium and the diameter of the IJ vein will increase. Another unique characteristic of the IJ vein is its distensibility. The IJ vein will enlarge when pressure in the vein is increased, such as when flow of blood back to the right atrium is obstructed, as with thrombosis. This distensibility can be advantageous for the placement of central venous access. Use of a head-down (Trendelenburg) position or a Valsalva maneuver will increase the diameter of the IJ vein and thereby increase the likelihood of successful puncture (Fig. 22.2).

Femoral Vein

The femoral anatomy is less complex than that of the neck and shoulder and contains fewer vital structures. The femoral vein is most easily cannulated percutaneously in patients with a palpable femoral pulse. The femoral vein begins at the adductor canal (also known as Hunter's canal) and ends at the

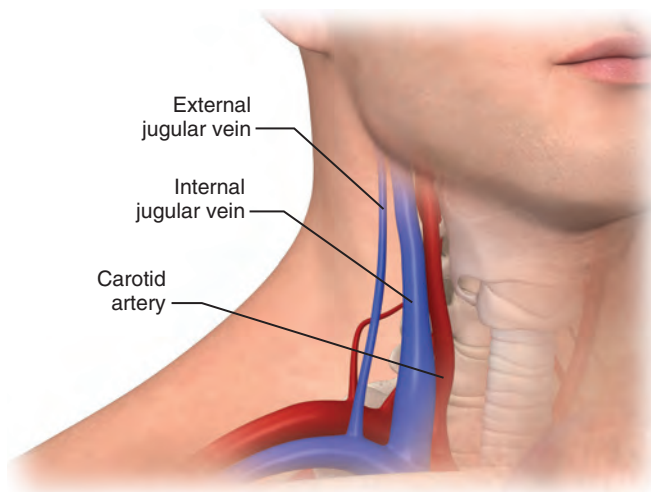

Figure 22.2 Internal jugular anatomy. The internal jugular vein runs parallel and lateral to the carotid artery but lies almost directly above the carotid artery at the level of the clavicle.

inferior margin of the inguinal ligament, where it becomes the external iliac vein. It is contained within the femoral triangle (inguinal ligament, medial border of the adductor longus, and lateral border of the sartorius muscle). Medially, the femoral vein abuts a robust system of lymphatics. Laterally, the vein is intimately associated with the femoral artery. The femoral nerve courses down into the leg just lateral to the femoral artery. These relationships from lateral to medial can be remembered with the mnemonic NAVEL (nerve, artery, vein, empty space, lymphatics). Note that as the femoral artery and vein course down the leg within the femoral sheath, their side-by-side relationship frequently rotates such that the femoral artery may lie on top of the vein. Therefore to avoid arterial puncture, keep cannulation attempts just under the inguinal ligament. When cannulating this vessel distal to the inguinal ligament, ultrasound guidance can be helpful to avoid arterial puncture (Fig. 22.3).

INDICATIONS

Central venous access has several clinical indications (see [Review Box 22.1](#)). If necessary, any central venous approach could be used for each of these situations. However, certain approaches offer advantages over others in specific clinical settings. The clinical indications are discussed in detail in the following sections.²⁰⁻²²

CVP Monitoring and Oximetry

For a period, pulmonary artery catheterization somewhat supplanted CVP monitoring; however, there is little evidence that this practice has any benefit with regard to patient mortality or quality of life. In the specific setting of resuscitation of patients in septic shock, CVP monitoring is an important component of “early goal-directed therapy” (EGDT).^{23,24} Continuous or episodic measurements of central venous oxygen saturation (ScvO₂) also have a prominent role in EGDT protocols for the aggressive treatment of septic shock.^{23,24} More recent evidence, however, does not demonstrate improvements

Figure 22.3 Femoral vein anatomy. The femoral vital structures are located in the femoral triangle: inguinal ligament superiorly, sartorius muscle laterally, and adductor longus muscle medially. The triangle can be remembered by the mnemonic “SAIL” (sartorius, adductor longus, and inguinal ligament). Note the femoral structures from lateral to medial: **n**erve, **a**rtery, **v**ein, **e**mpy canal, and **l**ymphatics (mnemonic—NAVEL). The femoral vein lies medial to the femoral artery. *Important anatomic note:* at sites more distal to the inguinal ligament, the vein lies directly above the artery.

in patient-centered outcomes with the use of CVP monitoring for volume responsiveness and ScvO₂ monitoring in patients with severe sepsis or septic shock.^{25–27} As a result, there has been a de-emphasis on CVP monitoring in septic shock.

Central venous catheterization is widely used as a vehicle for rapid volume resuscitation. Notwithstanding, short, large-caliber peripheral catheters can be as effective as central access because of the properties of Poiseuille’s law, which states that the rate of flow is proportional to the radius of the catheter and inversely proportional to its length.³ To illustrate, the gravity flow rate of saline through a peripheral 5-cm, 14-gauge catheter is roughly twice that through a 20-cm, 16-gauge CVC. Consequently, placement of large-bore peripheral catheters is generally the fastest method of volume loading.

Delivery of High-Flow Fluid Boluses and Blood Products

The advent of thermoregulating high-volume rapid infusers affords the advantage of using central venous catheterization in the setting of severe hemorrhagic shock or hypothermia. The available systems can infuse blood warmed to 37°C through an 8.5-Fr introducer sheath 25% more rapidly than through a 14-gauge peripheral intravenous (IV) line and up to 50% faster than through an 18-gauge peripheral IV line.²⁸ The Level 1 Rapid Infuser (Smiths Medical, St. Paul, MN) and the Belmont FMS 2000 (Belmont Instrument Corporation, Billerica, MA) are examples of modern systems with infusion rates as high as 1500 mL/min.²⁸ Massive air embolism was a concern

with early rapid infusers, but safety precautions have now been engineered to prevent this. However, if the catheter is misplaced, fluid or blood can be rapidly infused into the thorax, mediastinum, or peritoneum with serious consequences.

Emergency Venous Access and Inability to Achieve Peripheral Access

The predictable anatomic locations of the subclavian and femoral veins and the speed with which they can be cannulated have prompted their use in cardiac arrest and other emergency situations. The need for a central line during cardiopulmonary resuscitation (CPR) is controversial.^{29–31} When achieved easily, central venous cannulation, especially via the IJ vein or SV route, is preferred over peripheral venous access because it provides a rapid and reliable route for the administration of drugs to the central circulation of patients in cardiac arrest. With resuscitation for aortic catastrophes or thoracoabdominal trauma, two CVCs, “one above and one below” the diaphragm, are often used.

Patients with a history of IV drug use, major burns, chronic disease, dehydration, or morbid obesity and those who require long-term access may have inadequate peripheral IV sites. Central venous cannulation may be indicated as a means of venous access in these patients even under nonemergency conditions.³² More recently with the use of ultrasound, deep brachial, axillary, and basilic vein cannulation may be attempted before central venous catheterization. This approach avoids the complications that can be associated with central venous access.

Routine Serial Blood Drawing

The potential complications of CVCs make them inappropriate solely for routine blood sampling. However, lines already in place may be used for this purpose if they are properly cleared of IV fluid. A 20-cm, 16-gauge catheter contains 0.3 mL of fluid, so at least this much must be withdrawn to avoid dilution of blood samples. Moreover, to avoid aspiration of crystalloid-diluted blood from the peripheral vein, it is advised that the IV line be turned off for at least 2 to 3 minutes before using the catheter for a blood draw. Because of the increased risk for infectious complications, air embolism, and venous back-bleeding, the IV tubing should not be repeatedly disconnected from the catheter hub. Interposition of a three-way stopcock in the IV tubing simplifies access and is an acceptable method for sampling blood in the intensive care setting, regardless of the IV site. The oxygen level in blood from the SV can be determined for guidance in EGDT for sepsis if one chooses not to place a continuous oximetric monitor.

Additionally, serial lactate levels may help guide early goal-directed resuscitation. With an imbalance in oxygen supply and consumption, tissue hypoperfusion and hypoxia lead to anaerobic metabolism. The final product of this process is lactate. Arterial lactate levels would best represent overall perfusion because such samples contain blood coming from the pulmonary veins, superior vena cava (SVC), and inferior vena cava (IVC). Peripheral lactate preferentially reflects perfusion and metabolism in the compartment from which the blood was drawn, but not overall perfusion. Arterial and central venous lactate correlate closely more than 96% of the time, whereas peripheral venous lactate and arterial lactate correlate only 87% of the time.³³

Infusion of Hyperalimentation and Other Concentrated Solutions

Central venous hyperalimentation is safe and reliable. Use of the infraclavicular subclavian technique frees the patient's extremities and neck; this procedure is therefore well suited for long-term applications. Hyperosmolar or irritating solutions with the potential to cause thrombophlebitis if given through small peripheral vessels are frequently infused through central veins. Examples are potassium chloride (>40 mmol/L), hyperosmolar saline, 10% calcium chloride (but not calcium gluconate, which can safely be given peripherally), 10% dextrose infusions, chemotherapeutic agents, and acidifying solutions such as ammonium chloride. Vasoactive substances (e.g., dopamine, norepinephrine) are best administered through a CVC because they may cause soft tissue necrosis if extravasation occurs in peripheral sites.

Central catheters, though safer than peripheral IV lines, are not immune to extravasation; indeed, fatal cases have been reported if the catheter becomes wedged up against the vessel wall, valves, or endocardium.³⁴ Strategies to avoid this complication include delivering vesicant drugs only through the distal ports or reconfirming that the proximal port is safely in the vein by aspirating blood through it.³⁴

Other Indications

Other indications for central venous access include insertion of a pulmonary artery catheter or transvenous pacemaker, cardiac catheterization, pulmonary angiography, and hemodialysis. A pulmonary artery catheter can be valuable for determining fluid and hemodynamic status in the critically ill. Its widespread use in the 1980s and 1990s drew heavy criticism because data showing a benefit in patient-oriented outcomes

were lacking. Pulmonary artery catheters have subsequently lost popularity and should be used only when the diagnostic benefits outweigh the potential risks.^{35,36} Catheters such as the Uldall and Quinton devices can be inserted within minutes, thereby permitting emergency or short-term hemodialysis. However, these catheters are very large and relatively stiff and have been known to perforate the vena cava or atrial walls, with fatal outcomes.^{37,38} Extra caution should be applied during their insertion, possibly under ultrasound or fluoroscopic guidance.

CONTRAINDICATIONS

General contraindications to the various techniques of central venous access are presented in [Review Box 22.1](#). [Table 22.1](#) lists the general advantages and disadvantages with each approach. Most contraindications listed are relative and should be viewed in the context of the patient's overall condition, urgency of need, and availability of alternative options for vascular access. Perhaps the only true absolute contraindication is insertion of catheters impregnated with antibiotics (most commonly tetracycline, rifampin, or chlorhexidine) if the patient has a serious allergy to the drug.^{39,40} Local cellulitis and distorted local anatomy or landmarks preventing safe insertion are relative contraindications to any access route. Insertion of catheters through freshly burned regions, though somewhat challenging, is not associated with a higher incidence of infection until approximately 3 days after the burn, when bacterial colonization accelerates.^{41,42} One of the more commonly encountered impediments to CVC placement is morbid obesity.⁴³ Surface landmarks in the neck are often obscured, and an abdominal pannus can block the femoral access site and consequently require deeper insertions and steeper angles. An ultrasound-guided

TABLE 22.1 Advantages and Disadvantages of Central Venous Access Techniques

TECHNIQUE	ADVANTAGES	DISADVANTAGES
IJ	<ul style="list-style-type: none"> Good external landmarks Improved success with ultrasound Less risk for pneumothorax than with SV access Can recognize and control bleeding Malposition of the catheter is rare Almost a straight course to the superior vena cava on the right side Carotid artery easily identified 	<ul style="list-style-type: none"> More difficult and inconvenient to secure Possibly higher infectious risk than with SV access Possibly higher risk for thrombosis than with SV access
Femoral	<ul style="list-style-type: none"> Good external landmarks Useful alternative with coagulopathy 	<ul style="list-style-type: none"> Difficult to secure in ambulatory patients Not reliable for CVP measurement Highest risk for infection Higher risk for thrombus
SV, infraclavicular	<ul style="list-style-type: none"> Good external landmarks 	<ul style="list-style-type: none"> Unable to compress bleeding vessels "Blind" procedure Should not be attempted in children younger than 2 yr

CVP, Central venous pressure; IJ, internal jugular; SV, subclavian vein.

IJ approach is safer under these circumstances.⁴³ Insertion of another catheter on the same side as a preexisting one risks the complication of entrapment.⁴⁴ Combativeness is an important factor in the decision to place a CVC because the risk for mechanical complications greatly increases in uncooperative patients. Sometimes it is best to sedate and intubate critically ill patients before attempting central venous catheterization. Other relative contraindications include conditions predisposing to sclerosis or thrombosis of the central veins, such as vasculitis, previous long-term cannulation, or illicit IV drug use via any of the deep venous systems.

Coagulopathy is a frequent concern surrounding insertion of a CVC, with the overall risk for clinically significant hemorrhage in these patients approximating 2%.⁴⁵ A transfusion of fresh frozen plasma is commonly used to correct any existing coagulopathy. However, a 2005 review concluded that if good technique is used, correction of coagulopathy is not generally required before or during the procedure.⁴⁶ Mumtaz and coworkers found that even in thrombocytopenic patients (platelet count $<50 \times 10^9/L$), bleeding complications occurred approximately 3% of the time and were limited to bleeding at the insertion site⁴⁷; these complications were managed with additional sutures. Although the occasional patient may require a blood transfusion or replacement of clotting factors if a hemorrhagic complication arises, prophylactic correction of an abnormal international normalized ratio or platelet count before the procedure is not routinely necessary.^{46–48} Risk can be further reduced in coagulopathic patients with the use of ultrasound-guided placement techniques.^{14,49–52}

SV Approach

SV access is contraindicated in patients who have previously undergone surgery or sustained trauma involving the clavicle, the first rib, or the subclavian vessels; those with previous radiation therapy involving the clavicular area; those with significant chest wall deformities; and those with marked cachexia or obesity. Patients with unilateral deformities not associated with pneumothorax (e.g., fractured clavicle) should be catheterized on the opposite side. Subclavian venipuncture is not contraindicated in patients with penetrating thoracic wounds unless the injuries are known or suspected to involve the subclavian vessels or SVC. Generally, cannulate the vein on the same side as the chest wound to avoid the possibility of bilateral pneumothoraces. When (preexisting) SV injury is suspected, cannulate on the opposite side. Exercise greater caution when placing a CVC in the SV in coagulopathic patients because this vessel is not compressible. Formerly, subclavian venipuncture was not recommended for use in small children, but in experienced hands it has been demonstrated to be safe.^{53–55}

IJ Approach

Cervical trauma with swelling or anatomic distortion at the intended site of IJ venipuncture is the most important contraindication to the IJ approach. Likewise, the presence of a cervical collar is problematic. Although bleeding disorders are relative contraindications to central venous cannulation, the ultrasound-guided IJ approach is preferred over the SV route because the IJ site is compressible. However, prolonged compression of the artery to control bleeding could impair the cerebral circulation if collateral blood flow is compromised. In a study by Oguzkurt and colleagues, only minor bleeding

complications occurred in less than 2% of patients after ultrasound-guided IJ vein catheterization.⁵⁰ In the setting of severe bleeding diatheses, the ultrasound-guided femoral approach is an acceptable alternative. Ultrasound-guided IJ vein catheter placement is preferred in patients with abnormal anatomy from previous IJ vein trauma, small IJ vessels, and morbid obesity. Historically, carotid artery disease (obstruction or atherosclerotic plaque) is a relative contraindication to IJ vein cannulation because inadvertent puncture or manipulation of the artery could dislodge a plaque. If a preceding SV catheterization has been unsuccessful, the ipsilateral IJ route is generally preferred for a subsequent attempt. In this manner, bilateral iatrogenic complications can be avoided.

Femoral Approach

Contraindications to femoral cannulation include known or suspected intraabdominal hemorrhage or injury to the pelvis, groin, iliac vessels, or IVC. Additionally, avoid the femoral approach when known or suspected deep venous thrombosis is present. Palpation for femoral pulsations during CPR is difficult and the pulsations are often venous rather than arterial.^{31,56} Ultrasound-guided catheterization of the femoral vein during CPR is more successful, and it is less likely to incur inadvertent arterial puncture than the standard landmark-oriented approach.³¹

PROCEDURE

The most commonly used method for central venous cannulation is the Seldinger (guidewire) technique, in which a thin-walled needle is used to introduce a guidewire into the vessel lumen. Seldinger originally described this technique in 1953 as a method of placing a catheter for percutaneous arteriography.¹⁷ The Seldinger technique is illustrated in Fig. 22.9. To obtain vascular access, insert a small needle into the intended vessel. Once the introducer needle is positioned within the lumen of the vessel, thread a wire through the needle and then remove the needle. The wire, now within the vessel, serves as a guide over which the catheter is inserted. Although the Seldinger technique involves several steps, it can be performed quickly once mastered. More importantly, this technique broadens the application of central venous cannulation by permitting the insertion of standard infusion catheters, multilumen catheters, large-bore rapid infusion systems, introducer devices, hemodialysis devices, and even peripheral cardiopulmonary bypass cannulas. Given this flexibility, the use of Seldinger-type systems is advantageous despite their greater cost.

Ultrasound guidance has revolutionized the cannulation of central veins. As with all anatomic structures in the human body, veins are highly variable in their location. Not surprisingly, research has demonstrated that the ability to see the internal structure's location and proximity to other structures greatly increases the safety and success rate while decreasing the time required to perform the procedure.^{49–52,57–59} These advantages have been recognized by national organizations. In a report from the Agency for Healthcare Research and Quality (AHRQ), use of ultrasound guidance was listed as one of the top 10 ways to reduce morbidity and mortality.⁶⁰ Many hospitals now require the use of ultrasound guidance for the placement of all CVCs.

The basic materials required for central venous cannulation are shown in [Review Box 22.1](#) and are discussed here in further detail. The catheter may be a component in a guidewire system or may be of the over-the-needle variety (the other widely used method for catheter placement). Several types of CVC Seldinger-type prepackaged kits are commercially available and the variations in each kit are discussed in the next section.

EQUIPMENT

Preparation and organization of equipment ahead of time are imperative for a successful procedure. Most catheters now come from the manufacturer in convenient sterile kits. We strongly recommend stocking all additional equipment such as sterile gowns, gloves, and drapes in a dedicated “central line cart.” This is a fundamental part of the “bundling” practice that has been shown to reduce the search for supplies, improve compliance with full-barrier technique, and subsequently decrease catheter-related infections.^{61–66} Sterile barrier precautions with cap, face mask, sterile gown, and gloves should be used at all times during insertion of CVCs.^{64,67,68}

Ultrasound

Historically, many clinicians preferred to first locate the position of a central vein with a small exploratory or “finder” needle rather than directly cannulating the vein with a larger needle to accommodate a guidewire or catheter. This practice is less practical for the SV approach and has largely been replaced with the use of bedside ultrasound. Ultrasound-guided CVC placement allows the provider to survey the anatomy before the procedure, guide insertion of the needle into the correct vessel, and confirm placement of the catheter in the vessel^{14,50–52} (see [Ultrasound Box 22.1](#)).

Needle

Virtually any needle or catheter can be used to introduce a guidewire into a vessel, but there are advantages to using needles specifically designed for passage of a guidewire. These needles must be large enough to accommodate the desired wire, yet be as small as possible to minimize bleeding complications. The introducer needles provided with CVCs or introducer devices are usually thin walled to maximize lumen size relative to the overall needle diameter. If a needle that is not thin walled is used, choose a size that is 1 gauge smaller (larger bore) than that listed in [Table 22.2](#). If unsure, simply test the equipment first to ensure compatibility.

Standard needles may have a uniformly straight-bore lumen throughout their length. A wire passing into a straight needle may encounter an obstacle at the proximal end. The proximal end of a Seldinger needle incorporates a funnel-shaped taper that guides the wire directly into the needle ([Fig. 22.4](#)). It is advisable to use a non-Luer-Lok or slip-tip type of syringe because the added twisting that is required to remove a Luer-Lok syringe from the introducer needle may dislodge a tenuously placed needle. Safety syringe systems exist that permit passage of the wire without removal of the aspirating syringe by using a central tunnel in the barrel. This device incorporates a hollow syringe through which the guidewire can pass directly into the introducing needle without detachment. It also reduces the risk for air embolism, which can occur when the needle

TABLE 22.2 Needle Sizes for Venous and Arterial Catheters^a

STANDARD FULL-LENGTH COIL GUIDEWIRE CATHETER SIZE (Fr)	NEEDLE GAUGE ^b
3	21
4–4.5	20
5–6.0	20–19
6–8.5	19–18

^aAny size of catheter from 3.0 to 8.5 Fr may be introduced with a 22-gauge needle if a solid wire (e.g., Cor-Flex, Cook Critical Care) is used.

^bAll needle gauges are for thin-walled needles only, the type supplied in central line kits.

Figure 22.4 Introducing needles. **A**, Ordinary needle with a straight-bore lumen. **B**, Seldinger needle with a tapered lumen, which allows easy entry of the guidewire.

is open to air. It is not uncommon for the wire to become snagged at the junction of the safety syringe and the needle hub. In this case, simply remove the syringe and insert the wire directly.

Guidewire

Two basic types of guidewires are used: straight and J-shaped. Straight wires are for use in vessels with a linear configuration, whereas J-wires are for use in tortuous vessels. Both wires have essentially the same internal design ([Fig. 22.5](#)). The flexibility of the wire is the result of a stainless steel coil or helix that forms the bulk of the guidewire. Within the central lumen of the helix is a straight central core wire, called a mandrel, that adds rigidity to the steel coil. The mandrel is usually fixed at one end of the helix and terminates 0.5 and 3.0 cm from the other end to create a flexible or floppy tip. Wires are also available with two flexible ends, one straight and the other J-shaped. The flexible end of the guidewire allows the wire to flex on contact with the wall of a vessel. If the contact is tangential, as with an infraclavicular approach to the SV, a straight wire is generally preferred. If the angle is more acute, as with an external jugular approach to the SV, or if the vessel is particularly tortuous or valves must be traversed, a J-shaped wire may be used. The more rounded leading edge of the J-wire provides a broader surface to manipulate within the vessel and decreases the risk for perforation. This is especially advantageous when attempting to thread a wire through a vessel with valves. Many guidewires also contain a straight safety wire that runs parallel to the mandrel to keep the wire from kinking or shearing.

Figure 22.5 J-wire. **A**, Plastic sleeve in the retracted position demonstrating the J-tip. **B**, Plastic sleeve advanced to straighten the curve for easy introduction into the needle hub. **C**, Plastic sleeve inserted into needle hub. In an emergency, take care to not misplace or throw the sleeve away. Without it, placing the J-wire into the hub of the needle is very difficult. Some wires may have a “soft-tipped” straight end on the opposite end of the wire. These wires are engineered to be flexible (to avoid vessel injury) and may be used if there is difficulty passing the J end.

The standard size for guidewires is 0.025 to 0.035 inch (0.064 to 0.089 cm) in diameter, which permits introduction through an 18-gauge thin-walled needle. A modification of this standard wire uses a bare mandrel with the flexible coil soldered to its end. This construction provides a wire with a diameter of just 0.018 inch (0.047 cm) but with the same rigidity as the larger wires. The manufacturer states that such a wire can be introduced through a 22-gauge thin-walled needle yet still guide an 8.5-Fr catheter (Micropuncture Introducer Sets and Trays with Cor-Flex Wire Guides, Cook Critical Care, Inc., Bloomington, IN).

It is important to emphasize that guidewires are delicate and may bend, kink, or unwind. A force of 4 to 6 lb may cause a wire to rupture. Wires should thread easily and smoothly and never be forced; the worst complications of CVC placement are associated with the application of excessive force across parts of the apparatus that are not threading smoothly.⁶⁹ If a wire is not passing easily, withdraw the wire and the introducer needle as a single unit. Embolization of portions of the guidewire is possible, and sharp defects in the wire may perforate vessel walls (Fig. 22.6). If one encounters a good flash of blood but cannot readily manipulate the wire, this may indicate that the outer wire coils are entrapped against the proximal sharp edge of the needle bevel. The J-shape can be straightened remotely by applying gentle force on the wire in each direction, which may allow retrieval of the wire.⁵⁸ Wires should be inspected for small defects such as kinks, sharp ends, or spurs before use and especially after a failed attempt. Wires may be threaded into the introducer needle hub more easily by using the plastic sleeve attached to the wire as shown in Fig. 22.5C.

Catheters

A number of different catheter and introducer devices have been developed, and the method of passage into the vessel varies accordingly. The functions of catheters have become more sophisticated as well, most notably for continuous monitoring of SCVO₂ and cardiac output. Generally, one can

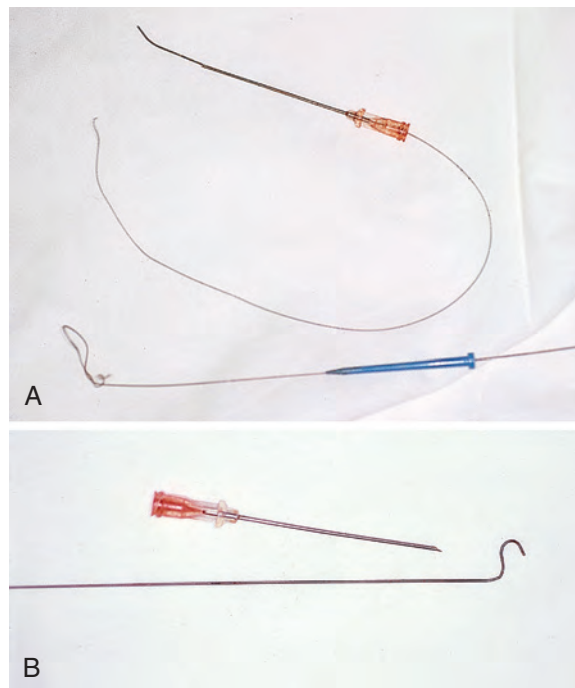

Figure 22.6 **A** and **B**, Although newer guidewires are more resistant to shearing, if a guidewire will not advance, withdraw both the needle and the wire in one motion. These pictures demonstrate a permanently deformed guidewire that could not be advanced. Withdrawing the wire with the indwelling introducer needle in place within a vessel may shear off a portion of the wire and result in systemic embolization.

place single-, double-, and triple-lumen catheters by sliding the catheter directly over a guidewire into the intended vessel (Fig. 22.7A). Catheter insertion lengths are listed in Table 22.3. Larger catheters or devices without lumens can be introduced with a sheath-introducer system. Over-the-needle catheters can be introduced once intravascular placement is attained.

The Desilets-Hoffman-type sheath introducer became available in 1965 to aid in arteriography procedures that require many catheter changes. This device is commonly but incorrectly termed a *Cordis*, which is a proprietary trade name. The sheath-introducer unit includes two parts, an inner dilator and an outer sheath, as shown in Fig. 22.7B. The dilator is rigid with a narrow lumen to accommodate the guidewire. It is longer and thinner than its sheath and has a tapered end that dilates the subcutaneous tissue and vessel defect created by the needle. The sheath (or introducer catheter when used as a cannula for inserting Swan-Ganz catheters, transvenous pacemakers, or other devices) has a blunt end and is simply a large-diameter catheter.

Many modifications of the sheath exist, such as side arms and diaphragms to aid in the placement of devices without lumens. Care must be taken when using side-arm sets for rapid administration of fluid because some catheters are 8.5 Fr in diameter but have only a 5-Fr side arm. Some sets have a “single-lumen infusion catheter,” which performs the same function but is more easily secured to the sheath introducer. Selection of the appropriate diameter of introducer catheter should correspond to the indication for placement of a CVC. Generally, an 8.5-Fr catheter is used to facilitate placement

Figure 22.7 **A**, Triple-lumen catheter. The catheter ports are used for infusion of fluids, administration of medications, and monitoring of central venous pressure and are typically labeled as proximal, medial, and distal. The distal or brown port, typically 16 gauge, facilitates passage of the guidewire. Note that the end cap of the distal port (arrow) must be removed before insertion to allow passage of the guidewire. **B**, Sheath introducer. This large-bore device (8.5 Fr) is used as an introduction catheter for devices such as Swan-Ganz catheters and transvenous pacemakers. Note that the dilator must be placed through the catheter before the device is inserted into the patient.

TABLE 22.3 Formulas for Catheter Insertion Length Based on Patient Height and Approach

SITE	FORMULA	IN SVC (%)	IN RA (%)
RSC	$(Ht/10) - 2$ cm	96	4
LSC	$(Ht/10) + 2$ cm	97	2
RJL	$Ht/10$	90	10
LJL	$(Ht/10) + 4$ cm	94	5

of a Swan-Ganz catheter and a 6.0-Fr catheter is used to facilitate transvenous placement of a pacemaker. If the introducer catheter is larger than required to support the intraluminal device, a leak may develop at the diaphragm insertion point.

Special catheters have been developed to prevent bacterial contamination and line sepsis.^{40,70,71} These catheters are impregnated with either antiseptics (silver sulfadiazine

and chlorhexidine) or antibiotics (minocycline, rifampin, or cefazolin) to reduce bacterial colonization and microbial growth. Heparin-coated catheters are also available that prevent fibronectin binding, thereby inhibiting the formation of bacterial biofilm on the catheter's surface. These catheters can decrease catheter-associated infection (CAI) significantly and are cost-effective when the prevalence of CAI is greater than 2%.⁴⁵ They should be avoided in patients with a history of heparin-induced thrombocytopenia.⁷² Minocycline- and rifampin-impregnated catheters are currently considered to be the most effective.^{40,70} Other interventions that decrease central line infections include the use of full sterile barrier precautions,^{64,68} skin preparation with chlorhexidine solution,^{64-66,73} and placement by experienced physicians.^{68,74-76}

Many different catheters are currently manufactured. Although this leads to great flexibility in choice and cost, it often results in confusion when a clinician is handed an unfamiliar catheter during an emergency. It is best to use one brand routinely and to ensure that all medical personnel are thoroughly familiar with its use.⁷⁷

TECHNIQUE

Preprocedure Preparation

When possible, discuss the procedure with the patient and obtain written informed consent. Place the patient and yourself in an appropriate position for the specific vessel being accessed. If available, perform an ultrasound survey to identify the patient's anatomy, ensure vessel patency, and confirm the puncture site (Fig. 22.8). Ultrasound-guided CVC placement has been shown to decrease procedure times, as well as complication rates.⁴⁹⁻⁵² Additionally, compliance with a central line bundling policy has been shown to significantly decrease central line-associated bloodstream infections (CLABSIs).⁶³⁻⁶⁶ Prepare and drape the puncture site while maintaining sterile technique, and observe universal precautions throughout the procedure (Fig. 22.9, steps 1 and 2). A gown, surgical cap, mask, eye protection, and sterile gloves should be worn throughout the procedure when possible. When performing ultrasound-guided placement of a CVC, ensure that a sterile transducer sheath and sterile transducer gel are used during the procedure (see Fig. 22.9, step 3). Using an assistant will prove valuable in patient preparation, maintenance of sterility, and handling of the equipment.

Guidewire Placement With the Seldinger Technique

When performing ultrasound-guided placement of a CVC, begin with an ultrasound survey of the target vein, surrounding structures, and venipuncture location, as shown in Fig. 22.8. Veins can easily be distinguished from the nearby artery by applying external pressure with the transducer. Veins collapse completely with pressure, whereas arteries may deform but do not usually collapse. Occasionally, the vein does not collapse with pressure. If this occurs, a thrombus may be present in the vein or the structure has been misidentified. If a suspected vein does not collapse with pressure, it is not an appropriate vessel for cannulation. If available, Doppler functions may also be helpful in the differentiation of veins and arteries. Select a venipuncture location where branching of the vein will allow

Figure 22.8 **A**, Ultrasound survey. Perform an ultrasound survey to identify the anatomy before beginning the procedure. **B**, Cross-sectional view of the artery and noncompressed vein. **C**, Cross-sectional view of the artery and compressed vein.

the shortest path of the needle, will not obstruct passage of the catheter, and will not allow inadvertent puncture of other vital anatomic structures. (See [Chapter 66](#) for additional information and descriptions of the ultrasound technique.)

Prepare the catheter for insertion by flushing each lumen with sterile normal saline. Anesthetize the insertion site with lidocaine or bupivacaine (see [Fig. 22.9, step 5](#)). Attach a small syringe to an introducing needle that is large enough to accommodate the guidewire. Insert the needle and syringe together. Slowly advance the needle into the vein and apply steady negative pressure on the syringe (see [Fig. 22.9, step 6](#)). When performing ultrasound-guided CVC placement, follow the needle trajectory in the soft tissue and observe penetration of the vessel. If the tip of the needle is not visualized at all times with ultrasound, the needle may be passed into structures other than the vein. The key concept in using ultrasound guidance for venous access is to visualize the tip of the needle at all times during cannulation ([Fig. 22.10](#)). Once the tip of the needle enters the vessel lumen, blood will be aspirated freely. Stabilize the needle hub to prevent movement of the needle and displacement of the tip from the vessel, and remove the syringe. This action can dislodge the needle tip and is the activity most associated with failure to pass a wire after the vein has initially been entered. The need to disconnect the syringe can be eliminated by use of the Arrow Safety Syringe (Teleflex, Morrisville, NC). After removing the syringe, cap the needle hub with your thumb before passing the guidewire to minimize the potential for air embolism.

Confirm that the blood flow is nonpulsatile. Bright red pulsatile blood is very suggestive of arterial puncture. Be aware that in shock states or marked arterial desaturation, dark,

nonpulsatile blood does not rule out arterial cannulation. If there are concerns about possible arterial puncture, either remove the introducer needle and draw a sample for blood gas analysis from the needle to compare with an arterial blood gas sample, or insert an 18-gauge single-lumen catheter over the wire and into the vessel because this step does not require the use of a dilator. The catheter can then be connected to a pressure transducer to confirm the presence of venous waveforms and venous pressure.

Introduce the flexible end of the guidewire into the hub of the needle (see [Fig. 22.9, step 7](#)). It may be easier to introduce the J-wire by advancing the plastic sleeve contained in the kit onto the floppy end of the wire to straighten the J-shape. This straightened end is then introduced into the needle hub. The guidewire should thread smoothly through the needle into the vessel without resistance. Do not force the wire if resistance is encountered, but remove it from the needle and reattach the syringe to aspirate blood and reconfirm intravascular needle placement. It is important for the wire to slip easily from the needle during removal. If resistance to removal of the wire is felt, the wire and needle should be removed as a single unit to prevent shearing of the wire and resultant wire embolism. It has been recommended by some that no wire should ever be withdrawn through the introducing needle.⁷⁸ Although there are no clinical data to support this recommendation and newer wires are stronger and more resistant to shearing, it represents the safest course of action. The recommendation to remove the needle and wire as a unit is sometimes disregarded because of reluctance to abandon a potentially successful venipuncture. The clinician performing the procedure must use both caution and good judgment to determine the best course of action but

Central Venous Catheterization (Internal Jugular Approach)

1 Prepare the area with chlorhexidine solution. A gown, surgical cap, mask, eye protection, and sterile gloves should be worn throughout the procedure.

2 Apply a full-body, sterile drape. Meticulous attention must be paid to sterile technique to avoid iatrogenic infection.

3 Insert the ultrasound probe into a sterile sheath and use sterile ultrasound gel during the procedure. Enlist the help of an assistant in patient preparation and maintenance of sterility.

4 Identify the anatomic structures with ultrasound. The internal jugular vein (IJ) and carotid artery (CA) must be clearly distinguished from each other (see text for more details).

5 Anesthetize the tissues overlying the vein with local anesthetic. Here, the operator is using ultrasound guidance to ensure a proper entry site.

6 Insert the needle and syringe while slowly advancing and applying negative pressure to the plunger. Follow the needle trajectory with ultrasound until the vein is entered and blood enters the syringe (arrow).

7 Remove the syringe and advance the guidewire through the needle. Use the straightener (arrow) to facilitate entry of the J-wire into the hub. NEVER FORCE THE WIRE!

8 Once the wire has been inserted to the appropriate depth (see text for details), remove the needle (arrow). It is essential to always maintain a grip on the wire throughout the procedure (!).

Figure 22.9 Ultrasound-guided internal jugular central venous catheterization.

Continued

Central Venous Catheterization (Internal Jugular Approach)

9 Make an incision at the site of the wire to facilitate dilator and catheter passage. Make the incision the width of the catheter and extend it completely through the dermis.

10 Thread the dilator over the guidewire. The wire must *always* be protruding from the end of the dilator and firmly in your grasp (!). Advance the dilator several centimeters into the vessel and then remove.

11 Advance the catheter over the wire. It can be difficult to align the two pieces; hold the very end of the catheter and the wire to make this step easier.

12 Advance the catheter into the vessel. The guidewire will emerge from the distal port. It is essential that the guidewire protrudes from the hub and is grasped before catheter advancement (!).

13 Remove the wire. Cover the open port with your thumb (arrow) until the end cap is screwed on.

14 Flush all ports with saline.

15 Suture the catheter into place using nonabsorbable silk sutures. Several knots should be made to secure the line. Avoid making knots that place excessive pressure on the skin.

16 Clean the area around the catheter insertion site with chlorhexidine. Place a simple dressing, avoiding excessive amounts of gauze and tape.

Figure 22.9, cont'd

Figure 22.10 A, Ultrasound-guided insertion of the introducer needle. B, Cross-sectional ultrasound image of the needle (*arrow*) within the vessel.

should not withdraw the guidewire against resistance. Manipulation of the wire within an introducer needle should be done only with standard coil guidewires. Solid wires (such as Cor-Flex Wire Guides from Cook Critical Care) have a small lip at the point at which the flexible coil is soldered to the wire. This lip can become caught on the edge of the tip of the needle and shear off the coil portion of the wire. Solid wires must thread freely on the first attempt or the entire wire and needle assembly must be removed. Keep backup wires on hand.

Occasionally, a wire must be teased into the vessel; rotating the wire or needle often helps in difficult placements. If the wire does not thread easily, pull back slightly on the needle itself just before advancing the wire. This helps if the opening of the needle is abutting the vessel's inner wall and blocking entry of the wire or if the vein is compressed by introduction of the needle. Changing wire tips from a straight wire to a J-wire or vice versa may also solve an advancement problem. If the inner lumen of a vessel is smaller than the diameter of the J, the wire will be prevented from returning to its natural shape and the spring in the coil will generate resistance. Any advantages of a J-wire will be negated if the wire fails to regain its intended shape. In this instance, it should be possible to introduce a straight tip without a problem. Alternatively, if the angle of entry of the needle into the vessel is more acute than suspected, a straight wire may not be able to bend appropriately as it encounters the vessel's far wall. A J-tipped wire may be used and threaded in such a manner that the wire resumes its J-shape away from the far wall. All these maneuvers are performed with gentle free motions of the wire within the needle. If at any time the wire cannot be advanced freely, suspect improper placement and reevaluate the attempt.

If threading easily, advance the guidewire until at least one quarter of the wire is within the vessel. The further into the vessel the wire extends, the more stable its location when the catheter is introduced. However, advancing the guidewire too far may result in ventricular ectopy secondary to endocardial irritation, myocardial puncture leading to tamponade, or entanglement in a previously placed pacemaker, internal defibrillator, or IVC filter. In both the left and right IJ vein and infraclavicular SV approaches, fluoroscopic study during passage of the guidewire has determined the mean distance from skin to the SVC-atrial junction to be 18 cm.⁷⁸ This distance has been recommended as the greatest depth of guidewire insertion for these approaches. It should be noted that 18 cm

is not necessarily the appropriate final depth for the catheter being placed (see following discussion).

Cardiac monitoring may be helpful during the insertion of central lines. Any increase in premature ventricular contractions or a new ventricular dysrhythmia should be interpreted as evidence that the guidewire is inserted too far and should be remedied by withdrawing the wire until the rhythm reverts to baseline. Usually, the procedure can be continued after a moment, with care taken to not readvance the wire. Persistent ventricular dysrhythmias require standard advanced cardiac life support treatment and consideration of a new vascular approach.

Occasionally, a wire threads easily past the tip of the needle and then suddenly will not advance farther. If the introducer needle demonstrated free return of blood at the time of wire entry and the initial advancement of the wire met no resistance, the two options are to halt the procedure or seek confirmation of the wire position. The guidewire within the lumen of the vessel can be visualized and confirmed via cross-sectional and longitudinal views on ultrasound. Alternatively, the needle may be removed, the wire fixed in place with a sterile hemostat, and a radiograph taken to confirm the position of the wire.^{78,79} A freely advancing wire may suddenly stop once it is well within a vessel if the vessel makes an unsuspected bend or is being compressed or deviated by another structure, such as a rib or muscle. This seems especially common with the infraclavicular approach to the SV and can sometimes be remedied by a more lateral approach.

Sheath Unit and Catheter Placement

Once the wire is placed into the vessel, remove the needle in preparation for passage of the catheter (see Fig. 22.9, step 8). Proper positioning of the guidewire within the vessel lumen can be confirmed by cross-sectional and longitudinal ultrasound imaging (Fig. 22.11).⁷⁹ This can be done at any point while inserting the wire to ensure that the correct vessel has been cannulated and that puncture of the posterior wall has not occurred. This technique can be quite useful when resistance is encountered while feeding the guidewire. A small skin incision is required at the site of the wire to widen the opening (see Fig. 22.9, step 9). Make the incision approximately the width of the catheter to be introduced and extend it completely through the dermis.

Figure 22.11 A and B, Cross-sectional and longitudinal ultrasound images demonstrating a guidewire (arrows) in the lumen of the targeted vein.

When placing soft multiple-lumen catheters, the tissue must be dilated from the skin to the vessel before placement of the catheter. Thread the guidewire through the distal opening of the rigid dilator until it extends through the proximal end of the dilator (see Fig. 22.9, step 10). The wire must always be visibly protruding from the end of the dilator or catheter during insertion to avoid inadvertent advancement of the wire into the circulation and potential loss of the wire. While maintaining control of the guidewire proximally, thread the dilator over the wire into the skin with a twisting motion. Advance the rigid dilator only a few centimeters into the vessel and then remove it. Once the dilator is removed, thread the soft catheter into position over the wire. Placement of multiple-lumen catheters requires identification of the distal lumen and its corresponding hub. Find the distal lumen at the very tip of the catheter. The corresponding hub is usually labeled “distal” by the manufacturer. If there is any confusion, inject a small amount of sterile saline through each hub until it is observed exiting the distal lumen. Once the distal hub is identified, remove its cover cap to allow passage of the guidewire. Place the catheter by threading the guidewire into the distal lumen and advancing it until it protrudes from the identified hub (see Fig. 22.9, step 11). It is imperative that the guidewire protrude from the catheter hub and that it be firmly grasped as the wire and catheter are advanced. If the wire does not protrude from the proximal end of the catheter, withdraw the wire at the skin entry point until it protrudes enough to be grasped. While maintaining control of the guidewire proximally, advance the catheter into the vessel to the desired catheter insertion length (see Fig. 22.9, step 12). Ultrasonography can be used to verify proper catheter placement. After insertion of the catheter, the wire must be removed (see Fig. 22.9, step 13) and the catheter must be anchored to the skin with sutures. When removing the wire from a catheter it must slip out easily. If any resistance is met, remove both the wire and the catheter as a single unit and reattempt the procedure. A common cause of a “stuck wire” is a small piece of adipose tissue wedged between the wire and the lumen of the catheter. Avoid this problem by creating a deep enough skin nick and adequate dilation of the tract before inserting the catheter.

When placing a single-lumen, Desilets-Hoffman sheath-introducer system, the dilator and larger single-lumen catheter are inserted simultaneously as a dilator-sheath unit. The

dilator-sheath unit must first be assembled by inserting the dilator through the catheter’s diaphragm (Fig. 22.12, step 2). When assembled correctly, the dilator snaps into place within the lumen of the sheath and protrudes several centimeters from the distal end of the catheter.

After successful guidewire placement and after the skin incision is made, thread the dilator-sheath assembly over the wire (see Fig. 22.12, step 3). It is imperative that the guidewire protrude from the proximal end of the dilator-sheath assembly and that it be firmly grasped as the wire and unit is advanced. If the wire does not protrude from the proximal end of the assembly, withdraw the wire at the skin entry point until it protrudes enough to be grasped. While maintaining control of the guidewire proximally, advance the assembly through the skin with a twisting motion until it is within the vessel. Grasp the unit at the junction of the sheath and dilator. This prevents the thinner sheath from kinking or bending at the tip or from bunching up at the coupler end. Keep the assembly intact and advance it through the skin to the hub. Once the catheter is placed, remove the wire and dilator from the sheath simultaneously (see Fig. 22.12, step 4). When removing the wire and dilator, the dilator must “unsnap” from the sheath unit and the wire must slip out easily. Once the single-lumen sheath-introducer catheter is placed correctly, it may be used to facilitate the placement of additional intraluminal devices such as a pulmonary artery catheter, transvenous cardiac pacemaker, or an additional multiple-lumen catheter. At times, critically ill patients who require initial large-volume resuscitation will later require multiple medications and therapies that dictate the need for a multiple-lumen catheter. An alternative method of placing a multiple-lumen catheter is to thread the catheter through a standard Desilets-Hoffman sheath-introducer system.

It is important to consider the depth of insertion of the catheter (see Table 22.3). The proper depth of catheter insertion is site specific (see later). After successful CVC placement, the catheter should be anchored to the skin with sutures (see Fig. 22.9, step 15). Each port should be immediately capped and flushed with a saline solution (see Fig. 22.9, step 14). The catheter insertion site should be dressed appropriately and all sharp implements disposed of in appropriate receptacles (see Fig. 22.9, step 16).

Replacement of Existing Catheters

In addition to placing new catheters, clinicians may use the guidewire technique to change existing catheters. Many patients with CVCs are seriously ill and will require subsequent monitoring of pulmonary artery wedge pressure, placement of a transvenous pacemaker, or insertion of a different catheter. The CVC that is initially inserted should have a lumen large enough to accept a guidewire and facilitate conversion to a different catheter. Clinicians may use the guidewire technique to change a single-lumen CVC to a triple-lumen catheter or a sheath-introducer set. Not all commercially available CVCs will accept a guidewire.

Replacement of an existing catheter begins with selecting a guidewire longer than either of the devices to be exchanged. Use meticulous aseptic technique.⁷³ Insert the guidewire into the existing CVC until a few centimeters of wire protrudes from the proximal end. With one hand holding the wire securely, remove the catheter and wire as a single unit until the tip of the catheter just clears the patient’s skin. Grasp the wire at

Figure 22.12 Insertion of the sheath introducer. Insertion of a sheath introducer varies slightly from that for a triple-lumen catheter—the dilator and the catheter are inserted simultaneously as depicted. The remainder of the steps are analogous to those in Fig. 22.9. Once inserted, sheath introducers facilitate the placement of devices such as pulmonary artery catheters and transvenous pacemakers.

the point where it exits the skin and only then release the wire at the other end. Then slide the catheter off the wire and insert the new device in the normal fashion. Exercise caution with this technique because catheter embolization can occur, especially if a catheter is cut to allow use of a shorter guidewire for the exchange. In patients without evidence of line sepsis, exchanging the guidewire does not increase the incidence of CAI if performed properly.⁷³

Over-the-Needle Technique

An optional method for cannulation is to place an over-the-needle catheter percutaneously. Over-the-needle devices (such as the Angiocath [Becton Dickinson, Franklin Lakes, NJ]) use a tapered plastic catheter that passes through the vessel wall into the lumen, with the tip of the needle being used as a guide. There are advantages with this system. The catheter does not pass through a sharp needle and there is less risk of shearing and resultant catheter embolization. Additionally, the hole made by the needle in the vessel wall is smaller than the catheter, thus producing a tighter seal. The IJ vein and SV via the supraclavicular approach are the most popular and appropriate approaches for this technique. These devices may be useful when rapid central venous access is required (e.g., in cardiac

arrest). These catheters are not suitable for high-volume fluid resuscitation and they are too small for passage of a pacemaker lead. Once the clinical situation stabilizes, exchange this device for a larger central catheter via the Seldinger technique.

Prepare the skin with chlorhexidine solution. Use a longer peripheral-type catheter (such as a 16-gauge, 5 1/4-inch angiocatheter) in an adult. Smaller-diameter devices, such as 20-gauge catheters, may be easier to pass but provide slower infusion rates. Attach the needle to a syringe and slowly advance it into the vein with steady negative pressure applied to the syringe. This may be difficult because of the longer length of the needle relative to the catheter. When using bedside ultrasound, follow the trajectory of the needle into the soft tissues and visualize penetration of the vessel. With over-the-needle catheters, the needle extends a few millimeters past the tip of the catheter. Return of blood will be obtained when the tip of the needle is in the vein, although the catheter may actually be outside the lumen. If the needle is withdrawn before the catheter is advanced, the tip of the catheter will remain outside the vein. It is therefore important to advance the needle a few millimeters after the venous flash is seen and then hold it steadily while advancing the catheter into the vein. Secure the catheter and verify its placement as detailed later in this chapter.

SITE SELECTION

Subclavian Approaches

Subclavian venipuncture is the most frequently used means of achieving central venous access. The infraclavicular SV approach was the first popular means of central venous access and has been used widely for nearly half a century. It is useful in many clinical situations and relatively easy to learn. It is often the best approach in trauma because a cervical collar can interfere with the IJ technique. The supraclavicular SV approach may be preferable during CPR because it minimizes physical interference in chest compressions and airway management. In addition, the supraclavicular SV technique has been performed in the sitting position in patients with severe orthopnea. The subclavian route is associated with the lowest incidence of catheter-related infections and deep vein thrombosis, but is associated with the highest risk for pneumothorax. Finally, the left SV provides a more direct route to the SVC and is the preferred site for pacemaker placement and CVP monitoring.

IJ Approach

The IJ vein provides an excellent site for placement of a CVC. However, there is a 5% to 10% risk for complications, with serious complications occurring in approximately 1% of patients.⁴⁹ Failure rates have been found to be 19.4% for landmark-placed IJ catheterization by a junior practitioner and 5% to 10% by a clinician with extensive experience.⁸⁰ Despite its potential complications, the IJ vein is in many cases preferred over other options for central venous access. In contrast to the SV, arterial punctures are easier to control because direct pressure can be used, and the incidence of pneumothorax is lower. Hematoma formation is easier to diagnose because of the close proximity of the IJ vein to the skin. In addition, the right IJ vein provides a straight anatomic path to the SVC and right atrium. This is advantageous for passage of catheters or internal pacemaker wires to the heart. Disadvantages of IJ vein cannulation over other sites include a relatively high carotid artery puncture rate and poor landmarks in obese or edematous patients.^{43,49}

The IJ technique is useful for routine central venous access and for emergency venous access during CPR because the site is removed from the area of chest compressions. The differences in morbidity between the SV and the IJ vein approaches have probably been overstated.^{20,70,81,82} Catheter malposition is more frequent in the SV, but the risk for infection is probably slightly higher with IJ sites.^{20,22,45,68} The rate of arterial puncture is higher with IJ vein attempts, but the SV is not a compressible site.^{20,45} Though counterintuitive, the evidence available does not support a significant difference in the rate of pneumothorax and hemothorax.^{20,45} Although there may be a slight difference in complications between the two routes, in the absence of specific contraindications clinicians should use the technique with which they are most familiar. The rapid development of real-time ultrasound guidance may tip the scales toward the IJ vein as the preferred site.^{14,50–52,83,84}

Femoral Approach

Cannulation of the femoral vein for central venous access has become increasingly popular, especially for venous access,

infusion ports, passage of transvenous pacemakers, and placement of pressure measurement catheters in critically ill patients.⁸⁴ The relatively simple and superficial anatomy surrounding the femoral vein affords a rapid approach to the central venous system and avoids many of the more significant complications associated with cannulation of the IJ vein and the SV. These benefits are tempered somewhat by several long-term disadvantages, including higher infection rates and an increased risk for venous thrombosis. Other indications for ED femoral cannulation include emergency cardiopulmonary bypass for resuscitation purposes, charcoal hemoperfusion for severe drug overdoses, and dialysis access. The femoral area is less congested with monitoring and airway equipment than the head and neck area, and conscious patients who are still bedridden may turn their head and use their arms more freely without moving the central line. The femoral site is contraindicated in ambulatory patients who require central access.

SPECIFIC VESSEL ACCESS TECHNIQUES

If SV or IJ vein approaches are planned, prepare the skin in the area, including puncture sites for both the infraclavicular and supraclavicular SV and IJ vein approaches. This permits the clinician to change the site after an unsuccessful attempt without repeating the preparation or having to obtain an interval chest radiograph. Prepare the area, including the ipsilateral anterior aspect of the neck, the supraclavicular fossa, and the anterior chest wall 3 to 5 cm past the midline and the same distance above the nipple line. Prepare for femoral access by trimming groin hairs and applying chlorhexidine to cover an area the breadth of and extending 10 cm above and below the inguinal ligament.

Each approach to central venous cannulation is described separately in the following sections. As with any invasive procedure, briefly describe the procedure to awake patients, and restate each step as it is about to be performed. After descriptions of the common approaches to the central veins, puncture site care, verification of placement, and other adjuncts to the procedure are summarized.

Infraclavicular Subclavian Approach

Descriptions of subclavian venipuncture often focus unduly on angles and landmarks. Indeed, recent studies have demonstrated that some traditional positioning maneuvers may actually hinder successful cannulation efforts.

Positioning

Place the patient supine on the stretcher with the head in a neutral position and the arm adducted at the side. Some authors have advocated various shoulder-, back-, head-, and arm-positioning maneuvers, but they take extra time and the help of an assistant and are often not helpful.^{85–95}

We believe that the best position for almost all infraclavicular SV attempts is the neutral shoulder position with the arm adducted.^{85–96} Turning the head away may be helpful but is certainly not required if cervical injuries are suspected.^{86,88,93} Interestingly, Jung and colleagues found that in children, tilting the head toward the catheterization site improved catheter malposition rates.⁹⁷ This technique has not been studied in adults.

In difficult cases, placing a small towel roll under the ipsilateral shoulder⁹³ or having an assistant place caudal traction of approximately 5 cm on the extremity may also be helpful.⁹⁶ Placing the patient in a moderate Trendelenburg position (10 to 20 degrees) decreases the risk for air embolism.^{88,98} The claim that this position distends the vein is controversial, but it may do so to a small favorable degree.^{86,88,90} If the Trendelenburg position is impractical, the SV approach is probably less affected than the IJ vein approach when resorting to a neutral or even an upright position.^{86,88,90}

Placing a pillow under the back is commonly recommended to make the clavicle more prominent, but as the shoulder falls backward, the space between the clavicle and the first rib narrows, thus making the SV less accessible.⁹⁵ Significant compression of the subclavian vessels between these bony structures occurs as the shoulders retract, which can cause a “pinch off” of the catheter as it slides through the SV between the clavicle and the first rib.^{95,99}

Venipuncture Site

The right SV is usually selected first because of the lower pleural dome on the right and the need to avoid the left-sided thoracic duct. The more direct route between the left SV and the SVC is a theoretical advantage of left-sided subclavian venipuncture; however, there is no higher incidence of catheter malposition when the right infraclavicular SV approach is used. In conscious patients, anesthetize the point of needle entry with 1% lidocaine. If possible, infiltrate the periosteum of the clavicle, found by touching the bone with the needle, to make the procedure less painful. Opinions vary regarding the best point of needle entry, more so than for the IJ or femoral approaches. With nonobese patients, look for the deltopectoral triangle, which is bounded by the clavicle superiorly, the pectoralis major medially, and the deltoid muscle laterally.^{91,100} The junction of the middle and medial thirds of the clavicle lies just medial to this triangle. Further medially, the vein lies just posterior to the clavicle and above the first rib, which acts as a barrier to penetration of the pleura. This protective effect is theoretically diminished when a more lateral location is chosen. However, when approaching the vein more medially, some clinicians have difficulty puncturing the SV, dilating the tissues, and passing the J-wire. Other recommended sites of approach include lateral and inferior to the junction of the clavicle and the first rib, with the needle aimed at this junction, and entry at the site of a small tubercle in the medial aspect of the deltopectoral groove. We recommend puncturing the skin at the lateral portion of the deltopectoral triangle via a shallow angle of attack.⁹¹

Needle Orientation

Orient the bevel of the needle inferomedially to direct the wire toward the innominate vein rather than toward the opposite vessel wall or up into the IJ vein. Align the bevel of the needle with the markings on the barrel of the syringe to permit awareness of bevel orientation after skin puncture.

Before inserting the needle, place your left index finger in the suprasternal notch and your thumb at the costoclavicular junction (Fig. 22.13). These landmarks serve as reference points for the direction that the needle should travel. Aim the needle immediately above and posterior to your index finger. Watch for vessel entry, signaled by flashback of dark venous blood, which usually occurs at a depth of 3 to 4 cm. If the tip of the needle is truly intraluminal, there will be free-flowing blood.

Figure 22.13 Intraclavicular subclavian approach. Place your index finger in the suprasternal notch and your thumb at the costoclavicular junction; these landmarks will serve as reference points for the direction that the needle should travel. Orient the bevel of the needle inferomedially and aim the needle above and posterior to your index finger. Note: to avoid puncturing the lung or the subclavian artery, once the needle tip is under the clavicle keep the needle parallel to the clavicle, NOT directed posteriorly.

Return of pulsatile flow signifies arterial puncture and the needle should be withdrawn immediately. A single arterial puncture without laceration rarely causes serious harm. Using this technique eliminates the need to measure angles, to “walk” the clavicle, or to concentrate excessively on maintaining the needle parallel to the chest wall. Avoid using sweeping motions of the tip of the needle to prevent unseen injuries.

Unsuccessful Attempts

Cannulation of the SV may not succeed on the first attempt. It is reasonable to try again, but after three or four unsuccessful attempts it is wise to move to a different anatomic approach or to allow a colleague to attempt the procedure. Use a new setup each time that blood is obtained because clots and tissue will clog the needle and mislead the clinician even if the vein has been entered successfully on subsequent attempts. If several attempts are made, inform the admitting clinician or anesthesiologist so that proper precautions are taken to identify subsequent complications. It is advisable to obtain radiographs of the chest even after unsuccessful attempts. If the initial puncture site was placed properly, use the same needle hole for subsequent attempts if possible for aesthetic reasons. If the SV route is unsuccessful on one side, attempt IJ vein catheterization on the same side rather than SV cannulation on the opposite side to avoid bilateral complications.

Supraclavicular Subclavian Approach

Positioning

The goal of the supraclavicular SV technique is to puncture the SV in its superior aspect as it joins the IJ vein. Insert the needle above and behind the clavicle, lateral to the clavicular head of the SCM muscle. Advance it in an avascular plane while directing it away from the subclavian artery and the dome of the pleura (Fig. 22.14). The right side is preferred

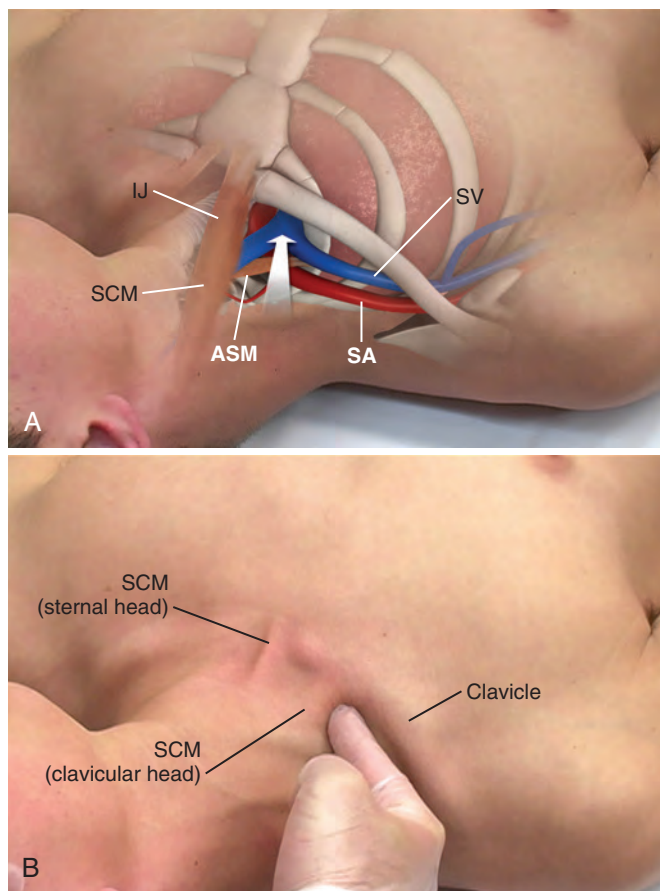

Figure 22.14 Supraclavicular subclavian approach. **A**, Anatomy. As the subclavian vein passes over the first rib, it is separated from the subclavian artery by the anterior scalene muscle. The dome of the pleura is posterolateral to the confluence of the great veins. **B**, Approach. Insert the needle 1 cm posterior to the clavicle and 1 cm lateral to the clavicular head of the sternocleidomastoid muscle such that the angle made by the clavicle and lateral border of the muscle is bisected. The needle traverses an avascular plane and punctures the junction of the subclavian and internal jugular veins behind the sternoclavicular joint. The right side is preferred because of a direct route to the superior vena cava and absence of the thoracic duct. The needle is directed 45 degrees from the sagittal plane and 10 to 15 degrees upward from the horizontal plane and aimed toward the contralateral nipple. Note that the vein is just posterior to the clavicle at this juncture. *Arrow*, Needle target; *ASM*, anterior scalene muscle; *IJ*, internal jugular; *SA*, subclavian artery; *SCM*, sternocleidomastoid muscle; *SV*, subclavian vein.

because of the lower pleural dome, its more direct route to the SVC, and location of the thoracic duct on the left side. The patient's head may be turned to the opposite side to help identify the landmarks.

Needle Orientation

After the area of the supraclavicular fossa has been prepared and draped, identify a point 1 cm lateral to the clavicular head of the SCM and 1 cm posterior to the clavicle. Alternatively, use the junction of the middle and medial thirds of the clavicle as the landmark for needle entry. Anesthetize the area with 1% lidocaine. If a 3-cm-long needle is used for anesthesia, it may also be used to locate the vessel in a relatively atraumatic

manner. The SV can almost always be located with this needle because of its superficial location and the absence of bony structures in the path of the needle. Advance a 14-gauge needle (or 18-gauge thin-walled needle) along the path of the scout needle. Apply gentle negative pressure with an attached syringe.

When seeking the SV, aim the needle so that it bisects the clavicosternomastoid angle and the tip points just caudal to the contralateral nipple. Orient the bevel medially to prevent the catheter from getting trapped against the inferior vessel wall. Point the tip of the needle 10 degrees above the horizontal. Successful vessel puncture generally occurs at a depth of 2 to 3 cm.

Subclavian Ultrasound Technique

Typically, puncture of the SV occurs at the point where the vein is coursing deep to the clavicle. However, with ultrasound, visualization of the SV can be difficult at this location because of interference with the overlying bone. Fortunately, more distally the vein lies farther away from the clavicle and chest wall. Hence, access to the SV typically occurs lateral to the curve of the clavicle bone, in the proximal axillary vein. As the vein moves laterally, the mean depth from the skin increases from 1.9 to 3.1 cm, whereas the distance from the rib cage to the vein increases from 1 to 2 cm. The arteriovenous distance also increases from 0.3 to 0.8 cm and there is less overlap of the artery and vein.¹⁰¹ Because the vein is not in close proximity to the clavicle, if a hematoma develops, manual pressure can be used to stop the bleeding. Furthermore, the axillary vein is farther from the chest wall and pleural surface, thus decreasing the possibility of pleural injury and subsequent pneumothorax. In clinical studies, ultrasound-guided axillary vein access had a first-needle pass success rate of 76% with successful placement in 96% of cases. Despite the use of ultrasound, however, the catheter malposition rate was unchanged at approximately 15%.¹⁰²

IJ Approach

Positioning

Position is critical for maximizing the success of blind (landmark technique) cannulation of the IJ vein. Place the patient in a supine position with the head down and turned approximately 15 to 30 degrees away from the IJ vein to be cannulated. Rotate the head slightly away from the site of insertion. Rotating the head more than 40 degrees has been shown to increase the risk for overlapping the carotid artery over the IJ vein.¹⁹ Occasionally, placing a towel roll under the scapula helps extend the neck and accentuate the landmarks. Stand at the head of the bed with all equipment within easy reach. This may involve moving the bed to the center of the room to allow a table or work surface to be placed at the head of the bed.

Ask the patient to perform a Valsalva maneuver just before inserting the needle to increase the diameter of the IJ vein. Alternatively, the patient can be asked to hum. Trendelenburg positioning, the Valsalva maneuver, and humming all increase the area of the vessel by approximately 30% to 40%.¹⁰³ If the patient is unable to cooperate, coordinate the insertion with respiration because the IJ vein is at its largest diameter just before inspiration. In intubated patients this relationship is reversed because mechanical ventilation increases intrathoracic pressure at end-inspiration. External abdominal compression also helps distend the IJ vein.

**Anterior Approach**

Insert needle along the medial edge of the sternocleidomastoid, 2-3 fingerbreadths above the clavicle.

Entry angle = 30° to 45°.

Aim toward the ipsilateral nipple.

Note: palpate the carotid artery during venipuncture. The artery may be slightly retracted medially.

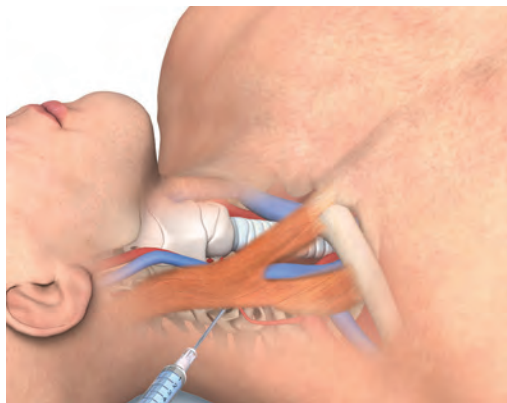

**Central Approach**

Insert needle at the apex of the triangle formed by the heads of the sternocleidomastoid muscle and the clavicle.

Entry angle = 30°.

Aim toward the ipsilateral nipple.

Note: estimate the course of the IJ vein by placing three fingers lightly over the carotid artery as it runs parallel to the vein. The vein lies just lateral to the artery, albeit often minimally so.

**Posterior Approach**

Insert needle at the posterior (lateral) edge of the sternocleidomastoid, midway between the mastoid process and the clavicle.

Entry angle = 45°.

Aim toward the suprasternal notch.

Note: avoid the external jugular vein, which crosses the posterior SCM border. During needle advancement, apply pressure to the SCM to lift the body of the muscle. The vein is usually reached at a depth of 7 cm.

Figure 22.15 Approaches to the internal jugular vein. *IJ*, Internal jugular; *SCM*, sternocleidomastoid.

Venipuncture Site

The right IJ vein provides a more direct route to the right atrium for transvenous pacing. The left IJ vein is often more tortuous and catheters must negotiate two 90-degree turns at the junction of the left IJ vein with the SV and at the junction of the SV with the SVC. However, if the right IJ vein is obstructed or scarred by previous access, the left IJ vein may be accessed with the same technique. Of note, the right IJ vein has been observed to be twice the size of the left IJ vein in 34% of normal adults.¹⁰⁴

Aspirate before injecting anesthetic so that it is not injected into the carotid artery or IJ vein. Once infiltration is completed, use the needle to locate the IJ vein by aspirating blood into the syringe. Note the depth and angle of needle entry and use this as a mental guide to finding the IJ vein with the introducer needle. Typically, an 18-gauge 2.5-cm introducer needle attached to a syringe is used initially to puncture the IJ vein. However,

needle selection may vary depending on the central line kit used. The operator may choose from three approaches: central, posterior, and anterior (Fig. 22.15).

Central Route

This approach is favored by some who believe that the incidence of cannulation of the carotid artery is decreased and the cupula of the lung is avoided.¹⁰⁴ First, palpate and identify the triangle formed by the clavicle and the sternal and clavicular heads of the SCM. Use a marking pen or a local anesthetic skin wheal to mark the lateral border of the carotid pulse, and perform all subsequent needle punctures lateral to this point.

When using the scout needle technique, attach a 22-gauge, 3-cm needle to a 5- to 10-mL syringe. Insert the needle near the apex of the triangle and direct it caudally at an angle of 30 to 40 degrees to the skin. Direct the needle initially parallel and slightly lateral to the course of the carotid artery. Estimate

the course of the IJ vein by placing three fingers lightly over the course of the carotid artery as it runs parallel to the vein, using the fingers as a guide for needle placement. The vein consistently lies just lateral to the carotid artery, albeit often minimally so. Prolonged deep palpation of the carotid artery may decrease the size of the vein, so use the three-finger technique lightly to identify the course of the artery.

Posterior and Anterior Routes

In the posterior approach, make the puncture at the posterior (lateral) edge of the SCM, approximately midway between its origin at the mastoid process and its insertion at the clavicle. The external jugular vein courses in this area and can be used as a landmark, with the puncture occurring where the external jugular vein crosses the posterolateral border of the SCM. Be careful to not strike the external jugular vein. Advance the needle toward the suprasternal notch, just under the belly of the SCM, at an angle of approximately 45 degrees to the transverse plane. During advancement of the needle, apply pressure to the SCM in an effort to lift the body of the muscle. The vein is usually reached at a depth of 7 cm in an average-sized adult. Because the posterior approach occurs higher in the neck, there is less risk for hemothorax, pneumothorax, or carotid puncture.¹⁰⁵ The benefits of the posterior approach are more dramatic in obese patients, with carotid puncture occurring in 3% of patients versus up to 17% with the anterior approach.¹⁰⁶

In the anterior approach, needle puncture occurs along the anterior or medial edge of the SCM approximately two to three fingerbreadths above the clavicle. Insert the needle at an angle of 30 to 45 degrees toward the ipsilateral nipple, away from the carotid pulse. If cannulation is unsuccessful, withdraw the needle to the skin and redirect it slightly toward the carotid artery.

Once the approach is chosen, slowly advance the needle toward the IJ vein. Create gentle negative pressure with the syringe while advancing the needle. Once blood is seen, stop advancing the syringe. Remove the syringe from the needle to determine whether the vessel is pulsatile. Be careful not to allow negative intrapleural pressure to draw air into the venous system through the open needle. Because the tip of the introducer needle is beveled, lateral motions of the needle tip may cause lacerations of the deep structures of the neck. It is therefore very important to remove the needle from the neck completely before any redirection of the needle.

Once cannulation of the IJ vein has been confirmed, remove the syringe from the needle and place a gloved digit over the needle hub to prevent air embolism. Insert a guidewire through the needle into the IJ vein and place the catheter using the Seldinger technique. Once the wire is inserted into the IJ vein, reduce the angle to the skin to make the needle nearly parallel to the vein. This allows a greater chance of directing the wire toward the heart. Do not let the guidewire extend into the right atrium. The average distance from the insertion site to the junction of the SVC and right atrium is 16 ± 2 cm for the right IJ vein and 19 ± 2 cm for the left IJ vein. The spring wires supplied in kits are often much longer, up to 60 cm in length. If the full length of the wire is inserted, the wire could enter the right atrium or ventricle and cause myocardial irritability and subsequent dysrhythmias. Monitor cardiac rhythm during insertion of the spring wire to detect cardiac irritability. The distance that the catheter is introduced depends on the distance from the site of introduction to the junction of the

SVC and right atrium. This distance will be shorter with the right IJ vein than with the left IJ vein.

IJ Ultrasound Technique

Cannulation of the IJ vein is an optimal location for the use of ultrasound guidance. Whereas the landmark approach is associated with a complication rate of between 5% and 10% irrespective of the technique used or experience of the operator, with the use of ultrasound, the complication rate is significantly reduced.¹⁰⁴ Even with novice users of ultrasound for IJ vein cannulation, first-attempt success is significantly increased when compared to the blind landmark technique (43% versus 26%).¹⁰⁷ With experience, however, the first-attempt success rate improves to more than 75%.^{16,17,108} Use of ultrasound for placement of central lines in the IJ vein has also been shown to decrease overall catheter placement failures by 64%, reduce complications by 78%, and decrease the need for multiple catheter placement attempts by 40% in comparison to the standard landmark placement technique.^{109,110} The primary reason for the increased success rate is the variation in anatomy of the IJ vein relative to the carotid artery. The anatomy of the IJ vein has been shown to be aberrant in 9% to 19% of cases.^{104,107,110} Furthermore, the IJ vein may be unusually small (i.e., <0.5 cm) in up to 14% of patients. The IJ vein is thrombosed in up to 2.5% of some patient populations.¹⁰⁷

With the use of ultrasound there is no need for reliance on normal anatomy for cannulation. Therefore the IJ vein may be cannulated despite abnormal anatomy. Hence, cannulation may occur at the apex of the triangle, near the base at the junction with the innominate vein, or anywhere in between.

Femoral Approach

Positioning and Needle Orientation

Place the patient in the supine position for the femoral vein approach. This approach does not require any special positioning or tilting of the bed. Fully expose and thoroughly cleanse the area with a soapy washcloth or surgical scrub brush to remove obvious soiling, which may be more common at this site. Next, prepare the skin at the site broadly with chlorhexidine, including the anterior superior iliac spine laterally and superiorly, extending to the midline, and continuing 10 to 15 cm below the inguinal ligament. Tape a urethral catheter to the contralateral leg. In an obese patient, have an assistant retract the abdominal pannus manually or secure it with wide tape.

After the instillation of local anesthetic, introduce the needle at a 45-degree angle in a cephalic direction approximately 1 cm medial to this point and toward the umbilicus (Fig. 22.16). Palpate the femoral pulse two fingerbreadths beneath the inguinal ligament. Note that while palpating the artery, pressure from the operator's fingers can compress the adjacent vein and impede cannulation. Avoid this anatomic distortion by releasing digital pressure while keeping the fingers on the skin to serve as a visual reference to the underlying anatomy. The depth of the needle required to reach the vein varies with body habitus, but in thin adults, the vein is quite superficial and is usually reached at a depth of approximately 2 to 3 cm, so advance the needle slowly. Return of dark, nonpulsatile blood signals successful venous penetration.

Although using the femoral arterial pulse as a guide is ideal, it may not be palpable in an obese or hypotensive patient. A

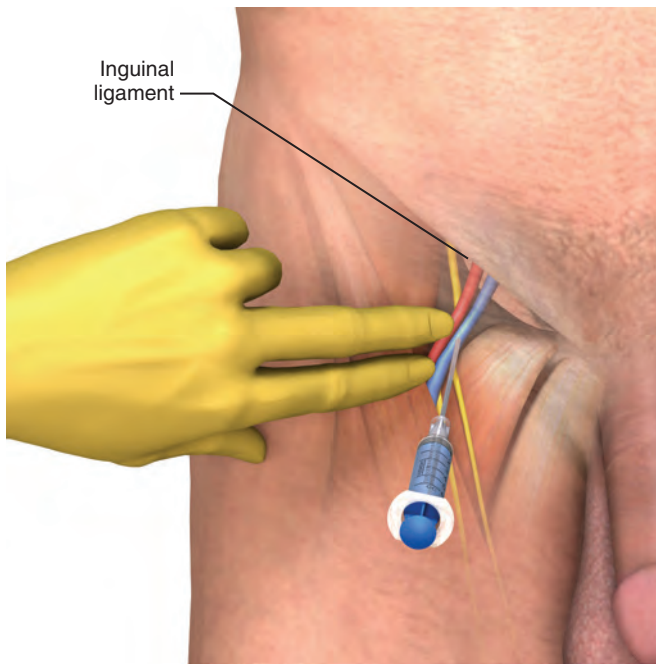

Figure 22.16 Femoral approach. Palpate the femoral artery two fingerbreadths beneath the inguinal ligament. Keep the fingers on the artery to aid the femoral vein cannulation and to avoid the femoral artery. Introduce the needle at a 45-degree angle in a cephalic direction 1 cm medial to this point and toward the umbilicus. Importantly, more distally the vein lies over the artery, so place the catheter near the inguinal ligament, or use ultrasound guidance.

more detailed understanding of the femoral landmarks can be used to guide cannulation attempts. On all but the most severely injured trauma patients with a disrupted pelvis (in which case a femoral approach would be contraindicated), the anterior superior iliac spine and the midpoint of the pubic symphysis are easily palpated. The line between these two bony references describes the inguinal ligament. When this line is divided into thirds, the femoral artery should underlie the junction of the medial and middle thirds. The femoral vein will lie approximately one fingerbreadth medial to this point. Alternatively, the vascular anatomy of the region can be evaluated and the line placed via ultrasound guidance.

Venipuncture

During advancement of the needle, maintain gentle negative pressure on the syringe at all times while the needle is under the skin. Direct the needle posteriorly and advance it until the vein is entered, as identified by a flash of dark, nonpulsatile blood. If the vessel is penetrated when the syringe is not being aspirated, the flash of blood may be seen only as the needle is being withdrawn. The femoral vein lies just medial to the femoral artery at the level of the inguinal ligament. It is closer to the artery than many clinicians appreciate. As the vein progresses distally in the leg, it runs closer to and almost behind the femoral artery.

Femoral Ultrasound Technique

Cannulation of the femoral vein under ultrasound guidance is very similar to that for the IJ vein. Using ultrasound, the common femoral vein, its junction with the saphenous vein, and the branches of the common femoral vein (i.e., the

superficial and deep femoral veins) are easily identified. Typically, placement of the catheter should occur proximal to the bifurcation of the common femoral vein and preferably proximal to the junction with the saphenous vein.

ANCHORING THE CENTRAL LINE

After the CVC is placed, it will need to be anchored in place by one of three techniques: StatLock (Bard Medical, Covington, GA), suture, or staple (Fig. 22.17). The StatLock may not hold well in patients with oily skin but is excellent for older patients with thin skin. For suturing, one will need the sterile, nonabsorbable suture material (usually 2-0 silk) provided in the CVC kit. The straight suture needles found in many sets are awkward for many clinicians, so a curved needle with a driver may be helpful. To avoid a needlestick with the straight needle, pass the blunt end of the needle through the anchoring devices and pull the suture forward manually. Place the suture in the skin approximately a half centimeter from the catheter to anchor the central line in place. Several knots should be made to secure the line. Avoid making knots that place excessive pressure on the skin because this can lead to difficulty removing the knots and necrosis. Loose knots can lead to migration of the catheter and loss of access. Stapling a central line into place can be just as effective as suturing; however, the staples tend to fall out after a few days.

Dressing

Clean the area around the catheter insertion site with chlorhexidine, and then use a clear dressing (such as Tegaderm [3M, St. Paul, MN]) to cover up the insertion site of the catheter once secured (see Fig. 22.9, *step 16*). Apply a chlorhexidine patch (Biopatch [Ethicon, Somerville, NJ]) at the site where the catheter enters the skin (see Fig. 22.17E and F). Because dressings are inspected and changed periodically, place a simple dressing and avoid excessive amounts of gauze and tape. Take care to protect the skin against maceration.

Assessing Line Placement

Check all tubing and connections for tightness to prevent air embolism, loss of fluid, or bleeding. Before infusing IV fluids, lower the IV fluid reservoir to below the level of the patient's right atrium and check the line for backflow of blood. Free backflow of blood is suggestive but not diagnostic of intravascular placement. Backflow could occur from a hematoma or hemothorax if the catheter is free in the pleural space. A pulsatile blood column may be noted if the catheter has been inadvertently placed in an artery. Less pronounced pulsations might also occur if the catheter is advanced too far and reaches the right atrium or ventricle. In addition, pulsations may be noted with changes in intrathoracic pressure as a result of respirations, although these pulsations should occur at a much slower rate than the arterial pulse. A final method of checking intravascular placement is to attach a syringe directly to the catheter hub and aspirate venous blood. It is also advisable to ensure that the catheter is easily flushed with a saline solution. This carries the additional benefit of removing air from the system. Radiographs are also always indicated to verify catheter location and assess for potential complications, except after routine femoral line placements. In an awake patient, infusing fluids

by Christine Butts, MD

IJ Vein

When evaluating the internal jugular (IJ) vein, the transducer (7.5 to 20 MHz) should be initially placed over the right or left side of the neck to evaluate the anatomy. An ideal initial location to begin is at the apex of the triangle formed by the two heads of the subclavian muscle (Fig. 22.US1). Placing the transducer over this area in the transverse orientation will enable the vessels to be located in cross section, where they can best be evaluated. The internal carotid artery and IJ vein will be seen as paired structures with anechoic central areas (Fig. 22.US2). The position of one relative to the other can be variable, but typically the IJ vein lies lateral and superficial to the carotid artery. Several characteristics of the IJ vein serve to distinguish it from the carotid artery. The IJ vein is typically more oval in shape (versus the rounded shape of the carotid artery), is thinner walled, and will compress with gentle pressure. Additionally, the size of the IJ vein will change with respiration and should be seen to increase in size with a Valsalva maneuver.

Complications can be reduced by several methods. First, ensure that the target vessel is indeed the vein and not the artery. Variant anatomy or variations in volume status (either depletion or overload) may make the vessels difficult to distinguish from one another. Confirmation should be attempted by noting multiple characteristics of the vessel (compressibility, shape, anatomic location, etc.). Once the vessel has been confirmed as the vein, the operator must take great care to ensure that the position of the tip of the needle is apparent at all times. Most complications occur when the tip of the needle is deeper or more medial than the operator realizes, thus placing it in proximity to other structures (e.g., lung, carotid artery). An extensive discussion of each approach can be found in the basic ultrasound chapter (see Chapter 66), and each approach has its drawbacks in determining position. In the transverse method, the angle of approach can be difficult to ascertain and cause the tip of the needle to be deeper than the operator realizes. Additionally, the tip of the needle may be difficult to follow. In the longitudinal approach, the medial to lateral orientation of the needle can be difficult to appreciate. Additionally, slight movements of the transducer may result in loss of the appropriate image. A combination of these two, or an oblique approach, may minimize these difficulties.

Figure 22.US1 Placement of the ultrasound transducer at the apex of the triangle formed by the heads of the sternocleidomastoid.

Femoral Vein

The femoral artery and vein lie together with the femoral nerve within a common sheath. They can be found at the level of the inguinal crease on the medial aspect of the thigh. Palpating the femoral pulse will also aid in localizing the vascular bundle. The transducer (7.5 to 10 MHz) should be placed in a transverse or slightly oblique orientation overlying this area. Slightly rotating the thigh externally may facilitate this step. Classically, the artery is described to lie lateral to the vein. However, this is often not the case and multiple variations may be noted. The femoral artery and vein will appear as rounded anechoic structures (Fig. 22.US3). The femoral vein can be recognized

Figure 22.US2 Transverse image of the carotid artery and internal jugular (IJ) vein. The IJ vein can be recognized by its oval or triangular shape and its thinner walls, and it will collapse with light pressure. Although both are rounded and contain anechoic (black) fluid, the IJ vein is slightly larger and more oval in shape. Though not evident in this image, slight pressure will cause collapse of the IJ vein. CA, Carotid artery.

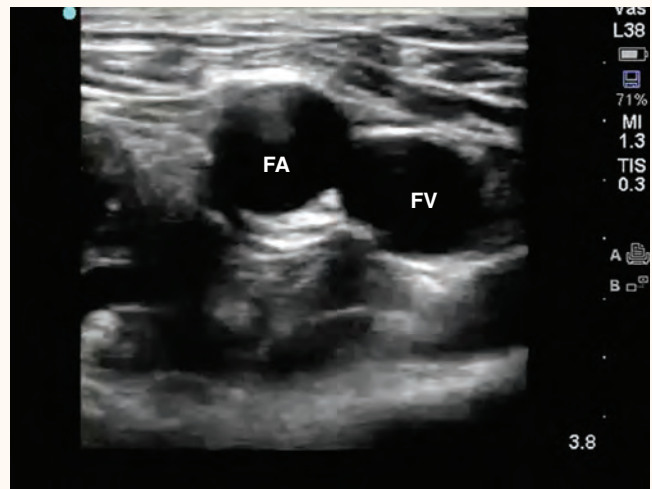

Figure 22.US3 Transverse image of the femoral artery and femoral vein. Similar to vessels in the neck, the femoral vein is more oval or triangular in shape. Though not evident in this image, slight pressure will cause collapse of the vessel. FA, Femoral artery; FV, femoral vein.

ULTRASOUND BOX 22.1: Central Venous Catheterization—cont'd

by its thinner walls and slightly more oval shape, and it will collapse with gentle pressure. It will also typically increase in size when the lower part of the leg is squeezed. The vascular bundle may need to be followed inferiorly or superiorly to determine the most optimal location for puncture.

Complications can be reduced by several methods. First, ensure that the target vessel is indeed the vein and not the artery. Variant anatomy or variations in volume status (either depletion or overload) may make the vessels difficult to distinguish from one another. Confirmation should be attempted by noting multiple characteristics of the vessel (compressibility, shape, anatomic location, etc.). Once the vessel has been confirmed as the vein, the operator must take great care to ensure that the position of the tip of the needle is apparent at all times. The tip of the needle may be difficult to follow in the transverse approach and result in an inadvertent puncture of the posterior wall of the vessel. When the artery lies deep to the vein, arterial puncture or cannulation may result. In the longitudinal approach, the medial to lateral position of the needle may be difficult to appreciate and result in accidental arterial puncture. The oblique approach may minimize these difficulties.

Subclavian Vein

The subclavian vessels can be imaged from either a supraclavicular or an infraclavicular approach. For the supraclavicular approach, the transducer (7.5 to 10 MHz) is placed along the long axis of the clavicle on the superior aspect (Fig. 22.US4). It should be angled downward. In this view, the vessels should be seen in their long axis (Fig. 22.US5). The vein can be identified by its variation with respiration and change in size with the Valsalva maneuver. The vein can also be followed to identify the junction with the IJ vein, thereby offering further confirmation. In the infraclavicular approach, the transducer is placed beneath the clavicle at its most lateral aspect, in a sagittal or slightly oblique orientation, following the position of the clavicle (Fig. 22.US6). In this view, the vessels will be seen in cross section or a slightly oblique plane (Fig. 22.US7). The pleura may also be seen deep to the vessels as an echogenic vertical line that slides back and forth with respiration.

Figure 22.US4 Placement of the ultrasound transducer superior to the clavicle to enable visualization of the subclavian vessels in the long axis.

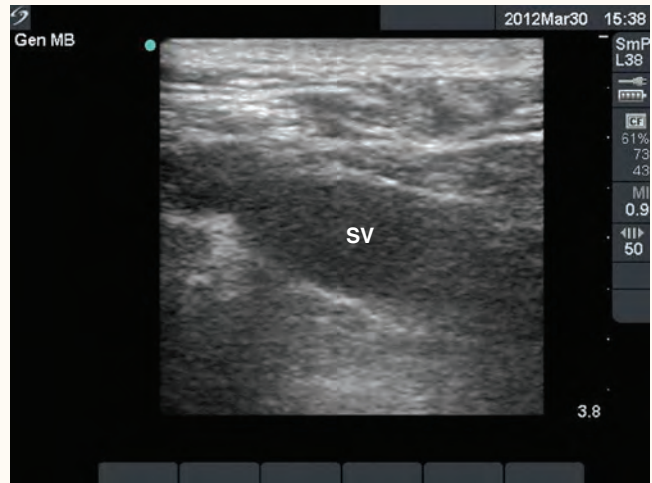

Figure 22.US5 Long-axis view of the subclavian vein. The subclavian artery, not seen in this image, will be seen as a similar-appearing vessel deep to the vein. Color flow and Doppler can be used to distinguish between the two vessels. *SV*, Subclavian vein.

Figure 22.US6 Placement of the ultrasound transducer inferior to the clavicle to enable visualization of the subclavian vessels in short axis. A sagittal (shown) or slightly oblique orientation should be used.

Figure 22.US7 Short-axis view of the subclavian artery (*arrowhead*) and vein (*arrow*) as seen from the inferior aspect of the clavicle.

ULTRASOUND BOX 22.1: Central Venous Catheterization—cont'd

A longitudinal approach should be used in which the needle is introduced from the end of the transducer in either the infraclavicular or the supraclavicular approaches. This will enable a shallow angle to be used and thereby minimize the chance of damaging deeper structures such as the lung. Once a flash of blood has been obtained, the ultrasound transducer can be set aside and the procedure continued as described previously.

The subclavian artery and vein lie in close opposition to the pleura, so pneumothorax is a more common complication. Using a long-axis approach (in which the needle is introduced from the end of the transducer rather than from the middle) offers the advantage of visualizing the entirety of the needle in its course toward the vein. A shallow angle can be used, and the relationship of the needle to the pleura can also be appreciated.

Securing a Central Venous Catheter

A

A white rubber clamp is provided to secure the catheter when the full length is not needed. Twist open the pliable clamp and place it over the catheter at a site a few centimeters from the insertion site.

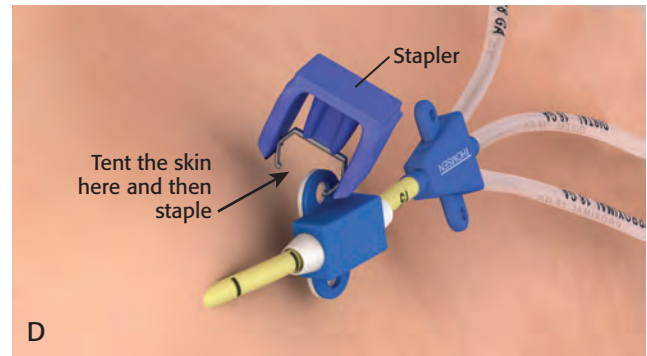

B

The rubber clamp is covered with a blue plastic fastener, and both the clamp and fastener are sutured to the skin to secure the catheter. The hub of the catheter is also sutured to the skin.

C

To avoid a needlestick, the blunt end of the needle is used to pass the suture through the holes of the fastening devices.

D

Alternatively, skin staples may be used. Tent the skin and pass the staples through the anchoring eyes.

E

This Biopatch is a chlorhexidine-containing hydrophilic covering placed at the site where the catheter enters the skin to deliver local antiseptics for 7 days.

F

A simple Tegaderm clear covering is then applied.

Figure 22.17 Methods to secure a central venous triple-lumen catheter.

Figure 22.18 Chest radiographs obtained after placement of: **A**, right internal jugular central venous catheter, and **B**, left subclavian central venous catheter. The tips of the catheters are appropriately placed in the superior vena cava (*arrows*). The tip should not lie within the right atrium or the right ventricle.

via a catheter tip positioned in the IJ vein may produce an audible gurgling or flowing sound in the patient's ear.¹¹¹

Radiographs

Following placement of lines involving puncture of the neck or thorax, listen to the lungs to detect any inequality of lung sounds suggestive of a pneumothorax or hemothorax. Obtain a chest film as soon as possible to check for hemothorax, pneumothorax, and the position of the tip of the catheter (Fig. 22.18). Because small amounts of fluid or air may layer out parallel to the radiographic plate with the patient in the supine position, take the film in the upright or semi-upright position whenever possible. In ill patients, a rotated or oblique projection on a chest radiograph may be obtained, and the clinician may be confused about the proper position of the catheter. In such cases, repeat the radiograph. A misplaced catheter tip is usually obvious on a properly positioned standard posteroanterior chest radiograph (Fig. 22.19), but occasionally, injection of contrast material may be required. For example, a catheter in one of the internal thoracic veins may simply appear more lateral than expected, but because of the close proximity of these veins and the SVC, malposition may not be appreciated by this subtle finding. Misplaced catheters should be repositioned or replaced.

Attention should also be given to the possibility of a retained guidewire. Although this complication is rare, if not specifically considered it can be overlooked by both clinicians and radiologists.^{112,113}

A postprocedure radiograph is routine after initial placement, but radiographs are not always necessary for routine replacement of catheters over guidewires. If such patients are stable and hemodynamically monitored, radiography may be deferred safely in the absence of apparent complications or clinical suspicion of malposition.^{114,115}

Redirection of Misplaced Catheters

Improper catheter tip position occurs commonly. It has been reported that only 71% of SV catheters are located in the SVC on the initial chest film. Complications of improper positioning include hydrothorax, hemothorax, ascites, chest wall abscess, embolization to the pleural space, and chest pain.

Figure 22.19 Chest radiograph obtained after left internal jugular catheterization. Note that the course of the catheter (*small arrows*) does not cross the midline and that the tip (*large arrow*) projects to the left of the midline near the aortic arch. Although the catheter may have been located intravascularly in a venous anatomic variant, it was decided to remove this line and replace it with a new catheter.

More commonly, improper location yields inaccurate measurements of CVP or is associated with poor flow caused by kinking. An unusual complication attributable to improper tip position is cerebral infarction, which can occur following inadvertent cannulation of the subclavian artery.

Misdirection or inappropriate positioning of the tip of a CVC, when promptly recognized and corrected, is an inconsequential complication. Loop formation, lodging in small neck veins, tips directed caudally, and innominate vein position are common problems. Reposition misplaced catheters as soon as logistically possible. If the catheter is being used for fluid resuscitation, the malposition may be tolerated for some time. If vasopressors or medications are infused, proper positioning of the tip of the catheter is more critical. A number of options are available to remedy malpositioning. One strategy is to insert a 2-Fr Fogarty catheter through the lumen of the central line and advance it 3 cm beyond the tip. Withdraw the entire

assembly until only the Fogarty catheter is in the SV. Inject 1 mL of air into the balloon and advance the Fogarty catheter. It is hoped that blood flow will direct the assembly into the SVC. Deflate the balloon and advance the central line over the Fogarty catheter, which is then withdrawn.

Another anecdotal strategy is to withdraw the catheter until only the distal tip remains in the cannulated vessel. This measurement is best appreciated by comparing the length of the indwelling catheter with another unused catheter. The clinician then simply readvances the catheter in the hope that it becomes properly positioned. Other manipulations with guidewires have been suggested, but reinsertion with another puncture is often required for the misplaced catheter to be positioned properly. This approach also decreases the risk for infection by avoiding the introduction of bacteria into the vessel from any nonsterile segment of the CVC.

SPECIAL CONSIDERATIONS FOR OTHER VESSELS

External Jugular Vein Approach

Central venous catheterization via the external jugular vein is time-consuming and often difficult. The difficulty in converting an external jugular catheter into a CVC frequently renders it a lower-yield clinical procedure. Use of the external jugular vein for achieving central venous access requires that a guidewire be used. After cannulation of the vein and intraluminal placement of the guidewire, advance the guidewire into the thorax by rotating and manipulating the tip into the central venous circulation. Advancement of the guidewire is the most difficult and time-consuming portion of the procedure, and the time requirement limits the usefulness of this technique in an emergency. A small-radius J-tipped wire, a distended vessel lumen, and exaggeration of patient head tilt, coupled with skin traction, may facilitate successful passage of the guidewire. Partially withdrawing the wire and twisting it 180 degrees before readvancing the tip may also be helpful.

Basilic and Cephalic Approaches

Passing a catheter into the central circulation is difficult via the basilic and cephalic routes, and failure is common. Insertion of a peripheral IV central catheter through these routes is often performed by specialized teams and is less suitable for emergency indications. The cephalic vein may terminate inches above the antecubital fossa or bifurcate before entering the axillary vein and send a branch to the external jugular vein. The cephalic vein may also enter the axillary vein at a right angle, thereby defeating any attempt to pass the catheter centrally. Furthermore, both the basilic and the cephalic systems contain valves that may impede catheterization. Abduction of the shoulder may help advance the catheter if resistance near the axillary vein is encountered. The incidence of failure to place the catheter in the SVC ranges from a high of 40% to a low of 2%.^{47,116} The greatest success rate (98%) reported was obtained with slow catheter advancement with the patient in a 45- to 90-degree upright position.⁴⁷ A flexible catheter was introduced into the basilic vein until the tip was judged to be proximal to the junction of the cephalic and basilic veins and distal to the junction of the IJ vein with the innominate vein. The wire stylet was withdrawn 18 cm and the catheter

was advanced slowly 1 cm at a time, with 2 seconds allowed between each 1-cm insertion. The natural flexibility of Bard catheters contributed to negotiation into the SVC when the patient was upright. This time-consuming technique is contraindicated when the patient cannot tolerate an upright position.

The basilic and cephalic venous systems are entered through the large veins in the antecubital fossa. Placement of a tourniquet aids venous distention and initial venous puncture. When veins are not visible, they may be identified with bedside ultrasound (as described in [Chapter 66](#)). The basilic vein, located on the medial aspect of the antecubital fossa, is generally larger than the radially located cephalic vein. Furthermore, the basilic vein usually provides a more direct route for passage into the axillary vein, SV, and SVC.

Vascular Access in Cardiac Arrest

Immediate vascular access is required for resuscitation during cardiac arrest. Intraosseous access is a reasonable alternative to central venous access. Femoral CVCs are often used in this setting. The infraclavicular SV approach is also commonly used during cardiac arrest if logistics permit. The intuitive rationale for femoral CVC placement has been that much of the resuscitation activity, including chest compressions, occurs on the thorax, thus limiting the clinician's ability to safely place a higher line. During cardiac arrest, the availability of drugs delivered to the central circulation may be slower via the femoral route than via supraclavicular SV or IJ vein infusions.^{116,117} Additionally, pulsations felt in the groin during CPR may be venous instead of arterial,³¹ and there is a high rate of unrecognized catheter malposition and arterial injury.^{31,118} To place a femoral catheter blindly (without ultrasound guidance or clear identification of the arterial pulse), divide the distance from the anterior superior iliac spine to the symphysis pubis into thirds. The artery typically lies at the junction of the medial and middle thirds and the vein is 1 cm medial to this location. Blind femoral central line insertions during arrest are less than optimal. The increasingly available intraosseous placement systems and bedside ultrasonography are commonly used to supplant such blind CVC placements during cardiac arrest and other emergencies that require immediate vascular access.

CVP MONITORING

CVP Measurement

Although described by Forssmann in 1931, it was not until the early 1960s that measurement of CVP became commonplace as a means of assessing cardiac performance and guiding fluid therapy.¹⁰ CVP measurement has been used as a guide for determination of volume status, fluid requirements, and investigation of tamponade,¹¹⁹ but its reliability has not been consistently demonstrated in the literature.^{120,121} Furthermore, advancements in our knowledge of complex hemodynamics (particularly during sepsis) and improvements in noninvasive dynamic imaging (ultrasound) have largely supplanted CVP monitoring in the critical care environment.^{122,123} Still, astute clinicians can maximize the usefulness of this diagnostic tool by understanding its basic principles, indications, and limitations.¹²⁴⁻¹²⁶

Physiology

Simply stated, CVP is the pressure exerted by blood against the walls of the intrathoracic venae cavae. Because pressure in the venae cavae is generally within 1 mm Hg of right atrial pressure, CVP reflects the pressure under which blood is returning to the heart. Pressure in the central veins has two significant hemodynamic effects. First, CVP promotes filling of the heart during diastole, a factor that reflects right ventricular end-diastolic volume (preload). Second, CVP also represents the back-pressure of the systemic circulation, which opposes return of blood from peripheral venous circulation to the heart. CVP values are determined by a complex interaction of intravascular volume, right atrial and ventricular function, venomotor tone, and intrathoracic pressures.^{119,124,125,127}

To measure CVP, the tip of a pressure-monitoring catheter is inserted into any of the great systemic veins of the thorax or into the right atrium.^{124,126} The femoral vein may also be used for CVP measurements as long as there is no abnormally increased abdominal pressure.^{10,127} The catheter is connected to a simple manometer or to an electronic pressure transducer interfaced with a monitoring system that is capable of calculating a mean pressure value and displaying pressure waveforms.^{124,126} When the catheter tip is placed in the right atrium the waveforms produced correlate with the cardiac cycle and create a typical wave pattern.

A common misconception is that CVP consistently reflects pressure in the left side of the heart. A different measurement, called pulmonary capillary wedge pressure (PCWP), is capable

of reflecting left atrial pressure and corresponding changes in left ventricular pressure by transducing back-pressures from the left-sided circulation through the pulmonary capillary system. Additionally, flow-directed pulmonary artery catheters allow repeated calculations of PCWP, thus facilitating reliable estimation of left atrial pressures.¹²⁶

Indications for and Contraindications to CVP Measurement

The five traditional major indications for monitoring CVP are:

1. Acute circulatory failure.
2. Anticipated massive blood transfusion or fluid replacement therapy.
3. Cautious fluid replacement in patients with compromised cardiovascular status.
4. Suspected cardiac tamponade.
5. Fluid resuscitation during goal-directed therapy in patients with severe sepsis.

The procedure is contraindicated when other resuscitative therapeutic and diagnostic interventions take priority over central venous access and CVP transducer setup and calibration, or in the setting of large vegetations on the tricuspid valve, SVC syndrome, or tumors or thrombus in the right atrium.

CVP monitoring is most helpful in patients without significant preexisting cardiopulmonary disease. Numerous studies highlight the unreliability of right-sided hemodynamic monitoring in patients with underlying cardiac or pulmonary disease.^{114,118}

Central Venous Pressure Measurement

Indications

- Acute circulatory failure
- Anticipated massive blood transfusion or fluid replacement therapy
- Cautious fluid replacement in patients with compromised cardiovascular status
- Suspected cardiac tamponade
- Fluid resuscitation during goal-directed therapy for severe sepsis

Contraindications

- Other resuscitative interventions that take priority over central venous access and central venous pressure setup
- Large vegetations on the tricuspid valve
- Superior vena cava syndrome
- Right atrial tumor or thrombus

Complications

- Faulty central venous pressure readings:
 - Increased intrathoracic pressure (ventilator, straining, coughing)
 - Failure to calibrate or zero the transducer
 - Malposition of the tip of the catheter
 - Obstruction of the catheter
 - Air bubbles in the circuit
 - Readings during the wrong phase of ventilation
 - Vasopressors (presumed)

Equipment

Ultimately, however, the inconsistencies noted are not due to the failure of CVP monitors to reflect central hemodynamics. Rather, the discrepancies noted in the literature simply highlight the complex relationships between ventricular and vascular compliance, blood volume, and filling pressures in various disease states. As with pulmonary artery occlusion pressure measurements, the clinician is cautioned to be aware of the assumptions inherent in taking these measurements and to

recognize the physiologic scenarios in which these assumptions do not hold true.

Procedure

Although CVP may be determined with a manometry column assembled at the bedside (Fig. 22.20), the most common technique in practice is measurement with an electronic

Figure 22.20 Measurement of central venous pressure with a manual manometer.

Measurement of Central Venous Pressure: Transducer

1 Insert a bag of normal saline into a pressure bag and inflate to the recommended pressure (usually 300 mm Hg).

2 Flush all air bubbles from the system by opening the stopcock and running saline through the line. Any air left in the system will cause erroneous central venous pressure readings. Take care to not flush air into the patient.

3 Connect the flushed transducer tubing to the patient's central line (*arrow*).

4 Mount the transducer at the level of the patient's right atrium. This level can be approximated on the skin surface as a point at the midaxillary line and fourth intercostal space.

5 Adjust the stopcock so that the transducer is open to air, and zero the system (*arrow*). The exact process for the zeroing procedure will vary by the equipment manufacturer.

6 Finally, set the stopcock so that it is open to the transducer and the central venous catheter. Observe for a venous waveform and central venous pressure reading on the monitor (*arrow*).

Figure 22.21 Measurement of central venous pressure with an electronic transducer.

transducer interfaced to a bedside monitoring system (Fig. 22.21). Typical transducers include a nipple valve attached to a pressurized bag of saline to allow easy flushing of the system. The transducer is connected through the patient's central line with a length of tubing filled with saline. A three-way stopcock is placed between the patient and the transducer to simplify line flushing and calibration.

Flush all air bubbles from the system by opening the stopcock to air and flushing saline through the line. Do not flush air bubbles into the patient. Even tiny bubbles left in the tubing will dampen the CVP wave and potentially cause underestimation of venous pressure.

After the system has been flushed, place the stopcock (with the transducer still open to air) at the level of the patient's right atrium. Zero (calibrate) the monitor with the transducer at the level of the right atrium, which can be approximated on the skin surface as a point at the midaxillary line and the fourth intercostal space.^{124,126} Finally, set the stopcock so that the transducer is in continuity with the patient's venous catheter.

In spontaneously breathing patients, take readings at the end of a normal inspiration. If the patient is receiving positive

pressure ventilation, the changes in CVP during the respiratory cycle are reversed: it rises with inspiration and decreases with expiration. In these patients, take readings near the end of expiration.¹²⁶ Thus, during both normal and mechanical ventilation, the lowest reading is a useful estimate of mean CVP.

Readings should be taken only after accurate placement of the catheter tip has been established. To ensure optimal measurement, place the patient in the supine position. Whenever the patient is repositioned, take care to ensure that the transducer has been recalibrated to reflect the new position of the patient.

Errors in CVP Measurement

A number of extrinsic factors may alter the accuracy of the CVP reading (Box 22.1).^{119,124,126} In addition to the position of the patient, changes in intrathoracic pressure, malposition of the tip of the catheter, obstruction of the catheter, and failure to calibrate or zero the line may all adversely impact CVP measurements. Activities that increase intrathoracic pressure, such as coughing or straining, may cause spuriously high measurements. Make sure that the patient is relaxed and

BOX 22.1 Reasons for Faulty Central Venous Pressure Readings

- Increased intrathoracic pressure (ventilator, straining, coughing)
- Failure to calibrate or zero the transducer
- Malposition of the tip of the catheter
- Obstruction of catheter
- Air bubbles in the circuit
- Readings during the wrong phase of ventilation
- Vasopressors (presumed)

breathing normally at the time of measurement. In mechanically ventilated patients CVP will be elevated to an extent directly proportional to the ventilatory pressure being delivered and inversely proportional to the mechanical compliance of the lung. Care should be exercised in interpreting filling pressures in this circumstance because ventilator-induced elevations in CVP are not artifactual but represent changes in the hemodynamic physiology of the patient. As in spontaneously breathing patients, CVP measurements are meaningful only in relaxed, sedated, or paralyzed subjects.

Another reason for faulty readings is malposition of the tip of the catheter. If the catheter tip has not passed far enough into the central venous system, peripheral venous spasm or venous valves may yield pressure readings that are inconsistent with the true CVP.

If the tip of the catheter has passed into the right ventricle, a falsely elevated CVP measurement will be recorded. Recognition of a characteristic right ventricular pressure waveform on the patient's monitor should hopefully preclude this error. Such fluctuations may also occasionally be seen in appropriately positioned CVP lines when significant tricuspid regurgitation or atrioventricular dissociation (a cannon "a" wave) is present.¹²⁷ Inaccurate low venous pressure readings are seen when a valve-like obstruction at the tip of the catheter occurs as a result of either clot formation or contact against a vein wall. Wave damping secondary to air bubbles in the transducer tubing also leads to faulty readings. Using poorly zeroed lines may result in inaccurate measurements that may be interpreted as a change in the patient's status when none has actually taken place. The transducer should be zeroed to the same level for every measurement.

Interpretation of CVP Measurement

Normal CVP values are as follows:

Low: <6 cm H₂O.

Normal: 6 to 12 cm H₂O.

High: >12 cm H₂O.

In the late stages of pregnancy (30 to 42 weeks), CVP is physiologically elevated, and normal readings are 5 to 8 cm H₂O higher. A CVP reading of less than 6 cm H₂O is consistent with low right atrial pressure and reflects a decrease in the return of blood volume to the right heart. This may indicate that the patient requires additional fluid or blood. A low CVP reading is also obtained when vasomotor tone is decreased, as with sepsis, spinal cord injury, or other forms of sympathetic interruption.

A CVP reading falling within a normal range must be viewed in relation to the clinical scenario. A reading higher than 12 cm H₂O indicates that the heart is not effectively circulating the volume presented to it. This may occur in a normovolemic patient with underlying cardiac disease, such as left ventricular hypertrophy (with associated poor ventricular compliance), or in a volume-overloaded patient with a normal heart. High CVP can also be related to variables other than pump failure, such as pericardial tamponade, restrictive pericarditis, pulmonary stenosis, tricuspid regurgitation, pulmonary hypertension, and pulmonary embolism.¹²⁸

Changes in blood volume, vessel tone, and cardiac function may occur alone or in combination with one another; therefore it is possible to have a normal or elevated CVP in the presence of normovolemia, hypovolemia, and hypervolemia.¹²⁸ Interpret the specific CVP values with respect to the entire clinical picture. The changes in CVP during an infusion are more important than the initial reading.

Fluid Challenge

Monitoring CVP may be helpful as a practical guide to fluid therapy.^{119,124-126,129} Serial CVP measurements provide a fairly reliable indication of the capability of the right side of the heart to accept an additional fluid load. Although PCWP is a more sensitive index of left heart fluid needs (and in some clinical situations measurement of PCWP is essential), serial measurement of CVP can nonetheless provide useful information.

A fluid challenge can help assess both volume deficits and pump failure.¹²⁵ Although a fluid challenge can be used with either PCWP or CVP monitoring, only the fluid challenge for CVP monitoring is discussed here. Slight variations in the methodology of fluid challenge are reported in the literature. Generally, fluid boluses of 250 to 500 mL of crystalloid are administered sequentially and CVP is measured 10 minutes after each bolus. Repeat the fluid challenge until measurements indicate that adequate volume expansion has occurred. Discontinue the fluid challenge as soon as hemodynamic signs of shock are reversed or signs of cardiac incompetence are evident.

Cardiac Tamponade

In cardiac tamponade, pericardial pressure rises to equal right ventricular end-diastolic pressure. The pericardial pressure encountered in pericardial tamponade characteristically produces an elevated CVP.¹²⁸ The degree of elevation in CVP is variable, and one must interpret measurements cautiously; CVP readings in the range of 16 to 18 cm H₂O are typically seen with acute tamponade, but elevations of up to 30 cm H₂O may be encountered. The precise CVP reading is often lower than one might intuitively expect, and it is not uncommon to encounter tamponade with a CVP of 10 to 12 cm H₂O. A normal or even low CVP reading may be seen if the tamponade is associated with significant hypovolemia. An excessive rise in CVP after fluid challenge may be more important than a single reading in the diagnosis of pericardial tamponade. Additionally, physician-operated point-of-care ultrasound has proven to be exceptionally sensitive for visualizing tamponade physiology when pericardial pressures have begun to impair right ventricular filling.¹²⁹

Excessive straining, positive pressure ventilation, agitation, inflation of pneumatic antishock garments, and tension

pneumothorax may all increase intrathoracic pressure, produce a high CVP reading, and erroneously suggest the diagnosis of pericardial tamponade. Increases in vascular tone, as seen with the use of dopamine or other vasopressors, may also elevate CVP and thus mimic tamponade and complicate estimations of volume.

COMPLICATIONS

The medical literature is replete with reports of CVC complications. Understanding the pathophysiology surrounding CVC complications helps clinicians anticipate, recognize, and manage complications should they arise and better educate patients and their families during the informed consent process.

More than 15% of patients who receive CVCs experience some type of complication, and complications occur despite pristine technique.^{45,76} This percentage is not surprising in view of the close proximity of vital structures, the complexity of patients' medical conditions, and the exigent circumstances under which many of these procedures are often performed. The number of complications increases, especially thrombosis and line infection, with longer durations of indwelling catheters and increasing severity of illness.²⁸ Common complica-

tions and the different approaches are summarized in [Box 22.2](#) and can generally be categorized as mechanical, infectious, and thrombotic. Key complications and injuries by approach are discussed in the following sections.

The number of lumens does not directly affect the rate of catheter-related complications.^{45,76} One 3-year retrospective review of all central catheters placed in the ED (supraclavicular SV, IJ, and femoral lines) reported a mechanical complication rate of 3.4%, or 22 of 643 lines placed.¹³⁰ Complications were defined as pneumothorax, hematoma, line misplacement, hemothorax, or any issue with the CVC (excluding infection or thrombosis) that required an inpatient consultation. In general, failure and complication rates increase as the number of percutaneous punctures increases. Historically, operator skill and experience have reliably predicted complication or success rates.^{45,76} It has previously been reported that clinicians who have placed more than 50 CVCs have less than half the complication rates of those who have fewer than 50 attempts.⁷⁶

Published complication rates vary in the literature and can now be classified according to whether ultrasound guidance was used during the procedure ([Table 22.4](#)).^{45,50} Studies have demonstrated that ultrasound-guided CVC placement techniques have improved success rates, reduced complication rates, and decreased time needed to perform the procedure.^{49–52}

BOX 22.2 Complications of Central Venous Access

General

Mechanical

Puncture of an adjacent artery
Hematoma formation
Air embolus
Pneumothorax
Pericardial tamponade
Catheter embolus
Arteriovenous fistula
Mural thrombus formation
Large-vein obstruction
Dysrhythmias
Catheter knotting
Catheter malposition

IJ, Internal jugular; SV, subclavian vein.

Infectious

Bloodstream infection
Generalized sepsis
Septic arthritis
Osteomyelitis
Cellulitis at the insertion site

Thrombotic

Pulmonary embolism
Venous thrombosis

SV and IJ Approaches

Pulmonary

Pneumothorax
Hemothorax
Hydrothorax
Chylothorax
Neck hematoma and tracheal obstruction
Endotracheal cuff perforation
Tracheal perforation

Neurologic

Phrenic nerve injury
Brachial plexus injury
Cerebral infarct

Femoral Approach Intraabdominal

Bowel perforation
Psoas abscess
Bladder perforation

TABLE 22.4 Frequency of Complications Without and With Ultrasound Guidance

COMPLICATION	Without Ultrasound			With Ultrasound
	IJ	SV	FEMORAL	IJ
Arterial puncture	6.3–9.4%	3.1–4.9%	9.0–15.0%	1.8%
Hematoma	<0.1–2.2%	1.2–2.1%	3.8–4.4%	0.4%
Hemothorax	0%	0.4–0.6%	NA	0%
Pneumothorax	<0.1–0.2%	1.5–3.1%	NA	0%
Infection (rate per 1000 catheter-days)	8.6	4	15.3	NA
Thrombosis (rate per 1000 catheter-days)	1.2–3	0–13	8–34	NA

IJ, Internal jugular; NA, not applicable; SV, subclavian vein.
Data from References 47, 78, and 129.

As a result, ultrasound guidance for CVC placement is recommended by the US Department of Health and Human Services. Reports by the AHRQ list ultrasound guidance for central vein cannulation as one of its most highly rated safety practices.^{60,131}

Mechanical Complications

The most commonly reported mechanical complications are arterial puncture, hematoma, and pneumothorax. Inadvertent arterial puncture and hematoma formation are usually easily recognized and controlled with simple compression. Rarely, an artery is lacerated to such an extent that bleeding is significant and operative repair is necessary. In cardiac arrest, low-flow, or shock states, arterial puncture may not be obvious, and arterial cannulation and intraarterial infusions have occurred. This can lead to the development of ischemia or thrombosis of the artery and limb. When systolic blood pressure rises, arterial pulsations become more obvious. In critically ill patients, however, this complication may escape detection for some time. It has been reported that ultrasound-guided placement of IJ CVCs decreases the rate of arterial puncture to 1.4%.⁵⁰

Though poorly studied, patients with coagulopathies may experience significant bleeding from CVC placement, especially if arterial puncture or laceration has occurred. Mumtaz and coworkers cited a 3% bleeding rate in coagulopathic patients who experienced only minor bleeding that could be controlled with digital pressure.⁴⁷ Although central venous access procedures may be performed safely in patients with bleeding disorders without antecedent correction of the coagulopathy, caution is strongly urged. Areas amenable to arterial compression are preferred in these patients.⁴⁷

Pneumothorax occurs in up to 6% of subclavian venipunctures and can also occur with the IJ approach^{45,76,132} (Fig. 22.22A). Initially, the importance of this complication was minimized, but reports of fatalities caused by tension pneumothorax, bilateral pneumothorax, and combined hemo-pneumothorax followed.⁵⁸ One would expect a higher incidence of pneumothorax if the procedure is performed during CPR or positive pressure ventilation. A small pneumothorax can quickly become a life-threatening tension pneumothorax with positive pressure ventilation. Treatment of a catheter-induced pneumothorax is controversial, but not all patients will require formal tube thoracostomy. Some authors have reported that many stable outpatients exhibiting a pneumothorax after insertion of a CVC can be managed successfully by observation alone (60% in one series) or catheter (pigtail/Heimlich valve) aspiration, with large tube thoracostomy being reserved for refractory cases or emergency settings.^{132,133} Critically ill patients or those undergoing mechanical ventilation are more likely to require invasive treatment for a catheter-induced pneumothorax.

Hemothorax may occur after laceration of the SV or subclavian artery, puncture of the pulmonary artery, or intrathoracic infusion of blood (see Fig. 22.22B). Hydrothorax occurs as a result of infusion of IV fluid into the pleural space. Hydromediastinum is also possible. These are rarely serious complications, but fatalities have been reported. Surgical repair is occasionally required. Arteriovenous fistula formation has also been reported.¹³⁴ Additional pulmonary complications include tracheal and endotracheal cuff perforation.

Air embolism is a very rare, but potentially life-threatening complication of central venous cannulation. Undoubtedly,

Figure 22.22 Pneumothorax and hemothorax. A chest radiograph should be taken routinely to assess the position of a central venous catheter introduced via the subclavian or internal jugular route. This confirms placement of the catheter. Chest radiography can also show potential complications of the procedure. **A**, Large right pneumothorax after right internal jugular catheterization. The catheter is still in place (*large arrow*), and the absence of lung markings on the right and the pleural reflection (*small arrows*) are readily apparent. **B**, Left hydro-pneumothorax after left subclavian venipuncture (the catheter was removed before this radiograph). Note the straight line of fluid (air-fluid level, *black arrows*) and no meniscus, indicating that a pneumothorax must also be present. The edge of the partially collapsed lung is difficult to appreciate. No clinician can place central venous catheters and fail to have at least some complications that are inherent to the procedure, regardless of even flawless technique.

minor and clinically inconsequential amounts of air enter the venous circulation during many cannulation procedures. Maintaining constant occlusion (with the operator's finger) on all needles that are located in central veins can minimize this occurrence. A 14-gauge needle can transmit 100 mL of air per second with a 5-cm H₂O pressure difference across the needle.⁹⁸ Air embolism may occur if the line is open to air during catheterization or if it subsequently becomes disconnected. The recommended treatment is to place the patient in the left lateral decubitus position to relieve air bubble occlusion of the right ventricular outflow tract.⁹⁸ If this is unsuccessful, aspiration with the catheter advanced into the

right ventricle has been advocated.⁹⁸ Emergency thoracotomy to aspirate air (see Chapter 18) and cardiothoracic surgical consultation may also be warranted.

Catheter or wire embolization resulting from shearing of a through-the-needle catheter by the tip of the needle is a serious and generally avoidable complication. Embolization can occur when the catheter or wire is withdrawn through the needle or if the guard is not properly secured. Adverse events after embolization include arrhythmias, venous thrombosis, endocarditis, myocardial perforation, and pulmonary embolism.⁷⁸ The mortality rate in patients who did not have these catheters removed has been reported to be as high as 60%.⁷⁸ Transvenous retrieval techniques by interventional radiology are usually attempted, followed by open surgery if unsuccessful.⁷⁸ Entire guidewires may also embolize to the general circulation if the tip is not constantly secured by the operator throughout the procedure. Initiatives by national safety bodies such as the National Quality Forum in the United States have focused on reducing the incidence of retained wires by classifying them as “never” events that require mandatory reporting in many states.

Delayed perforation of the myocardium is a rare, but generally fatal complication of central venous catheterization by any route.¹³⁵ The presumed mechanism is prolonged contact of the rigid catheter with the beating myocardium. The catheter perforates the myocardial wall and causes tamponade either by bleeding from the involved chamber or by infusion of IV fluid into the pericardium. The right atrium is involved more commonly than the right ventricle.⁹⁸ All clinicians who insert such catheters or care for such patients should be aware of this deadly complication, which results in profound deterioration with hypotension, shortness of breath, and shock. Emergency echocardiography, pericardiocentesis, and operative intervention by a thoracic surgeon may all be required for salvage of the patient. This can also occur with misplacement of the CVC in the pericardiophrenic vein.^{136,137} Fortunately, this complication is preventable by using a postinsertion chest film to confirm the position of the tip of the catheter and retracting the catheter if the tip is within the cardiac silhouette.

Catheter knotting or kinking may occur if the catheter is forced or repositioned or if an excessively long catheter is used.¹³⁶⁻¹³⁸ The most common result of kinking is poor flow of IV fluids, although rare complications as severe as SVC obstruction have been seen.¹³⁶⁻¹³⁸

Thoracic duct laceration is a frequently discussed complication of left-sided subclavian venipuncture; however, it is extremely uncommon and has been reported only as a complication of IJ vein, not SV, cannulation.

Neurologic complications are extremely rare and presumably caused by direct trauma from the needle during venipuncture. Brachial plexus palsy and phrenic nerve injury with paralysis of the hemidiaphragm have been reported.^{139,140} Infusing hypertonic medications into the IJ vein via a malpositioned catheter may result in a variety of neurologic complications from retrograde perfusion of intracranial vessels.¹⁴¹ Again, this complication can be easily avoided by inspecting a postprocedure x-ray to confirm proper placement prior to utilization of a newly placed catheter.

Infectious Complications

Infectious complications include local cellulitis, thrombophlebitis, generalized septicemia, osteomyelitis, and septic arthritis.⁵⁷

The incidence of septic complications varies from 0% to 25%.^{73,142} The frequency with which infectious complications occur is directly related to the attention given to aseptic technique during insertion and aftercare of the catheter. Femoral venous catheterization carries a greater risk for infection than subclavian catheterization. Merrer and associates reported the overall infectious complication rate from femoral and subclavian catheters to be 19.8% and 4.5%, respectively.¹³⁵ Ultrasound-guided IJ CVC placement has resulted in a decrease in the rates of CLABSI.⁵² The exact mechanism by which ultrasound-guided CVC placement results in a lower risk for infection is unclear; it may be related to a reduced number of skin punctures. Organisms most commonly recovered from colonized femoral catheters are coagulase-negative staphylococci, Enterobacteriaceae, *Enterococcus* species, and *Pseudomonas aeruginosa*.¹³⁵

CVCs cause an estimated 80,000 CLABSI and are implicated in up to 28,000 deaths per year in patients in the intensive care unit.⁶³⁻⁶⁵ The average cost has been estimated at \$2.3 billion annually.⁶³⁻⁶⁵ The Centers for Disease Control and Prevention has recommended that central line bundling policies should be implemented to significantly decrease the incidence of CLABSI.^{64,65} This bundling policy includes five evidence-based interventions: (1) hand washing, (2) maximal barrier precautions, (3) chlorhexidine skin antisepsis, (4) optimal catheter site selection with avoidance of the femoral vein if possible, and (5) daily review of the necessity for the line and prompt removal of unnecessary lines.⁶⁶

Thrombotic Complications

Thrombosis and thrombophlebitis are significant risks associated with placement of a CVC. The risk for catheter-related thrombosis is directly related to the site of access. In one trial, catheter-related thrombosis was reported in up to 21.5% of patients with femoral CVCs and in 1.9% of patients with SV CVCs. For SV and IJ CVCs, it is important to determine that the tip of the catheter rests in the SVC, especially during the infusion of irritating or hypertonic solutions.¹³⁵ Thrombi may form secondary to prolonged contact of the catheter against the vascular endothelium. One autopsy study found a 29% incidence of mural thrombi in the innominate vein, SVC, and right ventricle of patients who had central lines in place an average of 8 days before death.⁶⁸ The clinical importance of these thrombi remains unclear; however, any thrombosis has the potential to embolize. Moreover, catheter-related thrombosis is a cause of SVC obstruction syndrome.¹⁴³

Subclavian Approaches

Although both approaches to the SV are relatively safe, the infraclavicular SV approach is more likely to be associated with complications. In a randomized, prospective comparison of supraclavicular SV and infraclavicular SV puncture in 500 ED patients, complication rates were 2.0% and 5.1%, respectively.¹⁴⁴ The most significant complications are pneumothorax and puncture of the subclavian artery; the highest reported incidence of pneumothorax is 2.4%.^{18,69,144} Adherence to the techniques recommended for supraclavicular SV puncture decreases the risk for these complications because the needle is directed away from the pleural dome and subclavian artery. The relatively superficial location of the vein when approached from above the clavicle (1.5 to 3.5 cm) lessens the risk for puncture or laceration of deep structures.

IJ Approach

Many complications of IJ vein cannulation are similar to those of SV access. The incidence of complications appears to be higher with use of the left IJ vein than with the right.¹⁶ One common complication unique to the IJ approach is a localized hematoma in the neck.¹⁴⁵ With the IJ approach, pressure can easily be maintained on the area of swelling, and most hematomas will resolve spontaneously. If puncture of the carotid artery is recognized and treated with compression, it rarely causes significant morbidity in the absence of marked atherosclerotic disease, although arteriovenous fistulas may occur after IJ vein puncture.¹³⁴ Several neurologic complications unique to the IJ site of venipuncture have also been reported as a result of hematomas or direct injury. Such complications include damage to the phrenic nerves, iatrogenic Horner's syndrome, trauma to the brachial plexus, and even passage of a catheter into the thecal space of the spinal canal.¹⁴¹ If the carotid artery is punctured, one may again attempt IJ vein or SV cannulation on the same side after appropriate, prolonged (15- to 20-minute) compression. The IJ vein valve is frequently damaged when cannulated, which often results in incompetence of the valve. The clinical significance of this, if any, is unknown.¹⁴⁶

Femoral Approach

Because vital structures in the neck and chest are not at risk, complications of femoral vein cannulation are generally less severe than those of other routes for central venous access. The most common immediate complications involve bleeding from damage to either the femoral artery or the femoral vein (Fig. 22.23). This can usually be managed with 10 to 15 minutes of direct pressure. Extra care should be taken in anticoagulated patients or after the administration of thrombolytic agents. In extreme cases when hemostasis cannot be achieved through direct pressure, a vascular surgeon should be consulted.

The peritoneum can also be violated with resultant perforation of the bowel. Bowel penetration is especially likely if the patient has a femoral hernia. Injury to the bowel is usually minimal and unlikely to require specific treatment. Nonetheless, the potential bacterial contamination of the femoral puncture site can pose a significant problem. Aspiration of air during placement of a femoral line necessitates removal of the catheter and reinsertion at another site. Other complications include muscular abscesses, infection of the hip joint, damage to the femoral nerve, and puncture of the bladder. Risk for these outcomes can be mitigated by strict aseptic technique, thorough assessment of landmarks, careful control of the needle's depth, and the use of bedside ultrasound.

Two more complications merit special mention. The first is the increased risk for catheter infection. Presumably caused by anatomic association with the anogenital region, many studies have found that femoral lines become infected at significantly higher rates than IJ vein or supraclavicular SV lines do.^{64,65,68,135} Of note, some studies have failed to find a statistical difference, and it is unclear how much of the effect is due to the actual location of the line versus how it is placed and managed. The second is the incidence of deep vein thrombosis that is also

Figure 22.23 A femoral vein catheter is more prone to deep vein thrombosis and infection than a subclavian or internal jugular line, but it is a standard access route in the emergency department. Strict attention to sterile technique and limiting use to a few days will negate most of the negatives of this approach. **A**, Significant hemorrhage can occur after puncture of the femoral artery, but this area is readily compressed. The femoral route may be the approach of choice in a patient with an inadvertently placed arterial catheter who requires a central line. **B**, Bleeding from an inadvertently placed arterial catheter that was removed without adequate pressure in an anticoagulated patient.

increased in lines placed via the femoral route, which has been shown in the majority of studies,^{135,147} although the clinical significance of these clots has not been definitively addressed.

TRAINING AND SIMULATION

CVC placement and ultrasound guidance techniques have a relatively steep learning curve. Simulation is recommended by the AHRQ to teach these techniques.^{60,131} Simulation training is independently associated with higher rates of correct needle insertion on the first attempt, as well as with higher successful CVC placement rates.^{131,148,149} There are many simulation models that can be used. Kendall and Faragher described a phantom model as an easy, inexpensive method for ultrasound-guided CVC placement training.¹⁵⁰

Venous Cutdown

Veronica Vasquez and Pablo F. Aguilera

Management of critically ill or injured patients requires immediate and adequate vascular access, especially during trauma resuscitation, when rapid infusion of crystalloid or blood products may be necessary. Venous cutdown, a time-honored surgical technique, has largely been replaced by alternative methods of obtaining venous access, including intraosseous lines, the Seldinger technique, and ultrasound-guided central and peripheral venous cannulation.¹ Nonetheless, venous cutdown still has a role as an emergency method of achieving vascular access when other techniques and equipment are unavailable, particularly in settings outside the United States.

First described by Keeley in 1940 and Kirkham in 1945,^{2,3} venous cutdown offered an alternative to venipuncture in patients with shock. Though no longer taught as a mandatory procedure in the Advanced Trauma Life Support course, venous cutdown is considered optional and continues to be taught at the discretion of the instructor.⁴ Realistically, percutaneous vascular access may be infeasible in a pulseless, hypovolemic, or anatomically scarred patient. With a thorough understanding

of the anatomy, the procedure, and its potential complications, this mechanically simple procedure can be performed quickly and effectively.⁵

INDICATIONS

Venous cutdown may be used as an alternative to venipuncture for critical patients in need of vascular access when less invasive options have been exhausted or are not available. Patients with severe shock, asystole, or pulseless electrical activity will lack palpable femoral pulses, thus making percutaneous femoral vein catheterization more difficult. Surface landmarks may be obscured and veins may be unusable in intravenous (IV) drug users, the extensively injured, or severely burned patients. Attempts at percutaneous venous cannulation may be complicated or even impossible in such patients. Venous cutdown (Video 23.1) and intraosseous routes (see Chapter 25) are both viable options in such scenarios.

Children

Venipuncture in small children poses a challenge in even the healthiest of patients, let alone those in extremis whose veins may be poorly visualized. Central vein catheterization, intraosseous line placement, or venous cutdown should be considered as an alternative means of emergency vascular access when other peripheral sites have been exhausted. The distal saphenous vein at the ankle is often recommended for venous cutdown in children given its large diameter and anatomic predictability at this location.^{6,7}

Venous Cutdown

Indications

As an alternative to venipuncture in critically ill patients in need of vascular access and in whom venipuncture may be difficult:

- Shock
- Asystole or pulseless electrical activity
- Sclerosed veins of intravenous drug abusers
- Extensive burn or other injury
- Small children

Contraindications

Absolute:

- When less invasive options exist for venous access
- Major blunt or penetrating trauma at proposed cutdown site

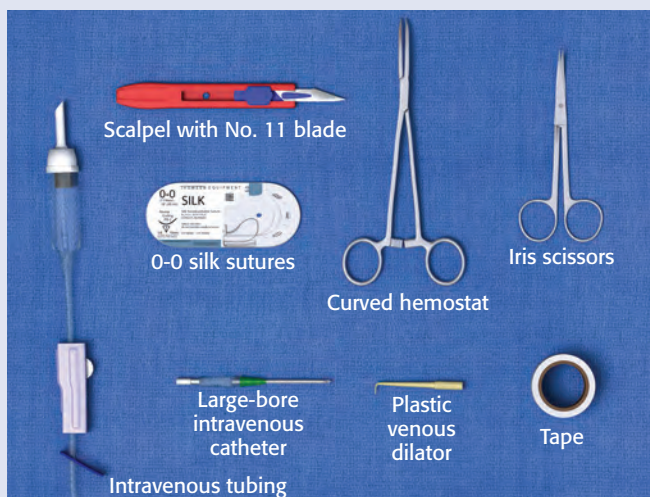

Relative:

- Overlying soft tissue infection
- Bleeding diathesis
- Immunocompromise
- Extremity injuries proximal to the site

Complications

- | | |
|---------------------------|----------------------------------|
| Transection of the vein | Phlebitis |
| Transection of the artery | Sepsis |
| Bleeding | Thrombus formation |
| Hematoma | Injury to surrounding structures |

Equipment

Review Box 23.1 Venous cutdown: indications, contraindications, complications, and equipment.

Hypovolemic Shock

Initially popularized during the Vietnam War for rapid transfusion, venous cutdown has since been used for resuscitation of patients with profound hypovolemia.^{8,9} The flow rate of saline through a standard IV extension set cut to a length of 28 cm (12 inches) and inserted directly into the vein is 15% to 30% greater than through a 5-cm, 14-gauge catheter. This difference is larger if pressure is applied to the system. Moreover, the improvement in flow rate through large-bore lines is greater for blood than for crystalloid solutions because the viscous characteristics of blood impede its passage through small-bore tubing.⁹ A unit of blood can be transfused in as little as 3 minutes through IV extension tubing inserted directly into the vein. Consequently, large-bore lines placed by venous cutdown are an excellent mechanism for the treatment of severe hypovolemia.

CONTRAINDICATIONS

Venous cutdown is contraindicated when less invasive alternatives exist and when performing the procedure would cause excessive delay.¹⁰ Highly skilled clinicians may perform a cutdown in less than 60 seconds.¹¹ However, multiple studies by Westfall,¹² Rhee,¹³ Iserson,¹⁴ and their colleagues have indicated that on average, the procedure takes at least 5 to 6 minutes to complete. Use of the modified Seldinger technique described both by Shockley and Butzier, and by Klofas, has been shown to decrease that time by 22%.^{15,16} In general, the use of percutaneously inserted central venous catheters in either the subclavian, internal jugular, or femoral vein is preferable to a cutdown.

Absolute contraindications include major blunt or penetrating trauma involving the extremity on which the procedure is to be performed.¹⁷ Relative contraindications include vascular injury proximal to the cutdown site, overlying soft tissue infection, coagulopathies, compromised host defense mechanisms, and impaired wound healing. Other considerations include any previous saphenous vein harvest for coronary artery bypass or other vascular surgery proximal to the anticipated cutdown site.¹⁸ The indications for venous cutdown should be weighed against the potential complications.

ANATOMY AND SELECTION OF THE SITE

Knowledge of the relevant anatomy is imperative for success. Veins in both the upper and lower extremities may be used. The size and accessibility of the target vessel, along with the clinician's experience and training, are the principal factors in selection of the site. There are four primary locations at which venous cutdown is performed: the great saphenous vein distally at the ankle and proximally at the thigh, the basilic vein above the elbow, and the cephalic vein below it. Brachial vein cutdown is no longer recommended as an emergency venous access route because of its time-consuming dissection and risk for neurovascular injury. The anatomy of individual vessels and their relative merits as cutdown sites are described in the following sections.

The Great Saphenous Vein

The great saphenous vein is the longest vein in the body, and it runs subcutaneously throughout much of its course

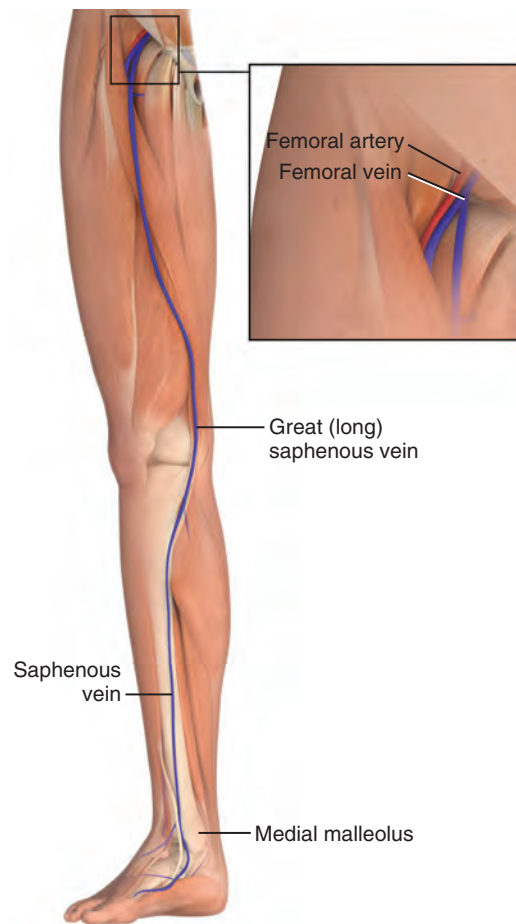

Figure 23.1 Superficial veins of the lower limb.

(Fig. 23.1). It is most easily accessible at the ankle but may also be cannulated below the knee and below the femoral triangle. The great saphenous vein begins just anterior to the medial malleolus where it is a continuation of the medial marginal vein of the foot. The vein crosses 1 cm anterior to the medial malleolus and, together with the saphenous nerve, ascends along the anteromedial aspect of the leg.^{19,20} The saphenous nerve at this level is of relatively little clinical significance, for if transected, it causes sensory loss in only a small area along the medial aspect of the foot. At the ankle, the vessel can be exposed with minimal blunt dissection. The vein's superficial, predictable, and isolated location has made the distal saphenous vein the traditional pediatric cutdown site.¹⁹

At the knee, the saphenous vein lies superficially and medially. A cutdown performed 1 to 4 cm below the knee and immediately posterior to the tibia has been described in the pediatric literature.⁶ This site is seldom used, however, because of its many disadvantages, including kinking of the line as the knee is flexed, and risk for injury to the saphenous branch of the genicular artery and the saphenous nerve.²¹ Of note, the great saphenous vein is duplicated in the calf in 25% of the population and may be present on exploration.²²

In the thigh, the saphenous vein begins on the medial aspect of the knee and crosses anterolaterally as it ascends toward the femoral triangle. Approximately 4 cm below the inguinal ligament and 3 cm lateral to the pubic tubercle, the saphenous

Figure 23.2 Subcutaneous dissection in the proximal part of the thigh. The saphenous vein is easily distinguished from surrounding fat with blunt dissection. The hemostat is under the vein. (Courtesy Pablo Aguilera, MD, Hospital Dr. Sótero del Río, Santiago, Chile.)

vein dips through the fossa ovalis, where it penetrates the femoral sheath and joins the femoral vein. The saphenous vein is easily isolated from the surrounding fat at this site because of its large caliber (4 to 5 mm in outside diameter) and superficial relationship to the femoral sheath (Fig. 23.2). Also lying anteromedially in the thigh is the lateral femoral cutaneous vein, which has a smaller diameter and lies lateral to the great saphenous vein.²⁰ The saphenous vein at the thigh is a preferred site for cutdown given its large diameter and ease of accessibility. An 8.5-Fr catheter is easily introduced at this level and is ideal for rapid infusion of crystalloid or blood during resuscitation.¹⁷

The Basilic Vein

The basilic vein is a preferred site for venous cutdown in the upper extremity because of its predictable anatomic location. The size of this vein enables it to be located easily, even in hypotensive or hypovolemic patients. Superficially at this level there are no important associated structures, but the brachial artery and the median nerve are found deep to the basilic vein.

Veins of the dorsal venous network of the hand unite to form the cephalic and basilic veins, which travel along the radial and ulnar sides of the forearm, respectively (Fig. 23.3). At the midforearm level, the basilic vein crosses anterolaterally and then courses ventrally at the medial epicondyle. The medial cubital vein crosses over from the radial side of the arm to join the basilic vein just above the medial epicondyle. The basilic vein then continues proximally, where it occupies a superficial position between the biceps and pronator teres muscle. In this segment it lies in close proximity to the medial cutaneous nerve, which supplies sensation to the ulnar side of the forearm. At approximately midway in the upper part of the arm, the basilic vein perforates the deep fascia, where it joins the brachial vein and continues on into the axillary vein.²⁰

The basilic vein is consistently found at the antecubital fossa, 2 cm above and 2 to 3 cm lateral to the medial epicondyle, on the anterior surface of the upper part of the arm. It is exposed through a transverse incision on the medial aspect of

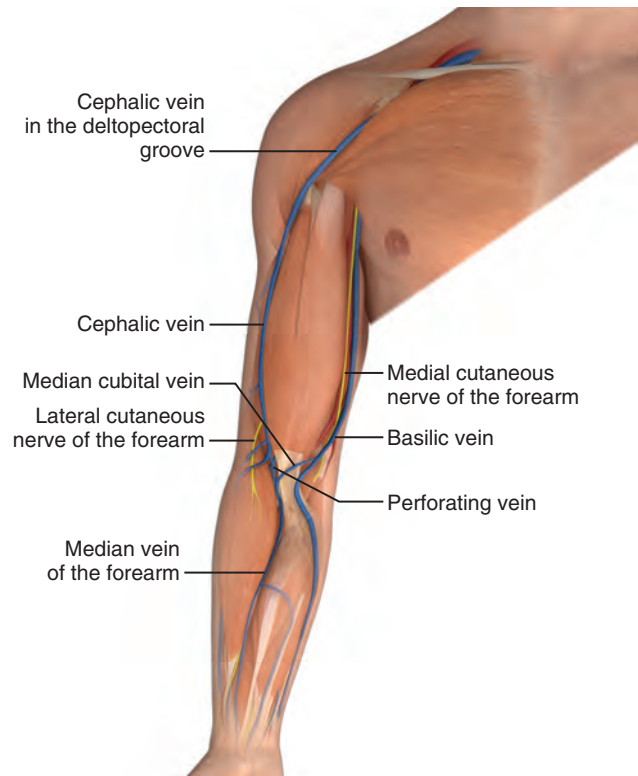

Figure 23.3 Veins of the upper limb.

the proximal antecubital fossa. It is this predictability in anatomic location that makes the basilic vein an ideal site for venous cutdown in the upper extremity.

A more proximal cutdown site had previously been recommended to avoid the network of interconnecting veins at the level of the antecubital fossa.²³ However, a closer association between the basilic vein and the medial cutaneous nerve in this segment may result in transection of the nerve and subsequent sensory loss on the ulnar side of the forearm.

The Cephalic Vein

This cephalic vein begins on the radial aspect of the wrist, crosses anteromedially, and ascends toward the antecubital fossa. In the forearm, it lies in close association with the lateral cutaneous nerve, which supplies sensory innervation to the radial aspect of the forearm (see Fig. 23.3). In the antecubital fossa, it lies subcutaneously and just lateral to the midline. It is at this level where the median cubital vein connects to the cephalic and basilic veins. The cephalic vein then ascends in the upper part of the arm over the lateral aspect of the biceps muscle and through the deltopectoral groove. Just below the clavicle, it pierces the clavipectoral fascia, becomes a deep structure, and enters the axillary vein.²⁰

Venous cutdown is easily performed on the cephalic vein because of its large diameter and superficial location. In the forearm, it is important to avoid the lateral cutaneous nerve. A preferred location is in the antecubital fossa at the distal flexor crease. Cutdown on the cephalic vein at the wrist has also been reported, but the thin skin overlying the vein at this level usually permits simple percutaneous cannulation when the vein is available for cannulation.²⁴ The cephalic vein may also be entered in the deltopectoral groove. However, the

slightly deeper position and possible interference with the performance of other procedures make this approach more difficult.

EQUIPMENT

The material required to perform a formal venous cutdown is shown in [Review Box 23.1](#). Perhaps the most important piece of equipment and the most difficult to find is the vein dilator/lifter, a plastic device with a 90-degree angle that is used to facilitate entrance of a catheter into the cut vein. For pediatric patients, use a warming table, or radiant warmer, and a padded extremity board.

Choose a catheter based on the desired function of the venous line. When central venous pressure (CVP) needs to be monitored, choose a catheter long enough to reach the superior vena cava. Approximate this distance by aligning the catheter over the chest with the tip at the level of the manubrial-sternal junction. The average distance from the antecubital fossa to the superior vena cava is 54 cm in adult men. Lumen size is relatively unimportant when the line is inserted for monitoring CVP or to infuse drugs, but it is a critical factor in the treatment of hypovolemia. Short, large-bore catheters are preferred when fluid must be delivered rapidly. Silastic catheters, IV plastic tubing, or 5- or 8-Fr pediatric feeding tubes may be used as infusion catheters in older children and adults.

[Tables 23.1 to 23.3](#) list the flow rates of various fluids through some commonly used catheter systems. It is essential to know the relative flow rates if maximal benefit is to be obtained from the time spent performing the cutdown. Excellent flow rates can be achieved by threading IV tubing directly into the vein or by using a 5-cm, 10-gauge IV catheter. Cut sterile tubing to the appropriate length and leave a slight bevel on the end to facilitate cannulation of the opened vein.^{11,25}

TECHNIQUE

The technique of venous cutdown is essentially the same regardless of the vessel cannulated ([Fig. 23.4](#)). Prepare the skin around the incisional area with an antiseptic solution and then cover it with sterile drapes. Place a tourniquet proximal to the cutdown site to help visualize the vein. For children, immobilize the lower part of the leg or elbow (depending on the cutdown site) on a padded board before beginning the procedure.

In conscious patients, apply a local anesthetic before the procedure. Make a skin incision perpendicular to the course of the vein. A longitudinal incision, even though it decreases the risk of transecting neurovascular structures, may not provide sufficient exposure. Incise the skin through all its layers until subcutaneous fat bulges through the incision. Very carefully dissect the subcutaneous tissues bluntly by spreading them gently with a curved hemostat parallel to the course of the vein and with the tips pointed downward. This is the most difficult and delicate portion of the procedure and may damage the vein and render it unable to be cannulated. Bleeding, however, is usually minimal unless the vein is nicked. Use a tissue spreader or a self-retaining retractor, if needed, to provide a wider field. Isolate the vein from the adjacent tissue and mobilize it for 1 to 3 cm.

For the standard venous cutdown technique, after mobilizing the vein, use a hemostat to pass proximal and distal silk ties under the vein for stabilization ([Fig. 23.5](#)).

Tie the distal ligature after initial placement, but leave the ends long for maneuvering the vein. As an option, use traction on the distal suture to control the vein, but do not tie it off. If the distal suture is tied, the vein will be sacrificed for future use. Leave the proximal ligature untied to maneuver the vein for insertion of the catheter or tubing and control of backbleeding (by lifting the sutures). Elevate the vein with a hemostat and stretch it flat. This provides good visualization, controls the vessel, and limits bleeding when the vessel is incised. Alternatively, place gentle traction on the proximal tie to control oozing around the puncture site. Using a No. 11 scalpel blade or a pair of iris scissors, incise through one third to one half the diameter of the vein at a 45-degree angle. If the incision is too small, the catheter may pass into a false channel in the adventitia. Conversely, if the incision is too large, the vein may tear completely and retract from the field buried within tissue.²⁶ If desired, make a longitudinal incision in the vein to avoid transecting the vessel, but realize that this technique makes it more difficult to identify the lumen. Be aware that some bleeding will normally occur after the vein has merely been nicked on the surface. To perform a mini-cutdown at this point, puncture the vein with an IV catheter and introducer needle and do not make an incision in the vein.

Before introducing the cannula into the vein, make a bevel in the cannula at a 45-degree angle. This is unnecessary if the cannula has a tapered tip. Make the bevel short, but be careful to not make it sharp to avoid piercing the posterior wall or otherwise damaging the vein. If using the rounded tip of a feeding tube, it may be more difficult to introduce but can be advanced less traumatically. If using an IV cannula, introduce it directly through the skin incision or through a separate stab incision.

Threading the catheter into the vein is often the most difficult and time-consuming portion of the procedure. Difficulty threading has several causes. The lumen may have been incorrectly identified, or a false passage into the adventitia may have been created. This can be difficult to recognize because a catheter can easily pass between layers of the vessel wall and never reach the lumen of the vein. Other causes include penetrating the posterior vessel wall, getting stuck in a valve, or using a catheter that is too large to cannulate the vein.

Use of a plastic venous dilator can help identify and elevate the vessel lumen. Thread the small, pointed tip of the dilator into the vein to expose the lumen before advancing the tip of

Venous Cutdown

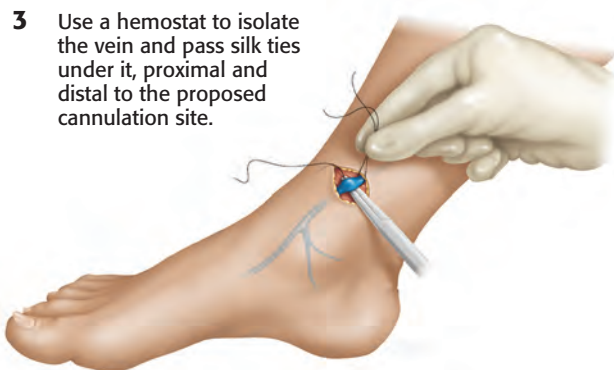

- 1** After applying a tourniquet and cleansing the skin, make a skin incision perpendicular to the course of the vein.

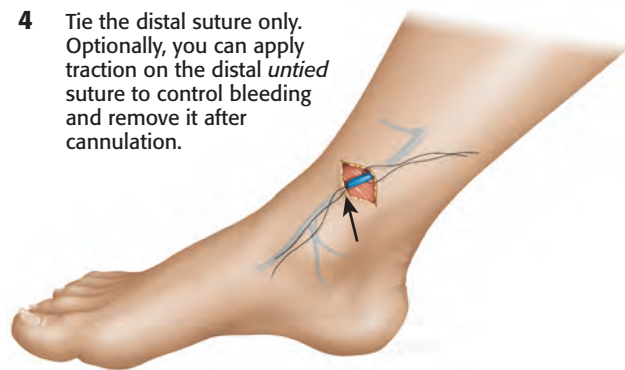

- 2** Bluntly dissect, isolate, and mobilize the vein.

- 3** Use a hemostat to isolate the vein and pass silk ties under it, proximal and distal to the proposed cannulation site.

- 4** Tie the distal suture only. Optionally, you can apply traction on the distal *untied* suture to control bleeding and remove it after cannulation.

- 5** Incise the vein while retracting the proximal ligature. Lift the proximal untied suture to control backbleeding.

- 6** Use the venous dilator to lift the flap and then advance the catheter into the vein. Attach intravenous tubing to the catheter.

- 7** Tie the proximal silk suture around the vein and catheter. Remove the proximal suture and suture the skin. If the distal suture has not been tied, remove it before suturing the skin.

Figure 23.4 Venous cutdown. (Adapted from Custalow CB: *Color atlas of emergency department procedures*, Philadelphia, 2005, Saunders.)

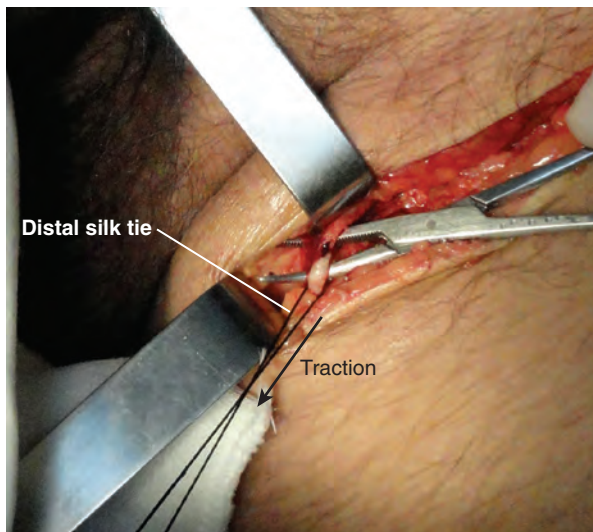

Figure 23.5 With the assistance of a hemostat, proximal and distal silk ties may be placed under the vein for stabilization. Above, a distal tie is placed under the great saphenous vein at the thigh to aid in stabilizing the vein during cannulation. Traction on this suture will occlude blood flow and minimize bleeding during catheterization of the vein. Traction on the proximal suture will also control backbleeding (proximal suture not shown here). Note that a small incision has been made in the vein to accept a catheter, but traction (*arrow*) on the distal suture prevents bleeding. Once the catheter is in place, the distal suture is usually tied. (Courtesy Pablo Aguilera, MD, Hospital Dr. Sótero del Río, Santiago, Chile.)

Figure 23.6 Advancement of the standard intravenous catheter under direct vision through the great saphenous vein at the thigh. The distal suture is tied, thereby sacrificing the vein for further use. The proximal suture is not yet secured around the catheter. (Courtesy Pablo Aguilera, MD, Hospital Dr. Sótero del Río, Santiago, Chile.)

the catheter. Alternatively, bend a sterile 20-gauge needle at a 90-degree angle to serve as a venous dilator or elevator. A vein dilator is useful for very small veins, such as in pediatric cutdowns, but is generally unnecessary in adults. To thread large catheters in adults, grasp the proximal edge of the vessel with small forceps or a mosquito hemostat. Apply countertraction and advance the catheter (Fig. 23.6). Never force a catheter that will not advance easily.

Once the catheter is advanced into the lumen, backbleed any air from the cannula and connect it to IV tubing. Tie the proximal ligature around both the vessel and the cannula (Fig. 23.7). If the distal suture has not been tied, remove it. If it has been tied, cut the ends of the suture near the knot. Remove the tourniquet, affix the catheter to the skin, and close the incision. Apply antibiotic ointment at the point where the catheter passes through the skin, and dress the wound. In an emergency situation one may delay skin closure if necessary and simply wrap the wound with sterile dressing. Loop the IV tubing under the outer layers of the dressing to minimize the risk of pulling the cannula out if the external IV line is inadvertently tugged.

Mini-Cutdown

The mini-cutdown is an alternative method designed to preserve the vein and bypass the time-consuming step of inserting a catheter into the vein.²⁷ It is preferred if time is limited. Basically, a deep vein is cannulated through an incision under direct vision with a standard peripheral IV catheter. Use a skin incision and blunt dissection to locate the vessel. Once identified, puncture the vein under direct vision with a percutaneous

Figure 23.7 Once the catheter is inserted into the lumen of the vein, tie the proximal ligature around both the vessel and the cannula. (Courtesy Pablo Aguilera, MD, Hospital Dr. Sótero del Río, Santiago, Chile.)

venous catheter. Introduce the needle through either the skin incision or a separate stab incision. If an over-the-needle device (e.g., Angiocath [Becton Dickinson, Franklin Lakes, NJ], Medicut [Medtronic, Minneapolis, MN]) is used, withdraw the needle and discard it. With a through-the-needle device,

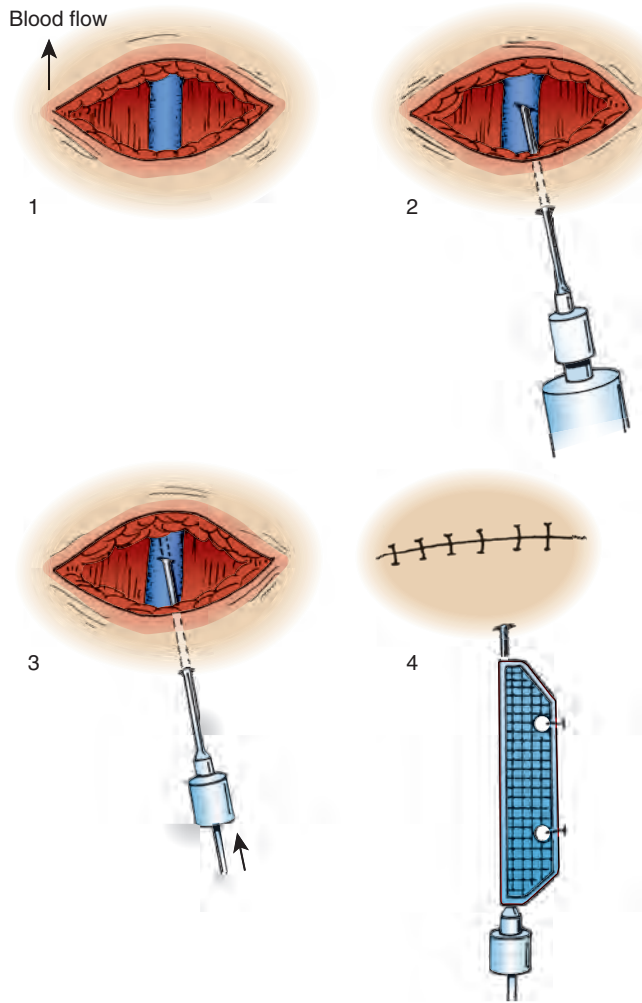

Figure 23.8 The mini-cutdown technique is an alternative to the venous cutdown method. The vein is cannulated under direct vision with standard percutaneous catheters. A separate entry site (shown) may be used, or the vein can be cannulated through the skin incision. Note that the vein is not tied off with this technique. A standard Angiocath (Becton Dickinson) intravenous set may also be used instead of the through-the-needle catheter shown here.

thread the cannula into the vein and withdraw the needle to the surface of the skin (Fig. 23.8). Place a guard on the tip of the needle, fix the catheter device to the skin, and close the incision. This method eliminates the need for tying or cutting the vein, thereby permitting repeated catheterization. Venipuncture is easier and uses the same equipment as percutaneous venous cannulation. A simple skin incision may also permit direct visualization of veins in an obese patient and facilitate standard percutaneous venipuncture.

Hansbrough and associates described a mini-cutdown procedure with a 10-gauge IV catheter (Deseret 10-gauge Angiocath [Deseret Medical, Salt Lake City, UT]).²⁵ Flow rates of blood and saline with this catheter are equal to those obtained when IV extension tubing is placed in a vein via the more time-consuming standard venous cutdown technique. This catheter allows one to infuse a unit of whole blood in 2 to 3 minutes if high pressure and oversized IV tubing are used.

Modified Cutdown Technique

Shockley and Butzier described a further modification in which a guidewire, dilator, and sheath system is inserted after standard cutdown and venotomy.¹⁵ To perform this modification set up the guidewire, dilator, and sheath system before making the skin incision. Once the vein has been incised, insert the end of the guidewire followed by the dilator and sheath. Remove the wire and dilator while leaving the sheath. Ligatures are not usually needed with this technique. These authors found that when performed by novices, this technique saved more than 2 minutes in comparison to the standard technique. Moreover, in the event of a transection, there was an increased vein salvage rate. Klofas used a similar technique at the distal saphenous vein.¹⁶ He also developed a model for teaching the modified technique with wood, gauze, cast padding, and tape.

To remove catheters inserted by cutdown, cut the skin stitches holding the catheter in place and then withdraw the catheter. Control backbleeding from the proximal venous end by applying a simple pressure dressing.

COMPLICATIONS

Complications of venous cutdown include: local hematoma, infection, sepsis, phlebitis, embolization, wound dehiscence, and injury to associated structures. An indirect but significant complication is deterioration of an unstable patient during a time-consuming attempt at cutdown. Documentation of complications and their frequency in the literature has been sparse. Bogen reported a 15% complication rate in 234 cases.²⁸ Infection and phlebitis each occurred at a rate of 4%. Infectious complications may result from the introduction of pathogens during placement of the line, transcutaneous invasion along the course of the cannula, or deposition of blood-borne organisms on the tip of the catheter.²⁹ A clear correlation exists between the incidence of infectious complications and the length of time that a catheter is left in place. Moran and colleagues found that the infection rate rose from 50% to 78% when a catheter was left in place for more than 48 hours.³⁰ Druskin and Siegel,²⁹ studying a mixed population of patients who had undergone cutdown and others who had catheters inserted percutaneously, found that the incidence of culture-positive catheter tips rose from 0% to 52% after 48 hours.²⁹ In the study by Moran and coworkers,³⁰ *Staphylococcus albus* was the predominant organism that was isolated, but organisms more commonly thought of as pathogenic (*Staphylococcus aureus*, *Enterococcus* spp, and *Proteus* spp) were isolated with greater frequency from cutdowns that had been in place for long periods. Rhee and coauthors reported a 1.4% infection rate and one episode of cellulitis after 73 cutdown attempts.¹³ All catheters were removed within 24 hours.

Some evidence indicates that the rate of infectious complications decreases when a broad-spectrum topical antibiotic ointment is applied to the cutdown site. Moran and colleagues found an infectious complication rate of 18% when topical polymyxin B–neomycin–bacitracin (Neosporin) was used as opposed to a 78% rate in a placebo-treated group.³⁰ In this study, topical antibiotic use resulted in only a moderate decrease (from 53% to 37%) in the incidence of phlebitis, but a significant decrease (from 86% to 14%) in the incidence of phlebitis associated with positive cultures. This suggests that phlebitis is often a chemical or an irritative process rather than the

result of infection. Whatever the cause, the incidence of phlebitis is clearly related to the duration of catheterization.^{8,28,31} Early catheter removal is a key factor in the prevention of both phlebitis and the infectious complications of venous cutdown. This is especially true of lines inserted during emergency resuscitative treatment. Such lines should be removed as soon as the patient's condition permits and alternative access routes are in place.^{9,10}

Proper attention to details of the surgical technique will limit the occurrence of minor complications such as local hematoma, abscess, and wound dehiscence. One can avoid injury to associated structures by selecting a site where the

vein is well isolated, and the physician feels most comfortable performing the procedure.

ACKNOWLEDGMENT

The authors and editors wish to sincerely thank Patricia Lanter and Justin Williams for their contributions to this chapter in previous editions.

Indwelling Vascular Access Devices: Emergency Access and Management

Scott H. Witt, Christine M. Carr, and Diann M. Krywko

Indwelling vascular access devices (IVADs) provide routes for short- and long-term infusion of antibiotics, antifungal agents, hyperalimentation fluids, chemotherapeutic agents, blood products, analgesics, and anesthetic agents. In addition, they provide access for lifesaving procedures such as hemodialysis (HD) and plasmapheresis. As of 2013, nearly 422,000 patients were receiving HD therapy, with 3 to 5 million central venous catheters being placed yearly in patients in the United States.^{1,2} For the purpose of this chapter, all implanted devices and intermediate- to long-term catheters for vascular access are considered IVADs. Arteriovenous (AV) fistulas and AV grafts are included because of their similarities to IVADs.

HISTORICAL PERSPECTIVE

A major advance that ultimately led to the development of several types of indwelling catheters was the introduction of Silastic (polymerized silicone rubber) in 1948 by the Dow Corning Corporation. This biocompatible material is an ideal substrate for intravenous (IV) catheters because it is chemically inert, antithrombogenic, rigid at room temperature, and pliable at body temperature. In 1973, Broviac and coworkers used this material to develop an indwelling right atrial (RA) catheter for total parenteral nutrition (TPN).³ In 1979, Hickman and colleagues reported their experience with a catheter that could be used for blood products and drug therapy in bone marrow transplant recipients.⁴ A totally implantable vascular access device (TIVAD) was described by Fortner and Pahnke in 1976.⁵ Since that time, TIVADs have become a mainstay of treatment in oncology patients, improving quality of life by allowing less painful IV access and permitting unrestricted mobility.

Temporary access for HD via an external AV shunt was pioneered by both Quinton and Scribner and their coworkers in 1960.^{6,7} This original shunt was composed of a loop of tubing lying on the volar aspect of the forearm that connected the radial artery to a wrist vein. Although it provided effective dialysis, it was associated with a high rate of infection, thrombosis, and restriction of patient activity. Brescia and colleagues then introduced the peripheral subcutaneous autogenous AV fistula in 1966.⁸ This Brescia-Cimino internal fistula used a side-to-side anastomosis to connect the radial artery to the cephalic vein in the nondominant hand. Erben and associates described the routine use of percutaneous cannulation of

the subclavian vein for HD in 1969.⁹ Finally, in 1979, Uldall and coworkers reported the development of a single-needle, subclavian HD catheter.¹⁰

INDWELLING VASCULAR ACCESS DEVICES (IVADS)

IVADs are typically chosen based on the least invasive, smallest catheter, with the lowest risk for complications, which will last as long as the length of therapy that is anticipated.¹¹ Length of therapy is often the major consideration when choosing a device. Long-term IVADs consist of cuffed, tunneled RA catheters, and implantable ports (Video 24.1). Medium-term IVADs include midline catheters (lasting weeks) and peripherally inserted central catheter (PICC) lines (lasting months). Short-term devices (see Chapter 21) include short peripheral IV, subcutaneous (butterfly), and percutaneous, nontunneled central catheters. Additional IVADs include those used for dialysis, in addition to AV fistulas and grafts.

Cuffed, Tunneled Right Atrial (RA) Catheters (Broviac, Hickman, Hemocath, Leonard, Raaf)

Several cuffed, tunneled RA catheters are available, each with differences tailored to specific applications (Fig. 24.1A). The Broviac (Bard Peripheral Vascular, Tempe, AZ) is an all-Silastic, single-lumen catheter, with a 1.0-mm internal diameter (ID). It is 90 cm long with a thin intravascular segment (55 cm). The Hickman (Bard), also a Silastic catheter, has a 1.6-mm ID. It allows more frequent blood sampling without jeopardizing luminal patency.¹² Single-, double-, and triple-lumen variations exist. Hemocath/Permacath has the largest bore of the RA catheters, with an ID of 2.2 mm. Quinton Instrument Company (Bothell, WA) manufactures these catheters for HD, plasmapheresis, long-term nutritional support, and pain control. The main advantage of these catheters is that they can be used immediately as a bridge to longer-term devices. They are not recommended for long-term access in patients undergoing dialysis if an AV fistula or graft (Video 24.2) is possible, as long-term dialysis with tunneled catheters has been associated with an increased risk for death, a five- to tenfold increase in the risk for infection, and a decreased likelihood of adequate dialysis.¹³

Nonemergency insertion of RA catheters is typically done in an operating room or interventional radiology suite. The device is introduced via the arm, upper anterior chest wall, or neck, and tunneled subcutaneously to enter the superior vena cava (SVC) system via the cephalic, subclavian, internal, or external jugular vein (Fig. 24.2), advancing the distal tip of the flexible catheter to the distal SVC or into the mid-RA area. The subcutaneous tunnel isolates the venous puncture site from the skin and decreases the potential for bacterial contamination. Dacron cuffs (one near the venous entrance site and one near the skin exit site) anchor the catheter and are believed to inhibit colonization of the SVC by skin organisms.¹⁴ However, no study has been able to support this belief. Advantages of an RA catheter include ease of insertion and use, minimal interference with patient activity, low incidence of major complications or unintended dislodgment, ease of removal, and potential repair via a kit. Disadvantages include the need for regular maintenance and the potential for unacceptable cosmesis.

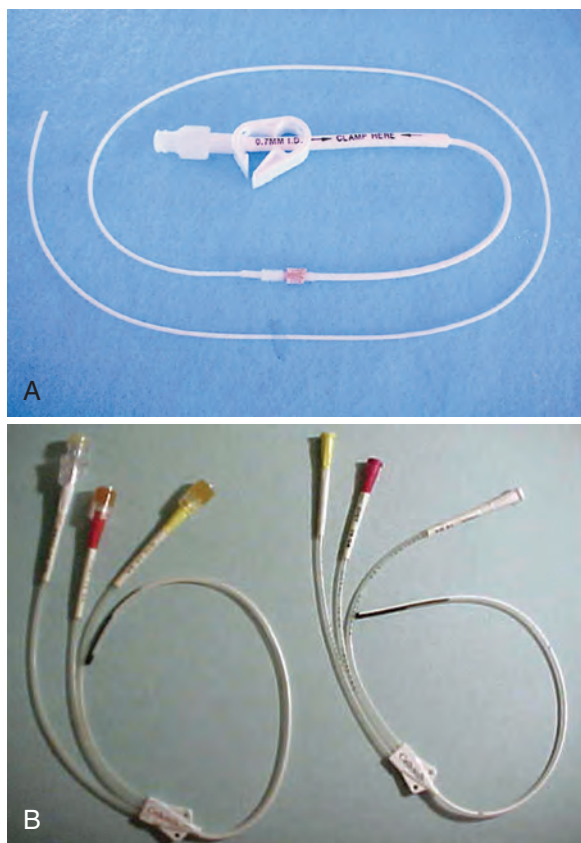

Figure 24.1 A, Broviac (Bard) Pediatric 4.2-French Single-Lumen CV Catheter with SureCuff Tissue Ingrowth Cuff and VitaCuff Antimicrobial Cuff. B, The Groshong (Bard) catheter has a valve to prevent backbleeding.

Groshong Catheter

In contrast to the Broviac and Hickman catheters, the Groshong (Bard) catheter has slit-like openings just proximal to the end of the intravascular portion of the catheter (see Fig. 24.1B). This functions as a one-way valve to stop backbleeding and prevent air entry and embolism from the negative intrathoracic pressure. This feature obviates the need to use a heparin lock (saline may be used). In addition, external catheter clamping is not necessary. Disadvantages are its high cost and requirement for pressurized infusion systems.¹⁵

TIVADs/Ports

(Port-A-Cath, Proport, Infuse-A-Port, Mediport)

Since 1983, implanted ports have become the mainstay for long-term cancer therapy. TIVADs are tunneled RA catheters, but they differ from Broviac and Hickman catheters in that they have a subcutaneous titanium or plastic portal with a self-sealing septum (Fig. 24.3) that may be accessed by puncturing a specially designed needle (90-degree angled Huber needle) through intact skin (Fig. 24.4). Cosmetically, they are superior to external tunneled catheters, require less maintenance, and afford patients greater freedom of movement and activities, such as swimming or bathing.

TIVADs may be inserted on an outpatient basis under local anesthesia via a subcutaneous tunnel or open cutdown. The

Figure 24.2 A, Subclavian-placed catheter with a subcutaneous tunnel. B, Quinton dialysis catheter in the right internal jugular vein, often used for emergency dialysis or as a bridge until a dialysis fistula or graft is ready for use (i.e., when it matures).

cutdown technique offers potential speed (mean placement time, 15 minutes), safety (negligible risk for pneumothorax), and avoidance of early and late complications.¹⁶ Placement is typically in the nondominant arm, with the portal in the upper part of the arm or chest, unless a vein is occluded or radiation therapy is planned on that side.

Disadvantages of this type of device include increased cost, the need for a specific non-coring Huber access needle, and the small gauge (20 to 22) of the access needle, which limits fluid infusion rates.¹⁵ Typical TIVADs do not have the capability to withstand the pressure required for power injection. Power-Port by Bard is an implantable port that allows for venous access and power injections required for contrast-enhanced computed tomography scans.

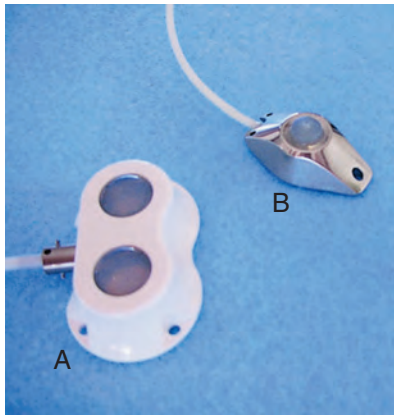

Figure 24.3 A, Port-a-Cath (Deltec, Inc., St. Paul, MN) double-lumen port (for chest placement). B, Port-A-Cath single-lumen port (for upper extremity placement). The Port-A-Cath system is accessed by inserting a Huber needle through the skin into the portal septum.

Figure 24.5 The double-lumen percutaneously inserted central catheter (5.0 Fr, 18 gauge) is placed in the arm with the tip of the catheter in the superior vena cava. Shorter, 20-cm versions (not shown) look similar but terminate in the axillary vein and are termed midline peripheral catheters.

Peripherally Inserted Central Catheter (PICC) (Nontunneled, Noncuffed)

PICC lines are centrally placed lines that were first described in the 1970s and originally developed for the neonatal population. Subsequently, their use expanded into the adult arena for prolonged antibiotic therapy, IV fluids, chemotherapy, TPN, and delivery of medications that are irritating to peripheral

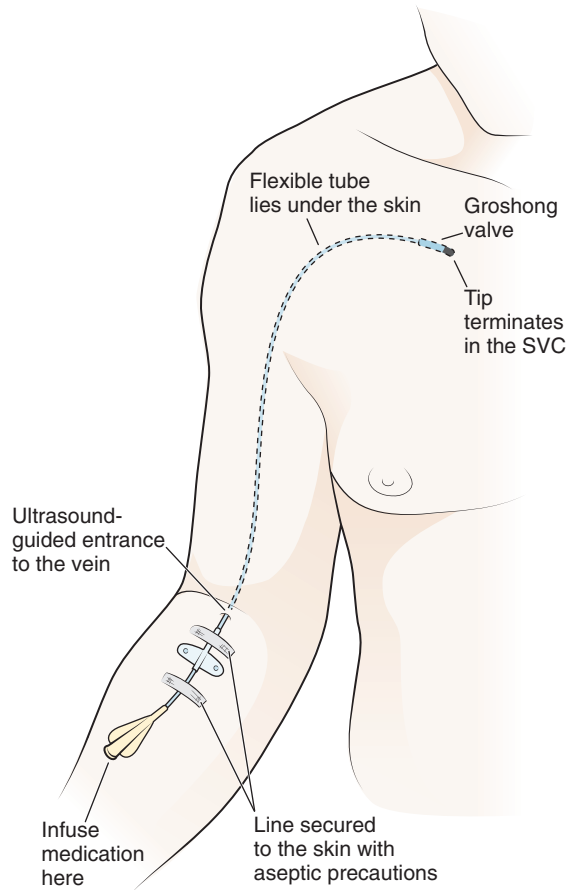

vessels. PICCs (Fig. 24.5) are made of two substances, either polyurethane (Intracath) or silicone (Intrasil), are radiopaque, and measure 50 to 60 cm in length, with an outside diameter of 2 to 7 Fr. The catheter may have a single- or double-lumen configuration and can be open- or close-ended or valved (e.g., Groshong). An open-ended PICC cannot prevent feedback of blood into the catheter and therefore must be flushed one or more times daily with heparinized saline. The Groshong valve reduces backup of blood into the catheter and therefore requires flushing as infrequently as once a week.

Selection of the device should be based on the number of lumens necessary for therapy. Selection of the access site depends on many factors including: the suitability of target vessels, body habitus, handedness, ability to manage self-care, comorbid conditions, desired infusion rate, number and compatibility of concurrent infusions, infusate characteristics, and the estimated duration of therapy. Infusate that is hyperosmolar (e.g., TPN) or vesicant requires rapid dilution. Accordingly, the tip must be in the SVC, where the estimated flow rate is 2000 mL/min. PICC lines are most frequently placed in the superficial veins proximal to the antecubital fossa (usually the basilic or cephalic vein) (Fig. 24.6). However, they may also be placed via a transhepatic or translumbar approach when the SVC is thrombosed or occluded.¹⁷

Advantages of PICC lines include usefulness in a wide variety of clinical situations, ease of placement, and ease of use and maintenance. They do not require surgical insertion and may be placed in an outpatient setting. A PICC line is an excellent vehicle for medium- to long-term IV therapy. With proper care, PICCs can remain in place for long periods, even months to years.¹⁸ To remove a PICC line, simply withdraw it from the vein, and apply pressure and a sterile bandage.

Midline Peripheral Catheters

Midline catheters are often confused with PICC lines. They are also placed peripherally in the superficial veins of the antecubital fossa or upper part of the forearm. They differ from PICCs in that they are peripheral, not central catheters. Midlines are typically shorter (20 cm), with the tip terminating near the axillary vein. Placement above the axillary vein results

A

B

Figure 24.6 A, Percutaneously inserted central catheter (PICC) line placement in the upper extremity with the internal catheter tip at the superior vena cava (SVC). B, Most PICC lines are used for outpatient therapy, such as prolonged antibiotic therapy, so proper aseptic technique at the catheter site is essential.

in a higher risk for thrombosis. They are designed for short- to medium-term use, a shorter period than with a PICC. Because midline catheters do not enter the central circulation with high flow, delivery of medication and infusion types are limited, and routine blood withdrawal is not recommended. Differentiating between these two catheters in situ may be difficult because their outward appearance is similar. Obtaining an x-ray film for visualization of tip placement will help in determining catheter type.

Figure 24.7 Mahurkar 11.5-Fr. x 16-cm Double-Lumen Catheter (Medtronic, Minneapolis, MN) for temporary hemodialysis, apheresis, and infusion.

Hemodialysis (HD) IVADs

Vascular access for dialysis, which is often referred to as the Achilles heel of patients with end-stage kidney disease, remains problematic. From the moment that the first access is created, an ongoing process is started that will end with the loss of all access sites if the patient survives long enough.¹⁹ Clinical practice guidelines of the National Kidney Foundation—Disease Outcomes Quality Initiative (NKF-DOQI) recommend early construction of an AV fistula and avoidance of catheters for permanent or prolonged vascular access, except in rare circumstances where AV graft or fistula formation is not feasible because of a lack of acceptable anatomic sites or limited life expectancy of the patient.²⁰ However, close to 70% of patients in the United States begin dialysis with a central catheter because a well-developed AV fistula is not available at the time of the initial catheter requirement.²¹

Temporary Dialysis Catheters (Quinton, Mahurkar, Tessio, Vascath, Uldall)

Temporary vascular access catheters (Fig. 24.7) are used for emergency HD or for temporary HD access if a more permanent dialysis route (AV fistula or graft) is not available, or has recently been placed and has not matured yet. The advantage of tunneled catheters is the ability to provide immediate access or temporary access while a more permanent structure matures, but this carries an increased long-term risk for infection, dysfunction, and central venous stenosis. The majority of bacteremia episodes in patients undergoing HD are caused by HD catheters, with an approximate 20% to 25% risk over the average duration of use.

These large-bore catheters allow the necessary blood flow rate of 300 mL/min for dialysis. The Quinton catheter has two ports, one to deliver the patient's blood to the dialysis machine, and another to return the blood to the patient's circulation (see Fig. 24.2B). These catheters are placed in a central vein, either the internal jugular, subclavian, or femoral. The right internal jugular approach is preferred, even if permanent access is to be created on the right side, because it has the lowest thrombosis rate. The NKF-DOQI recommends avoiding the subclavian vein unless no other options exist or the ipsilateral arm has no more permanent access sites. For patient comfort a special 180-degree catheter can be used (Fig. 24.8). There are two avenues to place this catheter: percutaneous or surgical. Emergency percutaneous placement may be performed by the emergency clinician at the bedside. Using sterile technique and after injection of a local anesthetic, insert the catheter by following the same procedure for placing a central line into one of the central veins.

Figure 24.8 MedComp (Medical Components, Inc., Harleysville, PA) Duo-Flow Internal Jugular Vascular Catheter (11.5 Fr \times 15 cm). The angle of the catheter makes it more comfortable for the patient.

The second technique uses a slightly larger catheter (Quinton, Hickman) and is performed in the operating room under local anesthesia, with or without general sedation. This catheter is placed in much the same fashion as the tunneled RA catheters described previously. Surgically implanted catheters are preferred if more than temporary use is anticipated because the risk for infection is decreased and they can be used for a longer time.

Chronic HD Vascular Access

The goal of chronic HD vascular access is to provide safe, effective, and repeated easy access to the circulation. The three principal types of access are native AV fistulas, synthetic grafts, and double-lumen tunneled cuffed catheters (described previously). Fistulas and grafts are collectively termed shunts. It may be difficult to distinguish a fistula from a graft by gross inspection alone. Hints to identification include location and shape. Grafts are rarely placed in the forearm, which is the preferred site for fistulas. Fistulas tend to be more tortuous and serpentine, whereas synthetic grafts are straighter or C shaped.

HD access types differ in failure rates, patency, complications, and other morbidity. Both grafts and fistulas are subject to vascular perturbation and integrity issues from the high flow rates and repeated access. Grafts are subject to pseudoaneurysms when there is a breach in the integrity of the graft and they are more likely to rupture. Fistulas, also subjected to bulging of the vessel walls, may form a true aneurysm. Dilated veins in a fistula can simulate an aneurysm. Both types of vascular deformities can rupture. Multiple defects may require a replacement access.

Both fistulas and grafts must mature before they can be used for HD, a process that may take several weeks to several months. HD is often performed via a Quinton catheter during this hiatus, so a patient in the emergency department (ED) with both a catheter and a shunt either has a nonfunctioning fistula or graft, or an access site that is still immature.

Complications common to both grafts and fistulas are thrombosis, infection, steal syndrome, venous hypertension, bleeding (Video 24.3), seromas, and aneurysms (Fig. 24.9). Overall, grafts are more likely to experience infection and thrombosis requiring thrombectomy or require other types of access intervention.

Arterial Venous (AV) Fistulas

In general, fistulas are preferred over grafts because of superior long-term patency and lower complication rates. An AV fistula

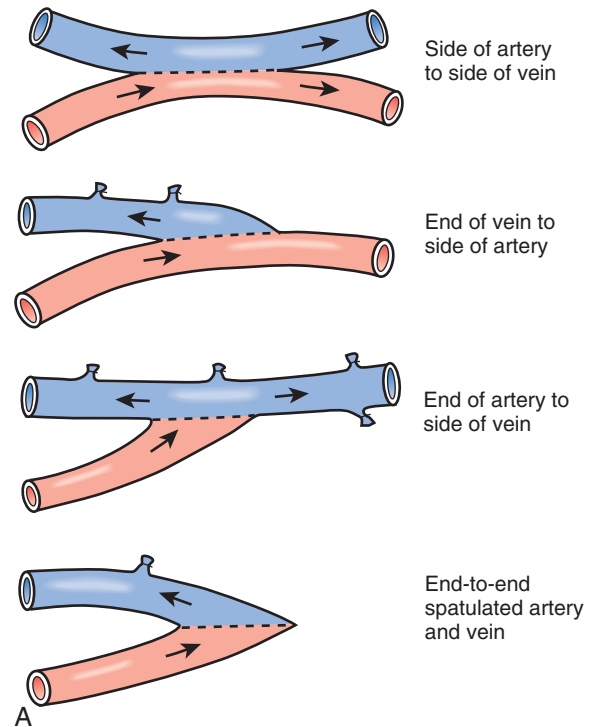

Figure 24.9 **A**, Various possible anastomotic configurations between the artery and vein for autogenous fistula formation. A thrill should be palpated if this fistula is functioning. **B**, Older dialysis fistula. Fistulas can develop multiple aneurysms (arrows) from multiple time use. It may be difficult to distinguish a fistula from a graft by merely looking at the site. (**A**, Adapted from Ozeran RS: Construction and care of external arteriovenous shunts. In Wilson SE, Owens ML, editors: *Vascular access surgery*, Chicago, 1980, Year Book Medical.)

is a direct subcutaneous anastomosis of an artery and vein without prosthetic material and is the preferred means of vascular access for HD (see Fig. 24.9). The minimum time for fistula maturation is at least 1 month, much longer than required for graft cannulation.

Historically the percentage of patients with AV fistulas fell well below the recommended goal, with most patients receiving AV grafts or long-term vascular access catheters. In recent

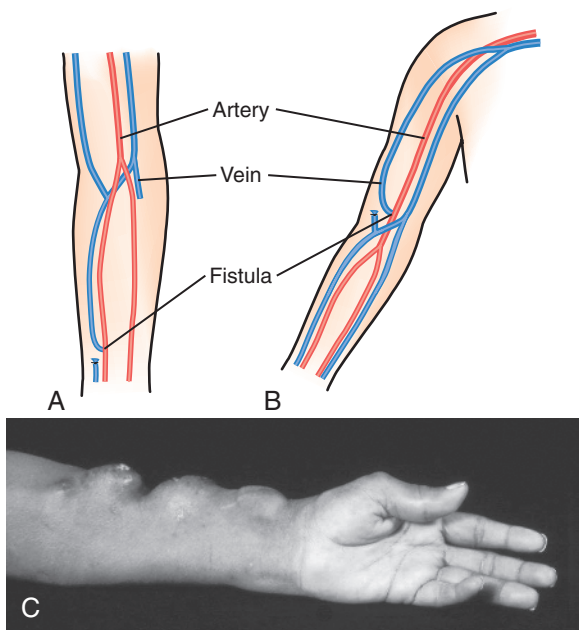

Figure 24.10 Arteriovenous fistula. **A**, Brescia-Cimino (radial-cephalic) fistula performed at the level of the wrist. **B**, Brachial-cephalic fistula performed proximal to the antecubital fossa. **C**, Multiple asymptomatic pseudoaneurysms resulting several years after creation of an autogenous wrist (Brescia-Cimino) arteriovenous fistula. (B, Adapted from Rutherford RB, ed: *Vascular surgery*, ed 5, Philadelphia, 2001, Saunders.)

years there has been a concerted effort to increase the utilization of AV fistulas, most notably the National Kidney Foundation's *Fistula First Breakthrough Initiative*.²² The most recent data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) show that from 2002 to 2011 AV fistula use in the United States almost doubled (32% to 62%), and AV graft use fell by more than 50%.²³ Use of an autogenous fistula is associated with the longest period of patency with relative freedom from thrombotic and infectious complications.

Fistulas have a 15% rate of primary failure, defined as being unable to provide reliable access as a result of early thrombosis or failure to mature.²⁴ However, once a fistula matures, long-term patency is high (48% of AV fistulas versus 14% of AV grafts at 5 years), with low infection rates relative to grafts.²⁵

An autogenous AV fistula is constructed by anastomosing an artery to a vein (see Fig. 24.9), preferably a nearby one. Various configurations are possible, but AV fistulas are typically an end-to-side, vein-to-artery anastomosis. The radial-cephalic (Brescia-Cimino) fistula in the forearm is the most frequently used (Fig. 24.10), with the brachial-cephalic, brachial-basilic, and rarely the proximal part of the thigh being alternatives. Over time, the venous portion of the shunt is subjected to high pressure, and the fistula becomes arterialized (hypertrophied and dilated), which renders it suitable for repeated vascular access. Full epithelialization of the shunt does not occur for 3 to 6 months, thus necessitating anticipatory placement as renal function worsens.

AV Grafts

If a forearm radiocephalic fistula cannot be constructed or has failed, an AV bridge graft using a donor vein or synthetic

Figure 24.11 Three possible graft configurations for jump grafts in which standard sites have been used. Note the typical C shape of the graft. (Redrawn from Tilney NL, Lazarus JM, editors: *Surgical Care of the Patient with Renal Failure*, Philadelphia, 1982, Saunders; as shown in Haisch CE: Chronic vascular and peritoneal access. In Davis JH, Sheldon GE, editors: *Clinical surgery*, St. Louis, 1995, Mosby.)

material is a well-accepted alternative. Several synthetic materials are used for grafts. Grafts can usually be cannulated earlier than fistulas, often within weeks of placement. Polytetrafluoroethylene (PTFE) is most commonly used, but takes 3 weeks to mature. An available polyurethane graft (Vectra [Bard]) has the ability to be accessed within 24 hours. A standard graft is 6 to 8 mm in diameter and usually positioned in a U-shaped subcutaneous tunnel in the forearm. The graft is attached by end-to-side anastomoses to the brachial artery and antecubital vein. If no suitable antecubital vein is available, a straight bridge graft between the brachial artery and either the axillary or the basilic vein is often used. Multiple configurations are possible (Fig. 24.11). A jump graft between opposite extremities with creation of a loop across the chest or anastomosis of the axillary artery to the iliac vein is a possibility, if all other sites have been exhausted.

When compared with AV fistulas, AV grafts have a significantly higher incidence of thrombosis, infection, pseudoaneurysm formation, and limb loss. The risk for infection with HD grafts is approximately 10% over prolonged use and 1% with HD fistulas.²⁶ Graft infection requires complete excision to eradicate an infection of the foreign material, whereas fistula infections may resolve with IV antibiotic use. AV grafts have a low primary patency rate (31% at 1 year according to one study).²⁷ However, they have a low incidence of aneurysm formation and are comparatively easy to revise. The estimated life span of an AV graft in clinical practice is often less than 2 years.

ACCESSING IVADS IN THE ED

When IV access is required in patients with IVADs, standard methods of peripheral access should be attempted first to preserve the life span of the vascular access device and avoid complications. However, IVADs, AV fistulas, and grafts may be accessed as a last resort in emergency situations for phlebotomy and infusion of medications and fluids. Because of the complications of infection and catheter malfunction, dislodgment, and fracture, only personnel with the requisite knowledge

and skill should access IVADs if feasible. When IVADs are accessed, ensure antisepsis throughout the procedure. Assuming that proper access methods are used to prevent infection, the greatest risk is sludging in the catheter with resultant occlusion.

Accessing Long-Term Venous Access Catheters

To access the catheter (with the exception of Groshong catheters, which have backflow valve protection), first clamp it to prevent air embolism. Patients usually carry their own clamps, but a hemostat with teeth will suffice in an emergency. In this case, wrap sterile tape or tubing around the teeth of the hemostat. Remove the cap of the catheter and withdraw any mobile clots with a syringe. Remove approximately 3 to 5 mL of blood and then attach a 10-mL syringe to a single-dose vial of sterile normal saline. Smaller syringes generate greater amounts of pressure for infusion, which can lead to increased intraluminal pressure and rupture of the catheter. Inject 3 to 5 mL of solution and then again withdraw it to ensure patency. Flush again with saline. More pronounced infusion might be necessary to ensure the patency of Groshong catheters.

To accomplish phlebotomy, withdraw the dead space solution, reclamp it, and use a separate syringe to remove the desired amount of blood.²⁸ If clots are withdrawn, continue withdrawing blood until it is clot free. Inject bolus medications and infuse IV solutions through the catheter, and clamp it whenever it is unattached. Do not administer medications concurrently that are known to be incompatible when mixed (e.g., calcium and bicarbonate), even through separate ports of multilumen catheters. Deliver a 5-mL normal saline flush between medications through a 10-mL syringe. On completion of either blood withdrawal or medication infusion, inject 3 to 4 mL of saline to flush it and then inject 3 to 5 mL of heparin (1000 Units/mL). Clamp the line and reposition the cap.²⁸ Note that 1000 Units/mL of heparin should be used; less concentrated solutions may promote clotting. Do not inject larger amounts because it can systemically heparinize the patient. Groshong catheters need not be flushed with heparin but instead may be flushed briskly with 5 to 10 mL of saline. Multilumen central catheters have one port for each lumen, so access each one in the same manner. After antiseptic preparation, gain access either by inserting a needle or a syringe into the protective cap or by removing the cap entirely. Flush with 5 mL normal saline or sterile water, and verify backflow before all subsequent procedures. Perform phlebotomy through the proximal lumen to prevent mixing with medications being delivered through the other ports. Deliver IV infusions in similar fashion, and inject a normal saline flush between medications. Following the procedure, flush 3 to 5 mL of heparin (1000 Units/mL) through each port.

Accessing TIVADs

The procedure for accessing TIVADs is unique because these devices are not external. Instead, a circular reservoir (cylinder) lies subcutaneously on the anterior chest wall. First, palpate the cylinder and then prepare the overlying skin with povidone-iodine solution. Fill a 10-mL syringe with normal saline and attach it to connecting tubing. Attach this to a 19- to 22-gauge, 90-degree tapered (Huber) needle. The Huber needle is a specialized needle designed for use with TIVADs to prevent

damage to the portal septum. It has a 90-degree bend with a slightly curved tip and the opening on the side rather than on the end. Most importantly, the Huber is a noncoring needle. This avoids damage to the Silastic septum and allows up to 2000 punctures. Do not access the TIVAD with a standard needle unless an arrest is in progress and a Huber needle is not immediately available. Apply a clamp to the connecting tubing whenever the system is open. Expel the air and insert the Huber needle through the septum of the reservoir. Insert the needle slowly and steadily through the diaphragm until it contacts the back of the reservoir. Be aware that although incomplete perforation of the septum will block flow, substantial pressure may also damage the back of the device and bend the tip of the needle. Remove the clamp slowly and inject 5 mL of solution to ensure patency. If patency is not easily demonstrated, consider using alteplase (recombinant tissue plasminogen activator) as a fibrinolytic agent for catheter occlusion.²⁹

Once the solution has been injected, apply gentle negative pressure to demonstrate backflow of blood. Stabilize the Huber needle by building a 4- × 4-inch gauze pad about the needle and further reinforce it with 2.54-cm (1-inch) silk tape. First, remove 8 to 9 mL of blood with a separate syringe and waste it, and then perform phlebotomy through the extension tubing. If necessary, deliver IV solutions through extension tubing, but remember that the rate of flow will be limited by the smaller radius of the Huber needle. Deliver a 5-mL sterile normal saline flush between medications. Complete the procedure with a 3- to 5-mL heparin (1000 Units/mL) flush and remove the Huber needle.²⁸

Accessing AV Fistulas, Grafts, and HD Catheters

AV fistulas, grafts, and temporary dialysis catheters are placed in patients who require HD, and they represent the sole access for that purpose. Consequently, routine use of these sites for phlebotomy and fluid administration is strongly discouraged. In fact, venipuncture in the same extremity as a patent AV shunt is not recommended, except for the veins in the dorsum of the ipsilateral hand. However, when standard IV access cannot be obtained under emergency circumstances, fistulas, grafts, and catheters may all be used to administer IV solutions and medications (Fig. 24.12). Though avoided whenever possible, the option to access these sites is based on clinical judgement by the clinician. If possible, ascertain patency of the fistula by noting a bruit and palpable thrill, although these signs may not be appreciable if the patient is in extremis.

Prepare the area overlying the fistula with antiseptic solution and access the fistula with the smallest gauge needle that is appropriate.³⁰ Puncture 1 to 2 cm from the end of the anastomosis nearest the venous side and avoid aneurysmal sites.³⁰ Access AV shunts similarly by placing the smallest needle possible in the catheter and bridging the arterial and venous circulations. Apply local pressure for at least 5 minutes after the procedure is completed and monitor subsequently for hemorrhage. Access the Uldall and Mahurkar catheters in much the same way that multilumen central catheters are accessed. Remove or inject through the retaining cap on each arm. Up to 5000 units of heparin are present within the two lumens, thus it is imperative to aspirate before administering fluid or medications. After use, flush each catheter arm with 10 mL of normal saline and instill 1.5 mL of heparin solution (1000 Units/mL) into each one.

Figure 24.12 For resuscitation or delivery of advanced cardiac life support drugs, a venous catheter may be used to access a shunt, but otherwise avoid this whenever possible.

COMPLICATIONS OF IVADS

IVADs are now sufficiently commonplace that patients with these devices are seen in the ED on a regular basis. Given a complication rate of 4% to 10%,³¹ it is essential that emergency clinicians be aware of these complications and their management. The risk for complications associated with an IVAD is dependent on several factors including: the type of catheter, underlying patient pathology and anatomy, the site chosen for placement, and the experience of health care workers obtaining access and caring for the device.³²

Complications of IVADs include: (1) infection, (2) hemorrhage and coagulation abnormalities, (3) malfunction, and (4) miscellaneous problems (Box 24.1).

Infection

Infection is the most common complication leading to removal of IVADs and potentially the most serious. Infection can also result in shunt thrombosis, rupture, or massive hemorrhage. It is estimated that more than 250,000 cases of nosocomial IVAD-related bacteremia occur annually in the United States with an associated mortality rate greater than 10%.³³ Infectious complications include endocarditis, septic arthritis, pulmonary emboli, osteomyelitis, and spinal epidural abscess. The definitions of IVAD-related infections are not uniform, which makes it difficult to compare the results of various investigations. However, it is generally agreed that risk factors for infection include the site of insertion, duration of catheter placement, type of catheter, and patient factors. Most studies show a lower incidence of infection for TIVADs than for external systems, presumably because of lack of direct access by cutaneous organisms. Rates of IVAD infection tend to be highest in the first 3 months after insertion, with skin flora being most common.^{31,34} The rate of infection decreases significantly and reaches a plateau after 5 to 6 months.³⁴

Clinical findings are unreliable in the diagnosis of infection secondary to IVADs. Fever, rigors, and an elevated white blood cell count are nonspecific, whereas purulent drainage at the insertion site is specific but not sensitive. Therefore evaluation

BOX 24.1 Complications of Indwelling Vascular Access Devices

INFECTION

- Skin/exit site
- Reservoir/pocket

beyond physical examination alone is essential when infection is suspected, including Gram stain of purulent material at the site, blood cultures, and culture of catheter segments. In addition, transesophageal echocardiography is indicated if valvular vegetations are suspected by blood cultures positive for *Staphylococcus aureus*, persistent bacteremia or fungemia after removal of the catheter, or lack of clinical improvement.

Draw two sets of blood for culture, with one set through the catheter itself and one from a peripheral site. Positive blood cultures for *S. aureus*, coagulase-negative staphylococci, or *Candida* species, in the appropriate patient setting and in the absence of another identifiable source of infection, should increase suspicion for catheter-related bloodstream infection.³¹ Similarly, if cultures drawn from the IVAD become positive 2 or more hours before peripherally drawn cultures, it suggests the patient has a catheter-related bloodstream infection.³⁵ Infusate-related bloodstream infection is uncommon and defined as isolation of the same organism from both the infusate and separate percutaneous blood cultures, along with no other source of infection. When this diagnosis is suggested, cultures

of the infusate should be performed in addition to catheter and peripheral blood cultures.³¹

When a catheter-related infection is suspected, an important management decision is required to determine whether to remove the catheter. Removal is recommended in patients who have a catheter placed solely for short-term use. In patients with long-term catheters, removal of the catheter is advised in the setting of severe sepsis, suppurative thrombophlebitis, endocarditis, or persistent positive blood cultures (longer than 72 hours) while on appropriate antibiotics, as well as if the infection is caused by *S. aureus*, *Pseudomonas aeruginosa*, fungi, or mycobacteria. For patients who require long-term vascular access for survival or have no other vascular access options, salvage of the catheter may be attempted if the infecting agent is not *Bacillus*, *Micrococcus*, or *Propionibacterium*, in addition to the previously listed organisms. If the decision is made to leave the catheter in place, obtain blood for repeated cultures and remove the catheter promptly if they remain positive following 72 hours of appropriate antibiotic therapy.³⁶

If an IVAD is removed, determination of the offending organism is made by culturing a portion of the catheter. Place the catheter in a sterile container and send it to the laboratory for culture, sensitivity, and Gram stain. The most widely used laboratory technique for the clinical diagnosis of catheter-related infection is the semiquantitative method, in which a segment of the catheter is rolled across the surface of an agar plate and colony-forming units (CFUs) are counted after incubation overnight. Quantitative culture of the catheter segment requires either flushing the segment with broth or vortexing in broth, followed by serial dilutions and surface plating on blood agar. A yield of 15 CFUs or more from a catheter by semiquantitative culture or a yield of 102 or more from a catheter by quantitative culture with accompanying signs of local or systemic infection is indicative of a catheter-related infection.³¹

The process of HD requires several connections to the HD catheter, thereby increasing the risk for infection. The rate of bacteremia in HD patients attributed to the vascular access site varies from 48% to 73%. The incidence is highest when central venous dialysis catheters are used, whereas native AV fistulas carry the lowest risk for infection.³⁷ As with other IVADs, if infection is suspected, initiate empirical antibiotic therapy based on epidemiologic and patient factors, followed by narrowed-spectrum therapy after isolation and determination of sensitivities. The most common infecting organism is *S. aureus*.

Antimicrobial Therapy

Pending the results of culture, the initial choice of an antibiotic is empirical and depends on the clinical setting, site of infection, type of device, host factors (e.g., immunocompromised state), severity of illness, and whether the device has been left in situ. If an IVAD-related bloodstream infection is suspected, vancomycin should be initiated empirically as coagulase-negative *Staphylococcus* is the most common infectious organism and the prevalence of methicillin-resistant *S. aureus* continues to increase.³⁸ This should be followed by a semisynthetic penicillin or other appropriate antibiotics as guided by sensitivity studies. If the patient is severely ill, septic, in an immunocompromised state, or has a femoral catheter in place, additional coverage for gram-negative bacilli should be initiated.³⁸ Institute a third-generation cephalosporin unless the organism is extended-spectrum β -lactamase positive, in which case a carbapenem is more appropriate.³⁹ If there is concern for *P. aeruginosa*, initiate

therapy with a fourth-generation cephalosporin (e.g., cefepime) or carbapenem, with or without an aminoglycoside. In addition to bacterial pathogens, fungemia should be suspected in septic patients who are receiving TPN; those with prolonged use of antibiotics; those with a history of a hematologic malignancy, or a bone marrow or solid organ transplant; or if a femoral catheter is in place.³⁸ If fungemia is suspected or confirmed, initiate an antifungal medication and remove the catheter. An echinocandin medication (e.g., micafungin, caspofungin) is the recommended empirical treatment of suspected fungal infection.³⁹ Although there are no compelling data to specify a duration of antibiotic therapy, expert recommendation is to treat *S. aureus* infection for 14 days, gram-negative bacilli for 7 to 14 days, and candidal infection with antifungal therapy for 14 days after the first negative blood culture. Complicated infections (e.g., those with suppurative thrombophlebitis, endocarditis, or other similar infections) require 4 to 6 weeks of antibiotic treatment.³⁹

If an exit site infection is suspected, any drainage from the site should be cultured in addition to obtaining blood cultures. For uncomplicated exit site infections (those lacking signs of systemic infection, positive blood cultures, or purulence) initial treatment consists of topical antimicrobials. If the infection does not resolve with topical antimicrobials, systemic antibiotics should be administered and consideration given to removing the catheter. Patients with a tunnel infection or port abscess should have the catheter removed and receive systemic antibiotics for 7 to 10 days.³⁹

If the IVAD is retained, consider antibiotic lock therapy (ALT). ALT is a therapeutic option if the goal is to salvage the catheter. Most infections in tunneled catheters originate in the hub and spread to the catheter lumen. A biofilm can form and make eradication of the organism difficult because systemic antibiotics cannot achieve therapeutic levels there. ALT involves filling the catheter hub and lumen with a higher concentration of antibiotics and leaving them in place for extended periods. It is recommended that dwell times not exceed 48 hours before reinstilling the antibiotic solution.^{39,40} If it is a femoral catheter, dwell time should not exceed 24 hours. ALT should always be used in conjunction with systemic antibiotics, and the recommended duration of treatment is 7 to 14 days.³⁹

Prophylactic Measures

Antibiotic Prophylaxis During Initial Line Insertion

Prophylaxis with vancomycin or teicoplanin during central line insertion has not demonstrated a benefit in reducing catheter-related bloodstream infections. Based on the limited data available, Centers for Disease Control and Prevention (CDC) guidelines currently recommend against giving vancomycin prophylactically because it is an independent risk factor for the acquisition of vancomycin-resistant enterococci and staphylococci, with reduced susceptibility to glycopeptides.⁴¹ Rather than using antibiotic prophylaxis, focus efforts on interventions designed to discourage the emergence of antimicrobial resistance such as maximal barrier precautions.⁴²

Impregnated Catheters

Using antimicrobial- or antiseptic-impregnated catheters or silver-impregnated collagen cuffs may be an effective intervention to reduce IVAD-related bloodstream infection. A 2013 metaanalysis favored impregnated catheters in reducing central line-associated bloodstream infections (CLABSIs), but it was

acknowledged that the overall methodology of the studies included was poor.⁴² Nonetheless, the CDC currently recommends the use of these devices if the catheter is anticipated to remain in place for more than 5 days and if the institution's CLABSI rate is not decreasing after implementation of a comprehensive strategy to reduce catheter-associated infections.⁴⁰

Routine Line Changing

Despite the incidence of infection and the potential complications, routine changing of IVADs is not recommended.⁴⁰ Cobb and coworkers found that replacement of IVADs every 3 days did not prevent infection and that doing so over a guidewire actually increased the risk for bloodstream infection.⁴³

Thrombus Formation

It has been estimated that 2% to 42% of IVADs are associated with deep venous thrombosis (DVT).⁴⁴ Risk factors for catheter-related DVT include the composition, diameter, and position of the IVAD; elevated intraluminal pressure; turbulent blood flow; vascular calcification; endothelial injury; and increased levels of fibronectin.^{44,45} Polyurethane and silicone catheters have a lower rate of IVAD-related DVT than do polyethylene or Teflon-coated catheters. A catheter with an external diameter of less than 2.8 mm has a lower incidence of DVT. Incorrect placement of the IVAD in the SVC, as opposed to the junction of the SVC and right atrium, results in a higher incidence of catheter-related DVT.⁴⁴ The majority of these thromboses are asymptomatic. The incidence of clinically overt DVT has been found to range from 0.3% to 28.3%, with most studies finding the incidence to be less than 5%. The first 6 weeks after catheter insertion presents the greatest risk for thromboembolic complications.⁴⁶

Most HD access failures (80%) are related to thrombosis, with greater than 90% of these thromboses associated with venous outflow stenosis.⁴⁷ Histologically, hyperplasia of the endothelium and fibromuscular vessel wall occurs. This may continue to the point of complete occlusion, and prevent infusion or aspiration from the access site. Early detection may be enhanced by maintaining a high index of suspicion and noting prolonged bleeding after withdrawal of the cannula. Clinically, an absence of a thrill or change in the bruit on examination indicates occlusion of the fistula or graft. Prompt consultation with a vascular surgeon for declotting of the thrombosed access and correction of any underlying stenosis is indicated.⁴⁸

Catheter Occlusion

Occlusion of the catheter or low flow can be caused by the following: improper positioning, kinking, or compression of the catheter; intraluminal thrombi; extraluminal thrombi; fibrin deposits at the tip of the catheter; or intraluminal precipitation of infusate. Pinch-off syndrome occurs when the line (most often a PICC) is compressed between the clavicle and the first rib. It is manifested clinically as difficulty injecting that is posturally related.¹⁵ Overzealous withdrawal of the syringe will collapse the catheter and cause occlusion. Chest radiographs may reveal scalloping of the catheter.

Maneuvers to facilitate flow of a potentially occluded catheter include the Valsalva maneuver, the reverse Trendelenburg position, slight tension on the catheter, placement of the catheter more laterally, IV hydration, and extension of the arms above

the head.^{28,49} If these measures are unsuccessful, the occlusion may be caused by clot formation. The clinician should be familiar with local institutional recommendations for thrombolysis in the setting of recent IVAD occlusion attributed to a fibrin plug. Admission and consultation are usually required, and maneuvers to address clotted or occluded catheters are not a standard ED procedure, but may be performed under proper circumstances and according to local guidelines. Alteplase has been shown to be both effective and safe in treating central venous catheter occlusions caused by a clot.⁵⁰ If attempted, first withdraw any mobile clot by aspiration with a syringe. Instill 2 mL of alteplase (1 mg/mL) and allow it to dwell for up to 120 minutes. If it remains occluded, the dose may be repeated once.

Embolization

A serious but uncommon complication of IVAD use is embolization with air, a catheter fragment, or thrombotic emboli.⁵¹⁻⁵⁴ Air emboli develop when the lumen of the catheter is left open to air, or the catheter is fractured, perforated, or cut. The one-way valve in the Groshong catheter prevents this complication. Be careful to maintain a closed system by clamping the catheter appropriately to prevent delivery of air into the venous circulation. Should the externalized portion of a catheter be damaged, immediately place an appropriate clamp between the damaged portion and the skin.²⁸ Be suspicious for air embolism if an open or damaged catheter is found in association with tachypnea and hypotension.⁵¹ Place the patient in a left lateral decubitus and Trendelenburg position to reduce ventricular outflow obstruction by air pockets. Initiate supportive measures, including high-flow oxygen. If this is unsuccessful, attempt aspiration with the catheter advanced into the right ventricle, if possible. Cardiothoracic surgery consultation and emergency thoracotomy to aspirate air (see Chapter 18) may be warranted.

Embolization of a catheter fragment is a potentially life-threatening complication that can cause acute dyspnea, palpitations, atypical chest pain, hypoxia, and atrial fibrillation. As with any foreign-body embolus sequelae include: sepsis, lung abscess, dysrhythmias, vascular or cardiac perforation, and sudden death. Catheter fragments may be identified radiographically, or potentially by ultrasonography, and may be removed either surgically or by intravascular retrieval methods.⁵²

Embolization of thrombi with potentially lethal sequelae may occur during routine flushing and injection of solutions through the catheter. Anderson and coworkers prospectively evaluated the size and frequency of catheter thrombi in 43 patients by aspirating after a urokinase flush.⁵³ Clots were noted in 40 of 43 subjects and in 153 of 508 total specimens. Thrombi varied in size from small fragments to 5 cm in length. Burns and McLaren reported one case of a hemodynamically significant pulmonary embolus associated with PICC placement in a 77-year-old man.⁵⁴

Hemorrhagic Complications

Bleeding may be seen with any indwelling IVAD or AV shunt and is a potentially fatal complication. Between 2000 and 2006 over 1600 dialysis patients in the United States died from vascular access hemorrhage.⁵⁵ It is often related to mechanical trauma, transient or preexisting thrombocytopenia, uremia or drug-induced platelet dysfunction, and infection. Repeated

cannulation of the fistula or graft weakens the wall of the device. Many fistulas will develop aneurysms from repeated use; synthetic grafts can develop pseudoaneurysms from frequent punctures (Fig. 24.13). Severe life-threatening hemorrhage from this high-pressure system may occur and necessitates rapid control. The primary goal should be to control bleeding and prevent exsanguination; however, take care to minimize damage to the IVAD that would prevent future use. Use full universal precautions because there is an increased risk for communicable disease in this patient population (2.4% for hepatitis B virus and 7.4% for hepatitis C virus in the United States).⁵⁶ When the bleeding stops, observe the patient for 2

Figure 24.13 Because of repeated access and high venous pressure, the integrity of the shunt vessel can be compromised. Pseudoaneurysms form in a synthetic graft and are covered with skin. True aneurysms form in a fistula from bulging of the entire vessel. Both can rupture. A tortuous vein under pressure can mimic an aneurysm.

hours for evidence of rebleeding and to detect shunt thrombosis. Treatment of hemorrhage can be divided into mechanical modalities and correction of coagulopathy.

Mechanical

Literature addressing acute hemorrhage in patients with IVADs is clearly lacking. Many of the techniques discussed are anecdotal examples used by emergency clinicians, nephrologists, and vascular surgeons informally polled at our institutions. Individual institutional guidelines, techniques, and preferences may vary; therefore discussion with consultants is recommended when possible.

Approach to Bleeding Complications

It is important to identify the specific bleeding site, which is challenging when hemorrhage is massive (Fig. 24.14). This is most easily accomplished by (1) applying concomitant digital pressure over the feeding and draining vessels of the shunt above and below the bleeding site (see Fig. 24.17), or (2) applying a pneumatic blood pressure cuff or tourniquet *distal* to the fistula or graft to impede distal-to-proximal arterial flow, unless it is a loop graft, in which case it is applied above (*proximal* to) the device. The most easily controlled bleeding is typically that occurring immediately after dialysis, when the bleeding is from dialysis access puncture sites. Spontaneous bleeding between dialysis treatments often signifies more serious problems, such as infection, or mechanical problems with the access site. High pressure from venous stenosis secondary to long-term dialysis complicates the control of bleeding (Fig. 24.15).

Direct Pressure

Begin management of bleeding with direct pressure. Always use sterile technique to lessen the chance of infecting a bleeding shunt. With gloved hands, apply direct pressure with fingers and a sterile gauze bandage. For bleeding AV fistulas and grafts secondary to cannulation, apply pressure

Figure 24.14 A, Spontaneous rupture of this fistula resulted in massive hemorrhage and hypovolemic shock. Failure to put direct pressure over the bleeding site, as indicated in B, exacerbated the blood loss. B, This infected pseudoaneurysm (arrowhead) precipitated the spontaneous massive hemorrhage seen in A. The actual graft is exposed. Note that control of bleeding to identify the compromised site is achieved by firm digital pressure on the vessels on both sides of the rupture (arrows). Infected grafts must be replaced. Infected fistulas may be salvaged with antibiotics. Bleeding of a shunt can also signal thrombosis of a major vein.

Figure 24.15 Edema of the hand and breast occurred as a result of the high venous pressure of chronic venous stenosis secondary to long-term hemodialysis. **A**, Obstruction of the innominate vein or superior vena cava may cause breast and face swelling, and sometimes headaches because of intracranial hypertension. This may be difficult to differentiate from thrombosis. Anticoagulation will not help this unfortunate patient. Surgical revision to divert blood flow into a patent vein is sometimes possible to restore unobstructed flow. **B**, Arm edema may also be a sign of shunt infection.

focally over the site of cannulation. For tunneled catheters, apply pressure over the site of vascular entry of the catheter, not the subcutaneous exit site. Note that this is not possible with subclavian IVADs. Hold the pressure for a minimum of 5 minutes and then reevaluate for hemostasis. Holding direct pressure for extended periods or maintaining more diffuse pressure may cause thrombosis and ultimate shunt failure, which is a known and unfortunate risk. Wrapping the site with an elastic bandage for a few minutes is acceptable, but longer application in this broad manner may lead to the entire graft clotting.

Dialysis Clamps

Special self-retaining dialysis clamps may be applied over a specific bleeding site (Fig. 24.16). Be careful that the clamp does not slip off the bleeding site because the surface area of the clamp is small. Place sterile gauze or topical thrombin-impregnated gauze under the clamp. Ten to fifteen minutes may be required to stop the bleeding, but it is best to avoid frequent checks during the first 5 to 8 minutes to avoid disrupting hemostasis.

Thrombogenic and Dermal Adhesive Agents

If venous oozing fails to stop with direct pressure, oxidized cellulose hemostatic agents (Oxycel [Becton Dickinson, Franklin Lakes, NJ], Surgicel [Ethicon, Somerville, NJ]), or a skin adhesive such as 2-octyl-cyanoacrylate, may be used to achieve hemostasis. Apply topical hemostatic agents directly over the site of bleeding and hold them in place with gloved hands and a gauze bandage or clamp. If utilizing a skin adhesive, apply the adhesive over the site of bleeding while also applying direct pressure proximally.⁵⁷ After achieving hemostasis the patient should be observed to ensure rebleeding does not occur.

Vasoconstrictive Agents

Subcutaneous injection of 2 to 4 mL of lidocaine (2%) with epinephrine to form a wheal around the site may decrease bleeding by both vasoconstriction and local pressure. This may be used in conjunction with chemical cautery.

Figure 24.16 Bleeding from a dialysis graft or fistula can be massive because of the high pressure. This dialysis graft clamp with sterile gauze (option: impregnate the gauze with topical thrombin) is kept in place for approximately 10 minutes. Other options for a bleeding graft are discussed in text. Bleeding after dialysis is related to needle size and the degree of anticoagulation, but prolonged bleeding may signal outflow stenosis, infection, or skin atrophy and the need for evaluation of the shunt.

Chemical Cautery

Silver nitrate (AgNO_3), a mildly caustic and hemostatic agent, may stop residual bleeding. The agent needs to be protected from light until just before use. When ready, remove the wooden stick from the container and black plastic wrap and gently

apply the gray-tipped end directly on the site. Do not apply it aggressively because this can result in dissolution or dislodgment of the formed clot.

Once the bleeding is controlled, rebleeding is infrequent. It is prudent to observe the patient for 30 to 45 minutes and have the patient walk around and use the arm gently to ensure that bleeding will not recur when discharged. If no bleeding recurs, discharge is appropriate unless precluded by other conditions.

Suture

If direct pressure and previously mentioned techniques fail to achieve hemostasis, suturing may be necessary. Inject the bleeding site subcutaneously with lidocaine with epinephrine. Place a figure-of-eight or horizontal mattress suture with 4-0 nonabsorbable polypropylene or nylon (noncutting needle) at the site of bleeding (Fig. 24.17). Be careful to suture as superficially as possible to prevent damage to the underlying graft or fistula. The patient may require a venogram for evaluation of shunt patency before use. Remove the suture in a few days.

Coagulopathy

Control of hemorrhage may require treatment of an underlying coagulopathy. HD patients are generally considered to be at increased risk for bleeding because of uremic platelet dysfunction. The incidence of major bleeding in these patients is increased with the concomitant use of anticoagulant medications.⁵⁸ Perform laboratory testing for evaluation as follows: complete blood count, blood urea nitrogen, prothrombin time, international normalized ratio (INR), partial thromboplastin time, and other tests depending on the patient's medical history or signs. Consult nephrology, vascular surgery, or both if possible before reversing therapeutic anticoagulation given the potential for shunt thrombosis and the need for close follow-up.

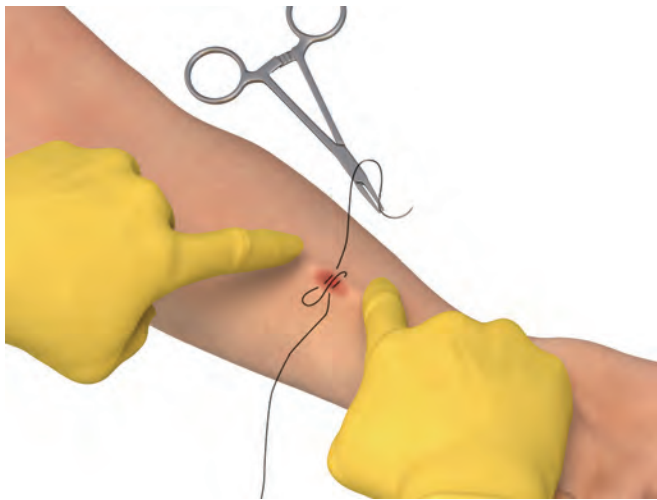

Figure 24.17 To suture a bleeding dialysis shunt, instruct an assistant to apply proximal and distal pressure to stem the flow of blood and then inject the site with lidocaine with epinephrine. Place a figure-of-eight (shown) or horizontal mattress suture as superficially as possible to prevent damage to the underlying graft or fistula.

Uremic Platelet Dysfunction

If platelet dysfunction is suspected because of uremia, administer desmopressin (DDAVP) or cryoprecipitate to control the hemorrhage.³⁰ Adult dosing of DDAVP to control uremic bleeding is 0.3 $\mu\text{g}/\text{kg}$ intravenously as a single dose or every 12 hours. Onset occurs in 1 to 2 hours, and its duration is 6 to 8 hours after a single dose. Disadvantages include high cost and adverse reactions, including anaphylaxis, water intoxication or hyponatremia, and thrombotic events (rare). Use of DDAVP may be most appropriate if the platelet count and standard coagulation profile is otherwise normal.

Heparin-Associated Coagulopathy

Heparin is routinely administered during dialysis, and although there is no standardized dosing there are common regimens, which include providing an initial bolus (25 to 30 IU/kg) followed by intermittent, lower dose boluses (500 to 2000 IU) or an initial bolus followed by a continuous infusion.⁵⁹ Heparin is usually stopped approximately 1 hour before the end of dialysis, and hence heparin-related bleeding is unusual in the ED. If uncontrollable bleeding occurs in the context of recent heparin use, reversal of heparin's effect with protamine sulfate may be necessary. Administering 1 mg of protamine sulfate will effectively reverse the anticoagulant effect of 100 units of unfractionated heparin. Protamine is less efficacious in the reversal of low-molecular-weight heparins. Nonetheless, current recommendations are to administer 1 mg of protamine for every 1 mg of low-molecular-weight heparin that the patient received.⁶⁰

Warfarin-Associated Coagulopathy

The use of warfarin predisposes patients to potentially serious bleeding complications. In an actively bleeding patient with an elevated INR, immediate reversal of the medication's effect can be achieved with fresh frozen plasma or prothrombin complex concentrates (PCCs). PCCs have the advantage of requiring less total volume to achieve reversal of anticoagulation and therefore less risk for volume overload.⁶⁰ Vitamin K should also be considered for reversal, following warfarin-associated bleeding guidelines.

Catheter Displacement or Malposition

Catheter displacement may occur accidentally secondary to patient movement, iatrogenically, or both. The catheter should be firmly secured with sutures, sterile tape strips (with care taken to avoid direct contact with the catheter itself), and premanufactured devices.¹⁸ Even with these measures disruption of placement may still occur. With regard to TIVADs, malposition of the intravascular portion may occur as a result of incorrect initial positioning or secondarily from forceful flushing, neck flexion, obesity, severe coughing, emesis, or upper extremity movement. Malposition of the port body may occur intentionally or by unintentional manipulation of the port (twiddler's syndrome). Obtain a computed tomography scan of the chest to diagnosis this condition. Surgical intervention is usually necessary.⁶¹

Catheter Fracture

Fracture of an IVAD can occur either subcutaneously or in the externalized portion.⁶² It may take place with certain physical activities that involve repetitive and excessive motion

such as golfing, swimming, and weight lifting. Subcutaneous fractures cause pain and swelling and require removal of the line. Fractures in the externalized portion may be repaired with commercially available kits and do not always require replacement.

Steal Syndrome

Vascular steal syndrome is an uncommon but serious complication of AV fistulas and grafts, which is difficult to predict and may lead to access failure.⁶³ It occurs because of preferential flow through the low-resistance fistula at the expense of the distal circulation. The syndrome is manifested by classic arterial insufficiency symptoms with exacerbation during dialysis: pain, pallor, numbness, motor weakness, and diminished or absent pulses distal to the shunt.⁶⁴ Steal syndrome must be differentiated from diabetic or uremic neuropathy because it may lead to the development of irreversible neuromuscular dysfunction, tissue necrosis, and amputation. Prompt recognition and correction of hand ischemia leads to increased salvage and use of functioning shunts. Steal syndrome usually requires ligation of the AV access with placement of a new access device in the opposite extremity.

AFTERCARE INSTRUCTIONS

Before release from the ED instruct the patient regarding proper catheter care to prolong the device's lifetime, and to decrease morbidity and mortality.²⁸ Patients may bathe and swim normally after maturation of the site; they should avoid

direct pressure on the reservoir and report bruising or bleeding immediately. Long-term venous access catheters and multilumen catheters should be dressed in sterile fashion and observed daily for bleeding and signs of infection, including fever, pain, redness, swelling, and purulent drainage. IVADs should be gently flushed on a routine basis.²⁸ Heparin flushes are essential to prevent thrombosis. Tunneled (e.g., Hickman) and nontunneled (e.g., PICC) catheters require flushing twice weekly with 5 mL of heparin (10 Units/mL). TIVADs require flushing with heparin every 4 weeks and after use. Generally, Groshong catheters are flushed with 5 mL of saline once weekly. Mahurkar and Uldall catheters are flushed during dialysis. Mahurkar catheters are also used for apheresis, in which case they are treated three times a week with normal saline and heparin, as outlined earlier. Patients should not allow phlebotomy or infusion into an extremity with an IVAD, with the exception of phlebotomy in the ipsilateral dorsum of the hand, nor should they have blood pressure measured in that extremity. Clinicians should be knowledgeable about indwelling devices and complications. They should practice sterile technique, use care in handling, and avoid use unless an emergent situation requires access of the IVAD.

Intraosseous Infusion

Kenneth Deitch

Establishing vascular access in critically ill and injured patients is central to the practice of emergency medicine. Moreover, placing an intravenous (IV) catheter in an acutely ill child can be one of the most challenging and frustrating procedures that a clinician can be called on to perform. Children have small peripheral vessels that collapse during shock, and their higher proportion of body fat makes visualization and palpation of peripheral vessels difficult. These factors often result in prolonged attempts and high failure rates.

In a review of vascular access success rates in children in cardiac arrest, the average time needed to establish percutaneous peripheral IV access was 7.9 ± 4.2 minutes, with only a 17% success rate.¹ Some authors advocate the use of central venous lines in children, but such lines are also difficult to place and are associated with risk for arterial injury, infection, and pneumothorax. Alternative routes of drug administration, such as the endotracheal and rectal routes, are not reliable in patients in shock or cardiac arrest.²

Peripheral IV access can also be difficult in adults, including those who are obese, have burn injuries, are volume-depleted, or are in shock.³ This difficulty is compounded in the prehospital or military setting, where environmental factors and the need for rapid transport can challenge even the most skilled practitioners.⁴

 Intraosseous (IO) access (Videos 25.1 to 25.5) can provide rapid, lifesaving intravascular access in challenging environments and in both pediatric and adult patients. All drugs and fluids that are delivered through a peripheral or central venous line can also be administered through an IO cannula. Drug and fluid dosing is the same as for IV administration. The serum concentrations and onset of action of IO administered medications during cardiopulmonary resuscitation (CPR) are comparable to those achieved with IV administration. Per animal studies, the IO route is as effective as central venous administration and may be superior to the peripheral IV route during cardiac arrest.

The American Heart Association, the American Academy of Pediatrics, and the American College of Surgeons all recommend IO access in children in emergency situations when IV access is not immediately possible.^{5,6} The latest edition of the advanced trauma life support course of the American College of Surgeons also notes that IO access using specially designed equipment is an important option in adult trauma patients.⁵ IO access is often faster than IV access, and the success rate after failed IV attempts is high. In a retrospective study of pediatric cardiac arrest patients, time to IO access was significantly shorter than time to IV access.⁷ In a similar review of intravascular access during pediatric cardiac arrest, Brunette and Fischer¹ noted that when compared with central venous access and venous cutdown, IO access and IV access were faster, and the success rate for IO access was 83% versus 17% for IV access. IO access can also be a rapid and successful

technique in adults.⁸ Because of their success under difficult battlefield conditions, the US military has adopted the use of IO infusion devices.⁵

IO access is not always successful. In a 5-year review of prehospital IO needle placement, success rates were higher in children younger than 3 years (85%) than in older children or adults (50%).⁷ The main causes of failure were errors in identification of landmarks and bending of the needles. Better needle design and new devices have helped overcome problems with bone penetration (see later section on [Equipment and Setup](#)).

HISTORICAL PERSPECTIVE

One of the earliest references describing the IO route is attributed to Drinker and colleagues,⁹ who examined the circulation of the sternum in 1922 and suggested it as a site for transfusion. The route was not used clinically until 1934 when Josefson,¹⁰ a Swedish clinician, injected liver concentrate into the sternum of 12 adult patients with pernicious anemia and reported that all 12 improved. Subsequently the technique became widespread in Scandinavian countries. In 1944 British physician Hamilton Bailey¹¹ described the utility of sternal IO access in blackout conditions in London during World War II.

In 1940 the technique was introduced to American clinicians by Tocantins and associates,¹²⁻¹⁴ who described a series of animal and clinical studies demonstrating that fluid is rapidly transported from the medullary cavity of long bones to the heart. They recommended using the manubrium in older children and adults and the upper part of the tibia or lower part of the femur in children 3 years or younger. Over the next two decades, thousands of cases of IO infusion of blood, crystalloid substances, and drugs were reported.¹⁵⁻¹⁹ The procedure was more commonly used in children because of the difficulty in achieving other forms of IV access. Nevertheless, during the 1940s IO infusion was also used extensively in adults, and a sternal puncture kit for bone marrow infusion was a common component of emergency medical supplies during World War II.^{4,20} This resulted in more than 4000 reported cases of successful IO access in wounded soldiers.¹⁹ During this time relatively few complications were reported despite the fact that the needles were often left in place for 24 to 48 hours. In 1947 Heinild and coworkers¹⁷ reviewed 982 cases of IO infusion and reported only 18 failures and 5 cases of osteomyelitis. None of the cases of osteomyelitis occurred in patients who received isotonic solutions.

With the introduction of plastic catheters and improved cannulation techniques, the need for IO infusion as an alternative route for IV access diminished, and the technique was all but abandoned. In the mid-1980s James Orłowski brought about a renaissance in the use of IO access for pediatric resuscitation. While traveling through India during a cholera epidemic, he observed emergency health care workers using IO access to deliver fluids and medications. In 1984 he wrote an editorial, "My Kingdom for an Intravenous Line,"²⁰ in which he advocated the use of IO access during pediatric resuscitation. After Orłowski's editorial, others began promoting the use of IO access to allow rapid drug delivery during CPR in children.^{1,21,22} In 1988 IO techniques were adopted by the American Heart Association and included in the pediatric advanced life support guidelines.⁶ Since then the technique has become widespread throughout the United States and is recognized

Intraosseus Infusion

Indications

Emergency intravascular access when other methods have failed
 Cardiac arrest in infants and young children
 Military applications
 Obtaining blood for laboratory evaluation

Contraindications

Osteoporosis and osteogenesis imperfecta
 Fractured bone
 Prior use of same bone for IO infusion
 Cellulitis or burn overlaying insertion site

Complications

<i>Technical difficulties</i>	<i>Soft tissue and bony complications</i>
Over-penetration	Infection
Incomplete penetration	Bony inflammatory reaction
Needle obstruction	Skin sloughing
Fluid extravasation	Compartment syndrome
	Epiphyseal injury
	Fat embolism
	Pain with infusion

Equipment

Review Box 25.1 Intraosseous infusion: indications, contraindications, complications, and equipment.

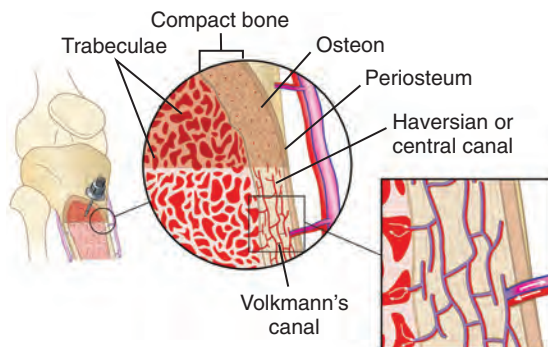

Figure 25.1 Schematic diagram illustrating the vascular anatomy of a long bone with an intraosseous needle in place.

as an accepted alternative to IV access in pediatric emergencies, and, increasingly, in neonatal and adult emergencies. In addition, the safety, ease, and effectiveness of the technique have led to its use in prehospital emergency care.^{7,23–26}

ANATOMY AND PHYSIOLOGY

Long bones are richly vascular structures with a dynamic circulation. They are capable of accepting large volumes of fluid and rapidly transporting fluid or drugs to the central circulation. The bone, like most organs, is supplied by a major artery (nutrient artery). The artery pierces the cortex and divides into ascending and descending branches, which further subdivide into arterioles that pierce the endosteal surface of the stratum compactum to become capillaries. The capillaries drain into medullary venous sinusoids throughout the medullary space, which in turn drain into a central venous channel (Fig. 25.1).

The medullary sinusoids accept fluid and drugs during IO infusion and serve as a route for transport to the central venous channel, which exits the bone as nutrient and emissary veins.²⁷ The medullary cavity thus functions as a rigid, noncollapsible vein, even in the presence of profound shock or cardiopulmonary arrest.²⁸ Radiographic studies have demonstrated that radiopaque dye spreads only a few centimeters in the medullary space before being transported to the venous system.²⁹

Almost every drug and fluid commonly used during resuscitation has been reported upon in clinical and preclinical IO studies. Essentially, all medications and fluids that might be delivered via a venous line can also be administered through the IO route. Dosing of IO medications and fluids is the same as for IV administration. Medications and fluids that have been administered through IO infusion are listed in Box 25.1. Crystalloid infusion studies in animals have demonstrated that infusion rates of 10 to 17 mL/min may be achieved with gravity infusion and rates as high as 42 mL/min with pressure infusion.^{30–32} In a swine model of hemorrhagic shock, Neufeld and colleagues³¹ found that the IO delivery rate of crystalloid was similar to that with both peripheral and central venous administration. IO crystalloid infusions have also been shown to produce a significant increase in blood pressure in a hemorrhagic shock model in rabbits.³² In small animals (7 to 8 kg), the size of the marrow cavity is the rate-limiting factor, whereas in larger animals (12 to 15 kg), the size of the needle determines the flow.^{33,34} Blood under pressure can be infused approximately two-thirds as fast as crystalloid fluids.³³ However, in a swine model evaluating IO infusion for mild therapeutic hypothermia, IO infusion of ice-cold saline was not as efficacious as intravenous infusion.³⁵

Comparisons of IO and IV infusion of drugs have demonstrated that the drugs reach the central circulation by both routes in similar concentrations and at the same time.^{14,36} This holds true even during CPR, during which sodium bicarbonate

BOX 25.1 Medications and Fluids That Can Be Administered Intraosseously

MEDICATIONS	Mannitol
Adenosine	Morphine

Data from Getschman SJ, Dietrich AM, Franklin WH, et al: Intraosseous adenosine. As effective as peripheral or central venous administration? *Arch Pediatr Adolesc Med* 148:616, 1994; and Sawyer RW, Bodai BI, Blaisdell FW, et al: The current status of intraosseous infusion, *J Am Coll Surg* 179:353, 1994.

has been shown to provide greater buffering capacity when administered by the IO route than by the peripheral IV route.³⁷ Early IO access and infusion of epinephrine improved 24-hour survival in a swine model of ventricular fibrillation versus delayed IV administration.³⁸ IO infusion of iodinated computed tomographic contrast material has also been reported as being successful,³⁹ as has scorpion antivenin.⁴⁰ In a porcine model of septic shock, IO and IV infusions had similar peak concentrations.⁴¹ Intraosseous infusion of intralipid reversed bupivacaine toxicity in a rat model.⁴² Cyanide toxicity reversal with hydroxycoalbumin has been shown to be equally efficacious between the IO and IV routes in a porcine model.⁴³ Intraosseous administration has been successfully used for rapid sequence intubation.⁴⁴ Intraosseous injection of iodinated computed tomography contrast agent in an adult blunt trauma patient has also been shown to be successful.⁴⁵

Voelckel and associates³⁶ demonstrated that bone marrow blood flow responds to both the physiologic stress of hemorrhagic shock and vasopressors given during resuscitation after hypovolemic cardiac arrest in dogs. After successful resuscitation, bone marrow blood flow decreased after high-dose epinephrine but was maintained after high-dose vasopressin. These findings in animal models suggest the need for pressurized IO infusion techniques during hemorrhagic shock and certain drug therapies.

INDICATIONS

When children or adults need immediate resuscitation and IV access cannot be achieved quickly or reliably, the IO route

provides a rapid and effective means of administering drugs, fluid, and blood. Once the patient has been stabilized, percutaneous peripheral or central intravascular access may be achieved.

Obtaining venous access can be a difficult task even under the best circumstances. This difficulty is compounded during high-stress situations or low-flow states such as cardiac arrest. Studies have shown that IO devices provide a rapid and effective means of fluid and drug administration during pediatric CPR.¹ This is also true during resuscitation of critically injured infants and children in whom IO infusion of blood, colloids, or crystalloids (or any combination thereof) may be lifesaving. IO infusion is also beneficial in the management of children with other medical conditions, including those with respiratory distress, neurologic insults, dehydration, and sepsis.⁴⁶⁻⁴⁸ The widespread use of IO devices has led to improved prehospital vascular access and a marked reduction in critical transport with failed vascular access.⁴⁹

IO access is not commonly used in infants, but it is recommended as an alternative for medication and crystalloid administration when venous access is not readily obtained.⁵⁰ IO infusion has been used with success in both premature and term infants.⁵¹⁻⁵³ In one study, 30 IO lines were placed in 20 preterm and 7 full-term neonates with a variety of illnesses (e.g., respiratory distress syndrome, perinatal asphyxia, congenital cardiac anomalies) in whom conventional venous access had failed.⁵⁴ All survived resuscitation with no long-term effects from IO line placement. Gestational age ranged from 32 to 41 weeks and birth weight ranged from 515 to 4050 g.⁵⁴ In 2000 Abe and coworkers⁵³ reported on the speed and ease of establishing newborn emergency vascular access by using turkey bones and plastic infant legs to simulate IO access and fresh umbilical cord to simulate umbilical venous catheterization. They demonstrated that for individuals who do not perform newborn resuscitation frequently, IO placement was easier and quicker than umbilical venous catheterization. A comparison of umbilical venous versus IO access in a simulated model of neonatal resuscitation showed that IO access was faster with no difference in error rate or perceived difference in ease of use.⁵⁴

IO infusion is also indicated for adult patients in whom attempts at peripheral or central venous access have been unsuccessful. This may include adult patients with burns, trauma, shock, dehydration, or status epilepticus.⁵⁵ Intraosseous placement for resuscitation has been shown to be significantly faster than central line placement, with a significantly lower failure rate.⁵⁶ Multiple sites including the iliac crest, femur, proximal and distal ends of the tibia, radius, clavicle, and calcaneus may be used.⁵⁷⁻⁶⁰ Of these, the tibia may be less desirable because red marrow is replaced by less vascular yellow marrow or fat by the fifth year of life. In contrast, the sternum has been advocated as the best site to establish IO access in adults because it is large and flat and can readily be located.⁶¹ In addition, the sternum's cortical bone is thin (1 to 2 mm) and the marrow space relatively uniform (6 to 11 mm).⁶²

There has also been renewed interest in IO access by the US military. In addition to logistic constraints that limit the volume of isotonic crystalloid fluids available to resuscitate injured soldiers, hypotension, environmental and tactical conditions, and the presence of mass casualties can lead to excessive delay in obtaining vascular access.⁴ The Army Institute for Research has compared several IO infusion devices, including the FAST-1 IO Infusion System (PYNG Medical Corporation, Richmond, British Columbia, Canada), the Bone Injection

Gun (BIG; Waismed, Yokenam, Israel), the Sur-Fast Hand-Driven Threaded-Needle (Cook Critical Care, Bloomington, IL), and the Jamshidi Straight-Needle (Allegiance Health Care, McGaw Park, IL).⁵⁶ Success rates with these devices were similar (94% to 97%), and all were inserted in less than 2 minutes. The participants rated no individual device as being significantly better than the others. It was concluded that each device was easy to master and could be used appropriately during special operations when IV access could not be accomplished.⁵⁶ The US Army Committee on the Tactical Combat Casualty Care (TCCC) guidelines (2010) recommends using IO infusion in any resuscitation scenario in which IV access is not obtainable.⁶³

In addition to serving as a route for fluid administration, the IO needle may be used to obtain blood for typing, cross-matching, and determining blood chemistry in the marrow cavity. Serum electrolyte, blood urea nitrogen, creatinine, glucose, and calcium levels are very similar to those in samples obtained from an IO aspirate.⁶⁴⁻⁶⁶ Blood gas values obtained from the IO site were similar to those obtained from central venous sites during steady and low-flow states in one animal model.⁶⁷ Brickman and colleagues⁶⁸ demonstrated that bone marrow aspirates obtained from an IO needle in the iliac crest could be used reliably to type and screen blood for transfusion. A complete blood cell count may not be reliable because it reflects the marrow cell count rather than the cell count in the peripheral circulation. Furthermore, the aspirated blood usually clots within seconds, even if placed in a tube that contains heparin.

CONTRAINDICATIONS

Relatively few contraindications to IO infusion exist. Osteoporosis and osteogenesis imperfecta are associated with a high potential for fracture; therefore unless absolutely necessary, the procedure should be avoided when these diagnoses are known. A fractured bone should be avoided because as fluid is infused, it increases intramedullary pressure and forces fluid to extravasate at the fracture site. This may slow the healing process, cause nonunion of the bone, or lead to a compartment syndrome. Similar extravasation of fluid can occur through recent IO puncture sites placed in the same bone. Hence, recent previous use of the same bone for IO infusion represents a relative contraindication to IO line placement. Needle

insertion through areas of cellulitis, infection, or burns should also be avoided. Patients with right-to-left intracardiac shunts (e.g., tetralogy of Fallot, pulmonary atresia) may be at higher risk for fat or bone marrow embolization.^{69,70}

EQUIPMENT AND SETUP

The following is a review of products currently available for IO infusion. Information regarding the use of these products is limited, and few prospective studies have compared IO needles or devices in clinical practice. Until more information becomes available, practitioners are encouraged to review the products available and choose those that best meet their needs.

IO Needles (Fig. 25.2)

Needles used for IO access range in size from 13- to 20-gauge and must be sturdy enough to penetrate bone without bending or breaking. They must also be long enough to reach the marrow cavity. Standard needles used for drawing blood or administering medications are not adequate for IO infusions; they are not sturdy enough to penetrate bone and do not have a stylet to prevent bone from plugging the lumen. A cadaver study of IO puncture suggested that nonstyletted needles (2.5-cm, 18-gauge phlebotomy needles and 7.6-cm, 14-gauge IV needles) enter the marrow space successfully only approximately half the time.⁷¹ In the past, an 18-gauge spinal needle was commonly used in children younger than 12 to 18 months. This needle, although readily available in most emergency departments (EDs), often bends, is too long for rapid infusion of fluid, and has a greater risk for occlusion from clotted blood.⁷² Very small “butterfly” needles have been used with success in preterm infants.⁷³

Bone Marrow Aspiration Needle

Bone marrow aspiration needles can be used if needles specifically designed for IO access are not available. These needles are large enough (16 gauge) to be used in older children and adults and are suitable for rapid administration of fluid.

Illinois Sternal/Iliac Aspiration Needle

The Illinois Sternal/Iliac Aspiration Needle (Monojet, Division of Sherwood Medical, St. Louis, MO) was designed for bone marrow aspiration but can be used for IO infusion. The needle

Figure 25.2 Various intraosseous needles.

is available in both 16- and 18-gauge. It has an adjustable plastic sleeve to prevent the needle from penetrating through the opposite bony cortex. However, its long shaft and poorly designed handle make it prone to dislodgement during transport and other procedures.

Jamshidi Disposable Sternal/Iliac Aspiration Needle

Like the Illinois Sternal/Iliac Aspiration Needle the Jamshidi Disposable Sternal/Iliac Aspiration Needle (Cardinal Health, Dublin, OH) was designed for bone marrow aspiration, but it has a shorter shaft and smaller handle, which makes it easier to use. It comes in either 15- or 18-gauge and also features an adjustable plastic sleeve to prevent overpenetration. Once inserted the needle protrudes approximately 2 inches from the skin, which increases the risk for accidental dislodgement. In a study using a turkey bone model participants rated the Jamshidi needle easier to use than the Cook IO needle.⁷⁴

Cook IO Needle

The Cook IO Needle (Cook Critical Care) is specifically designed for IO insertion and infusion. It comes in a variety of sizes from 18- to 14-gauge and can be inserted to a depth of 3 to 4 cm. It has a detachable handle, which reduces the risk of it being dislodged, and a depth marker to help ensure proper placement.

Sur-Fast Needle

The Sur-Fast Needle (Cook Critical Care) is also specifically designed for IO insertion and infusion. It has a threaded shaft that helps secure the needle in the bone and a detachable handle that may be reused with multiple needles. In a study by Jun and associates,⁷⁵ the Sur-Fast IO needle had a success rate similar to that of a standard bone marrow aspiration needle.

IO Devices

FAST-1 Intraosseous Infusion System (Fig. 25.3)

The FAST-1 Intraosseous Infusion System (PYNG Medical) uses an impact-driven device designed for sternal placement only. The FAST-1 has been used successfully by both military and prehospital care providers.^{56,76} In one prehospital study, flow rates of 80 and 150 mL/min were obtained by using gravity and a pressure bag, respectively.⁷⁷ In a prospective prehospital evaluation, the mean time to successful placement was 67 seconds.⁷⁸ The device has a series of stabilizing probes that help maintain good contact with the sternum and serve as the depth control mechanism for insertion of the needle. These probes use the surface of the manubrium rather than the patient's skin to ensure the proper depth of insertion. Once the device is positioned against the sternum, additional pressure triggers the release of a hollow needle into the medullary space. The needle comes preconnected to IV tubing. The handle is automatically released from the stylet and infusion tubing once the needle has met its preset depth. Removal of the needle requires a threaded tool provided with the device. The FAST-1 is larger and heavier than other IO devices and once triggered cannot be reused.

Bone Injection Gun—BIG

The BIG (PerSys Medical, Houston, TX) is another spring-loaded, impact-driven device that comes in both pediatric and adult sizes. (Fig. 25.4) Like the FAST-1 system, this device is designed for single use only. An advantage of the BIG is the

Figure 25.3 FAST-1 Intraosseous Infusion System. (Courtesy PYNG Medical Corporation, Richmond, British Columbia, Canada.)

Figure 25.4 Bone Injection Gun. (Courtesy PerSys Medical, Houston, TX.)

ability to adjust the depth of insertion, which allows it to be used at different sites (e.g., tibia, humerus). However, if the device is not carefully stabilized before and during insertion, incorrect placement can easily occur. In addition, there is the potential for operator and patient injury if the device is accidentally triggered or mistargeted.⁷⁸ In a prospective, prehospital setting the BIG device was shown to have a 71% success rate in children and a 73% success rate in adults.⁷⁹ In another prehospital study, 91% of 181 patients had successful insertion on the first attempt.⁸⁰

EZ-IO Device (Fig. 25.5)

The EZ-IO Device (Teleflex, San Antonio, TX) is a handheld, battery-powered device that drills an IO needle to the appropriate depth in the IO space. The EZ-IO device allows the operator

Figure 25.5 EZ-IO Device (Teleflex, San Antonio, TX).

to control the pressure or force used during insertion.⁸¹ Placement can be achieved in less than 10 seconds in the vast majority of patients, with first-time successful insertion rates ranging from 77% to 97%.^{81–84} In the United States, the EZ-IO has been approved for use at two anatomical sites, the proximal tibia and the humeral head.²⁸ The EZ-IO has been shown to have a first pass success rate in the prehospital setting of 84% to 92%.⁸⁵

NIO Device

The New Intraosseous (NIO) device (PerSys Medical) is a Food and Drug Administration (FDA)-approved device that is spring-loaded and used primarily for tibial insertion (Fig. 25.6). It can also be used in the humerus. It is lightweight, does not require batteries, and is a self-contained unit designed for a single use and ease of deployment. There is some early published evidence that suggests that it has comparable successful deployment rates for both tibial and humeral placement as the EZ-IO (Teleflex).

Comparative Trials Between Devices

The effectiveness, speed, and complication rates of manually placed versus mechanical drill-assisted IO catheters by emergency medicine resident physicians were compared in a 2013 study.⁸⁶ The mechanical placement was shown to be significantly faster (3.66 vs. 33.57 seconds, $P = 0.01$), the Jamshidi 15G needle, the FAST-1, and the BIG were compared in a helicopter-based emergency service system.⁸⁷ In this randomized controlled trial, The Jamshidi needle and the FAST-1 had similar success and complication rates. However, the Jamshidi needle was placed significantly faster than the FAST-1.⁸⁷ Frascone and colleagues⁸⁸ conducted two sequential prospective nonrandomized trials to compare the FAST-1 with the EZ-IO, both in the prehospital setting. Of 178 IO insertions evaluated, 64 of the 89 FAST-1 insertions were successful as were 78 of the 89 EZ-IO insertions (72% vs. 87%). During the 5-year study period, 11 technical complications were recorded with the EZ-IO and 25 with the FAST-1. There were no differences in provider comfort or provider assessed device performance between the two devices. The BIG has also been compared to the EZ-IO in the adult population in two randomized trials. Twenty patients were treated with the BIG and 20 with the EZ-IO, with success rates in the first attempt of 85% and

Figure 25.6 NIO intraosseous device (PerSys Medical, Houston, TX).

90%. Mean procedure time was 2.2 min \pm 1.0 for the BIG, versus 1.8 min \pm 0.9 for the EZ-IO. Five technical problems were reported with the BIG, none with the EZ-IO. In five patients who were treated with the BIG, the stylet became stuck within the cannula and could only be removed with a clamp.^{57,89} In a large multi-year retrospective analysis of a trauma database, rates of success on first attempt were significantly higher with the EZ-IO compared with the manual needle and the BIG. Overall success rates were 50% with the manual needle, 55% with the BIG, and 96% with the EZ-IO.⁹⁰

Simulation Studies Comparing Devices

In a simulation cadaver model laboratory with US military providers, four IO devices were compared: the FAST-1, the BIG, the hand-driven threaded Sur-Fast needle, and the Jamshidi needle. High success rates were recorded for all four devices (94%–97%), but the BIG had the fastest placement time.⁹¹ In another randomized crossover study, the BIG and the EZ-IO were tested on a turkey bone model. Study results showed that the EZ-IO had a one-attempt success rate of 96.5% (28/29) compared to 65.5% (19/29) for the BIG, and that nearly 70% of the study subjects chose the EZ-IO as their preferred device. Six technical complications were reported with BIG, none with the EZ-IO.⁹² In another study, using a cat cadaver model, the EZ-IO, the BIG and the Jamshidi manual needle were compared. This study showed a higher success rate with the EZ-IO than the other two devices (96% vs. 75% and 88%, respectively).⁹³ In another simulation study using

paramedics, the BIG had the highest success at first pass (91%) versus the EZ-IO (82%) and the Jamshidi needle (47%).⁹⁴

PROCEDURE

Sites for IO Needle Placement

The patient's age and size are the two most important factors when choosing the best site for needle penetration. In infants and children younger than 6 years, the proximal end of the tibia is the preferred site, followed by the distal ends of the tibia and femur. Other sites such as the clavicle and humerus have been used, but neither has gained popularity. In adults, the distal part of the tibia has been the most common site for IO access. However, with the introduction of spring-loaded and drill devices, IO locations once reserved only for children are now also potential sites in adults. In addition, the FAST-1 System makes the sternum a simple and effective location for IO access in adults.⁸²

Proximal Tibia

The tibia is a large bone with a thin layer of overlying subcutaneous tissue that allows landmarks to be palpated readily. Insertion here does not interfere with airway management or CPR. This is one of the most common infusion sites. On the proximal end of the tibia, the broad, flat, anteromedial surface is used, and the tibial tuberosity serves as a landmark. The site of IO cannulation is approximately 1 to 3 cm (2 finger widths) below the tuberosity (Fig. 25.7A). This location is far enough away from the growth plate to prevent damage, but it is in an area where the bone is still soft enough to allow easy penetration with the needle. In adults, penetrating the thick bone in the proximal end of the tibia is much more difficult and requires a 13- to 16-gauge needle. A spring-loaded device such as the BIG or a battery-powered drill such as the EZ-IO can make penetration much easier and allows the use of smaller-gauge needles. In a comparison of first-attempt

success between tibial and humeral IO insertion during out-of-hospital cardiac arrest, tibial placement was significantly more successful (90%) than humeral placement (60%) with a lower rate of needle dislodgement.⁹⁵

Distal Tibia

The distal end of the tibia, although a preferred site in adults, may also be used in children.^{72,96} The cortex of the bone and the overlying tissue are both thin. The site of needle insertion is the medial surface at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein (see Fig. 25.7B). The needle is inserted perpendicular to the long axis of the bone or 10 to 15 degrees cephalad to avoid the growth plate.⁹⁷

Distal Femur

The distal portion of the femur is occasionally used as an alternative site in children, but because of thick overlying muscle and soft tissue it is more difficult to palpate bony landmarks (see Fig. 25.7C). If chosen, the needle should be inserted 2 to 3 cm above the femoral condyles in the midline and directed cephalad at an angle of 10 to 15 degrees from the vertical.⁹⁸

Humerus

The proximal end of the humerus is a relatively new option for IO access, but it is well tolerated and easily accessed. The close proximity of the greater tubercle of the humerus to the heart provides rapid infusion of medication and fluid into the general circulation. The humerus has been shown to be an effective site relative to peripheral or central access in a prospective resuscitation model.^{98,99} A study evaluating flow rates through all three sites in a porcine model showed that the proximal humerus had almost double the flow rate than either the tibial or distal femur site.¹⁰⁰ In a retrospective study in a prehospital setting of cardiac arrest, IO insertion into the humerus had a higher success rate than into the proximal tibia.⁹⁵ However, in another study first pass success for humeral placement in a paramedic performed prehospital population

Figure 25.7 Intraosseous (IO) insertion sites. **A**, Proximal tibia. Insert the IO needle 1 to 3 cm distal to the tibial tuberosity and over the medial aspect of the tibia. Direct the bevel of the needle away from the joint space. **B**, Distal tibia. Insert the IO needle on the medial surface of the distal end of the tibia at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein. Direct the needle cephalad, away from the growth plate. **C**, Distal femur. Insert the IO needle 2 to 3 cm above the femoral condyles in the midline and directed cephalad away from the growth plate.

during cardiac arrest was over 90%.¹⁰¹ The patient's arm should be placed such that the hand is resting on the patient's umbilicus, with some adduction. Medial rotation of the humerus will allow better identification of the proximal humeral head. The humerus is most easily palpated at the insertion point for the deltoid muscle, between the biceps and triceps muscles. This point is approximately midway along the length of the arm. Palpation of the bone requires pressure because of overlying structures. The surgical neck can be located by palpating up the length of the humerus until the clinician feels a notch or groove. The appropriate insertion site is approximately 1 cm above the surgical neck for most adults (see Fig. 25.12). A study evaluating the humeral head approach during tactical situations was shown to have a 96% first pass success rate using an EZ-IO, and a 90% success rate using a manual driver.¹⁰²

Sternum

The sternum has several advantages over peripheral bones but is rarely used in the ED. Its advantages include a large, relatively flat body that can be readily located; retention of a high proportion of red marrow, which allows rapid transfer of infused fluids and drugs to the central circulation; and thinner, more uniform cortical bone overlying a relatively uniform marrow space. In addition, the sternum is less likely to be fractured in major trauma.⁷⁶ Introduction of the FAST-1 System, which allows safe and effective penetration of the sternum, has led to increased use and popularity of sternal IO insertion in adults.

Other Sites

Other sites, including the clavicle and calcaneus, can be used as alternatives, but these sites are less popular.

Site Preparation

To prepare the proximal end of the tibia or distal end of the femur for IO insertion, place a small support such as a towel roll behind the knee. Cleanse all insertion sites with chlorhexidine, povidone-iodine, or an alcohol-based antibacterial solution. If the patient is conscious, anesthetize the skin and periosteum.

Manual Needle Insertion (Fig. 25.8)

Before insertion stabilize the site with the free hand (i.e., the hand not holding the IO needle) and use it to identify the landmarks. For example, during the proximal tibia insertion, stabilize the proximal end of the tibia with the thumb and index finger of the free hand and use them to palpate the tibial tuberosity (the main bony landmark for proximal tibia insertion). During insertion avoid injury to this hand by keeping it out of the plane of insertion and clear of the puncture site. Direct the IO needle perpendicular (90 degrees) to the bone's long axis and slightly caudad (60 to 75 degrees). Directing the needle slightly caudad helps avoid penetration of the growth plate. Advance the needle with a twisting or rotating motion (but not a rocking motion) to drive it into the bone and to puncture the cortex. Once the cortex has been penetrated, there will be a sudden decrease in bony resistance and a "crunchy" feeling as the needle enters the marrow cavity. Penetration of the inner cortex usually occurs at a depth of approximately 1 cm.

Aspirate for blood or marrow contents (or both) to confirm correct placement; however, aspiration may not always produce blood even with a properly placed IO needle. Other signs of correct placement include the needle's ability to remain upright

without support and to have free-flowing fluid without signs of extravasation into surrounding tissue. Note that some resistance to flushing is expected because the bone marrow is not distensible.^{103,104}

Once proper placement is confirmed, secure the needle and tubing with tape. Fasten the leg to an appropriately sized leg board to further stabilize a lower extremity insertion site in infants and small children. Protect the needle from accidental dislodgement by cutting the bottom out of a plastic cup and taping and bandaging the cup in place over the device. Commercially made shields are also available for this purpose. Remove the IO needle as soon as IV access has been secured, and apply a sterile dressing over the site. Control excessive bleeding by applying direct pressure over the site for 5 minutes.¹⁰⁵

USE OF SPECIFIC IO DEVICES

FAST-1 (Fig. 25.9)

The FAST-1 device (PYNG Medical) was designed specifically to penetrate the sternum.^{62,106} It is prepackaged with alcohol and iodine and comes with a protective dressing to hold the device in place. It also includes a threaded tip remover for easy removal of the metal tip and infusion tubing (see instruction video at: <http://www.pyng.com/fast1/>).

After disinfecting the skin site over the sternum, place the target patch over the midline of the manubrium with the hole in the middle of the target approximately 1.5 cm below the sternal notch. Next, place the FAST-1 introducer in the center of the target zone. The introducer has a "bone cluster" of needles that form a circle. These needles "sense" the cortex of the sternum and help ensure proper needle depth. Once the introducer is in position over the target zone, apply pressure to the handle to release the inner needle located in the center of the bone cluster. This needle has a small metal tip that is preconnected to plastic infusion tubing. After release, the central IO needle will advance 5 mm beyond the circular cluster of needles, stop at the bony cortex, and position the metal tip at the cortex-medullary junction. At this point withdraw the handle so that only the plastic infusion tube is left protruding from the insertion site. Marrow aspiration and rapid flow of fluid help verify the appropriate position. Attach the plastic dome to the target patch via Velcro fasteners and secure the tubing in place. Removal of the infusion tube requires the use of a threaded-tip remover, which is included. The tube can also be removed by directly pulling it; however, the metal tip is sometimes left behind and must be extracted through a small incision.⁶¹

BIG (Fig. 25.10)

The BIG (Waismed) incorporates a loaded spring to facilitate penetration of the bone (see instruction video at: <http://www.waismed.com/BIGmovie.html>). To adjust the depth of insertion remove the safety pin from one end and turn the other end clockwise or counterclockwise to reduce or increase needle depth, respectively. Place the BIG firmly against the skin perpendicular or slightly caudad to the long axis of the bone. Fire the gun by applying palmar force on the back of the unit and pulling on the flanges with the middle and ring fingers. Confirm placement by aspirating marrow, flushing with the same syringe, and observing flow through the IV

Manual Intraosseous Needle Insertion

1
Cleanse the skin with antiseptic.

2
Stabilize the leg and identify the tibial tuberosity with your free hand. Insert the needle perpendicular or slightly caudad with a twisting or rotating motion.

3
Remove the stylet once the cortex is penetrated (feel for a decrease in resistance and a "crunchy" feeling).

4
Aspirate blood and/or marrow to confirm the correct position. If the patient is awake, very slowly infuse 2–5 mL of 2% lidocaine a few minutes prior to infusion. Flush the needle with 10 mL of saline to prime the infusion.

5
Connect the IV tubing to the needle.

6
Secure the IO needle in place with tape.

7
Protect the needle from dislodgement with a plastic cup in which the bottom has been cut out, and then tape and bandage if in place over the needle.

Figure 25.8 Manual intraosseous (IO) needle insertion. *IV*, intravenous.

FAST-1 Intraosseous Device

1 Cleanse the overlying skin with antiseptic and then place the adhesive target patch over the midline of the manubrium; the target hole should be approximately 1.5 cm below the sternal notch.

2 Place the introducer in the center of the target zone. Apply pressure to the handle to release the needle. The central IO needle will advance to the cortex-medullary junction.

3 Attach the plastic dome to the target patch to secure the tube in place.

Figure 25.9 Insertion of the FAST-1 Intraosseous Device (PYNG Medical Corporation, Richmond, British Columbia, Canada).

tubing. Slide the slotted safety pin into the needle to maintain stability. To remove the needle, rotate it back and forth using the small clamps provided with the unit. Dress the site in a manner determined by the care provider.

EZ-IO Needle (Figs. 25.11 and 25.12)

This battery-operated “drill” can drive the IO needle through thick bone with relative ease. The EZ-IO kit comes with a battery-operated drill and an IO needle with a stylet. The EZ-IO AD (adult) comes with a 15-gauge, 25-mm IO needle for use in patients heavier than 40 kg, and the EZ-IO PD (pediatric) comes with a 15-gauge, 15-mm needle for use in patients lighter than 39 kg. To operate the drill, insert the needle into the driver tip and make sure that it is securely seated onto the drill. Remove the safety cap from the needle and position the drill perpendicular (or slightly caudad) to the

insertion site. While applying gentle pressure, squeeze the trigger to penetrate the skin. When the tip of the needle comes in contact with the bone, at least 5 mm of the IO catheter should be visible. If not, the overlying soft tissue may be too deep for the needle to enter the marrow cavity. To penetrate the bone, continue to squeeze the trigger while applying steady downward pressure until a sudden “give” or “pop” occurs, which signals entry into the medullary space. Too much pressure on the device can cause the drill to stall and prevent the needle from penetrating the cortex.

After entry into the marrow cavity, attach the EZ-Connect extension set provided with the EZ-IO kit and aspirate blood and bone marrow contents to confirm correct placement. Once catheter placement has been checked, fluids or medications can be infused. Avoid attaching syringes and IV tubing directly to the IO needle because this can enlarge the hole in the cortex and result in extravasation of fluid. Secure

The Bone Injection Gun (BIG)

1 Hold the bottom part of the device firmly, perpendicular to the leg.

2 Squeeze and pull out the safety latch.

3 While holding firmly at the bottom part, press down with the palm of your hand.

4 Pull up the Bone Injection Gun (BIG) slowly.

5 Remove the trocar needle.

6 Secure with the safety latch.

7 Flush with 10–20 mL of normal saline.

Figure 25.10 Use of the Bone Injection Gun (BIG) (Waismed, Yokenam, Israel).

the tubing with tape and cover the area with an appropriate dressing.

NIO Needle (Fig. 25.13)

Place the device approximately 2 cm medial and 1 cm proximal to the tibial tuberosity. Unlock the NIO by rotating the cap 90 degrees in either direction. Place the dominant hand over the cap and press the device against the patient. While pressing down on the device with the palm, pull trigger wings upwards with fingers. Gently pull the NIO up in a rotating motion

while holding the needle stabilizer against the insertion site. Continue holding the needle stabilizer in place and pull up the stylet to remove.

COMPLICATIONS

Technical Difficulties

Technical difficulties are the most common complications, but they decrease as familiarity with the technique increases

EZ-IO Intraosseous Device

Cleanse the site with an antiseptic agent per institutional protocol.

Connect the appropriate needle set to the driver (pink 15 mm = patients 3–39 kg; blue 25 mm = patients > 40 kg; yellow 45 mm = proximal humerus, patients with excessive tissue over the site).

Position the driver at the insertion site with the needle at a 90-degree angle to the surface of the bone. Gently pierce the skin with the needle set and advance needle *without using the trigger yet*, until the needle set tip touches the bone.

Penetrate the bone cortex by now squeezing the driver's trigger and applying gentle, consistent, steady downward pressure. Allow the driver to do the work.

Remove the power driver from the needle set while stabilizing the catheter hub, and then remove the stylet by turning it counterclockwise.

Attach the EZ-Connect tubing to the Luer-Lok adapter on the catheter hub. Confirm placement by aspirating blood and/or marrow contents.

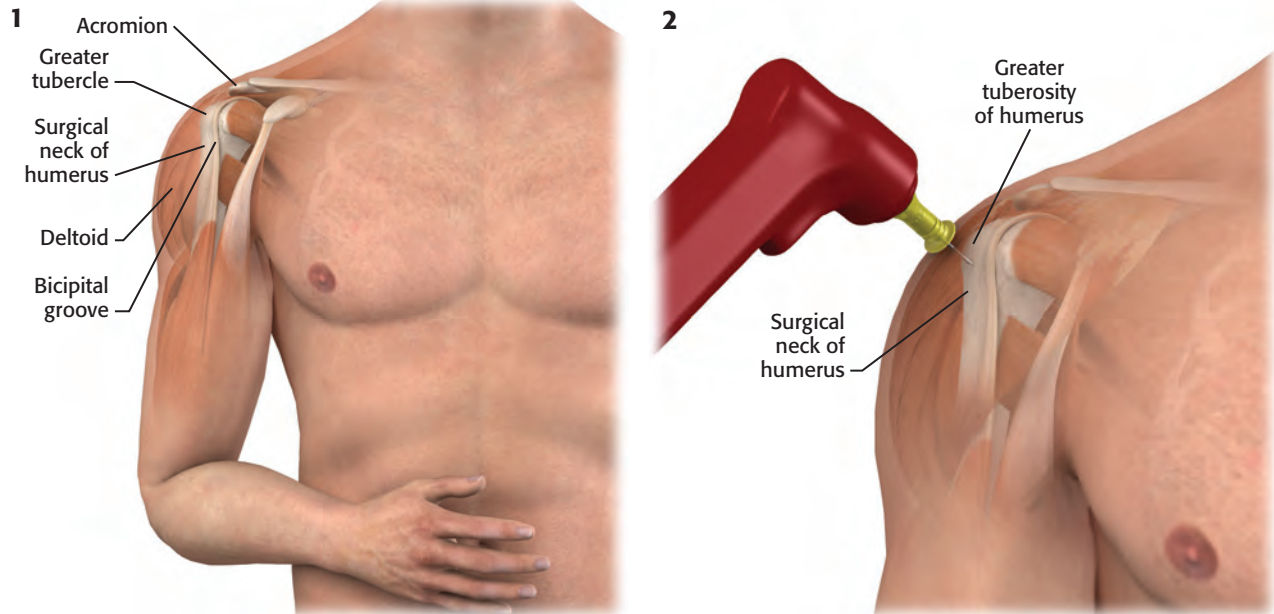

If the patient is responsive to pain, consider *slowly* administering plain 2% lidocaine for anesthetic effect *before* flushing with 10 mL of saline. Begin the infusion with a pressure bag.

Remove the device within 24 hours. Connect a sterile Luer-Lok syringe to the catheter hub, and rotate clockwise while pulling straight up. Avoid rocking the needle on removal.

Figure 25.11 Use of the EZ-IO device (Teleflex, San Antonio, TX).

EZ-IO Proximal Humerus Insertion

Position the patient with the arm adducted and the hand over the umbilicus. This results in internal rotation of the humerus and shifts the greater tubercle to a more anterior position. Identify the greater tubercle of the humerus (firm pressure may be required because of overlying structures such as the deltoid). Identify the surgical neck of the humerus by palpating up the humerus until a “notch” or “groove” is felt.

The appropriate insertion site is 1 cm superior to the surgical neck for most adults. Use the yellow 45-mm needle set. The process of EZ-IO insertion and removal at the humerus site is identical to that described in Fig. 25.12.

Figure 25.12 EZ-IO (Teleflex, San Antonio, TX) proximal humeral insertion.

Figure 25.13 Use of the NIO device (PerSys Medical, Houston, TX).

(Fig. 25.14). The most common mistake is to place excessive pressure on the needle during insertion and force it entirely through the bone and out the other side (Fig. 25.15). Minimize this risk by using appropriate landmarks and keeping the needle perpendicular to the long axis of the bone. In addition, hold the needle with the index finger approximately 1 cm from the bevel. When this finger touches the skin, the needle should

be in the marrow cavity and no further pressure needs to be applied. Some IO needles have a mark 1 cm from the bevel (e.g., Cook IO Needle), whereas others have a special guide or mechanism to ensure proper insertion and depth of penetration (e.g., Illinois Sternal/Iliac Aspiration Needle). If available, use of these adjuncts will also help prevent overpenetration.

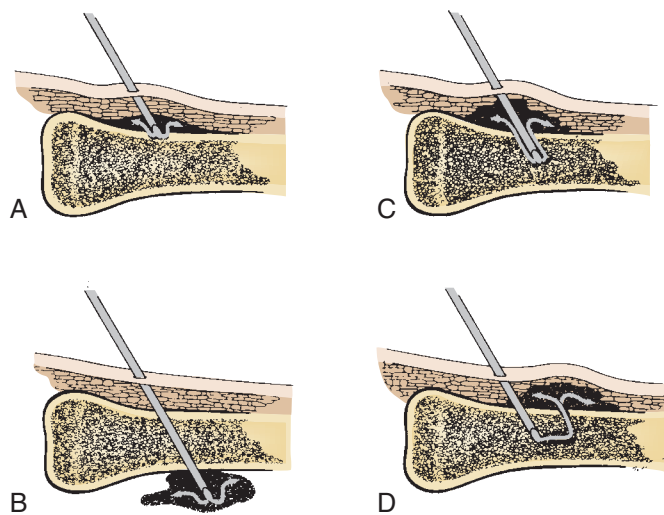

Figure 25.14 Schematic diagram of possible problems encountered with intraosseous infusion. **A**, Incomplete penetration of the bony cortex. **B**, Penetration of the posterior cortex. **C**, Fluid escaping around the needle through the puncture site. **D**, Fluid leaking through a nearby previous cortical puncture site.

Figure 25.15 Radiograph of bilaterally misplaced intraosseous needles with penetration through the posterior tibial cortices.

At times the needle appears to be in the marrow cavity, but blood or bone marrow cannot be aspirated and fluids do not flow freely. This may follow incomplete penetration of the bone or overpenetration into the opposite cortex. Incomplete penetration usually results in extravasation of fluids and can be corrected by replacing the stylet and slowly advancing the needle until successful aspiration of marrow contents and free flow of fluids occur. Penetration into the opposite cortex generally results in little or no flow. If overpenetration is suspected, pull the needle back 1 to 2 mm and check for free flow of fluids.

To ensure flow, rapidly inject 10 mL of saline into the marrow. This is a painful procedure in awake patients, but failure to initially flush the compartment is a common reason for inadequate flow. A pressurized bag system is suggested if large volumes of fluid are administered. Flush each dose of medication with 3 to 5 mL of saline. Fluids that initially flowed freely may stop flowing if the needle becomes clogged by blood clots or bone spicules. Flush the needle frequently with 3 to 5 mL of saline to help avoid this problem. If none of these maneuvers results in free flow of fluid, remove the needle and attempt insertion in the opposite extremity or another

site. This helps avoid fluid extravasation through the hole that is left after removing the needle.

Extravasation of fluid is less common but may be associated with a number of adverse events.^{106,107} Extravasation may be caused by fluids being infused under excessive pressure and with prolonged use of an IO site.¹⁰⁸ As noted previously, extravasation may also result from incomplete needle penetration or penetration through the opposite cortex. Even when an IO needle has been positioned properly, fluid can leak out through holes made by previous IO attempts or through an insertion site that was made too large by “rocking” during insertion or from an improperly secured needle that becomes loose with movement.^{106–110} Interestingly, the type of needle used does not appear to influence extravasation rates.¹¹¹ Regardless of the cause, if extravasation occurs, remove the needle quickly and apply pressure to the site. If left unchecked, extravasation can lead to a number of adverse events (see later section on **Soft Tissue and Bony Complications**). In addition, though not directly harmful, extravasation of fluid through multiple cortical defects from previous IO attempts has been associated with lower serum levels of infused drugs.¹¹²

Soft Tissue and Bony Complications

Infection

In the past, concerns about infection led clinicians to shy away from using the IO route. Although the potential for infection is real, its actual incidence is low. A literature review of more than 4000 cases from 1942 to 1977 found a 0.6% infection rate.³ Although most of the affected access sites were not placed under emergency conditions, the needles were often left in place for 1 to 2 days, thus increasing the likelihood of infection. A survey of more than 1000 US and foreign medical schools found that the incidence of infection for IO needles placed in emergency conditions was less than 3%.¹¹³ The most common infection is cellulitis at the puncture site, which usually responds well to antibiotics. Osteomyelitis is less common but also usually responds well to antibiotics. Heinild and coworkers¹⁷ reported three cases of osteomyelitis in 25 patients who received infusions of undiluted 50% dextrose in water. More recently, Platt and coworkers¹⁴ reported a case of fungal osteomyelitis and sepsis secondary to an IO infusion device. A case of tibial osteomyelitis with IO abscess has also been reported.¹¹⁵

In addition to infection, inflammatory reactions of the bone may be seen. Such reactions are most common when hypertonic or sclerosing agents are used and may produce an elevation of the periosteum on plain radiographs or a positive bone scan (Fig. 25.16). Unlike patients with osteomyelitis from bacteria, a child with a sterile inflammatory reaction should not appear ill. One hypertonic sclerosing drug that may be used during cardiac arrest is sodium bicarbonate. Heinild and coworkers¹⁷ reported 78 cases of bicarbonate infusion with no complications. Animal studies have reported a decrease in cellularity with edema and destruction of some cells, but these changes are temporary and resolve completely in a few weeks.^{116–119} A case of systemic fibrinolysis through IO vascular access in a patient with ST-elevation myocardial infarction has also been reported.¹²⁰

Skin Sloughing

Skin sloughing and myonecrosis have been reported secondary to extravasation of infused fluids and medications.¹¹⁹ This occurs if fluid or drugs extravasate from the puncture site into

Figure 25.16 A, Radiograph and B, bone scan of the tibia demonstrating an inflammatory reaction 4 days after the patient received intraosseous phenytoin and phenobarbital. The periosteum is elevated along the length of the bone and is mimicking osteomyelitis on the plain film and the bone scan. Diagnosis of osteomyelitis requires either clinical evidence of infectious toxicity or positive cultures (blood or periosteal aspirate).

the surrounding tissue. When drugs such as calcium chloride, epinephrine, and sodium bicarbonate are infused, be careful to prevent dislodgement of the needle and extravasation into tissue. In addition, it is best to infuse such drugs only by gravity because infusion under pressure increases the risk for extravasation.

Compartment Syndrome

Compartment syndrome may occur when fluids leak out of the bone into a closed compartment such as the anterior or deep posterior compartment of the lower leg.^{121–124} The risk for compartment syndrome can be reduced by carefully placing and securing the IO needle, limiting the number of attempts in the same bone, and removing the needle once IV access has been obtained. In addition, it is prudent to check the insertion site frequently, especially when fluids are being infused under pressure.

Epiphyseal Injuries

Injury to the growth plate and subsequent developmental abnormalities of the bone are ongoing concerns with the IO route. Regardless, these fears are largely unsupported in the available literature. In fact, there have been no reports of growth plate damage or permanent abnormalities of the bone. Two animal studies specifically examined damage to the epiphysis. Sodium bicarbonate was injected directly into the epiphysis and no radiologic evidence of epiphyseal injury was found.^{125,126} In addition, two prospective radiologic analyses failed to identify any growth abnormalities 1 year after tibial IO insertion.^{127,128} By pointing the needle away from the joint space and using the previously mentioned landmarks for insertion, the risk for epiphyseal injury is remote.

Whereas growth plate abnormalities appear to be very rare, tibial fractures have been reported after IO placement.¹²⁹ Hence,

it is appropriate to take follow-up radiographs of patients who have undergone IO needle attempts or placement. Cortical defects may be seen on radiographs for up to 40 days after injection.¹³⁰

Fat Embolism

Fat embolism is another potential complication of IO insertion.^{3,72} However, this condition is rare and has been reported only in adult patients.⁶⁵ Animal studies have found no changes in blood gases during IO infusion and limited evidence of fat globule collections in the lungs.^{69,70} In a swine cardiac arrest model, there was no difference in the risk for fat emboli in pigs that had an IO line inserted versus those receiving IV medications.^{131,132} Because the marrow in infants and children is primarily hematopoietic, this potential complication is unlikely to occur in this population.

Pain With Infusion

Most patients undergoing IO infusion will not be in a condition to sense pain, but infusion into the bone marrow can be quite painful. Slowly infusing 2 to 5 mL of 2% preservative-free lidocaine (0.5 mg/kg), over 1 minute before flushing and infusion of medications and fluids, has been suggested to relieve pain in awake patients. The duration of analgesic effect is approximately 1 hour and may be repeated as needed. A maximum dose of lidocaine per hour is 200 mg. Systemic opioids are also helpful. Medications intended to remain in the medullary space, such as local anesthetics, must be injected very slowly until the desired anesthetic effect is achieved. A 2010 study suggests that lidocaine is efficacious in attenuating the pain related to IO infusion.¹³³

TRAINING

Procedural training can be performed on simulation models, animal bones (e.g., chicken or turkey legs), or cadavers. IO insertion techniques are part of the curriculum of the pediatric advanced life support, advanced pediatric life support, and advanced trauma life support courses. Training typically consists of an hour of didactics followed by a hands-on session. Novice users have achieved success rates of 93% to 97% for manual and battery-powered IO placement in a variety of simulated settings.^{5,22,48,55,79,134,135} Battery-powered IO placement has also been shown to have high success rates after training.

DURATION OF USE

IO cannulation is temporary vascular access and should be replaced with a venous line as soon as possible. IO cannulation may be left in place during transport and for up to 24 hours, but local edema, infiltration, and an increased risk for osteomyelitis are seen after 24 hours.

Acknowledgment

The author would like to sincerely thank Rachael Stanley, MD, for her contribution to this chapter in previous editions.

Alternative Methods of Drug Administration

Solomon Behar

The rapid administration of lifesaving, pain-relieving, and sedative medications lies at the core of the practice of emergency medicine. The intravenous (IV) route is usually the delivery method of choice. However, there are circumstances in which vascular access is either not available or contraindicated. Thus, emergency providers need to have a working knowledge of alternative routes of drug administration. This chapter describes the endotracheal (ET), intranasal (IN), rectal, and subcutaneous routes. Intraosseous (IO) access is covered in [Chapter 25](#).

ENDOTRACHEAL (ET) ADMINISTRATION OF MEDICATION

Certain drugs can be delivered simply, rapidly, and effectively to the central circulation by way of the ET tube. Because the efficacy of ET medication administration is not clear,¹ this method is best reserved for situations in which a patient's condition warrants immediate pharmacologic intervention but more conventional means of drug delivery, such as IV and IO,

are not readily available. Such circumstances frequently arise in the prehospital or cardiac arrest setting. Knowledge of the appropriate drugs and dosages that can be delivered effectively by this route may prove to be lifesaving.

Historical Perspective

ET drug administration dates to 1857, when Bernard² demonstrated that the lung could rapidly absorb a solution of curare. In this historical experiment, he instilled a fatal solution into the upper respiratory tract of dogs by way of a tracheostomy. Over the following decades, other investigators expanded this work and demonstrated that solutions containing salicylates, atropine, potassium iodide, strychnine, and chloral hydrate were also rapidly absorbed from the lung and excreted in the urine after injecting aqueous solutions into the tracheas of experimental animals.³ The use of intrapulmonary medication for the treatment of lung disease gained further acceptance when studies demonstrated that inhaling epinephrine mist dramatically relieved the symptoms of asthma.⁴

In the late 1930s and 1940s, several important observations were made concerning ET drug therapy: (1) penicillin delivered by the ET route demonstrated a depot effect, which resulted in therapeutic blood levels that lasted twice as long as those with intramuscular (IM) injection⁵; (2) various diluents mixed with penicillin affected both the rate and the degree of absorption from the lungs; and (3) higher serum drug levels were attained with direct ET drug administration than with aerosolized administration.⁵ In the 1950s it was noted that drugs delivered endotracheally were absorbed much more rapidly than those applied to the posterior part of the pharynx. Drugs applied locally to the larynx and trachea were absorbed rapidly and even resulted in blood levels significant enough to cause adverse anesthetic reactions.⁶

Endotracheal Medication Administration

Indications

Cardiac arrest with no peripheral or intraosseous access

Contraindications

Peripheral or intraosseous access

Complications

Depot effect of drug
Transient hypoxemia
Loss of catheter or needle down endotracheal tube

Equipment

Review Box 26.1 Endotracheal medication administration: indications, contraindications, complications, and equipment. Gloves, mask, and eye protection are also necessary equipment for endotracheal medication administration. See text for further explanation on medication.

In 1967, Redding and coworkers⁷ studied the use of ET administration as a route of drug delivery in a canine model of cardiopulmonary arrest. They administered epinephrine by the IV, intracardiac, and intratracheal routes to resuscitate dogs that had undergone both respiratory and circulatory arrest secondary to hypoxia. They then evaluated the effectiveness of the epinephrine after administration of the drug by all three of these routes. Their study revealed that all three routes of drug administration were equally effective in restoring the circulation of dogs in hypoxia-induced cardiac arrest, again demonstrating that the ET route of drug delivery provides effective access to the systemic circulation.

In the late 1970s, Roberts, Greenberg, and colleagues^{8–11} studied ET drug delivery in a series of laboratory experiments and clinical applications of ET epinephrine. Since that time, a number of important animal and human studies, as well as case reports, have been published in which the various aspects of ET drug administration were investigated. These studies have addressed (1) the appropriate dose of drug to administer; (2) the effect of the drug solution's volume; (3) the effect of different diluent solutions; (4) the role of different ET drug delivery techniques; and (5) the effects of hypoxia, hypotension, shock, and cardiopulmonary arrest on the absorption, distribution, and efficacy of endotracheally administered drugs.

Recommendations for ET Drug Delivery

ET drug delivery is not the delivery method of choice if other routes are available. The American Heart Association (AHA) recommends that if IV access is not available, IO access should be obtained.¹² The AHA makes specific recommendations regarding the use of ET drug delivery for cardiac resuscitation (Table 26.1).^{12–14}

Appropriate Dose

Much of the existing literature is controversial and contradictory at times in regard to proper dosing of ET medications.^{10,15–19} The ET dose of a medication should be at least equal to the IV dose of the same drug when given for the same indication, but most studies agree that higher doses are needed when administering drugs via the ET route. For advanced cardiac life support (ACLS) medications in adults, the AHA recommends a dose that is 2 to 2.5 times the usual IV dose when administered via an ET.^{12,20–22} Studies using both normotensive and cardiac arrest canine models have shown that epinephrine doses of 0.01 mg/kg administered via ET produced serum levels approximately one tenth of that produced when the same dose is given intravenously.^{9,23,24} These studies suggested increasing the ET epinephrine dose to 0.05 to 0.1 mg/kg of

the 1:1000 dilution of epinephrine, and are the basis for the 2010 AHA recommendation (upheld in a 2015 update²⁵) to use this tenfold increased dose when administering ET epinephrine to pediatric patients.¹³ One notable exception of epinephrine concentration is in the neonatal population (the first month of life) in which the AHA recommends using the 1:10,000 (not 1:1000 that is used in pediatric patients and adults) concentration of epinephrine using a dose of 0.01 to 0.03 mg/kg.²⁶

ET drug delivery is associated with a “depot” effect, with ET drugs being “stored” and released slowly over time, similar to a continuous IV drip. This presumably occurs as a result of local vasoconstriction and lymphatic storage of the drug⁸ or pooling in lung tissue because of poor lung perfusion.²⁷ With ET epinephrine use, the depot effect can produce post-resuscitative dysrhythmias, hypertension, and tachycardia together with resultant increased myocardial oxygen demand. Given these conflicting data, it seems reasonable in adults to start with a dose 2.0 to 2.5 times the usual IV dose. If this is ineffective, higher doses may be used subsequently.

Volume for a Single Dose

For ET drugs, the AHA recommends a total volume of 10 mL in adults,¹² 5 mL in pediatric patients,¹³ and 1 mL in neonates.¹⁴ Animal and human studies demonstrate that diluting medications in higher volumes of liquid increases blood levels of the drug, but at the expense of decreases in partial pressure of arterial oxygen (PaO₂).^{28–31} Data and volume recommendations in the setting of multiple doses of the drug are lacking. It may be difficult or impossible to limit the total volume of the drug solution to 10 mL when using prefilled syringes. Prefilled syringes of epinephrine contain 1 mg in 10 mL (1:10,000). Giving 2.5 times the IV/IO dose requires the administration of 20 to 25 mL. It is possible to obtain epinephrine 1:1000 (1 mg/mL) and dilute it to a total volume of 5 to 10 mL, but the higher concentration of epinephrine may not be readily available during a cardiac arrest code. Likewise, prefilled syringes of atropine contain 1 mg in 10 mL (0.1 mg/mL). Prefilled syringes of lidocaine contain 20 mg/mL (100 mg/5 mL). A dose of 2 to 2.5 times the IV/IO dose could easily amount to 20 mL or more total volume in an obese patient.

Appropriate Diluent

Both normal saline and distilled water may be used as diluents for ET drug administration, but it remains unclear which is preferred. Normal saline may produce less pulmonary dysfunction than distilled water, but distilled water appears to deliver a greater amount of drug than when the drug is mixed in normal saline.^{29,30,32,33}

TABLE 26.1 American Heart Association Guidelines for Endotracheal Drug Administration

GUIDELINE	ADULT ¹²	PEDIATRIC ¹³	NEONATAL ²⁶
Medication dose	2–2.5 times the recommended intravenous dose	Epinephrine, 0.1 mg/kg (10 times the recommended intravenous dose) Atropine, 0.04–0.06 mg/kg Lidocaine, 2–3 mg/kg	Epinephrine (1:10,000) 0.05–0.1 mg/kg (class indeterminate)
Total volume to instill	10 mL	5 mL	1 mL
Diluent	Normal saline or distilled water	Normal saline	Normal saline

Technique for ET Drug Delivery

Techniques for ET drug administration include direct instillation into the proximal end of the ET tube, administration via a catheter that extends just beyond the distal tip of the ET tube, deep endobronchial administration using a longer catheter, administration via ET tube monitoring ports, administration with equipment developed specifically for ET atomized drugs, and injection through the side of the ET tube with a needle. Several studies have indicated that the use of a catheter or feeding tube may not be needed to enhance the drug's effectiveness,^{34,35} including neonates.³⁶ In studies of patients with normal perfusion, some support "deep bronchial" ET drug administration, whereas others do not.³⁷⁻³⁹ Some^{17,21} suggest that drug absorption with direct instillation into the ET tube is inconsistent during cardiopulmonary arrest, and one study found no difference in plasma epinephrine levels when epinephrine was instilled during apnea versus instillation during the ventilator inspiratory cycle.⁴⁰ Given these conflicting studies, use of a catheter to enhance deep pulmonary delivery seems reasonable. However, if a catheter is not readily available, direct injection into the ET tube appears to be acceptable.

Effects of Hypoxia, Hypotension, and Cardiopulmonary Arrest

Despite concerns that medications might not be absorbed in states of hypoxia or low blood flow, the data available reveal the opposite to be true. In a hemorrhagic shock model, Mace⁴¹ demonstrated that higher plasma lidocaine levels were obtained via the ET route during shock than during non-shock states. In a lamb model, when epinephrine was administered endotracheally, higher plasma epinephrine levels were achieved during hypoxia-induced low pulmonary blood flow than during baseline, normal pulmonary blood flow.⁴² Finally, plasma lidocaine levels rose earlier when lidocaine was administered endotracheally to dogs that were hypoxemic than to dogs that were not.⁴³

Indications

ET drug therapy is indicated when emergency pharmacologic intervention is needed and other access, either IV or IO, is not available. Specific indications for the delivery of a drug endotracheally are the same as those for IV and IO administration. However, only a limited number of emergency drugs can be given safely by the ET route. Medications that are appropriate for ET administration based on animal and human studies include epinephrine,^{8,10,44} atropine,⁴⁵⁻⁴⁷ lidocaine,^{38,43,48} and naloxone.^{11,49} Diazepam has also been shown to be effective,^{50,51} but with the possibility of a medication (or diluent) induced pneumonitis.⁵² The AHA has removed diazepam from its list of medications that can be given safely via the ET route.

Experimental studies of vasopressin,^{53,54} midazolam,⁵⁵ flumazenil,⁵⁶ and propranolol,⁴⁵ in animal models suggest that these medications may also be effective when administered endotracheally, but no clinical studies in humans have been conducted to verify these findings. Based on a study by Wenzel and colleagues,⁵³ the 2010 ACLS guidelines added vasopressin to the list of cardiac resuscitation drugs that can be administered via the ET route.¹² However, vasopressin was removed from the 2015 ACLS out-of-hospital cardiac arrest guidelines due to equivalency of response to epinephrine and a want to simplify arrest algorithms.⁵⁷ As midazolam is approved for IM use, it seems unlikely that ET administration would be frequently

used. Palmer⁵⁶ demonstrated that therapeutic blood levels of flumazenil were obtained within 1 minute after ET delivery of 1 mg of the drug diluted in 10 mL of saline, which is 10 times the recommended IV dose of 0.1- to 0.2-mg aliquots.

Contraindications

At present, the only true contraindication to the ET delivery of an appropriate drug is the presence of another form of access to the systemic circulation through which the needed drug can be delivered rapidly and effectively. Specific medications have been shown to be ineffective or unsafe when given via the ET route. Sodium bicarbonate and amiodarone have direct deleterious effects on the lungs.^{58,59} Bretylium and isoproterenol have not been shown to attain adequate serum levels despite high ET doses given.^{46,60}

Equipment

The patient must first be endotracheally intubated. In studies in which the recommended ET tube doses of medications were administered by Combitube (Kendall-Sheridan, Argyle, NY) or laryngeal mask airway (LMA North America, San Diego, CA), absorption of drugs was found to be subtherapeutic.⁶¹⁻⁶³ A Combitube, when placed in the esophagus (requiring medications to travel out the side holes to reach the trachea), needs 10 times more epinephrine than that used with an ET tube to obtain the same serum concentration and hemodynamic effects.⁶¹ Presumably, a Combitube that enters the trachea directly would function equivalently to an ET tube, but no studies have been done to support this assumption.

The equipment listed here is that required to perform any of the four different techniques described. This equipment is suggested for the ideal situation; at no time should drug delivery be delayed while searching for the "perfect" piece of equipment.

1. Manual bag ventilation device capable of delivering a fraction of inspiratory oxygen (F_{iO_2}) of at least 50%. When ET drug delivery is indicated, the patient's condition almost always warrants supplemental oxygen. Although the technique may not result in any significant deterioration in respiratory function, it is still advisable to administer additional oxygen after drug delivery. Use the bag ventilation device to also deliver several rapid insufflations immediately after drug delivery to assist in delivery of the drug distally, where it may be absorbed more rapidly and effectively.³⁴ The priorities of drug administration via the ET route must be balanced against the potential deleterious effects that such rapid insufflation might have on hemodynamics and cerebral perfusion. Excessive hyperventilation of victims of out-of-hospital cardiac arrest is common and associated with poor outcomes.⁶⁴
2. A fine-bore catheter or special ET tube designed to deliver the drug at or beyond the distal end of the ET tube. For adults, select a catheter that is at least 8 Fr in size and 35 cm (14 inches) in length. It should be long enough to protrude past the distal end of the ET tube. The diameter of the catheter should be large enough to allow rapid delivery of 10 mL of solution. In children, the distance to the end of the ET tube is usually equal to three times the circumference of the tube in centimeters measuring from the lip. So for example, in a child intubated with a 4.0 ET tube, make sure the catheter tip lies at least 12 cm distal to where the

ET tube enters the mouth. Several different types of tubes and catheters commonly available in the emergency department (ED) can be used for this purpose:

- a. A 16-gauge central venous pressure or cutdown catheter. Because most are only 30 cm in length, the proximal end of the ET tube should be shortened so that the catheter can protrude past the end.
- b. An 8- or 10-Fr polyethylene pediatric feeding tube (e.g., Argyle, St. Louis). These tubes are much longer than needed, so cut them to reduce dead space. Luer-Lok ends fit onto the proximal end of the tube. For neonates, use a 5-Fr feeding tube with a syringe and an IV adapter.
- c. An 8-Fr (or larger) pediatric pulmonary suction catheter without the control port. Because this catheter is designed to extend past the tip of the ET tube, it is an ideal length. However, with some brands it is difficult to attach a syringe or IV adapter lock after the suction control port is removed.

Alternatively, some ET tubes are made with built-in ports that allow the instillation of drugs without removing the bag ventilation device.

3. An IV adapter lock. This can be placed as needed onto the proximal end of the irrigation lumen of the Hi-Lo Jet Tracheal Tube (Nelcor, Pleasanton, CA) or on the catheters described previously to convert them for use with prefilled syringes. This adapter is generally unnecessary if a standard syringe is used.
4. A 10 to 20 mL syringe, preferably a Luer-Lok type, large enough to deliver the desired volume of drug solution plus an additional 5 mL of air. Most of the medications now prescribed for emergency situations come in prefilled syringes. This type of apparatus does not usually allow one to draw up diluent or an additional volume of air to empty the syringe of solution. In addition, depending on the manufacturer and model, some prefilled syringes have either needles or a needleless system that may require an IV adapter lock to use them for ET injection.
5. Diluent solution. Keep an adequate volume of diluent available, such as normal saline or distilled water.
6. Medication to be instilled.
7. An 18- or 19-gauge needle to draw up the medication and inject it. Use an 18-gauge, 8.9-cm (3.5-inch) spinal needle for direct instillation of medications into the proximal end of the ET tube.
8. Alcohol wipes to clean the vials and injection ports.
9. Gloves, mask, and eye protection. After instillation, the solution often refluxes out of the ET tube, which makes blood and body fluid precautions critical.

Procedure

The procedure of choice is one that will deliver the medication to the patient in the least amount of time. Secure the ET tube before instilling medications endotracheally to prevent the tube from being expelled if the patient coughs. Inflate the cuff of the tube, if present.

Direct Instillation Into the ET Tube

While the patient is being ventilated, draw up the desired drug into a syringe (or use a prefilled syringe) (Fig. 26.1, step 1). Dilute the drug to a final volume of 10 mL (adults), 5 mL (children), or 1 mL (neonates) with normal saline or distilled water. Attach an 18- or 19-gauge needle. Some authors recom-

mend using an 8.9-cm (3.5-inch) spinal needle. If using a prefilled syringe, draw up an appropriate volume of diluent in a second syringe so that the total instillation volume (drug plus diluent) equals 10 mL (adults), 5 mL (children), or 1 mL (neonates). Attach an 18- or 19-gauge needle which will be used to flush the ET tube after instillation of the drug.

Interrupt the connection between the proximal end of the ET tube and the bag ventilation device. Insert the needle of the syringe into the proximal opening of the ET tube (see Fig. 26.1, step 2). Hold the proximal end of the needle with one hand to prevent loss of the needle into the tube. Inject the drug solution rapidly and forcefully. If using a prefilled syringe, flush the tube immediately with the diluent in a second syringe. If the patient makes an effort to cough, place a thumb over the opening of the ET tube to prevent expulsion of the solution. Reattach the bag ventilation device and deliver five rapid insufflations.

Use of a Catheter

Draw the plunger back to add 5 mL of air to the liquid in the syringe. If the drug to be delivered is in a prefilled syringe, place an IV adapter lock on the catheter if necessary to accommodate the syringe needle or needleless tip. Attach the syringe to the catheter at this time or once the catheter has been placed within the ET tube. In addition, draw up the appropriate volume of diluent (normal saline or distilled water) plus 5 mL air into a second syringe to flush the catheter after instillation of the drug from the prefilled syringe. The air flush presumably forces out any medication adhering to the walls of the catheter's lumen. Rehan and colleagues³⁶ determined that, when using a catheter in a neonatal model, more medication was delivered with an additional air flush than without an air flush.

Disconnect the proximal end of the ET tube from the bag ventilation device. Place the catheter into the lumen of the ET tube in such a manner that the distal end of the catheter extends approximately 1 cm beyond the distal end of the ET tube (see Fig. 26.1, step 3). Hold the proximal ends of the catheter and ET tube at all times during the procedure. If it has not already been done, attach the syringe to the catheter. Inject the drug solution rapidly and forcefully through the catheter into the trachea followed by the 5 mL of air needed to flush the catheter of any remaining drug solution (see Fig. 26.1, step 4). If using a prefilled syringe, use the second syringe to promptly flush with the diluent and air. Immediately remove the syringe and catheter from the ET tube. Reconnect the bag ventilation device with supplemental oxygen to the ET tube and deliver five rapid ventilations.

Use of ET Tubes With Irrigation and Drug Delivery Lumens

The following tubes have built-in ports:

1. ET tubes designed for bronchoscopy (e.g., Hi-Lo Jet Tracheal Tube, Nelcor, Pleasanton, CA) (Fig. 26.2A). These tubes have two additional ports, one for monitoring or irrigation (opaque lumen) and one for jet ventilation (transparent lumen). They are available in only uncuffed sizes. The major disadvantage of this ET tube is the need to be familiar with the specific ports before use. If one has never seen the tube previously, determining which port is used for irrigation could prove to be time-consuming. In addition, the port requires placement of an IV adapter lock or Luer-Lok to use a prefilled syringe.

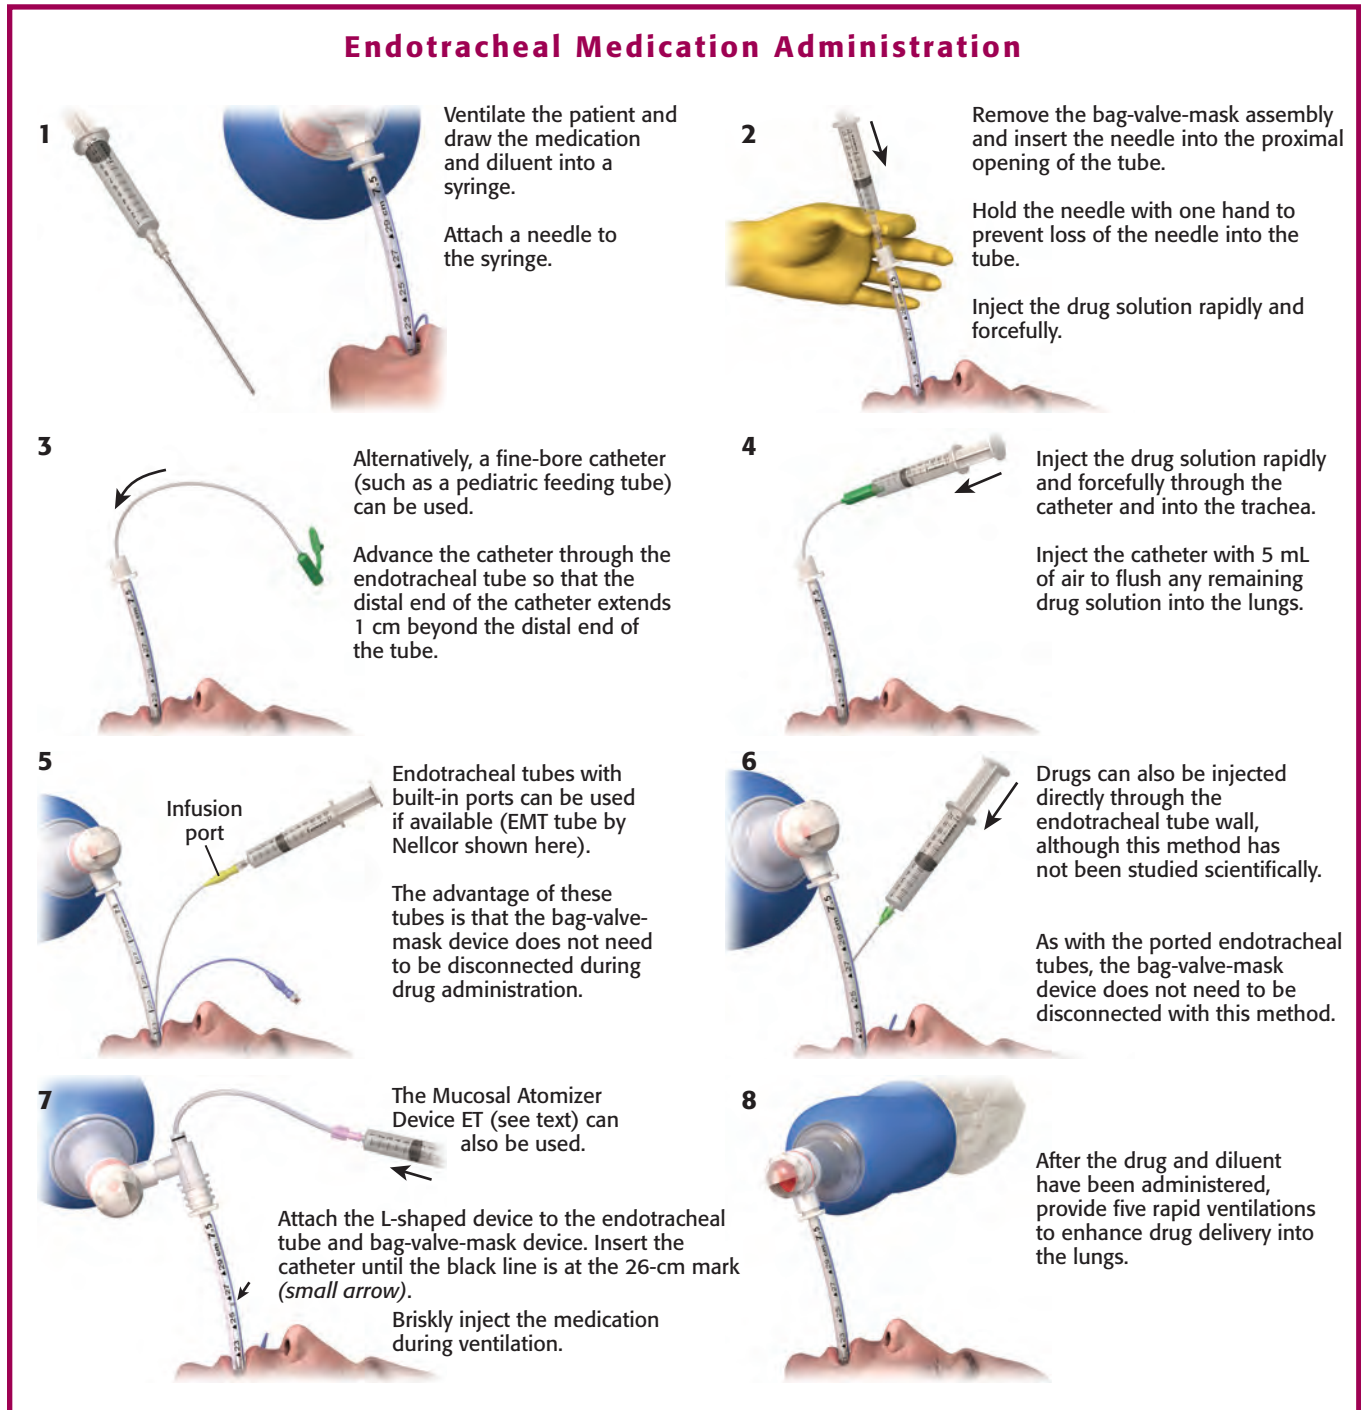

Figure 26.1 Endotracheal administration of medication.

2. ET tube with a side port (ETSP; e.g., EMT Emergency Medicine Tube, Nellcor, Pleasanton, CA) (see [Figs. 26.1, step 5](#), and [26.2B](#)). This tube is designed specifically for ET drug administration but is available in cuffed sizes only. The instillation lumen opens into the tube at the Murphy eye (a hole approximately 1 cm from the end of the tube). The injection port has an IV adapter lock, which makes it amenable to use with prefilled syringes. The ETSP is not available in pediatric sizes. In one study comparing the administration of lidocaine via the ETSP with administration through the proximal end of the standard ET tube, serum lidocaine measurements never reached therapeutic levels

in the ETSP group, in contrast to the ET group and IV control group.⁶⁵

3. Uncuffed tracheal tube with a monitoring lumen (Nellcor, Pleasanton, CA). This tube contains a separate monitoring lumen in the wall of the tube that opens inside the distal tip. A three-way stopcock with a Luer-Lok adapter provides access to the monitoring lumen. The major disadvantage of this ET tube is the need to be familiar with the additional port.

The advantage of all these specialized ET tubes is that they eliminate the need to disconnect the bag ventilation device and the ET tube.

Figure 26.2 Specialty endotracheal tubes with irrigation/drug delivery lumens. **A**, Hi-Lo Jet Tracheal Tube (Nellcor, Pleasanton, CA). This tube is designed for bronchoscopy and has two additional ports, one for jet ventilation and one for irrigation. This is an uncuffed tube and does not have a balloon inflation port. **B**, EMT Emergency Medicine Tube (Nellcor, Pleasanton, CA). This tube is designed specifically for endotracheal drug administration and has two ports: one for balloon inflation and one for drug instillation.

Injection Through the Wall of the ET Tube

This method of drug delivery has not yet been evaluated scientifically but has been used clinically.^{66,67} As with ET tubes with drug delivery lumens, this technique requires no interruption of the connection between the bag ventilation device and the ET tube (see Fig. 26.1, step 6). Placing an IV adapter lock on the needle allows it to be left inserted in the ET tube for use with additional medications.⁶⁷

Use of the ET Atomizer

The Mucosal Atomizer Device-Endotracheal Tube (MADett, LMA North America, San Diego, CA) is an L-shaped port that attaches to both the ventilator bag and the ET tube (Fig. 26.3; see also Fig. 26.1, step 7). A catheter is inserted into the adapter and a mark is aligned at the 26-cm line of the ET tube. The catheter is then locked into place in the adapter. The L shape allows ventilation of the patient to be uninterrupted while medication is administered via the catheter and atomized into the patient's lung mucosa at the distal tip that protrudes from the end of the ET tube. This device can be used only with ET tubes 7.0 mm or larger and longer than 28 cm.

Complications

Reported complications of ET drug therapy are rare, in part because of the infrequent use of this technique. Because most patients who receive ET drug therapy are in cardiopulmonary arrest or are otherwise critically ill, it is difficult to ascertain whether an adverse outcome is the result of the therapy.

With regard to the techniques of ET drug administration, no serious complications have been reported. A theoretical complication is loss of a needle or catheter down the ET tube, which can be prevented by holding the catheter or needle while instilling the drug.

After ET drug administration, the well-described systemic effects of drugs administered in emergency situations may

Figure 26.3 The Mucosal Atomizer Device-Endotracheal Tube (MADett, LMA North America, San Diego, CA). The L-shaped port attaches to both the bag-valve-mask device (BVM) and endotracheal tube (ETT) and allows uninterrupted ventilation during drug administration. The catheter should be inserted until the black depth marker is at the 26-cm mark on the ETT.

produce adverse effects. Administration of epinephrine during cardiopulmonary resuscitation (CPR) has been noted in case reports to produce prolonged hypertension, tachycardia, and arrhythmias after the return of a perfusing rhythm.^{10,23} It appears that these side effects are related to the depot effect, in which larger doses of drugs administered endotracheally are released slowly over time. In addition to epinephrine, atropine and lidocaine also exhibit a depot effect when administered endotracheally.⁵⁸ No serious long-term sequelae, however, have been reported to result from this effect.

A potential concern with ET drug therapy is a transient decrease in arterial oxygen content during or after drug delivery. If total volumes are maintained between 5 and 10 mL in adults, the effect on pulmonary function appears to be minimal. Supplemental oxygen should always be administered to improve oxygenation and offset any transient drop in arterial oxygen content that might develop.

One unusual complication of ET epinephrine is that, during CPR, some of the instilled medication may be expelled and enter the eye. This will produce a fixed dilated pupil, simulating brain death or, if unilateral, brain herniation.

INTRANASAL ADMINISTRATION OF MEDICATION

Anatomy and Physiology

The human nasal cavity is a convenient and readily available site to deliver medications. In adults, it has a volume of 15 to 20 mL and a total surface area of approximately 150 cm².⁶⁸ The nasal cavity is divided into two mostly symmetric halves by the nasal septum. Each half consists of four anatomically and histologically distinct regions: the vestibule, atrium, and the respiratory and olfactory regions (Fig. 26.4). The respiratory and olfactory regions are areas of high vascularity and good permeability. The respiratory region has the largest surface

Intranasal Medication Administration

Indications

Pain relief
Anxiolysis/sedation
Seizure control
Narcotic overdose

Contraindications

Abnormal nasal anatomy
Nasal trauma

Complications

Side effects of the specific medication
Local nasal irritation
For epinephrine: Fixed dilated pupil(s) if expelled into eye(s) during CPR

Equipment

Review Box 26.2 Intranasal medication administration: indications, contraindications, complications, and equipment.

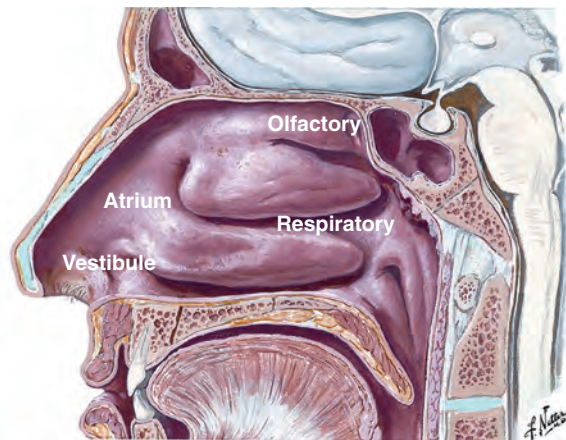

Figure 26.4 Regions of the nasal cavity. (Netter illustration from www.netterimages.com. © Elsevier Inc. All rights reserved.)

area at approximately 130 cm².⁶⁹ Blood flow in the nasal mucosa is higher, per cubic centimeter, than in muscle, brain, or liver tissue.⁷⁰

The olfactory mucosa has been theorized to have a direct connection to the brain and bypasses the first-pass metabolism of orally administered medications.^{71,72} Drugs that can be delivered via the nasal mucosa are generally small in molecular weight, stable, and dissolvable in the watery mucus of the nasal passages.⁷³

Indications and Contraindications

The IN route may be very useful in circumstances where placing an IV line is not possible or practical. This is especially true in patients at the extremes of age. Thus, knowledge of this painless, needleless route of drug administration is important for practicing emergency physicians. IN administration of

medication has been shown for more than 30 years to be effective.⁷⁴ Drugs used routinely in the ED that have been studied intranasally include the opioid antagonist naloxone, the benzodiazepine midazolam, the sedative-hypnotic ketamine, the opioids fentanyl and sufentanil, and most recently the α -agonist sedative dexmedetomidine. Most of these studies have focused on the pediatric patient population as an alternative to IV medication. The patient does not need to be developmentally able to “sniff” in order to enjoy the benefits of IN medication, but only to have the mucosal surface coated in the medication, making its use in the very young patient feasible.

Narcotic Overdose

The Food and Drug Administration approved in November 2015 IN naloxone for use in opioid overdose.⁷⁵ The 2015 AHA ACLS guidelines support its use in “a patient with known or suspected opioid overdose who has a definite pulse but no normal breathing or only gasping (i.e., a respiratory arrest), in addition to providing standard BLS (basic life support) care”.⁷⁶ IN naloxone at a dose of 2 mg was shown to be as effective as IV naloxone in patients with known or suspected opioid overdose.⁷⁷ Patients receiving IN naloxone had an increase in the respiratory rate that was statistically equivalent to that with IV naloxone. IN naloxone was shown to reduce the need to initiate an IV line in narcotic overdose patients.⁷⁸ Using the IN approach can help reduce the risk for needlestick injuries in the prehospital setting, especially in this high-risk patient population. Nebulized naloxone has also been used to treat opioid intoxication in the non-apneic patient.

Seizures

Bhattacharyya and colleagues studied IN midazolam versus rectal diazepam in pediatric seizure patients. Midazolam (0.2 mg/kg) delivered intranasally, was found to have a significantly more rapid onset of seizure cessation with minimal effect on respiration and oxygen saturation.⁷⁹ IN midazolam is now

used in both the prehospital setting and the ED to deliver antiepileptic medication until an IV line can be initiated. A systematic review and metaanalysis comparing non-IV midazolam (IN, buccal, IM routes) and per rectum (PR) diazepam showed non-IV midazolam is as effective and safe as intravenous or rectal diazepam in terminating early status epilepticus.⁸⁰ In a network analysis, IN midazolam was better than buccal midazolam, sublingual lorazepam, PR diazepam, and IM midazolam at stopping seizures at 10 minutes, and for seizures lasting more than 1 hour.⁸¹

Sedation

IN midazolam (0.3 mg/kg) compared favorably against buccal and oral routes of midazolam use in children requiring procedural sedation, exhibiting a faster onset of sedation, achieving adequate sedation in a greater proportion of patients, and more parents of pediatric patients stating that they would choose the same regimen again.⁸² Patients may experience local irritation of the nasal mucosa due to the acidity of midazolam. Local irritation is amplified when drops are used to instill the midazolam.⁸³ Premedication with IN lidocaine may decrease the local irritation associated with midazolam.⁸⁴

Ketamine (5 mg/kg) in combination with midazolam (0.3 mg/kg) administered intranasally has been used as an effective anesthesia induction agent with a rapid onset of sedation. Compared with IN midazolam (0.2 mg/kg) as a premedication agent, IN ketamine (5 mg/kg) had a longer time to onset and was associated with more side effects than midazolam.⁸⁵ For dissociative levels of sedation, doses of 7 to 9 mg/kg of IN ketamine^{86,87} have been necessary to attain this state. The volume of medication required to reach these higher doses often exceeds the nasal cavity capacity to absorb the medication, rendering IN ketamine for dissociative sedation impractical.

Dexmedetomidine, an α_2 -agonist with sedative, anxiolytic, and analgesic properties can be given intranasally (2–3 mcg/kg) to sedate children for nonpainful procedures.^{88–91} It has not been well studied for painful procedures. Onset of action is 10 to 25 minutes and its duration of action is 40 to 100 minutes (measured as ability to be discharged). Overall side effects of this medication are rare (bradycardia and hypotension) and have little effect on respiratory drive. There is a case report of vasovagal syncope and bradycardia in an 11-year-old child who had received IN dexmedetomidine at a dose of 2.4 mcg/kg.⁹²

Pain Management

Fentanyl is widely used for the management of acute pain. IN fentanyl has been shown to have desirable pharmacokinetics and high bioavailability in the treatment of acute pain.^{93,94} Foster and colleagues demonstrated that in adults, IN fentanyl (75 to 200 μ g) had only a slight, non-statistically significant lag in the onset of analgesia but equivalent pain reduction to the IV form of fentanyl.⁹⁴

IN fentanyl has been shown to be as effective as IV morphine and had a similar side effect profile.⁹⁵ IN fentanyl can be used for pain control in patients prior to initiating an IV line or as a noninvasive alternative to IV or IM injection. Onset of action of IN fentanyl is 2 to 5 minutes, lasting at least 60 minutes. Pediatric dosing is safe and most effective when given at a range of 1 to 3 mcg/kg.^{95–102} There is even a case report of IN fentanyl being successfully used to abort a blue “tet spell” in an infant with the cyanotic congenital heart condition Tetralogy

of Fallot.¹⁰³ Combination IN therapy using sufentanil (0.5 mg/kg) and ketamine (0.5 mg/kg) is effective in providing analgesia for acute pain.¹⁰⁴ Among adult patients, an average dose of 1 mg/kg of IN ketamine effectively reduced acute pain in just over one half of patients.¹⁰⁵ Effective adult dosing of IN ketamine has not been well studied.

Contraindications

There are no absolute contraindications to the intranasal administration of medication with the exception of medication allergy. Abnormal nasal anatomy or increased mucous production may reduce absorption and necessitate repeated dosing.⁷³

Equipment

The only equipment necessary is the desired medication, a needle to draw the medication from the vial, a 1-mL syringe, and an atomizing device if available (Review Box 26.2).

Procedure

Two methods to deliver drugs to the nasal mucosa can be used: drops or aerosol. Nasal drops require a cooperative patient and correct positioning to enhance drug delivery. Atomization of medication is much preferred to drops, in that much of the drug is lost to the environment by dripping out the nose or into the throat and then swallowed.^{106,107} This can result in metabolism of the drug in the liver through first-pass metabolism. Nasal atomization has been found to be the optimal method of enhancing mucosal coverage and increasing plasma concentrations of IN medications.^{68,106,107} Regardless of the method, the relatively small volume of the nasal cavity limits the volume of medication to approximately 1 mL per naris. If the volume is greater than 1 mL, split the dose and instill half into each naris. Use concentrated forms of medications to decrease the overall volume.⁷³

Nasal Drops

Draw up the appropriate dose and volume of medication. Position the patient properly to enhance delivery to the mucosa and prevent runoff or swallowing. Instill the drops slowly to prevent runoff.

One position is to place the patient on the back with the head down and nose pointing up. Slowly instill the drops into each naris along the nasal septum and allow the medication to flow into the turbinates. A second position is the lateral decubitus position with the head angled downward. Use pillows or towels to elevate the body at the shoulders if necessary. Instill the drops into the naris that is “up” so that the medication runs along the nasal septum and turbinates. An alternative, though more uncomfortable position is to place the patient on the knees with the head down and the vertex parallel to the bed, essentially in a position similar to starting a forward roll. Instill the medication against the septum and let it flow to the turbinates.^{106,107}

Nasal Atomization

Many commercial devices are available for home and outpatient use to deliver medications intranasally. The Mucosal Atomization Device (LMA North America, San Diego, CA) is small, easy to use, and attaches to nearly any syringe (Fig. 26.5). Atomization of midazolam was found to achieve higher plasma concentrations than nebulized midazolam.¹⁰⁸ Atomization results

in very fine particles that distribute over the surface and can be absorbed more readily.

Draw up an appropriate volume of medication into a syringe with an additional amount to accommodate for the dead space of the device (0.1 mL). Insert the device approximately $\frac{1}{4}$ to $\frac{1}{2}$ inch into the vestibule. Rapidly depress the plunger. If the total volume is greater than 1 mL, repeat this in the other naris (Fig. 26.6).

An obvious advantage of an atomizer is that proper positioning is not necessary and the medication is instilled rapidly. This can result in less runoff and requires less cooperation from the patient.

Complications

Aside from the side effects of the medications (allergy, nausea, apnea, etc.), there are few to no complications when using IN

Figure 26.5 Mucosal Atomization Device. (LMA North America, San Diego, CA.)

medications. As mentioned previously, midazolam has been noted to cause short-term local irritation. A single case of anosmia following long-term use of IN ketamine has been reported.¹⁰⁹

Nebulized Naloxone

Naloxone has been administered via nebulization, as an alternative to more traditional routes, to reverse opioid intoxication.¹¹⁰ The benefit of nebulized naloxone is that intravenous access is not required, the reversal effect may be prolonged or continued as long as the nebulizer is used, and there may be a more gradual, but often not complete, reversal of opioid intoxication, reversing opioid effects without producing acute

Figure 26.6 Insert the device approximately 1 cm into the vestibule and rapidly depress the plunger. If the total volume is greater than 1 mL, repeat in the other naris.

Rectal Administration Of Medication

Indications

Drug administration when more desirable routes are unavailable or impractical:

- Children frightened of intravenous catheterization
- Patients who refuse parenteral drug administration
- Patients with nausea/vomiting or inability to swallow

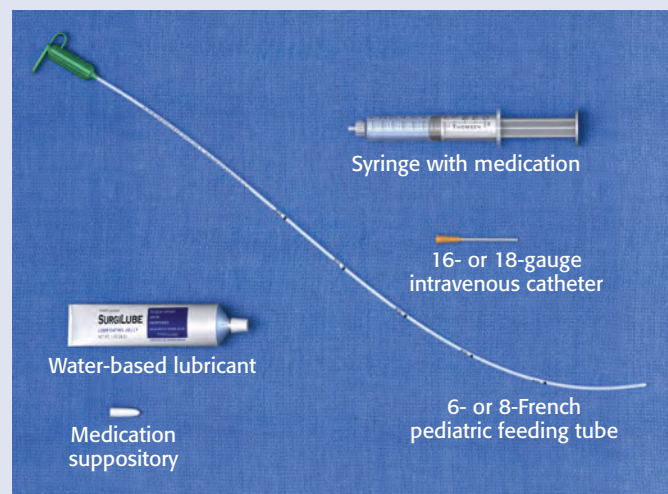

Contraindications

- Immunosuppression
- Severe thrombocytopenia or coagulopathy
- Active gastrointestinal bleeding
- Diarrhea
- Chronic anorectal problems (fissures, hemorrhoids, fistulas, etc.)

Complications

- Erratic absorption
 - Delayed, prolonged, or unusually rapid
- Local trauma
- Pain

Equipment

Review Box 26.3 Rectal medication administration: indications, contraindications, complications, and equipment.

withdrawal. Most reports are anecdotal experience or case reports, and there are little data on the specific use. Weber and colleagues¹¹¹ reported success with nebulized naloxone in approximately 80% of spontaneously breathing patients with suspected opioid intoxication when paramedics administered the medication. The procedure may be applicable to *nonapneic* patients and can be used by both prehospital and ED clinicians. Empirical dosing is 2 to 4 mg of naloxone in 3 mL of saline, delivered by an oxygen driven nebulizer, such as those used to deliver aerosolized β -agonists to asthmatics. Rescue IN, IM, or IV naloxone should be available for those not responding appropriately.

RECTAL ADMINISTRATION OF MEDICATION

Medications may be administered rectally when other more preferable routes are not available. This most often occurs when IV access is impractical or impossible, the medication is not suitable for IM administration, or other non-parenteral routes are unavailable or less desirable. In these situations, rectal administration may offer an alternative method of drug delivery. The major drawback to rectal drug administration is unpredictable and often erratic drug absorption.

Drug absorption from the rectum is a simple diffusion process across the lipid membrane. In general, the rate of absorption rises with increasing lipid solubility of the drug and, when applicable, with increased rate of drug release from its carrier (e.g., time to liquefaction of suppository preparations). Other factors affecting transmucosal rectal absorption include the volume of liquid, concentration of the drug, length of the rectal catheter (i.e., site of rectal drug delivery), presence of stool in the rectal vault, pH of the rectal contents, rectal retention of the drug or drugs administered, and differences in venous drainage within the rectosigmoid region.²⁸

Anatomy and Physiology

The rectum is the terminal portion of the large intestine; it begins at the confluence of the three taeniae coli of the sigmoid colon and ends at the anal canal. In adults, the anal canal is approximately 5 cm in length and the rectum is approximately 10 to 15 cm in length. In children, the size of the rectum varies with age (Table 26.2).

TABLE 26.2 Age-Related Changes in Rectal Dimensions

AGE	DIAMETER (cm)	LENGTH (cm)	VOLUME (mL)	LENGTH TO INSERT CATHETER (cm)
1 mo	1.5	3	7	1.5
3 mo	3.0	6	42	3
1 yr	3.5	7	67	3.5
2 yr	4.0	8	100	4
6 yr	4.5	9	143	4.5
10 yr	5.0	12	235	6

From Smith S, Sharkey I, Campbell D: Guidelines for rectal administration of anticonvulsant medication in children, *Pediatr Perinatal Drug Ther* 4:140-147, 2001.

The rectum has two main routes of venous drainage. The superior rectal vein drains into the portal circulation (by way of the inferior mesenteric vein), whereas the middle and inferior rectal veins drain into the caval system (by way of the inferior iliac vein). This pattern of venous drainage has a significant impact on the peak serum concentrations achieved by rectally administered drugs. Drugs administered high in the rectum (the area drained by the superior rectal vein) are carried directly to the liver via the portal vein and are subject to first-pass metabolism. In contrast, drugs administered low in the rectum are delivered systemically into the inferior vena cava, thereby avoiding first-pass elimination in the liver.

Indications and Contraindications

Rectal drug administration is indicated when more desirable routes are unavailable or impractical. For example, IV access in small children may be very difficult to obtain and frightening to the child. In these situations, the option of rectal administration may outweigh the benefits of IV drug delivery. Patients who refuse parenteral drug administration may also benefit from rectal delivery, as will those with nausea and vomiting or an inability to swallow.

There are few, if any, absolute contraindications to rectal drug administration. Rectal administration should be avoided in immunosuppressed patients, in whom even minimal trauma could lead to abscess formation, and in patients with severe thrombocytopenia or coagulopathy to avoid difficult-to-control bleeding.^{28,112} Patients with active lower gastrointestinal bleeding and those with severe diarrhea are not generally good candidates for rectal drug administration. Finally, patients with a variety of acute or chronic anorectal problems such as fissures, hemorrhoids, or perianal abscesses or fistulas may not tolerate rectal drug administration.

Equipment

For medications in suppository form, a water-soluble lubricant (e.g., Surgilube, HR Pharmaceuticals, Inc., York, PA) will reduce the discomfort associated with insertion. For liquid and gel formulations, use an appropriately sized syringe attached to a small (e.g., 6- or 8-Fr) rubber feeding tube or an 18- or 16-gauge plastic IV catheter with the needle removed. A specialized rectal catheter, the Macy Catheter (Hospi Corp, Newark, CA) (Fig. 26.7), is a device that offers a rectal route for administration of medications or fluids via rectal mucosal absorption. The catheter is a thin silicone tube 14-Fr in diameter with a 15-mL balloon at the tip, sized to allow secure retention, yet also provide for ready elimination in the event of need for defecation.

Figure 26.7 Macy rectal catheter. (Courtesy Hospi Corporation, Newark, CA.)

It features multiple exit ports for fluid and medication passage, and an internal one-way check valve to prevent backflow of fluids.¹¹³

Procedure

Suppositories

Place adults and large children in a lateral recumbent position on the stretcher or examination table. Flex the upper leg at the knee and hip, but keep the lower leg extended. Infants, because of their small size, can be placed in almost any position. Place the lubricated suppository at the rectal opening and gently push it into the rectum toward the umbilicus until the gloved index finger has been inserted approximately 7.5 cm in adults, 3.5 cm in children, or 1.5 cm in infants (see [Table 26.2](#)). To help prevent expulsion of the suppository, do not allow the patient to get up for approximately 10 to 15 minutes after insertion.

Most suppositories have an apex at one end (pointed end) and taper to a blunt base at the other end. For ease of insertion, manufacturers recommend inserting the tapered end first. However, in 1991, Abd-El-Maeboud and colleagues found that inserting suppositories blunt end first resulted in greater retention within the rectum and a lower expulsion rate.¹¹⁴ Nonetheless, these findings have not been corroborated and have been challenged by nursing educators as insufficient evidence on which to base clinical practice.¹¹⁵

Liquids and Gels

Position the patient as described for insertion of a suppository. Draw up the desired dose of medication into an appropriately sized syringe attached to a 6- or 8-Fr rubber feeding tube (adults and large children) or an 18- or 16-gauge IV catheter (infants and small children) with the needle removed ([Fig. 26.8](#)). The goal is to deposit the drug in the low to mid-portion of the rectum to avoid first-pass elimination by the liver. For adults, insert the rubber feeding tube approximately 7.5 to 10.0 cm and slowly inject the drug. In children, catheter depth varies with age (see [Table 26.2](#)). When administering rectal medication to infants and young children, be sure to squeeze the buttock cheeks closed after withdrawing the catheter to

prevent expulsion of the medication. A 3-inch piece of tape placed across the buttocks also works well and frees the clinician to perform other duties.

Medications

A variety of medications can be administered rectally. In emergency medicine practice the most common medications given rectally are analgesics and antipyretics, sedative-hypnotic agents, anticonvulsants, antiemetics, and cation exchange resins (e.g., Kayexalate).

Analgesics and Antipyretics

Acetaminophen is frequently administered rectally in children for both fever and pain. Common reasons for rectal administration include refusal to take the medication orally, vomiting, and altered mental status. Acetaminophen is commercially available in suppository form and is easy to obtain and administer. Studies comparing oral and rectal administration of acetaminophen have demonstrated equal antipyretic effectiveness.^{116,117} Rectal dosing of acetaminophen is the same as oral dosing ([Table 26.3](#)).

Though not commonly administered rectally, aspirin, nonsteroidal antiinflammatory drugs (NSAIDs) including indomethacin and diclofenac (diclofenac suppositories are not available in the United States), and morphine also come in rectal formulations and can be very useful in a variety of ED encounters. For example, aspirin is commonly administered rectally to adults with symptoms of a transient ischemic attack, an acute stroke, or an acute coronary syndrome who may have an impaired swallowing mechanism or are too unstable to take medication orally. Like acetaminophen, the oral and rectal doses of aspirin are similar (see [Table 26.3](#)). Rectal NSAIDs and morphine may be an alternative for patients discharged from the ED who require ongoing analgesia but cannot tolerate oral medications.¹¹⁸⁻¹²² Rectal doses of indomethacin and morphine are shown in [Table 26.3](#).

Sedative-Hypnotic Agents

Sedative-hypnotic agents, including midazolam, methohexital, and thiopental may be administered rectally in children requiring sedation in the ED.¹²³⁻¹²⁶ This occurs most often in pediatric patients in whom IV access may be problematic or for procedures that require only minimal sedation in conjunction with the use of local anesthetics (see [Chapter 33](#) for a detailed discussion of sedation and analgesia). Rectal administration of methohexital and thiopental is particularly useful for non-painful procedures such as sedating children before advanced imaging studies.^{124,126} The major drawback of rectal administration is an inability to titrate these medications to the desired level of sedation.

The rectal doses of midazolam, methohexital, and thiopental in children are 0.25 to 0.5 mg/kg, 25 mg/kg, and 5 to 10 mg/kg, respectively (see [Table 26.3](#)). To prepare a solution of methohexital for rectal administration, add 5 mL of sterile water or saline to a 500-mg vial of methohexital and mix well; this provides a methohexital solution of 100 mg/mL.

Anticonvulsants

Anticonvulsants are generally administered orally or intravenously in the ED. However, there may be situations, such as in actively seizing patients, in which oral or IV administration is impossible or unlikely to be accomplished in a reasonable

Figure 26.8 Pediatric rectal administration of medication via a pediatric feeding tube.

TABLE 26.3 Drugs Commonly Administered Rectally in the ED

CLASS	RECTAL DOSE/FREQUENCY	ONSET*	DURATION	COMMENTS
Analgesics/Antipyretics				
Acetaminophen	Adults: 325–650 mg q4–6 hr or 1000 mg q6–8 hr (max, 4 g/day) Children: 10–15 mg/kg q4–6 hr (max, 2.6 g/day)	<1 hr	4–6 hr	Studies have demonstrated equal antipyretic efficacy with rectal and oral administration of acetaminophen
Aspirin	Adults: 300–600 mg q4–6 hr (max, 4 g/day) Children: 10–15 mg/kg q4–6 hr (max, 4 g/day)	<1 hr	4–6 hr	Contraindications are the same as for oral administration (e.g., children with chickenpox or recent flulike symptoms)
Indomethacin	Adults: 25–50 mg/kg per dose q8–12 hr (max, 200 mg/day) Children ≥2 yr: 1–2 mg/kg per day q6–12 hr (max, 4 mg/kg per day) Children >14 yr: see adult dosing	≈30 min	4–6 hr	Indocin suppositories only come in 50-mg doses, which may exceed pediatric dosing needs
Diclofenac	N/A			Not available in a rectal formulation in the United States
Morphine	Adults: 10–20 mg q3–4 hr Children (≥6 mo and <50 kg): 0.15–0.2 mg/kg q3–4 hr	≈30 min	3–4 hr	Rectal absorption may vary widely; close observation for respiratory depression is mandatory in infants and children
Sedative Hypnotics				
Midazolam	Adults: seldom given rectally Children: 0.25–0.5 mg/kg	10–30 min	60–90 min	Because these drugs cannot be titrated when given rectally, close monitoring for oversedation is mandatory
Methohexital	Adults: seldom given rectally Children: 25 mg/kg	5–15 min	60 min	Prepare a solution of methohexital for rectal administration by adding 5 mL of sterile water or saline to a 500-mg vial and mix well
Thiopental	Adults: 3–4 g/dose Children: 5–10 mg/kg per dose	5–15 min	60 min	
Anticonvulsants				
Diazepam	Adults: 10 mg; may repeat once Children: 0.5 mg/kg; then 0.25 mg/kg in 10 minutes (max, 20 mg)	2–10 min	30 min	Dosing guidelines are for status epilepticus; the adult rectal delivery system contains 4 mL (20 mg) of diazepam gel with a 6-cm tip; the pediatric rectal delivery system contains 2 mL (10 mg) of gel with a 4.4-cm tip (see text for details)
Antiemetics				
Prochlorperazine	Adults: 25 mg Children >9 kg: 0.4 mg/kg per day q6–8 hr (not recommended in children <10 kg)	≈60 min	12 hr	Central nervous system effects similar to those with other routes of administration for both prochlorperazine and promethazine
Promethazine	Adults: 12.5–25 mg q4–6 hr Children >2 yr: 0.25–1 mg/kg per day q4–6 hr (max, 25 mg/dose)	≈30 min	4–6 hr (up to 12 hr)	
Cation Exchange Resin				
Sodium polystyrene sulfonate (Kayexalate)	Adults: 30–50 g q6hr Older children: 1 g/kg per dose q2–6 hr Young children/infants: calculate the dose (1 mEq K ⁺ /g of resin)	2–24 hr	6 hr	Avoid solutions containing sorbitol; see text for details regarding rectal administration

*The onset of action of rectally administered medications may vary widely because of erratic absorption and first-pass elimination in the liver.
ED, Emergency department; q, every.

period. In these cases, rectal administration may be an effective alternative.¹²⁷ Studies have demonstrated that diazepam, because of its high lipid solubility, is rapidly absorbed from the rectum and can quickly halt seizures.^{127,128} Lorazepam has much lower lipid solubility and is not recommended for rectal use.

Diazepam is commercially available in a gel formulation that is preloaded in a rectal delivery system (Diastat AcuDial). However, the undiluted parenteral formulation can also be used. The preloaded rectal delivery system is available for both pediatric and adult use. The adult device contains 4 mL (20 mg) of diazepam gel and has a 6-cm tip for rectal administration. This device is designed to deliver set doses of 10, 12.5, 15, 17.5, and 20 mg of diazepam. Two pediatric devices are available: one contains 0.5 mL of a 5-mg/mL gel, and the other contains 2 mL of a 5-mg/mL gel. The latter is designed to deliver set doses of 5, 7.5, and 10 mg of diazepam. Both pediatric devices have a 4.4-cm tip for rectal administration. The recommended dose of diazepam rectal gel for treating actively seizing children and those in status epilepticus is 0.5 mg/kg, followed by 0.25 mg/kg in 10 minutes if needed (maximum dose, 20 mg); the adult dose is 10 mg, which may be repeated once (see [Table 26.3](#)).

Antiemetics

Antiemetics are frequently used in the ED for patients with nausea and vomiting. In most cases, these medications are given intravenously. Oral dissolving tablets (ODT) antiemetics such as ondansetron have largely replaced the use of rectal antiemetics as this route is preferred by most patients. However, for patients with mild symptoms who do not otherwise require IV access and for discharged patients expected to have ongoing nausea and vomiting (e.g., patients with a viral gastroenteritis), rectal administration is an alternative. Rectal administration may also be used as the initial treatment of ED patients with active vomiting in whom IV access will be delayed, and ODT antiemetics have failed, such as those requiring central venous access.

Historically, the two most common antiemetics administered rectally in the ED are prochlorperazine and promethazine. Both come in suppository formulations, which makes rectal administration easy. Prochlorperazine requires a higher dose when given rectally, whereas promethazine dosing is the same regardless of the route of administration (see [Table 26.3](#)).

Cation Exchange Resin

The most commonly available cation exchange resin is sodium polystyrene sulfonate (Kayexalate). In the gut, sodium polystyrene sulfonate absorbs potassium and releases sodium. Each gram of resin may bind as much as 1 mEq of potassium and release 1 to 2 mEq of sodium. In the ED, sodium polystyrene sulfonate is frequently given to patients with hyperkalemia as a temporizing measure before dialysis.

Sodium polystyrene sulfonate may be given orally or rectally as a retention enema. Oral dosing is more effective if intestinal motility is not impaired. Common reasons for rectal administration include an inability or refusal to swallow (the oral solution is not very palatable), vomiting, and altered mental status. The resin comes in two forms: a powder that must be reconstituted and a premixed suspension containing sorbitol.

Before drug administration, perform a cleansing enema with warm tap water. Prepare a sodium polystyrene sulfonate enema by dissolving 50 g of the resin in 100 to 150 mL of tap water warmed to body temperature. In adults, administer the resin emulsion via a 6- or 8-Fr rubber feeding tube placed approxi-

mately 20 cm from the rectum with the tip well into the sigmoid colon. Retain the enema in the colon for at least 30 to 60 minutes and for several hours if possible. Once retention is complete, irrigate the colon with 50 to 100 mL of a non-sodium-containing fluid. The recommended dose of sodium polystyrene sulfonate for rectal administration in adults is 30 to 50 g every 6 hours. For children, the dose is 1 g/kg per dose every 2 to 6 hours. One may also calculate the dosage in neonates based on the exchange ratio of 1 mEq K⁺/g of resin (see [Table 26.3](#)).

Complications

Complications specific to rectal administration include erratic absorption and local trauma. Absorption of a rectally administered drug may be delayed or prolonged, or uptake may be almost as rapid as though the agent were administered intravenously.²⁸ Unusually rapid absorption resulted in the death of a 7½-month-old child receiving rectal morphine for postoperative pain.¹²⁹ In addition to erratic absorption, peak serum concentrations may vary considerably depending on how much of the drug undergoes first-pass elimination in the liver. These factors make rectal drug administration less desirable in most cases when parenteral administration is possible.

Insertion of a suppository or catheter into the rectum may cause mild pain and mucosal irritation, which is usually well tolerated by most patients. Similarly, bleeding from local trauma is usually of no clinical consequence, except in patients with a clinically significant coagulopathy or severe thrombocytopenia.¹¹² Development of a perianal or perirectal abscess is a theoretical concern in neutropenic patients, and thus rectal drug administration is best avoided in such patients.

OTHER ALTERNATE ROUTES OF ADMINISTRATION OF MEDICATION

There is a limited but growing body of evidence demonstrating the benefits of rehydration of patients (usually the elderly¹³⁰⁻¹³² or very young^{133,134}) in the emergency department using a subcutaneous route called “hypodermoclysis” ([Box 26.1](#)). Historically, hypodermoclysis in humans was used in the elderly in non-emergency situations for rehydration. The advent of human recombinant hyaluronidase has made it possible to give faster rates of IV fluid infusion making its use in the ED feasible. The most common practical use of this method is in the setting of dehydration when IV access is unobtainable, though theoretically, medications may also be given via this route. Potential advantages of subcutaneous rehydration compared with IV rehydration are that it expedites and simplifies parenteral access, requires fewer staff resources, and is potentially less distressing to parents and patients.¹³³

Anatomy and Physiology

Hypodermoclysis uses human recombinant hyaluronidase to break up hyaluronan, a mucopolysaccharide found in the intercellular matrix of connective tissue that normally prevents flow of fluids across the subcutaneous layer of tissue. This transiently increases permeability of the connective tissue matrix, allowing movement of subcutaneously administered fluids (and medications) into the surrounding tissues, with subsequent systemic absorption via the capillary beds.

BOX 26.1 Subcutaneous Hydration (Hypodermoclysis)

INDICATIONS

Moderate dehydration with difficult IV access

CONTRAINDICATIONS

Severe dehydration, hypovolemic shock, overlying cellulitis at insertion site

COMPLICATIONS

Pain, swelling with infusion
Cellulitis at IV site (rare)

EQUIPMENT

IV fluid bag with tubing
Small gauge butterfly needle (21-gauge or higher)
Hyaluronidase
Lidocaine 1%
Gloves
Alcohol swabs or povidone-iodine solution
Occlusive dressing

Indications and Contraindications

Subcutaneous hydration is indicated in the moderately dehydrated patient in whom IV access is not easily obtainable, and in whom enteral routes (oral [PO]/nasogastric [NG]) of rehydration have failed. This method should not be employed in the severely dehydrated patient in hypovolemic shock, where IO or central venous access should be considered. Do not use hypodermoclysis if an enteral route (PO, NG) is tolerated.

Equipment

An IV solution bag, a tube with a drip chamber, a small-gauge (21 or smaller) long-tube butterfly needle, povidone-iodine solution or alcohol skin preparation, and a sterile occlusive dressing.

Procedure

Hypodermoclysis sites include the abdomen, upper chest, above the breast, over an intercostal space and the intrascapular area, the lateral thighs, the abdomen, and the outer aspect of the upper arm (Fig. 26.9). In uncooperative adult patients or

Figure 26.9 Anatomic sites usable for hypodermoclysis. (From Bruno VG: Hypodermoclysis: a literature review to assist in clinical practice, *Einstein* 13(1):122–128, 2015.)

Figure 26.10 Appearance of interscapular hypodermoclysis in a child; **A**, prior to infusion, **B**, 4 minutes after infusion, and **C**, 44 minutes after infusion. (From Allen CH, Etwiler LS, Miller MK, et al: Recombinant human hyaluronidase-enabled subcutaneous pediatric rehydration, *Pediatrics* 124(5):e858–e867, 2009.)

pediatric patients, the intrascapular site may be preferred to avoid dislodgment of the setup by the patient (Fig. 26.10). Assemble fluid and tubing. Prime line with selected fluid and 150 units of hyaluronidase. Swab the site with povidone-iodine skin or alcohol preparation solution. Inject local anesthetic into insertion site. Pinching the skin between fingers, insert a 21-gauge (or smaller) needle, bevel up, into subcutaneous

tissue at a 45- to 60-degree angle. Administer 150 units of human recombinant hyaluronidase into the subcutaneous space. Secure needle and tubing with occlusive dressing. Adjust fluid drip rate as desired.

Autotransfusion

Mark J. Neavyn, Margarita E. Pena, and Charlene Babcock

INTRODUCTION

Autologous blood transfusion, or autotransfusion, is the collection and reinfusion of a patient's own blood for volume replacement.¹ Preoperative blood banking and intraoperative cell salvage techniques have increased in a multitude of surgical specialties.²⁻⁷ Autotransfusion in the emergency department (ED) is usually limited to patients with severe, traumatic hemothorax and clinically significant blood loss.

Autotransfusion is usually performed in trauma centers or in EDs with high trauma volume. Though not a uniform standard of care for emergency clinicians, it is applicable to

any ED. As the procedure requires familiarity with the equipment, continuing education, and quality control, it would be counterproductive to institute the procedure in a hospital that has a low trauma census or in a setting in which it will be used infrequently enough that staff education issues are problematic. Clinicians practicing in more austere environments with a paucity of clinical resources, such as combat and disaster zones, may find that the procedure's benefits outweigh its risks.⁸⁻¹⁰

BACKGROUND

Reports of autotransfusion can be found as early as 1818 when Blundell, an English practitioner, reinfused shed blood after witnessing a woman exsanguinate from uterine hemorrhage.¹¹ In 1886, Duncan published the first known human account of autotransfusion in which he reinfused shed blood in a patient with a traumatic amputation without any notable ill effects.¹² In 1917, Elmendorf published a description of the first case of autotransfusion in a patient with traumatic hemothorax.¹³

The discovery of ABO blood typing at the turn of the century and the institution of blood banks in the 1930s led to the almost exclusive use of allogeneic (homologous) blood up

Autotransfusion

Indications

- Hemothorax containing >1500 mL
- Hemothorax with an immediate need for transfusion and insufficient allogeneic blood available
- Hemothorax with an urgent need for blood and the patient's religious beliefs prohibit the use of banked blood

Contraindications

- Coagulopathy or disseminated intravascular coagulation
- Possibility of malignant cells in the salvaged blood
- Active infection
- Gross contamination of pleural blood from gastrointestinal contents

Complications

Hematologic

- Decreased platelet count
- Decreased fibrinogen level
- Increased fibrin split products
- Prolonged prothrombin time
- Prolonged partial thromboplastin time
- Red blood cell hemolysis
- Elevated plasma free hemoglobin
- Decreased hematocrit

Nonhematologic

- Bacteremia
- Sepsis
- Microembolism
- Air embolism
- Renal insufficiency

Equipment

Chest drainage and autotransfusion system. (Atrium Ocean ATS shown above, Atrium Medical Corporation, Hudson, NH)

to and following World War II. During the 1960s and 1970s, cardiopulmonary bypass surgery and combat trauma experience during the Vietnam War generated extensive data regarding intraoperative retrieval of large quantities of blood for reinfusion.¹⁴⁻¹⁷ This revitalized interest, coupled with increased experience in surgical, trauma, and combat situations, has thus initiated a new era in autotransfusion.

ANATOMY

Hemothorax refers to a collection of blood within the pleural space. Severe hemorrhage is more often associated with laceration of vessels on the inside of the chest wall, such as the internal mammary and intercostal arteries. Blunt trauma and penetrating trauma are by far the most common causes of hemothorax. Spontaneous hemothorax can occur secondary to intrathoracic malignancy,¹⁸ pulmonary infarction, bullous emphysema, virulent pulmonary or mediastinal infection, vascular malformation, and endometriosis of the pleura (catamenial).¹⁹

PATHOPHYSIOLOGY

The pathophysiologic sequelae of hemothorax include both hemodynamic instability and respiratory compromise. The pleural cavity can accommodate more than 50% of the total blood volume, so clinically significant intrathoracic blood loss can occur with minimal external signs of bleeding. The clinician should suspect hemothorax in the setting of chest trauma with clinical signs of hypovolemia. Physical examination may demonstrate decreased breath sounds and reduced tactile fremitus. Imaging during the initial resuscitation period is usually limited to supine chest radiographs, which may show haziness in the affected lung field as blood layers in the posterior pleural space (Fig. 27.1). Ultrasound is also useful in the initial evaluation of hemothorax (Fig. 27.2).²⁰ Tube thoracostomy is the treatment of choice for acute hemothorax, with thoracotomy and video-assisted thoracic surgery performed as indicated for severe or ongoing hemorrhage.

Figure 27.1 Hemothorax secondary to a gunshot wound. Note the haziness over the right hemithorax with the bullet seen in the right upper lobe. In this supine radiograph, the volume of the hemothorax may not be fully appreciated. (From Marx JA: *Rosen's emergency medicine*, ed 7, St. Louis, 2009, Mosby.)

ADVANTAGES

Shed blood from traumatic hemothorax is immediately available for rapid transfusion. The blood is normothermic and compatible, which avoids the risk of allergic reaction or infection from transfusion transmissible diseases. There are numerous transfusion transmissible diseases, including viruses such as human immunodeficiency virus (HIV) and hepatitis, bacteria, parasites, and most recently reported, variant Creutzfeldt-Jakob disease.^{21,22} Although the risk for transfusion transmissible diseases has decreased dramatically in developed countries, it is still very problematic worldwide.²³ Immunologic transfusion reactions and posttransfusion sepsis continue to be risks as well.²⁴ In trauma patients, allogeneic transfusions have been shown to be an independent risk factor for infection,²⁵⁻²⁸ which may be dose dependent and independently associated with increased morbidity and mortality.²⁸⁻³⁰ In patients whose religious convictions (e.g., Jehovah's Witness) prohibit transfusions with homologous blood, reinfusion of autologous blood that does not involve blood storage may be an acceptable alternative.³¹

A recent multicenter study by Rhee and colleagues³² compared outcomes in 136 patients receiving autotransfused blood from a traumatic hemothorax to an equal number receiving only allogeneic transfusions. There was no difference between the groups in mortality or in-hospital complications (sepsis, disseminated intravascular coagulation [DIC], acute lung injury, or renal insufficiency). Despite its retrospective design, this study offers support for the practice of autotransfusion based on patient-oriented outcomes.

Autologous blood provides societal benefits by preserving the limited stores of banked blood and reducing the cost of medical care.³³⁻³⁵ Adias and colleagues compared the direct cost of banked blood with the cost of autologous blood transfusion and found substantial savings with autotransfusion.³⁶

Box 27.1 summarizes the advantages of autotransfusion.

INDICATIONS

In general, all victims of severe trauma, whether blunt or penetrating, should be considered potential candidates for

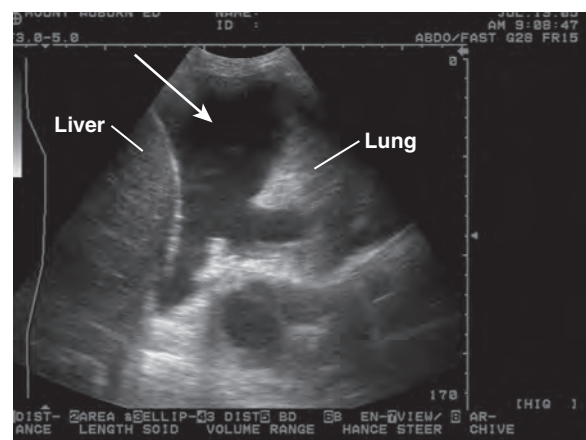

Figure 27.2 Ultrasonographic appearance of hemothorax. Blood in the pleural cavity appears anechoic (arrow) and is easily seen interspersed between the collapsed lung and diaphragm.

BOX 27.1 Advantages of Autotransfusion

1. Immediately available—no delay in crossmatching and no storage required
2. Blood compatibility and allergic reaction not an issue
3. Autologous blood usually normothermic
4. No risk for transfusion transmissible disease
5. No risk for hypocalcemia or hyperkalemia^{38,52}
6. Decreased risk for acute respiratory distress syndrome
7. Higher levels of 2,3-diphosphoglycerate than in banked red blood cells⁷⁵
8. Decreased use of banked blood; more available for subsequent patients in need³⁵
9. Decreased cost of medical care^{33–35}
10. May be acceptable to religions opposed to homologous blood transfusions^{38–40}
11. May be a valuable alternative to banked blood in developing countries where infected donor blood is a problem

autotransfusion. Several categories of patients for whom emergency autotransfusion is suitable have been described and are summarized in [Review Box 27.1](#). Reul and associates described the ideal autotransfusion candidate as a blunt or penetrating trauma victim with hemothorax consisting of 1500 mL or more of blood.³⁷ Other patients who may benefit include those with an immediate need for transfusion for whom insufficient homologous blood is available (because of a shortage or a difficult crossmatch) and those whose religious convictions prohibit homologous transfusion.^{38–40}

CONTRAINDICATIONS

In some situations, emergency autotransfusion may pose more risk than benefit. Coagulopathy and DIC are important contraindications.^{8,41} Others include active infection, gross contamination, and the possibility of malignant cells in the salvaged blood.⁴² With direct autotransfusion of pleural blood through a microfilter, the risk of reinfusing tumor cells is unknown. However, work using perioperative cell salvage suggests that the risk for dissemination of malignant disease is minimal.⁴³ Concerns regarding gross contamination from concomitant gastrointestinal tract injury have also been disputed.⁴⁴ An early study of autotransfusion before cell washing was implemented found that despite reinfusion of massively contaminated blood, 17 of 25 patients survived without evidence of septic complications.⁴⁵

Work on contamination involving cell salvage systems incorporates a cell-washing step.^{46,47} Several investigators believe that reinfusion of limited amounts of contaminated blood from the peritoneal cavity may now be accomplished with acceptable risk. Nonetheless, the current consensus is that exsanguinating hemorrhage without available homologous blood is the only acceptable indication for autotransfusion when there is recognized intestinal contamination.^{48–50} Concurrent use of systemic antibiotics is advised.^{8,9,46,47,50,51}

Autotransfusion should be performed within 4 to 6 hours from the time of injury,^{52,53} although it has been performed after this period in combat situations without significant complications.^{8,47}

EQUIPMENT AND MATERIAL**Blood Filters**

In-line filtration is used routinely during reinfusion of blood products to reduce the danger of microembolization and resultant pulmonary insufficiency.^{1,52,53} The relationship between the presence of microaggregates and the development of acute respiratory distress syndrome is controversial. However, most investigators advise the use of a micropore filter with pore size recommendations ranging from 20 to 170 μm .^{54–56} The majority of investigators believe that a pore size of 40 μm minimizes the risk for microembolization without undue elevation in filtration pressure.^{37,57,58} The manufacturers of the commercial devices discussed in this chapter also recommend at least a 40- μm filter size.²

Vacuum Suction

The level of vacuum suction should be limited to minimize hemolysis of red blood cells.⁵⁸ The precise level at which clinically significant hemolysis occurs is uncertain, and there is wide variation (5 to 100 mm Hg) in recommendations.^{14,37,55,59–61} Several commercial products recommend a starting vacuum pressure of 20 mm Hg.⁶²

Anticoagulation

Blood retrieved from the pleural and abdominal cavities frequently will not clot because it is devoid of fibrinogen.⁶³ This is believed to be because moderate rates of bleeding allow time for defibrination by contact with the serosal surfaces and by mechanical agitation from respiratory and cardiac movement. For this reason, some recommend simple reinfusion through a filter without any anticoagulant.^{17,54,60,64} However, wounds of the great vessels may bleed at a rate that allows coagulable blood to enter the collection reservoir and clot the entire system.^{51,60,61} In the ED setting where autotransfusion is indicated for rapid blood loss, anticoagulation is recommended.

The use of heparin as an anticoagulant in trauma patients is not recommended by the manufacturers of autotransfusion devices.⁶² Heparin anticoagulation is possible; however, local heparinization of the tubing and reservoir may lead to the formation of platelet microaggregates on the filter and in the line, as well as increase the risk for systemic heparinization.^{37,65}

Citrate compounds, an alternative to heparin, are frequently recommended for autotransfusion.⁴¹ Citrates bind with the calcium ion and prevent conversion of protein fibrinogen into insoluble fibrin, which would cause the blood to clot. Because citrate binds only with calcium, it anticoagulates just the blood in which it is dissolved. Once the anticoagulated blood is infused, citrate is rapidly metabolized by the liver. Early studies used acid citrate dextrose (ACD).⁵² More recently, citrate phosphate dextrose (CPD) has been used because it necessitates less volume as an anticoagulant and results in less acidosis than ACD.^{37,66,67} Rarely, excessive use of CPD can cause cardiac dysrhythmias.³⁷ Moreover, use of insufficient or outdated CPD may result in clotting of collected blood. Baldan and colleagues described the use of simple autotransfusion in more than 200 patients with penetrating chest injuries and recommended using half-dose citrate phosphate dextrose adenine solution.⁹ Although anticoagulant therapy and dosage recommendations are at the

discretion of the physician, commercially available devices do offer some general guidelines (Table 27.1).

Historical Techniques Using Standard ED Equipment

Before purpose-built systems were available, autotransfusion was possible by using common items available in most EDs. These techniques have not been as widely tested and are more appropriate for use in dire situations, such as may occur in a disaster or on the battlefield.⁹

Symbas described a simplified collecting system involving a standard chest tube bottle.⁶⁸ More than 400 patients were autotransfused via this method with no adverse effects attributable to the procedure. After insertion of a chest tube, blood was collected into a standard bottle containing 400 mL of normal saline, with suction maintained at 12 to 16 mm Hg. The blood collected in the chest bottle can be reinfused in one of two possible ways as shown in Fig. 27.3. Improvements on his historical technique, such as the addition of anticoagulation and blood filters, should be considered.

Autotransfusion Units

All the commercially available autotransfusion systems (ATSS) are based on the same three-stage system (called the *three-bottle system*) for collection of pleural fluid (Fig. 27.4). Currently used devices incorporate the three-bottle system into one unit.

TABLE 27.1 ACD-A and CPD Dosage Recommendations

BLOOD VOLUME EXPECTED	FOR 1:7, ADD THIS AMOUNT OF ACD-A	FOR 1:20, ADD THIS AMOUNT OF ACD-A
ACD-A Dosage Recommendations ³ (Ratio of ACD-A to Blood)		
Low = 140–250 mL Incremental volume over 250 mL	20–35 mL 1 mL for each 100 mL of collected blood	7–12 mL 5 mL for each 100 mL of blood collected
Medium = 250–500 mL	40–70 mL	12.5–25 mL
High = 500–1000 mL	70–140 mL	25–50 mL

CPD DOSAGE RECOMMENDATIONS

Anticoagulant CPD solution can be added at the discretion of the physician at a control dosage of 14 mL of CPD solution to 100 mL of blood collected (70 mL CPD/500 mL blood).

³Dosage ratios are approximate. Note that 35 mL of ACD-A provides a 1:7 ratio of ACD-A to blood for low volume and a 1:20 ratio for high-volume blood and may be a good starting point if it is unclear how much blood will accumulate. ACD-A, Acid citrate dextrose anticoagulant; CPD, citrate phosphate dextrose. From *A personal guide to managing chest drainage autotransfusion*, Atrium Medical Corporation, pp 26, 27. <http://www.atriummed.com/PDF/Red%20Handbook.pdf>.

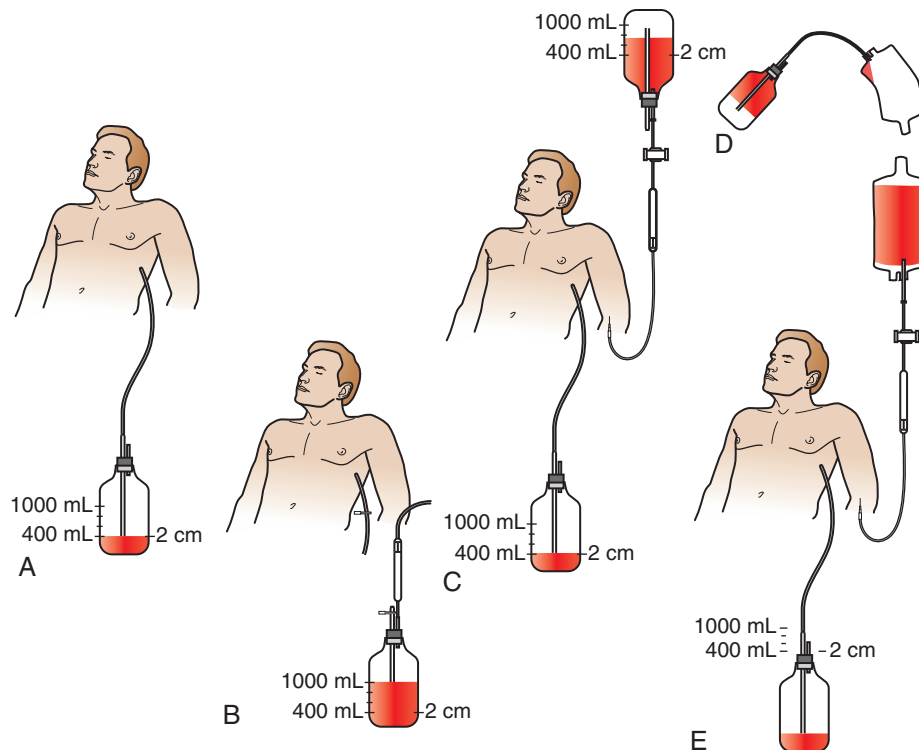

Figure 27.3 Historical technique of autotransfusion for traumatic hemothorax. **A**, Blood is collected into a sterile blood collection bottle with 400 mL of normal saline. **B**, After blood is collected, the chest tube is disconnected from the collection bottle. **C**, Blood is infused directly from the blood collection bottle whilst a new chest tube drainage bottle is connected to the chest tube, or **D**, blood collected from the chest tube is transferred into a sterile blood bag. **E**, Blood transferred into the blood bag is infused into the patient. (From Symbas PN: Extraoperative autotransfusion from hemothorax, *Surgery* 84:722, 1978.)

Stage 1 is the collection of pleural fluid (blood). Stage 2 is the water seal stage, in which water acts as a one-way valve (water seal) that allows air to be sucked out of the pleural space but not leak back in. Stage 3 is the suction control stage, which is essentially a safety stage so that if the degree of suction suddenly increases beyond the set point, the system will pull air from the atmosphere instead of inappropriately increasing suction in the pleural cavity. Historically, water was (and still frequently is) used in the suction control stage.

The disadvantage of using water in stages 2 or 3 is that if the device is knocked over, loss of the water seal and spillage of water from the suction control stage can occur. Newer designs have solved this problem, and two systems currently available do not use water (Atrium Express [Atrium Medical

Corporation, Hudson, NH] and Pleur-evac Sahara [Teleflex, Morrisville, NC]). These newer devices use a one-way valve instead of a water seal in stage 2 and a pressure regulator instead of water in the suction control stage (stage 3).

To collect blood for autotransfusion, a collection bag can be connected beforehand in series with the chest drainage system. With this arrangement, blood goes from the patient to the blood collection bag to the chest drainage system. When the blood bag is filled, it is removed and replaced with a new blood collection bag. If the bag overfills, the fluid will spill into the usual chest fluid collection system. Eventually, when no more blood needs to be autotransfused, the blood collection bag is taken out of the series and the chest tube drainage system functions as usual. Because blood goes directly into the blood collection bag, anticoagulant needs to be added to the blood collection bag before the blood flows into it.

Blood may also be drawn directly from a chest drainage system. Some devices have an additional port at the bottom called an ATS access line. This is referred to as a self-filling ATS. Not all devices permit withdrawal of blood directly from the chest drainage system. In devices without this option, any blood that goes into the chest drainage system is not available for transfusion. The advantage of the ATS access line is that autotransfusion need not be anticipated before the chest tube collection system is connected to the chest tube. Because blood first goes to the collection chamber of the chest drainage device, anticoagulant needs to be added to the collection chamber before blood enters it.

Some models allow these chest drainage systems to be connected directly to the patient to provide continuous autotransfusion. In this setup, a blood filter with intravenous (IV) blood tubing is hooked up to an IV infusion pump. The blood can then be continuously reinfused as it collects in the chest drainage system; it goes from the blood collection chamber out the ATS access line and is pumped into the patient with an IV infusion pump in a closed system (Fig. 27.5). Other models offer continuous infusion directly from a blood collection

Figure 27.4 Three-bottle chest drainage system. **A**, From the patient's chest tube. **B**, Connection to a water seal bottle (stage 2). **C**, Connection to the suction control bottle. **D**, Connection to suction. **E**, Vent tube for suction control.

Figure 27.5 Continuous autotransfusion. Blood is continuously reinfused into the patient as it collects in the chest drainage system. *ATS*, Autotransfusion system. (Courtesy Atrium Medical Corporation, Hudson, NH.)

bag and not the chest drainage device. The blood simply goes from the chest tube into the blood collection bag, and a port on the bag is accessed to return the blood back to the patient.

PROCEDURE FOR AUTOTRANSFUSION

Whether in-line, self-filling, or continuous techniques are chosen depends on the chest tube drainage system used. Some systems allow more than one technique to collect blood for autotransfusion. The specific port locations and connections may vary slightly among the different designs, but the general concepts are relatively universal. See Figs. 27.6 and 27.7 for a description of several different systems from Atrium and Pleur-evac.

The procedure described here is for in-line blood collection and infusion using the Atrium Ocean model; however, all Atrium models have similar connectors. The procedure using Pleur-evac systems is also similar (Video 27.1).⁶⁹

In-Line Blood Collection and Infusion Procedure

1. Place the autotransfusion blood bag onto the chest drain via the attached flexible hanger.
2. Close both autotransfusion blood bag clamps and remove the protective caps over the autotransfusion bag connectors.
3. Close the patient's chest tube clamp.
4. Separate the connectors between the patient's chest tube and the Ocean chest drain by depressing the connector lock.
5. Insert the male patient chest tube connector into the female autotransfusion bag connector.
6. Insert the male autotransfusion bag connector into the female Ocean chest drain connector.
7. Open the clamps in the following order:
 - a. Open the autotransfusion bag clamp going to the Ocean chest drain.
 - b. Open the autotransfusion bag clamp going to the patient's chest tube.
 - c. Open the patient's chest tube clamp to resume drainage. (Blood will then flow from the patient's chest tube into the autotransfusion blood bag.)
8. When the blood bag is filled (600 mL maximum), close the patient's chest tube clamp and both autotransfusion blood bag clamps.
9. Disconnect the autotransfusion blood bag connection with the Ocean chest drain connection first.
10. Disconnect the autotransfusion blood bag from the patient's chest tube connector.
11. Insert the male patient chest tube connector into the female Ocean chest drain connector.
12. Open the patient's chest tube clamp so that drainage may resume into the Ocean chest drain device.

Figure 27.6 Pleur-evac chest drainage systems. (Courtesy Teleflex Medical, Research Triangle Park, NC.)

Figure 27.7 Atrium chest drainage systems. *ATS*, Autotransfusion system. (Courtesy Atrium Medical Corporation, Hudson, NH.)

13. Connect the male and female autotransfusion bag connectors to each other.
14. Connect and pre-prime the blood filter and the IV blood tubing with sterile saline (spike the blood tubing into the filter).
15. Invert the autotransfusion bag so that the spike port at the bottom points upward.
16. Remove the tethered cap with sterile technique.
17. Insert the saline-primed filter spike into the autotransfusion bag spike port with a firm twisting motion.

18. Return the autotransfusion bag to an upright position and place it on a standard IV pole.
19. Open the filtered air vent located on top of the autotransfusion bag first, and then open the IV tubing clamp.
20. Evacuate all the remaining air from the IV line and attach it to the patient to begin the infusion.
21. For gravity infusion, leave the air vent at the top of the autotransfusion bag open.
22. For pressure infuser application, the filtered air vent must remain closed (the maximum ATS bag infuser pressure is 150 mm Hg).

COMPLICATIONS

In general, complications from autotransfusion are clinically insignificant if proper technique is followed. Complications may be categorized as hematologic and non-hematologic (see Review Box 27.1).

Hematologic Complications

The degree to which autotransfusion contributes to the development or exacerbation of coagulopathy in an actively bleeding patient has still not been conclusively determined.⁷⁰

Broadie and coworkers found that blood collected from trauma victims during thoracotomy or laparotomy had markedly elevated prothrombin, partial thromboplastin, and thrombin times, as well as absent fibrinogen.⁶³ The dilemma is that severely injured trauma patients who are candidates for autotransfusion are more likely to have other independent risk factors for coagulopathy, such as hypothermia and acidosis. Horst and colleagues studied 154 trauma patients who underwent intraoperative autotransfusion and found that patients who received more than 15 units of autologous blood or more than 50 units of combined autologous and banked blood were coagulopathic but also more severely injured, hypothermic, and acidotic.⁷¹ Although coagulation test abnormalities following the infusion of salvaged blood have been interpreted as evidence of DIC, these changes are probably the result of infusion of fibrin degradation products and do not represent consumptive coagulopathy.⁷² In general, even though coagulopathy should be anticipated, it has not proved to be clinically important when volumes of autotransfused blood remain below 1500 to 2000 mL in adult patients.^{73,74} When reinfused volumes exceed 3500 mL, laboratory evidence of dilutional coagulopathy may become evident.⁵⁶ When volumes of autotransfused blood are greater than the patient's total blood volume, animal studies suggest that the risk for a true consumptive coagulopathy is increased.⁷⁵

Recommendations regarding the volume of autologous blood that should trigger the infusion of plasma or platelets range from 25% of the total blood volume (approximately 1250 mL in a 70-kg adult) to 3500 mL.^{56,76} (Box 27.2). Others advise reliance on laboratory tests and clinical findings rather than a volume-based protocol.⁷⁵ Prudent clinical judgment dictates application of the more liberal guidelines for replacement therapy in patients with extensive hepatic injury, intractable shock, or ongoing loss requiring immediate surgical intervention.

Hemolysis occurs with autotransfusion, in part because of prolonged exposure of cells to the serosa of the traumatized body cavities.⁷⁷ Hemolysis also results from mechanical damage during collection and reinfusion or from excessive exposure

BOX 27.2 General Autotransfusion Information

1. Use each liner bag only once.
2. Insert a new filter for each autotransfusion bag used.
3. To minimize risk for bacterial overgrowth, blood collected must be reinfused within 6 hours from the time of injury.⁸
4. After reinfusing a total of 3500 mL (approximately 7 units) of autologous blood, it has been suggested that 1 unit of fresh frozen plasma be given for every 2 units (approximately 1000 mL) of autotransfused blood.³⁷
5. If some or all the collected blood becomes clotted in the liner bag, the blood should be discarded.
6. To reduce the risk for air embolism, remove all the air from the bag with the collected blood before hanging it for reinfusion.⁷⁷

"The American Association of Blood Banks suggests no more than a 6-hour shelf life between collection and reinfusion.³³ The age of blood collected should be calculated from time of injury. Blood reinfused after this time should be considered hazardous.

to air-fluid interfaces.³⁷ The hematocrit falls in direct proportion to the quantity of blood transfused, with the average decline being 10% to 20%.^{37,49,68} However, nontraumatized red blood cell survival has been reported to be normal in all cases studied.^{17,56,78}

Nonhematologic Complications

The theoretical risk for sepsis after the administration of potentially contaminated blood always exists within the non-sterile environment of the typical ED. Experience has shown this risk to be minimal after autotransfusion from an isolated hemothorax, and there is no evidence suggesting that routine prophylaxis with systemic antibiotics is beneficial.^{15,52} Collected blood is generally transfused as soon as the collection bag is full. The American Association of Blood Banks guidelines allow a 6-hour interval between collection and reinfusion.⁵³ The age of collected blood, however, should be calculated from the time of injury (see Box 27.2). Blood reinfused after this 6-hour period should be considered potentially hazardous.

The risk for microemboli secondary to platelet aggregation and fat emboli has largely been eliminated by the use of micropore filters.^{49,56,59} During reinfusion of collected blood there is usually a mild increase in screen filtration pressure, indicative of the formation of microemboli trapped by the filter.⁵⁹ There has been no clinical evidence of pulmonary insufficiency or elevation of the alveolar-arterial oxygen gradient that might be attributed to the passage of microemboli beyond micropore filter systems.³⁷

As with all IV infusions, improper technique, such as applying pressure to air-containing systems, may lead to air embolism. This uncommon but potentially fatal complication has been associated with ATSs that use automated roller pump units in which the aspirate reservoir was inadvertently allowed to run dry.^{52,79-81} Air embolism with gravity or with a manually assisted technique is rare.

Infusion of large quantities of unwashed blood that contains hemolyzed red blood cells may contribute to renal failure, particularly in patients with preexisting renal insufficiency.⁴² Elevated plasma free hemoglobin is a consistent finding in

patients who have undergone autotransfusion.^{37,65,68} In the past it was believed that elevated levels of free hemoglobin following hemolytic transfusion reactions caused renal failure by its precipitation and obstruction of renal tubules. However, more recent evidence suggests that the mechanism in this setting is independent of free hemoglobin but rather is the result of an antigen-antibody-induced intravascular coagulation that when compounded by vasoconstriction and hypotension, leads to renal ischemia.⁸² Even though renal failure as a direct consequence of autotransfusion has not been reported, transient elevations in serum creatinine do occur. In the presence of shock and systemic acidosis, acute tubular necrosis remains a potential complication.^{28,38,83} The clinician must weigh the urgency of blood transfusion against the timely availability of an alternative source.

RESOURCES

Brief educational videos are available online for Atrium products at http://www.atriummed.com/EN/Chest_Drainage/edu-files/ATS-video1.asp and show in detail the step-by-step processes to initiate autotransfusion with their devices. They also have a 24-hour help line to assist with any questions during the setup or use of their devices (800-528-7486). Pleur-evac has some limited information available online (<http://www.teleflexmedical.com>) and can be contacted during regular business hours (866-246-6990, 8 AM to 7 PM EST) to answer questions.

Transfusion Therapy: Blood and Blood Products

Colin G. Kaide and Laura R. Thompson

Transfusion of blood components (red cells, white cells, platelets, whole plasma, or plasma fractions) is commonplace in the emergency department (ED). Annually in the United States, 15 million blood donations take place and 14 million units of red blood cells (RBCs) are transfused.¹ Although acute hemorrhage is the most common emergency indication for blood transfusion, more nonemergency transfusions and blood component therapy now occur in the ED as a result of the general migration of health care away from inpatient settings. Technical advances have made component therapy directed at specific acute and chronic pathologic conditions practical, safe, and affordable.

BACKGROUND

RBC Antigens and Antibodies

The first documented transfusion took place in the early 1600s, and sporadic advancement in transfusion medicine occurred over the next three centuries, mainly dabbling in cross-species whole blood transfusions. It was not until the early 1900s that the Austrian Karl Landsteiner found that an individual's serum reacted with the red cells of some but not all other individuals, thereby discovering the red cell antigen-antibody system.

RBC membranes contain a series of glycoprotein moieties, or antigens, that give the cell an individual identity. Two different genetically determined antigens, type A and type B, occur on the cell surface. Any individual may have one, both, or neither of these antigens. Because the type A and type B antigens on the surface of the cell make the RBC susceptible to agglutination, these antigens are termed agglutinogens. The presence or absence of agglutinogens is the basis for the ABO blood group classification, and the blood types are named accordingly as A, B, or AB. Blood type O contains neither the A nor the B agglutinogen. These blood type antigens are represented in Fig. 28.1.

Within the first year of life, antibodies begin to form against the standard red cell agglutinogens that are not present in the individual patient. These agglutinins are γ -globulins of the immunoglobulin (Ig) M and IgG types and are probably produced by exposure to agglutinogens in food, bacteria, or exogenous substances other than blood transfusions. In the absence of type A agglutinogens (blood types B and O), anti-A antibodies, or agglutinins, spontaneously develop in the plasma. Similarly, in the absence of type B agglutinogens (blood types A and O), anti-B antibodies develop. When both A and B agglutinogens are present (blood type AB), no agglutinins are

formed. Blood groups and their genotypes and constituent agglutinogens and agglutinins are shown in Fig. 28.1.

The reaction between red cell antigens and the corresponding agglutinins results in red cell destruction when noncompatible blood types are mixed. As many as 300 different red cell antigens have been identified, but clinically the A and B antigens are most important; severe, potentially fatal agglutination can occur with the first transfusion of ABO-incompatible blood. The Rh system is likewise very important because there is a chance that transfusion of Rh-positive blood to an Rh-negative patient will result in the formation of Rh antibodies. These antibodies are capable of causing severe hemolysis following a second exposure to the Rh antigen. Of the 40 antigens in the Rh system, D is the most antigenic, but others can also stimulate the production of antibodies in recipients lacking the antigen and thus complicate future transfusions. Other antigen systems in which antibodies could potentially cause hemolytic reactions are the Kell (K and k alleles), Duffy (Fy^a and Fy^b), Kidd (Jk^a and Jk^b), and MNS (M and N and closely linked S and s) systems. Other antigen systems are rarely of clinical importance in transfusion therapy, except in certain patient populations who may require repeated transfusions, such as those with sickle cell anemia.

Crossmatching

Compatibility testing, or crossmatching, involves mixing the donor's RBCs and serum with the serum and RBCs of the recipient to identify the potential for a transfusion reaction. The end point of all crossmatches is the presence of RBC agglutination (either gross or microscopic) or hemolysis. Testing is performed immediately after mixing, after incubation at 37°C for varying times, and with and without an antiglobulin reagent to identify surface immunoglobulin or complement. Each unit of blood product, when properly crossmatched, can be administered with the expectation of safety. Full crossmatching takes approximately 45 minutes to complete.

Types of RBC Preparations

Whole Blood

The normal blood volume of a healthy adult and healthy child is approximately 70 mL/kg and 80 mL/kg, respectively. Though intuitively an ideal transfusion agent, whole blood is seldom used except for autologous transfusions (e.g., autotransfusion) and for exchange transfusions. Whole blood is not indicated for the treatment of hypovolemic shock, which can be treated effectively with a combination of crystalloids (e.g., lactated Ringer's [LR] solution, 0.9% sodium chloride), colloids (e.g., plasma protein, albumin), and packed RBCs (PRBCs). It is also not indicated for the correction of thrombocytopenia, replacement of coagulation factors, or treatment of anemia.² The incidence of transfusion reactions following transfusion with whole blood is approximately 2.5 times greater than that with PRBCs.³ Whole blood contains antigenic leukocytes and serum proteins, which carry higher risk (approximately 1%) for an allergic reaction. Nevertheless, warm fresh whole blood has seen increased popularity in military settings and has been proposed as an alternative to component therapy for civilian use in massive transfusion protocols.⁴ Other methods of whole blood transfusion, including autologous transfusion in massive hemothorax, are being explored as promising alternatives to minimize reaction to whole blood transfusion.⁵

Figure 28.1 Blood group types and their associated antibodies and antigens. (From Abbas AK: *Cellular and molecular immunology*, ed 7, Philadelphia, 2011, Saunders.)

Packed Red Blood Cells

PRBCs are prepared by centrifugation and removal of most of the plasma from citrated whole blood. One unit of PRBCs contains the same red cell mass as 1 unit of whole blood at approximately half the volume and twice the hematocrit (55% to 80%) in 250 mL of volume.⁶ One unit of PRBCs raises the hematocrit approximately 3% in an adult or increases the hemoglobin level of a 70-kg individual by 1 g/dL. In children, there is an approximate rise in hematocrit of 1% for each 1 mL/kg of packed cells. For example, if 5 mL/kg of PRBCs is transfused, the hematocrit will rise by approximately 5%. Actual changes depend on the state of hydration and the rate of bleeding. Because most of the plasma has been removed, PRBCs cause fewer transfusion and allergic reactions than whole blood does.

PRBCs contain less sodium, potassium, ammonia, citrate, hydrogen ions, and antigenic protein than whole blood does. This may offer advantages in patients with reduced cardiovascular, renal, or hepatic function. The rate of urticaria is still relatively high at 1% to 3% of transfusions, but the incidence of adverse reactions to packed cells is approximately one third of that noted with whole blood. The benefit of increased hemoglobin must be weighed against the potential for volume, electrolyte, and acid-base imbalances following PRBC admin-

istration. In cases of massive transfusion (>10 units), there is a significant risk for metabolic and respiratory acidosis, as well as hypocalcemia, which can reach life-threatening levels. Although underlying illness or injury obviously plays a major role in the cause of death, the overall mortality of patients requiring massive PRBC transfusions is approximately 60%.^{7,8}

Transfusion of PRBCs is indicated to provide additional oxygen-carrying capacity and expansion of volume. Packed cells are most commonly used to treat acute hemorrhage and anemia that is not amenable to nutritional correction. When treating acute hemorrhage, PRBCs are usually given: (1) if the hemoglobin level falls below established critical levels for that particular given patient population (see the section on [Transfusion Thresholds](#)), (2) after rapid crystalloid infusion fails to restore normal vital signs, or (3) concurrently with crystalloid infusion in the treatment of obvious life-threatening blood loss.

Specially prepared or screened types of red cells are listed in the following sections. Their indications for use are presented in [Box 28.1](#).

Washed RBCs

After centrifugation, red cells can be washed to further remove leukocytes, platelets, microaggregates, and plasma proteins.

BOX 28.1 Indications for the Use of Specialty Red Blood Cells for Transfusion

IRRADIATED

Neonates
 Patients with hematologic malignancies
 Stem cell–transplant patients
 Directed donations from family members
 HLA-matched platelets
 Patients with cellular immune deficiency

WASHED

Recipients with a history of severe allergic transfusion reactions
 IgA-deficient patients
 Paroxysmal nocturnal hemoglobinuria

LEUKOCYTE REDUCED

Multiple-transfused patients
 Multiparous females
 Cancer patients undergoing chemotherapy

CMV AND EBV SERONEGATIVE

Seronegative patients who are currently pregnant
 Premature or low–birth-weight infants
 Bone marrow or organ transplant recipients
 Immunosuppressed patients

CMV, *Cytomegalovirus*; EBV, *Epstein-Barr virus*; HLA, *human leukocyte antigen*; IgA, immunoglobulin A; RBCs, *red blood cells*.

Abstracted from Williamson LM, Warwick RM: *Transfusion-associated graft-versus-host disease and its prevention*, Blood Rev 9:251–261, 1995; and Cushing MM, Ness PM: *Principles of red blood cell transfusion*. In Hoffman R, Benz EJ, Shattil S, et al, editors: *Hematology: basic principles and practice*, ed 5, Philadelphia, 2009, Churchill Livingstone/Elsevier, pp 2210–2216.

Washing reduces the titer of anti-A and anti-B, thereby permitting safer transfusion of type O PRBCs into non-O recipients.

Leukocyte-Reduced RBCs

Leukocyte-reduced blood products contain less than 5×10^6 leukocytes/unit, whereas standard RBC units contain 1 to 3×10^9 leukocytes. Reduction can be performed at the time of collection, in the transfusion laboratory, or at the bedside during transfusion. Leukocyte-reduced products are used to decrease the likelihood of febrile reactions, immunization to leukocytes, and transmission of disease. Currently, approximately 60% to 75% of the U.S. blood supply is leukoreduced.⁹ Several groups advocate the use of 100% leukocyte-reduced blood products because of the many adverse transfusion reactions that are associated with leukocytes. Non-leukocyte-reduced products are virtually the exclusive method of transmission of several viruses, including human T-lymphotropic virus 1 and 2, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). Additionally, they help reactivate and disseminate CMV and human immunodeficiency virus (HIV). Moreover, increased rates of bacterial contamination and postoperative and line infections have been associated with the use of non-leukocyte-reduced products. Furthermore, leukocytes lead to human leukocyte antigen (HLA) alloimmunization, which results in increased graft rejection and platelet refractoriness.¹⁰

Irradiated RBCs

Blood products can be irradiated to reduce the risk for graft-versus-host disease (GVHD) in susceptible patients. Irradiation destroys the donor lymphocytes' ability to respond to host foreign antigens. Box 28.1 lists the indications for use of irradiated PRBCs.

Infectious Complications of Transfusions

Though relatively uncommon, transmission of infectious diseases is the transfusion-related complication most feared by the lay public. Transmission of a wide variety of infectious diseases has been reported, but modern screening methods have sharply reduced the frequency of transmission. Viral illnesses remain the most problematic.

Between 1985 and 1999, 694 deaths associated with transfusion were reported to the Food and Drug Administration (FDA). Seventy-seven (11.1%) of these deaths were caused by bacterial contamination. However, sepsis is an uncommon occurrence because both the citrate preservative and refrigeration kill most bacteria. Concern over sepsis is responsible for the practice of completing transfusions within 4 hours and returning unused blood products to the blood bank refrigerator for future use only if they have been unrefrigerated for less than 30 minutes. Both gram-negative and gram-positive organisms are transmitted, with gram-negative virulence being more commonly associated with mortality. A prospective observational study found that the rate of nosocomial infections was significantly higher in patients receiving blood transfusion. Leukoreduction did not significantly reduce the rate of infection.¹¹ A 2001 multicenter study by the Centers for Disease Control and Prevention further evaluated the risk for bacterial contamination in the blood pool. The results showed the rate of bacterial sepsis to be much lower than previously thought. Only 0.21 cases and 0.13 deaths per million red cell transfusions occurred. The rate was slightly higher for platelet transfusions, with 10 cases and 2 deaths per million transfusions.¹² Mandatory screening of platelets for bacterial contamination began in 2004 and has further reduced the rate of reported death.

Syphilis may theoretically be transmitted by transfusion, but both refrigeration and citrate markedly reduce the survival of *Treponema pallidum*. Thus, transmission is only a concern with fresh blood or platelet transfusions. The incubation period for syphilis transmitted by transfusion is 4 weeks to 4 months, and the initial clinical manifestation is commonly a rash. No cases of transfusion-transmitted syphilis have been recognized for many years.^{13,14}

The risk for parasitic infection via transfusion is exceedingly low (<1 per 1,000,000), although prospective blood product donors who have been to an endemic region within 12 months or treated with malarial prophylaxis within 3 years are prohibited from blood donation. Those with a history of babesiosis or Chagas disease are permanently barred. Donors with a history of Lyme disease may donate if they are symptom free and have undergone a complete course of treatment.

Viruses are the organisms most likely to be transmitted by transfusion and are the agents with the greatest potential to cause serious disease. They include CMV, EBV, HIV, West Nile virus (WNV), and the hepatitis viruses.

Most blood products have the potential to transmit hepatitis. Routine testing of blood donors for hepatitis C virus (HCV) has occurred since 1991, but the initial screening tests were relatively inaccurate. Since April 1999, the use of nucleic acid amplification

testing (NAAT) to detect HCV RNA has been mandatory. This test has essentially eliminated false positives and has a sensitivity of greater than 99%.^{15,16} The American Association of Blood Banks (AABB) reported the risk for transmission of HCV to be less than 1 per 1,000,000 transfusions. The incubation period for HCV is 2 to 12 weeks following parenteral infusion. The reported risk for transmission of hepatitis B virus (HBV) is higher at 1 per 137,000 transfusions.

Both CMV and EBV may cause a mononucleosis-like syndrome 2 to 6 weeks after a transfusion. Indications for CMV- and EBV-negative preparations are listed in [Box 28.1](#). Alternatively, leukocyte-reduced products can help protect against CMV and EBV.

The AIDS epidemic has affected transfusion therapy profoundly. In the United States, 3% of AIDS cases have been linked to blood products. The estimated likelihood of transmitting HIV through transfusion is 1 in 1,900,000. Currently, NAAT is used to detect HIV in blood. Because the test detects genetic material in lieu of antibody to the virus, it has significantly reduced the window period during which infection is undetected. Other methods of reducing transmission, including techniques to kill the virus in collected samples (viral inactivation) and the use of blood component substitutes, are being investigated.

Efforts to reduce the risk for transmission of HIV to the general population receiving blood products began early in the course of the epidemic and have had considerable success. Voluntary deferral of blood donation by high-risk groups was encouraged beginning in 1983, and formal screening of all blood products commenced in 1985.

Transmission of WNV by blood transfusion was first documented in the United States in 2002.^{17,18} Since 2003, universal screening for WNV by investigational NAAT occurs on all blood donations. From 2003 to 2005, 1400 potentially infectious donations were removed from the blood pool. Since that time, however, multiple cases of transfusion-associated transmission of WNV have been confirmed. This residual risk for transmission is due to blood units with low levels of viremia. Public health authorities continue to look for ways to eliminate this risk from the blood pool.^{18,19}

Emerging infectious risks to the blood supply are always under investigation. Blood-transmitted infections under current surveillance include parvovirus B19, dengue virus, and the prions that cause Creutzfeldt-Jakob disease. Although a viremic phase of human herpesvirus-8, avian flu (H5N1), H1N1, and Lyme disease has been well documented, no cases of transmission through transfusion have been noted.^{19,20}

A summary of infection risks associated with red cell transfusion is presented in [Table 28.1](#).

Transfusion Reactions

Transfusion reactions can be divided into two phases: acute and chronic. The vast majority of transfusion reactions occur proximate to or concurrently with the administration of red cells. If the ED is the site for a nonemergency transfusion and the patient is otherwise stable enough for discharge, it is a common practice for the patient to be released shortly after the transfusion is completed.

Acute Reactions

Allergic

The most common manifestation of a minor allergic transfusion reaction is urticaria; however, wheezing and angioedema can

TABLE 28.1 Estimated Risks of Transfusion per Unit of Packed Red Blood Cells in the United States

RISK	RATE
Major allergic reactions	1/100
Anaphylaxis	1/20,000–50,000
Anaphylactic shock	1/500,000
Hemolytic reaction (minor)	1/6000
Hemolytic reaction (fatal)	1/100,000 allergic reactions
Death from sepsis (RBC)	1/5 million
Death from sepsis (platelets)	1/500,000
Parasitic infections (Lyme, malaria, Chagas)	<1/million—data lacking
Hepatitis C	<1/million
Hepatitis B	1/140,000
Parvovirus, Creutzfeldt-Jakob disease	Extremely rare—data lacking
HTLV 1/2 infection	1/200,000
HIV infection	1/2 million
West Nile virus	Extremely rare—data lacking
CMV/Epstein-Barr	Rare—data lacking
Acute lung injury	1/500,000
Graft-versus-host disease	Extremely rare—data lacking
Immunosuppression	Unknown
Syphilis	No cases reported currently

CMV, Cytomegalovirus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; RBC, red blood cell.

also be observed. The allergic response is due to the presence of atopic substances that interact with antibodies in the donor or recipient plasma, but the severity is not dose related.⁶ Whenever a transfusion reaction is suspected, the first step in management is to stop the transfusion. Treatment is the same as for other allergic reactions and includes antihistamines, corticosteroids, and intramuscular (IM) or intravenous (IV) epinephrine if needed. For mild reactions (e.g., those limited to skin findings), the transfusion can be resumed once treatment has been given.

Anaphylactic

The reported incidence of transfusion-associated anaphylaxis is 1 in 20,000 to 50,000. Anaphylaxis occurs most commonly in IgA-deficient patients who have IgA-specific antibodies of the IgE class.²¹ Manifestations of an anaphylactic transfusion reaction include shock, hypotension, angioedema, dyspnea, bronchospasm, and laryngospasm. The symptoms are typically rapid in onset and begin within seconds to minutes of starting the transfusion. If this type of reaction occurs, the transfusion

must be stopped immediately. Treatment includes airway management as necessary, IM or IV epinephrine, fluids, corticosteroids, and antihistamines, followed by appropriate supportive care and continued close observation. If a transfusion is still required, the patient needs to be pretreated with corticosteroids and antihistamines 30 to 60 minutes before the transfusion. Alternatively, or in addition, washed cellular products can be used.

Febrile (Nonhemolytic) Reactions

A febrile, nonhemolytic reaction is defined as an increase in temperature of 1°C or higher during or within 6 hours of the transfusion. The mechanism for this type of reaction is most commonly attributed to an interaction between recipient antibodies and donor leukocytes.^{22,23} This stimulates the release of cytokines such as interleukin-1, which ultimately produces a febrile response. Although this type of reaction is not life-threatening, it is difficult to distinguish from more serious transfusion reactions. Accordingly, all patients with a fever attributable to a transfusion must have the transfusion stopped. Symptoms can be treated with acetaminophen or nonsteroidal antiinflammatory drugs. There is no role for antihistamines in the treatment of this type of reaction. Although controversy exists, premedication with antipyretics and antihistamines may prevent these transfusion reactions.²⁴

Acute Hemolytic Reactions

An acute hemolytic reaction is usually the result of donor-recipient major ABO incompatibility. This in turn is most commonly the result of blood product misassignment related to clerical error. Hemolytic transfusion reactions are estimated to occur once per every 6000 blood units transfused, with a fatality rate of 1 per every 100,000 units transfused.

When incompatible blood is given, the result may range widely from no effect to death. If the recipient does not have antibodies (naturally occurring or acquired) directed against the foreign RBC antigen received, there will be no immediate reaction, but antibodies to the infused blood may develop within weeks, thus limiting the safety of subsequent transfusions from the same donor or same antigenic type. If the recipient's serum has preformed antibodies directed against the donor RBCs (e.g., an incompatibility in the major crossmatch), the recipient will begin to hemolyze the donor cells within seconds or minutes. In most cases of major crossmatch reactions, RBCs of the donor blood are agglutinated and hemolyzed. It is rare for transfused blood to produce agglutination of the recipient's cells because the plasma portion of the donor blood becomes diluted by the plasma of the recipient. This reduces the titer of the infused agglutinins to a level too low to cause significant agglutination. Because the recipient's plasma is not diluted to any significant degree, the recipient's agglutinins can react with donor cells. The end result of antigen-antibody incompatibility is red cell hemolysis. Occasionally this occurs immediately, but more often the cells first agglutinate. They are then trapped in small vessels and become phagocytized over a period of hours to days and release hemoglobin into the circulatory system.²⁵ Clinical manifestations of acute hemolysis include chills, fever, tachycardia, abdominal pain, back pain, hypotension, fainting, and a feeling of "impending doom." Derived from the liberation of intracellular material associated with hemolysis, vasoactive substances may cause hypotension and shock; other substances may precipitate disseminated intravascular coagulation and high-output cardiac failure. Acute

renal failure may also result. The presence of hemoglobinemia and hemoglobinuria is essential in making the diagnosis. A decrease in hematocrit and haptoglobin or an increase in lactate dehydrogenase may also be seen.

Treatment of an acute hemolytic reaction begins with immediate cessation of the transfusion. The blood bank should be alerted immediately because a second patient is now at risk for receiving the wrong product. Resuscitation and supportive care along with close monitoring of laboratory values are essential. A sample of blood from the recipient needs to be obtained for a direct antiglobulin test, plasma-free hemoglobin, and repeated type and crossmatch. Urine can also be tested for free hemoglobin. Renal function and electrolytes should be monitored for evidence of renal failure and hyperkalemia. Dialysis is occasionally required.^{25,26} Fluid resuscitation and diuresis with normal saline are recommended to maintain urine output above 100 to 200 mL/hr. LR solution should be avoided because calcium can precipitate clotting.

Drug-Induced Hemolysis

Drug-induced hemolysis is not a transfusion reaction per se; however, it can be indistinguishable from an acute hemolytic reaction in patients receiving blood transfusions. In this case, both autologous and transfused cells are affected. A patient's serum can react with red cells in the presence of certain drugs. Two examples of drugs that can cause this type of reaction are cefotetan and ceftriaxone.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) refers to noncardiogenic pulmonary edema occurring during or shortly after the transfusion of blood products. A leading cause of transfusion-related mortality and morbidity, TRALI has been reported to occur in as many as 3% of patients receiving transfusions.^{27,28} TRALI appears to be associated with components from female plasma; preferential distribution of male plasma by the American Red Cross has recently decreased its incidence.²⁹

The potential for TRALI is one reason why some authorities are reluctant to transfuse high ratios of plasma to PRBCs in massive transfusion protocols. TRALI is thought to result from the activation of recipient neutrophils in the lung and the production of vasoactive mediators, which leads to increased pulmonary capillary permeability and leakage. Initial symptoms include respiratory distress, hypoxia, hypotension, fever, and bilateral pulmonary edema; however, the spectrum of TRALI can also include much milder reactions.^{30,31}

Treatment of TRALI is supportive and includes supplemental oxygen, endotracheal intubation, and cardiovascular support as necessary. Diuresis and corticosteroids are not effective.^{32,33}

Delayed Reactions

Delayed Hemolytic Transfusion Reactions

Even when major and minor crossmatches indicate compatibility, delayed hemolytic transfusion reactions can occur days to weeks after transfusion. This is due to antibody production by either the donor or recipient B cells in response to exposure to antigens on red cells. Usually seen in patients who have had multiple transfusions or in multigravida women, these reactions may be unavoidable without complete RBC antigen typing, a procedure occasionally indicated for recipients of repeated transfusions. An incompatibility in the minor crossmatch does not usually result in a serious reaction, although the recipient's

red cells can be hemolyzed if the titer of the antibody is sufficiently large. Fortunately, 90% of transfusions are now given as PRBCs, which contain a very small volume of plasma, thus minimizing the chance of a transfusion reaction occurring as a result of donor sensitization.

The signs and symptoms of a delayed hemolytic reaction include low-grade fever, a decrease in hemoglobin, mild jaundice, a positive direct antiglobulin test, and elevation of lactate dehydrogenase.

Treatment of a delayed hemolytic reaction is not needed unless there is evidence of brisk hemolysis. In the case of brisk hemolysis, treatment consists of fluids, antigen-negative (type O) blood transfusions, or red cell exchange.

Graft-Versus-Host Disease

GVHD is a transfusion complication most commonly associated with allogeneic hematopoietic cell transfusions. However, it can occur whenever immunologically competent lymphocytes are transfused, especially in immunocompromised hosts. Donor lymphocytes engraft in the recipient and then attack host tissue. Symptoms are typically observed 7 to 14 days after the transfusion and include fever, rash, and diarrhea. Hepatitis and marrow aplasia also occur. GVHD is often fatal; failure of the host's marrow leads to overwhelming infection or bleeding. The use of gamma-irradiated cellular components prevents this complication by making the donor lymphocytes incapable of proliferating.^{22,30}

Posttransfusion Purpura

In rare cases, profound thrombocytopenia can develop 1 to 3 weeks after a transfusion associated with an antibody response to a platelet antigen. A probable pathophysiologic mechanism for this is the production of low-affinity antibodies that cross-react with autologous platelets. Eventually, as the immune response matures, the low-affinity antibody is eliminated and the thrombocytopenia resolves spontaneously. Only patients at risk for bleeding or hemorrhage need to be treated. Treatment consists of high-dose immune globulin, plasmapheresis, or platelet transfusion.

Miscellaneous Transfusion Issues

Transfusion Thresholds

PRBCs are a precious commodity. Guidelines to limit transfusions to those that are absolutely necessary have set transfusion thresholds or “triggers.” A liberal transfusion trigger is approximately 10 g/dL of hemoglobin, whereas restrictive thresholds are set at 7 to 8 g/dL. The limits for restrictive thresholds stem from the finding that aerobic metabolism can still occur at hemoglobin concentrations as low as 5 g/dL.^{34,35} Clinically, however, almost all patients show signs of physiologic stress at hemoglobin concentrations of less than 6 g/dL.^{35,36} It is at this level that patients will begin to reliably demonstrate the symptoms and signs of anemia: dyspnea on exertion or even at rest; pallor, particularly of the palms and mucous membranes (Fig. 28.2); and resting tachycardia.

The Transfusion Requirements in Critical Care study compared a strategy of restrictive transfusion triggers with conventional, more liberal triggers.³⁷ The authors concluded that a restrictive strategy appears to be at least as effective as a more liberal strategy, with the possible exception of patients with coronary insufficiency. In trauma patients, more liberal use of blood has also been questioned.³⁸ One of the risks

Figure 28.2 Physical finding of anemia. Marked pallor of the palmar creases (*above*) is apparent when compared with a patient with a normal hemoglobin level (*below*). This anemic patient had a hemoglobin level of 4.5 g/dL.

associated with restrictive transfusion thresholds is an increased incidence of infection.³⁸ Nonetheless, mortality, cardiac events, and length of hospital and intensive care unit (ICU) stay appear to be unaffected by more restrictive thresholds.³⁹ More recently, in a study of patients with acute upper gastrointestinal (GI) bleeding, Villanueva and colleagues found that using a transfusion threshold of 7 g/dL versus 9 g/dL resulted in decreased incidence of further bleeding, decreased adverse events, and increased survival at 6 weeks.⁴⁰ No single criterion should be used as an indication for red cell component therapy. Multiple factors related to the patient's clinical status and oxygen delivery needs should be considered. Current practice focuses on the needs of the individual patient. Particularly close attention should be paid to the subset of patients at risk for coronary ischemia, with more liberal triggers possibly being applied to these patients. In a U.S.-based study of Medicare patients with acute myocardial infarction, Wu and colleagues⁴¹ found RBC transfusions to be beneficial in elderly patients when hematocrit values were lower than 33%. In the setting of severe sepsis a more conservative threshold of 10 g/dL may also be appropriate.⁴² In contrast, new data from pediatric ICU settings suggest that adopting a threshold of 7 g/dL imparts no worse clinical outcome and may result in benefits in long-term mortality and morbidity.⁴³ Similar findings were documented in pediatric postsurgical patients.⁴⁴

In addition to cost and transmitted infections, there is a risk for systemic inflammatory response syndrome with transfusion. This syndrome is closely associated with diminished organ function and mortality in critically ill adult patients and its

incidence increases with the administration of more than 4 units of PRBCs.^{45,46} Red cell administration is also associated with an increased risk for life-threatening acute respiratory distress syndrome⁴⁷ and multiple-organ failure.^{48,49} This has been linked to immunologic alterations and their effects on plasma cytokine and cytokine receptor concentrations. In patients receiving more than 15 units of PRBCs, levels of both interleukin and soluble tumor necrosis factor were elevated.^{32,48} It remains unclear whether the use of leukocyte-reduced PRBCs can mitigate the expected inflammatory response.

The judicious and restricted administration of PRBCs appears to be clinically founded in the majority of patients. By implementing a restrictive transfusion strategy, the probability of a patient requiring blood can be decreased by 42% and the volume of PRBCs transfused can be decreased by 0.93 units per patient.^{39,50,51}

Another area of study focuses on the projected need for administration of PRBCs in any given patient. Knowing which patients will probably need blood based on initial findings can be helpful in resource allocation and determination of the need for crossmatching. Studies have correlated the base deficit (BD) with the need for transfusion by using a cutoff of -6 mEq/L. Patients with a BD larger than -6 mEq/L have a 72% chance of requiring blood, whereas those with BDs smaller than -6 mEq/L have only an 18% chance of requiring PRBCs. More elaborate scales have been proposed based on easily assessable parameters. The emergency transfusion score is a point system based on systolic blood pressure, the presence of free fluid on focused assessment with sonography for trauma (FAST), an unstable pelvic ring fracture, advanced patient age, admission from the scene, motor vehicle collision, or a fall as being predictors of future transfusion requirements.⁵²

It is impossible to define strict PRBC transfusion recommendations in the ED setting. Such decisions must be made in real time after considering multiple factors, some of which may not be known at the time. In summary, definitive data are lacking at this time and no dogmatic recommendations can possibly apply to all ED scenarios. As a general concept, however, the likelihood of a transfusion being of benefit is high when the patient's hemoglobin level is less than 6 to 7 g/dL and low when it is greater than 10 g/dL. The correct strategy is unclear when the hemoglobin level is between 7 and 10 g/dL. Continued blood loss of varying degrees renders transfusion strategies even more obscure. The elderly and those with cardiovascular or respiratory disease may not tolerate anemia as well as those without these parameters.

Massive Transfusion

Massive transfusion is loosely defined. In the 1970s it was considered to be the transfusion of more than 10 units of blood to an adult, equivalent to 1 blood volume, within 24 hours. Historically, massive transfusion was associated with dismal survival rates ($<10\%$).^{53,54} As blood banking technology and storage methods have improved, the mortality associated with massive transfusions has decreased significantly. There is no clear physiologic threshold to define a massive transfusion. Mortality in patients receiving fewer than 5 units is currently approximately 10%, in those receiving 6 to 9 units it is approximately 20%, and in those receiving 10 or more units it is greater than 50%.⁵⁵ Alternative triggers for initiation of a massive transfusion protocol are now being proposed, including elevation of the international normalized ratio (INR) and BD,

in addition to hemoglobin. Despite the challenges of treating the expected posttransfusion inflammatory and immunologic complications, patients requiring massive transfusions can have good outcomes.

Transfusion Coagulopathy

Pathologic hemostasis occurs following massive blood transfusions.^{54,56-59} Coagulopathy and subsequent uncontrolled bleeding are major contributors to trauma-related deaths.^{60,61} Although such abnormalities rarely develop within the time frame of the initial resuscitation in the ED, an understanding of the problem can lead to a more thoughtful approach to transfusion practices and the anticipation of potential problems. Significant alterations in blood and blood products occur during storage. Moreover, in patients who are given a transfusion equal to 2 blood volumes, only approximately 10% of the original elements remain. The development of transfusion coagulopathy is multifactorial; important factors include tissue injury, acidosis, the duration of shock, and hypothermia, in addition to activation, consumption, and dilution of coagulation factors.⁶²⁻⁶⁴

Transfusion coagulopathy is also related in part to dilution of the recipient's platelets by transfused blood devoid of functioning platelets. Dilutional thrombocytopenia is a well-recognized complication of massive transfusion, and a platelet count should be obtained routinely if more than 5 units of blood are transfused.

Disseminated intravascular coagulation (from a hemolytic reaction) may play a secondary role in posttransfusion bleeding. Factors V and VIII are labile in stored blood and absent in packed cells. Fibrinogen is relatively stable in stored blood but is absent in packed cells. A deficiency of most clotting factors, especially factors V and VIII and fibrinogen, occurs with massive transfusions. This deficiency probably occurs on a "washout" (i.e., dilutional) basis, although the dynamics are poorly understood. Replacement of these factors may be required. Specific assays for the individual factors are available, but it is more practical to measure the prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen levels. Plasma has been used to correct clotting factor abnormalities secondary to dilution from massive transfusions, but its effectiveness has not been firmly established. Cryoprecipitate has also been used to replace factor VIII and fibrinogen, but it is rarely required because plasma contains some fibrinogen. Fresh frozen plasma (FFP) should be infused to correct the coagulopathy as indicated by clotting studies. Cryoprecipitate may be required if fibrinogen levels fall below 100 mg/dL despite the use of plasma. Although blood component therapy can be based on measured coagulopathy parameters, as a general guide 1 to 2 units of plasma for each 5 to 6 units of blood may be given empirically.^{65,66}

Numerous massive transfusion protocols exist. Traditionally, transfusion-related coagulopathies have been evaluated and treated as per laboratory indicators, but rapid or massive transfusions do not allow equilibration or timely laboratory analysis. Although this approach is quite acceptable in most patients, the aim of transfusion protocols is to prevent transfusion-related coagulopathy before it occurs. Obviously one cannot simply continue to transfuse only PRBCs to patients experiencing significant blood loss, and some combination or ratio of plasma to PRBCs to platelets should be adopted. The ideal combination is, however, not known with certainty, and it is largely dependent on the underlying need for transfusion

and specific patient characteristics. Most protocols recommend a plasma-to-PRBC ratio of 1:1.5 or 1:1.8.⁶⁷ Other protocols also include empirical platelet administration and use of an RBCs to platelets to FFP ratio of 1:1:1.⁶⁸ A 2015 study, the Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial, compared the transfusion strategy of plasma, platelets and RBCs in a 1:1:1 ratio versus a 1:1:2 ratio. In patients with major trauma and severe bleeding they found no significant differences in mortality at 24 hours or 30 days using either strategy. They did note in the 1:1:1 group, “more patients achieved hemostasis and fewer experienced death due to exsanguination by 24 hours.”⁶⁹

At this time, however, no specific transfusion ratio has been proved superior. Strict adherence to any protocol must be balanced against the risk for multisystem organ failure and infection associated with high doses of platelets and plasma. All protocols recommend warming of blood and blood products because hypothermia occurs quickly during massive transfusions and can contribute to further coagulopathy.

Severe Trauma and Coagulopathy

A transfusion coagulopathy often develops in individuals who are injured during military combat and receive transfusions because of widespread tissue trauma. The U.S. military has advocated an approach to transfusion therapy that includes prompt initiation of 1:1:1 resuscitation ratios with RBCs, prethawed universal-donor AB plasma, and apheresis platelets, with conversion to fresh whole blood as soon as it can be obtained. This ratio has not been universally adopted by civilian hospitals.

Emergency Transfusions

In an emergency, three alternatives to fully crossmatched blood exist. The preferred substitute is type-specific blood with an abbreviated crossmatch. The abbreviated crossmatch includes ABO and Rh compatibility. In addition, the recipient's serum is screened for unexpected antibodies, and an immediate “spin” crossmatch is performed at room temperature. This abbreviated crossmatch requires approximately 30 minutes. Many institutions are now using this procedure as their standard crossmatch for most patients. The safety and utility of the type-specific abbreviated crossmatch have been demonstrated repeatedly, with transfusion reactions occurring only rarely.^{70,71} Brickman and coworkers demonstrated that bone marrow aspirates obtained with an intraosseous (IO) needle can also be used for crossmatching.⁷²

The second preference for an alternative to fully crossmatched blood is type-specific blood that is only ABO and Rh compatible, without screen or immediate spin crossmatch. The patient's ABO group and Rh factor can be determined within 2 minutes, and in an emergency, typing of the blood group and the Rh factor is all that is necessary before transfusion. Type-specific blood that has not been crossmatched has been used in numerous military and civilian series without serious consequences. While the type-specific blood is being transfused, the antibody screen and crossmatch are carried out in the laboratory. The transfusion should be stopped if an incompatibility is found.

A third alternative to fully crossmatched blood is group O blood, although type-specific blood is generally preferable.^{6,73} Commonly, this is available at the point of care and has the advantage of being immediately available in cases of severe shock with ongoing bleeding. Thus, despite the theoretical

preference for type-specific blood in emergency situations, type O is often a reasonable and practical alternative.

One may transfuse both Rh-positive and Rh-negative group O packed cells into patients who are in critical condition. It is a common misconception that patients who are Rh negative will have an immediate transfusion reaction if given Rh-positive blood. There is no particular advantage in determining the Rh factor because preformed, naturally occurring anti-Rh antibodies do not exist. Theoretically, individuals who are Rh negative may become sensitized either through pregnancy or by previous transfusions, and a delayed hemolytic transfusion reaction will result if Rh-positive blood is transfused. However, this scenario is very rare and is of little significance when compared with life-threatening blood loss. Sensitization to the Rh factor is most problematic for Rh-negative women of reproductive age.^{74,75} Any sensitized patient may experience a transfusion reaction if exposed again to Rh-incompatible blood. However, significant subsequent transfusion reactions with Rh-incompatible blood in men sensitized to the Rh factor are very rare. Many advise routine use of the more widely available type O Rh-positive packed cells in all patients in whom the Rh factor has not been determined, except in females of childbearing age, for whom future Rh sensitization may be an important consideration. Once resuscitated with Rh-positive packed cells, patients may receive their own type without a problem. Because individuals with type O Rh-negative blood represent only 15% of the population and the blood may be in short supply, it is reasonable to save type O Rh-negative blood for Rh-negative females of childbearing potential and to use type O Rh-positive packed cells routinely as the first choice for emergency transfusions. In a study of emergency blood needs, Schmidt and colleagues reported 601 units of blood into 262 untyped patients, including 8 Rh-negative women, before the blood type was determined.⁷⁴ No acute hemolytic reactions occurred and no women were sensitized. A non-emergency-based study found the rate of Rh sensitization in Rh-negative recipients receiving Rh-positive blood to be approximately 8% and this figure may be reduced if Rh immune globulin is given after transfusion.^{76,77} Thus, prophylaxis with Rh immune globulin is recommended only for Rh-negative women of childbearing potential receiving Rh-positive blood.

Rh immune prophylaxis with Rh₀(D) human immune globulin (RhoGAM) is also indicated for Rh-negative pregnant women who may be bearing Rh-positive children and may have fetomaternal transplacental hemorrhage, including bleeding in early pregnancy, such as spontaneous or elective abortion, ectopic pregnancy, and other potential causes of antepartum hemorrhage such as trauma. RhoGAM suppresses the immune response of Rh-negative women to Rh-positive RBCs and is effective when given up to 72 hours after exposure to fetal erythrocytes. Standard doses are 50 µg for women up to 12 weeks of pregnancy and 300 µg in the second and third trimester. In the setting of fetal-maternal transfusion greater than 15 mL (usually only in the third trimester when fetal blood volume becomes more substantial), higher doses may be necessary. In such circumstances, the correct dose may be calculated by quantitative testing for fetal erythrocytes in the mother's blood (Kleihauer-Betke test).⁷⁸

If non-crossmatched blood is transfused, the laboratory should receive a plain (e.g., without a serum separator) red-topped tube of venous blood as soon as possible to begin a formal crossmatch procedure. Whenever possible, this sample should be drawn before any blood is transfused.

Metabolic Disturbances

RBCs undergo metabolic, biochemical, and molecular changes during storage that are collectively known as the erythrocyte “storage lesion.”^{79,80} These changes are generally subtle but can be measured: a decrease in levels of 2,3-diphosphoglycerate (2,3-DPG), pH, and intracellular potassium and a concomitant increase in supernatant potassium.

Theoretically, citrate salts, which are the usual anticoagulants in donor blood, may combine with ionized calcium in plasma and produce hypocalcemia and rarely hypocalcemic-related cardiovascular depression. In clinical practice the hemodynamic consequences of citrate-induced hypocalcemia are minimal, although the QT interval may be prolonged on the electrocardiogram with citrate infusion. Supplemental calcium administration is not usually necessary, even during massive blood replacement, as long as circulating volume is maintained because the liver is able to remove citrate from the blood within a few minutes. Alterations to this recommendation may be necessary in patients with severe liver disease. If calcium replacement is deemed necessary by clinical judgment, 10 to 20 mL of calcium gluconate may be given intravenously, via a different vein, for each 500 mL of blood transfused. If calcium chloride is used, only 2 to 5 mL per 500 mL of blood should be given. Calcium chloride may be preferable in patients with abnormal liver function, such as those with bleeding esophageal varices, because citrate metabolism is decreased, which results in slower release of ionized calcium. Care must be taken to avoid administering too much calcium and inducing hypercalcemia, ideally by monitoring the ionized calcium concentration.

Directed and Autologous Donations

The system of “directed donations” by which friends or family members may donate blood for a specific individual has been proposed in response to concerns about the transmission of infectious disease. At this time, directed donation systems are in place in some institutions but the practice has not been widely supported. Directed donations probably do not decrease the risk for infectious disease transmission and may disrupt the normal anonymous blood donor system and thus leave fewer units available for other needy patients.^{81,82}

Although autologous donations are of limited clinical applicability in emergencies, they are commonplace in elective surgery. It has been suggested that up to 10% of the blood supply could be provided through this mechanism. However, current studies show that the peak of autologous donations represented less than 2% of the total blood collections and this number is declining.⁸³ Applications at this time include elective cardiac, gynecologic, orthopedic, and vascular surgery. Benefits include avoidance of exogenous blood-borne disease and sensitization. An individual can donate 1 unit of blood weekly until 3 days before surgery. Because blood can be stored for up to 35 days, donations usually begin 5 weeks before needed. The blood donor will require iron supplements and must maintain a hemoglobin level higher than 11 g/dL.

RBC Substitutes

Concerns over infection, availability, storage difficulties, and risk for transfusion reactions have fueled interest in the development of blood substitutes. The ideal blood substitute should: (1) deliver oxygen efficiently, (2) require no compatibility testing,

(3) cause few or no side effects, (4) have prolonged storage qualities, (5) persist in the circulation, and (6) be affordable.⁸⁴ Blood substitutes can be categorized as synthetic emulsions and hemoglobin-based oxygen carriers (HBOCs) or “stromal-free” hemoglobin solutions.

HBOCs can be derived either from humans (typically from outdated human PRBCs) or from animals, notably bovine. HBOCs are created by lysing red cells, extracting the hemoglobin, and then chemically cross-linking single hemoglobin molecules to create a larger molecule, one less likely to cause impairment in renal function by obstruction of the renal tubules.⁸⁵ Early HBOCs had a propensity to cause renal injury, but this has markedly improved in subsequent generations. Advantages of HBOCs over packed red cells include a much longer shelf life (1 to 4 years) and no need for crossmatching.⁸⁶ In some cases HBOCs are used to provide a bridge therapy for patients who cannot receive transfusions but in whom erythropoiesis-stimulating agents may be effective in 2 to 4 days.⁸⁷ An important disadvantage is a much shorter circulating half-life (1 day versus 31 days).⁶

Perfluorocarbons are carbon-fluorine compounds that have a high oxygen- and carbon dioxide-dissolving capacity.⁸⁸ They are not miscible with water and must therefore be emulsified for administration. Perfluorocarbons are totally synthetic, essentially limitless in supply, chemically stable, and harbor no risk for infection.⁸⁹ However, they are limited by a short half-life, with degradation occurring within 48 hours of administration. Trials to date have focused mainly on their adjunctive use with standard transfusion therapy. Preliminary studies are examining earthworm and marine worm hemoglobins, as these creatures survive and oxygenate without RBCs. This work is in the very early stages but may prove promising in the future.⁹⁰

Other potential blood analogues in the investigation phase include biodegradable micelles and hemerythrin, an oligomeric protein responsible for transport of oxygen in the marine invertebrate.⁵⁰ Alternative sources for red cell therapy include stem cells⁹¹ and placental umbilical cord blood⁹² as another stem cell analogue to create greater supplies of transfusion-safe blood.

OTHER BLOOD PRODUCTS

The individual blood components are discussed in the following sections. A summary of the dosages and characteristics of each component is provided in [Table 28.2](#).

Platelet Concentrates

Platelet concentrates are prepared by rapid centrifugation of platelet-rich plasma. Platelets are obtained by single-donor apheresis or from pooled random-donor whole blood units. Platelets obtained by single-donor apheresis have the advantage of exposing the recipient to only one donor. This reduces the risk for exposure to many different donors and confers a lower risk for transfusion-transmitted disease and other complications. HLA-matched platelets may be used when HLA antibodies develop as a result of repeated random-donor platelet transfusions. Platelet concentrates contain most of the platelets from 1 unit of blood in 30 to 50 mL of plasma.

Confusion sometimes arises about how to order platelets. Platelets are typically ordered by the “pack.” Many institutions use a “6-pack” composed of 6 individual units of platelets.

TABLE 28.2 Summary and Dosage of Blood Products

BLOOD COMPONENT	DOSE	NOTES	EXPECTED RESULTS
Platelets	≈ 1 unit/10 kg 1 apheresis pack or a 6 (4)-pack of pooled platelets	ABO and Rh compatible is preferred but in an emergency, is not necessary. 30–50 mL/unit ≈ 180–300 mL/6-pack Available in 5–15 min 3× the usual dose to reverse clopidogrel and ASA The duration of platelet life is severely diminished with ITP.	Each unit should raise the platelet count by 5000–10,000, so a 6-pack or 1 apheresis unit should raise the count by 30,000–60,000.
Fresh frozen plasma	15 mL/kg or ≈ 1000 mL or 4 units in a 70-kg patient	ABO compatibility is desirable but not required in an emergency, and Rh compatibility is never required. 200–250 mL/bag Available in 45–60 min Should begin with 4 units minimum to correct an elevated INR Not possible to get an INR <1.5 with FFP	Each unit raises all coagulation factors by 2%–3% in average-sized adults.
Cryoprecipitate	10–20 bags, depending on the indication	ABO compatibility is desirable but not required in an emergency, and Rh compatibility is never required. Hypofibrinogenemia <100 mg/dL: give 10 bags, 15–20 mL/bag Fibrinolytic-induced bleeding: give 10–12 bags Factor VIII deficiency when specific factor therapy is not available: 1 bag/5 kg Available in 20 min	With fibrinolytic-induced bleeding, recommended doses may help correct bleeding. In factor VIII deficiency, the recommended dose will raise factor VIII to 50% of normal.

ASA, Acetylsalicylic acid; FFP, fresh frozen plasma; INR, international normalized ratio; ITP, idiopathic thrombocytopenic purpura.

Some institutions use a 4-pack. A 4- to 6-pack of random-donor units delivers approximately the same amount of platelets as a single-donor apheresis unit. Unfortunately, some hospitals also refer to the 4- or 6-pack as a unit. It is important to become familiar with the blood bank terminology at your hospital. For this discussion, the term *unit* is used to describe individual units and not a 4- or 6-pack.

One individual unit of random-donor platelet concentrate raises the platelet count by 5000 to 10,000/mm³. The usual adult dose is 1 random-donor unit for every 10 kg of body weight. In an average adult, this works out as approximately 6 to 8 units of platelet concentrate. Assuming a zero platelet level, 6 units (or one 6-pack) or one single-donor apheresis unit given to a normal-sized adult should increase the platelet count to approximately 50,000/mm³. If there is no evidence of platelet consumption, this transfusion should be adequate for 3 to 5 days. In cases of severe platelet consumption, transfusion may be required every 6 to 24 hours. Some hospital blood banks prepare platelet concentrates regularly; in some cities a central blood bank service, such as the American Red Cross, prepares platelet concentrates regularly and delivers units on an as-needed basis within 1 to 2 hours of the request. Platelet concentrates are viable for 5 days when kept at room temperature and gently agitated at intermittent periods or when kept in motion. They should not be refrigerated.

The issue of prophylactic platelet transfusion remains controversial. Spontaneous bleeding rarely occurs if the platelet count is greater than 10,000 to 20,000/mm³. Even in the event of surgery or trauma, excessive bleeding is uncommon in patients whose platelet count exceeds 50,000/mm³. It is generally recommended that active hemorrhage be treated by platelet transfusion if the platelet count is lower than 50,000/mm³, but prophylactic transfusion may be withheld safely until the count is lower than 20,000/mm³, and more recent data suggest that this threshold can be lowered to less than 10,000 or even 5000/mm³.^{93,94}

Patients with idiopathic thrombocytopenic purpura (ITP) may be severely thrombocytopenic. Despite low platelet counts in ITP, it is uncommon to see spontaneous bleeding. Because of the presence of antiplatelet antibodies in these patients, transfused platelets may last only a short time (minutes to hours) before being removed from the circulation. Nonetheless, patients with ITP and life-threatening bleeding or severe head trauma should be given platelets at two to three times the normal dose.⁹⁵

Platelet transfusion should be avoided in patients with thrombotic thrombocytopenic purpura (TTP), a rare microangiopathic hemolytic anemia, because platelets will result in further microemboli. TTP may be suspected in patients with both anemia and thrombocytopenia but not leukopenia. Clinical

features often include fluctuating neurologic symptoms and signs, jaundice, renal dysfunction, and fever. Laboratory confirmation includes the identification of intravascular hemolysis on a peripheral blood smear (e.g., schistocytes), as well as other laboratory evidence of hemolysis. Treatment consists of plasma exchange, although emergency treatment may begin with an infusion of FFP.⁹⁶

Limited retrospective studies suggest an increase in morbidity and possibly increased mortality in patients with traumatic intracranial hemorrhage (ICH) who are taking platelet inhibitors such as aspirin and clopidogrel, in comparison to controls who are not taking antiplatelet agents.⁹⁷ One *ex vivo* study involving 11 healthy volunteers found that complete normalization of platelet function could be obtained in patients taking platelet inhibitors by giving 10 to 15 random-donor units (two to three 4- or 6-packs) or 2 to 3 single-donor apheresis units.⁹⁸ Another *in vitro* study (2015) looked at reversal of the effects of a three-drug antiplatelet therapy (aspirin, clopidogrel, and vorapaxar [Aralez Pharmaceuticals, Mississauga Ontario, Canada]) via the administration of platelets. In this study, the administration of a larger amount of platelets (up to 10 random-donor units) was able to reverse some of the antiplatelet effects of this three-drug combination.⁹⁹ Unfortunately, to date there have been no *in vivo* studies looking at outcomes in patients receiving platelet infusions for antiplatelet-associated bleeding.

At this time, no established guidelines exist for managing bleeding catastrophes in patients on antiplatelet agents, and the AABB states: “The AABB cannot recommend for or against platelet transfusion for patients receiving antiplatelet therapy who have intracranial hemorrhage (traumatic or spontaneous).”¹⁰⁰ Given the devastating nature of ICH in patients taking antiplatelet agents, the benefits of large-volume platelet transfusions may outweigh the risks; however, this is still unclear (Table 28.3).

Crossmatching is unnecessary for platelet transfusion, but the donor and the recipient should be ABO and Rh compatible. Note that platelet concentrates contain enough RBCs to sensitize an Rh-negative individual. In an emergency situation, if ABO-compatible platelets are not available, unmatched platelets can be transfused. This will reduce the number of platelets available from the transfusion but otherwise does not cause the same reaction that is expected with an incompatible red cell transfusion. Most institutions have a policy that limits the amount of incompatible platelets that can be given.¹⁰¹ With massive blood transfusions there may be a diluting effect of the platelet count, resulting in thrombocytopenia. When more

than 10 units of blood are transfused, the platelet count must be routinely evaluated and platelets must be replaced accordingly. Clinically significant platelet depletion rarely occurs if less than 15 units of blood (or 1.5 to 2 times the blood volume) has been transfused.¹⁰²

Each 4 to 6 units of platelets contains 250 to 350 mL of plasma (\approx 1 unit of FFP), which includes coagulation factors and may reduce the requirement for FFP. Platelets may be infused rapidly (1 unit/10 min) with the use of specialized platelet filters.

Fresh Frozen Plasma

FFP is prepared by separating plasma from the cellular components of single-donor whole blood, followed by rapid freezing and storage at 18°C or lower. Freezing preserves the soluble coagulation factors of the contact activation (intrinsic) and tissue factor (extrinsic) clotting systems, including the labile factors V and VIII. FFP also contains fibrinogen, though not as much as cryoprecipitate does. Plasma stored for 3 months retains approximately 60% of the normal factor VIII activity and has a shelf life of up to 1 year. Thawed solvent- or detergent-treated plasma stored at 4°C for 6 days still contains sufficient coagulant activity of factors II, V, VII, VIII, IX, XI, and XII; fibrinogen; antithrombin; protein C; and von Willebrand factor (vWF) antigen and can be safely administered.¹⁰³ Ideally, transfused plasma should be compatible with the recipient’s ABO group. Rh compatibility is not considered essential.¹⁰⁴ Each unit of FFP has a volume of approximately 200 to 250 mL. The INR of a unit of FFP is approximately 1.5. Transfusion of even very large amounts of FFP into a patient with an elevated INR will not correct the INR to below 1.5. It is not clinically useful to give FFP to patients with an INR lower than 1.7.¹⁰⁵

Because each unit of FFP increases levels of all coagulation factors by 2% to 3% in an average-sized adult, it is useful in clinical scenarios involving depletion of clotting factors. FFP may also be valuable in patients with hereditary or acquired clotting abnormalities, such as a deficiency of factor II, V, VII, X, XI, or XIII; von Willebrand syndrome; hemophilia A (factor VIII deficiency); hemophilia B (factor IX deficiency); or hypofibrinogenemia. However, because of the large volume of FFP that is generally required, its effectiveness is limited in these inherited diseases with severe clotting abnormalities. Specific factor replacement, when available, is always preferred over FFP.

TABLE 28.3 Summary and Dosage of Reversal Agents for Platelet Inhibitors

AGENT	DOSE	NOTES
Platelet transfusion	2 to 3 units of pooled platelets or 2 to 3 apheresis packs	Human studies proving the efficacy of the use of platelets in patients with antiplatelet agent-induced bleeding are lacking.
DDAVP (Desmopressin)	0.3 μ g/kg IV	Promotes platelet adherence May be effective in mild hemophilia and mild von Willebrand’s disease and in patients with uremic platelet dysfunction Consider for bleeding with platelet inhibitor use along with platelet transfusion Consider in mild von Willebrand’s disease

DDAVP, 1-Deamino-(8-D-arginine)-vasopressin; IV, intravenous.

FFP is also indicated for clotting factor deficiencies resulting from massive blood replacement. However, pathologic hemorrhage after massive transfusions is often caused by thrombocytopenia rather than by a depletion of clotting factors. More aggressive FFP replacement formulas are becoming commonplace, rather than the accepted 1 unit of FFP for every 5 to 6 units of PRBCs (see earlier section on [Massive Transfusion](#)).

Although FFP can be used for rapid reversal of serious acute bleeding from warfarin anticoagulants or for prophylaxis before surgery or an invasive procedure, the trend is moving toward the use of prothrombin complex concentrates (PCCs) for this indication. When used, the timing of FFP administration is important. In a study on warfarin-related ICH, each 30-minute delay in administering the first dose of FFP translated into a 20% lower chance of reversing the patient's coagulopathy within the first 24 hours.¹⁰⁶ In an emergency situation, 10 to 15 mL/kg of FFP will effect a rapid reversal of the vitamin K-dependent factors II, VII, IX, and X. As a general rule of thumb, in a life-threatening situation 4 units of FFP should be considered a starting dose. It is appropriate to use FFP to treat the acquired deficiency of multiple factors, such as seen in patients with severe liver disease, disseminated intravascular coagulation, or vitamin K depletion, and for plasma exchange in those with TTP or hemolytic-uremic syndrome. It is not appropriate for volume expansion or enhancement of wound healing.

Reactions to FFP include fever, chills, and allergic responses, and recipients have a risk for HIV infection and hepatitis similar to the risk with whole blood. FFP should be infused rapidly after thawing because the clotting factors are labile and rapidly lost.

One less common but very serious complication of the administration of blood products containing plasma (FFP and platelets) is TRALI. It is believed to be an immune-mediated process and can occur in up to 1 in 5000 transfusions containing plasma. It carries a mortality of 6% to 9%. Although it is more common with plasma products, it can also occur with RBC transfusions because of the small amount of residual plasma in PRBCs.^{107,108} It was described earlier in the section on [Transfusion Reactions](#).

Start by giving 4 units of FFP if the PT is greater than 1.5 to 1.7 times normal or the activated PTT is greater than 1.5 times the top normal value.¹⁰⁹ Each 5 to 6 units of platelets contain the equivalent of 1 unit of FFP, so concomitant platelet infusions may lower the requirements for FFP. In critically ill patients with acute hemorrhage and suspected coagulopathy (e.g., end-stage liver disease), it is appropriate to begin empirical treatment before the laboratory values are known.

Cryoprecipitate

Cryoprecipitate is prepared from single-donor plasma by gradual thawing of rapidly frozen plasma. This process causes precipitation of proteins rich in fibrinogen, as well as factor VIII. Each unit of cryoprecipitate typically yields 100 to 250 mg of fibrinogen, 80 to 100 units of factor VIII, and 50 to 60 mg of fibronectin.¹¹⁰ Cryoprecipitate is a plasma product and therefore requires ABO compatibility (see earlier discussion in the section on [Fresh Frozen Plasma](#)). The volume of each bag unit is approximately 15 to 18 mL.

Cryoprecipitate is indicated for the treatment of patients with fibrinogen deficiency, congenital afibrinogenemia, dysfibrinogenemia, and factor XIII deficiency and in some patients

with hemophilia A or von Willebrand's disease.^{111,112} It can also be used as a second-line treatment to correct a deficiency in coagulation factor VIII (in hemophilia A) when factor VIII concentrates are not readily available. Because cryoprecipitate contains no factor IX, it is of no value in the treatment of factor IX deficiency (hemophilia B).

Mild deficiencies in factor VIII are defined as 10% to 30% of normal activity and severe deficiencies as less than 3% of normal activity. When treating bleeding, the goal depends on the site and severity of hemorrhage, but in general one should aim for at least 50% of normal factor VIII activity. For life-threatening hemorrhage, aim for 100% activity. The amount of cryoprecipitate required to correct coagulation defects ranges from 10 to 20 units/kg for minor bleeding, such as hemarthrosis, to 50 units/kg for control of bleeding in surgery or trauma. Guide specific replacement by laboratory assay of factor VIII activity. The half-life of factor VIII in plasma is 8 to 12 hours.

One bag of cryoprecipitate per 5 kg of body weight will raise the recipient's factor VIII level to approximately 50% of normal. In a 70-kg patient, this equals 14 bags. The large number of units that must be given increases the chance of exposure to blood-borne diseases. Factor VIII concentrate is a better choice because of improved methods of viral inactivation and the availability of factor VIII prepared with recombinant DNA technology.

The vWF in cryoprecipitate degrades during storage, thus leading to variable amounts in each bag. It can be used for life-threatening bleeding in patients with von Willebrand's disease but only when the proper preparations of concentrated vWF (Humate-P [CSL Behring GmbH, Marburg, Germany]) are not available.

Cryoprecipitate may be required to correct significant hypofibrinogenemia (<100 mg/dL). A typical adult dose of approximately 10 bags of cryoprecipitate raises the fibrinogen level by up to 1 g/L (60 to 100 mg/dL). In cases of severe bleeding after the use of a fibrinolytic agent such as tissue plasminogen activator, cryoprecipitate can be used to help control the bleeding. A consensus on dosing has not been reached, but many sources recommend between 10 and 12 bags.¹¹³

Specific Factor Therapy

A summation of the dosages and characteristics of each factor appears in [Table 28.4](#).

Factor VII

Activated recombinant factor VII (rFVIIa) is a DNA product which is structurally similar to human serum factor VIIa. It has been approved by the FDA for the prevention and treatment of bleeding in patients with hemophilia A or B who have inhibitors to factors VIII and IX, as well as prevention and treatment of bleeding in patients with congenital factor VII deficiency. It works by binding to the surface of activated platelets, which then activate factor X by using the tissue factor pathway (formerly known as the extrinsic pathway). This obviates the need for either factor VIII or IX. Activated factor X then complexes with factor Va, which leads to thrombin burst and clot formation. Factor VII has a half-life of 2.7 hours. A thromboembolic rate of 1% to 2% has been reported.¹¹⁴ A large meta-analysis of 35 randomized trials showed that arterial clots were more common than venous clots and the risk appears to increase with age.¹¹⁵

TABLE 28.4 Managing Elevated International Normalized Ratios

CONDITION	ACTION
INR above the therapeutic range but <5.0 AND No bleeding	Lower or omit the dose, monitor more frequently, and resume at a lower dose when the INR is therapeutic; if only minimally above the therapeutic range, dose reduction may or may not be required.
INR \geq 5.0 but \leq 10 AND No significant bleeding	Omit the next 1 or 2 doses, monitor more frequently, and resume at a lower dose when the INR is in a therapeutic range. Consider the use of vitamin K, 1–2.5 mg orally, particularly if at increased risk for bleeding. Note that INR correction with vitamin K in this situation may result in prolonged warfarin resistance for the next 3–5 days.
INR >10 AND No significant bleeding	Hold warfarin therapy and give a higher dose of vitamin K (5–10 mg orally) with the expectation that the INR will be reduced substantially in 24–48 hrs. Monitor more frequently and use additional vitamin K if necessary. Resume therapy at a lower dose when the INR is therapeutic.
Serious or life-threatening bleeding at any elevation of INR	Hold warfarin therapy and give vitamin K (10 mg by slow intravenous infusion), AND 4-factor prothrombin complex concentrate or fresh frozen plasma.

INR, International normalized ratio.

Adapted from Holbrook A, Schulman S, Witt DM, et al: Evidence-based management of anticoagulant therapy: antithrombotic therapy and prevention of thrombosis 9th edition: American College of Chest Physicians evidence-based clinical practice guidelines, *Chest* 141:e152S–184S, 2012.

Increasingly, activated factor VII is being used to control bleeding in patients who are not hemophiliacs.¹¹⁶ One multicenter study found that of 701 patients receiving factor VII, 92% were for off-label uses.¹¹⁷ However, a previous well-designed systematic review of the use of rFVIIa for the prevention and treatment of bleeding in patients without hemophilia denoted an increased arterial clot risk while failing to show a mortality benefit.¹¹⁸ Several randomized, controlled trials have investigated the use of rFVIIa in specific settings, including ICH, GI bleeding, and trauma. Dosing has varied markedly from 5 to 400 μ g/kg. A significant consideration when contemplating the use of factor VII is cost. At an average cost per dose of \$5000 (80 μ g/kg), this can be a limiting factor, especially when some studies use protocols consisting of eight sequential doses.¹¹⁹

Hemophilia

Although factor VII is being used increasingly in nonhemophiliac patients, its original indication was for hemophiliacs in whom factor VIII inhibitors had developed and who were having acute bleeding events. Study dosages in these patients were generally higher than for off-label use (100 to 300 μ g), but the drug was effective in controlling bleeding episodes, with an acceptably low rate of thromboembolic events.^{120,121} Its use as a more general hemostatic drug remains unproven, and use outside its current approved indications and clinical investigations should be avoided.

Intracranial Hemorrhage

ICH is a predictor of poor survivability and neurologic function in a patient who has undergone an acute stroke. The risk for hemorrhage expansion within the first 24 hours is between 20% and 40% in these patients. The risk of hematoma expansion is doubled in patients on vitamin K antagonists (warfarin).¹²² This would make it seem logical to attempt to rapidly reverse the anticoagulant effects of warfarin and this strategy is recommended in national and international guidelines. Many older studies acknowledged that reversal of elevated INR did not

necessarily translate into improved survival or neurologic outcomes. One study by Parry-Jones and colleagues suggested that reversal of warfarin with PCC, FFP, or both demonstrated improvement in 30-day mortality compared to no reversal.¹²³ However, the study authors acknowledge the presence of many confounding variables that may have affected the results. Interestingly, no single strategy to reverse warfarin has been conclusively shown to improve clinical outcome better than any other strategy.¹²³

In 2005, Mayer and associates¹²⁴ published a double blind, placebo-controlled trial that evaluated the use of rFVIIa for acute ICH. They randomized 399 patients to placebo or to 40 μ g/kg, 80 μ g/kg, or 160 μ g/kg of rFVIIa within 1 hour of a baseline computed tomography (CT) scan of the head. CT was repeated in 24 hours. The primary outcome measured was the percent change in volume of ICH from the initial to the repeat scan. The study showed a 29% increase in the volume of ICH in the placebo group versus 16%, 14%, and 11% in the treatment groups, respectively. Ninety-day outcomes were also evaluated and showed a 69% rate of death or severe disability in patients in the placebo group and 55%, 49%, and 54% in the rFVIIa groups, respectively. When looking at mortality alone, the rate was 29% in the placebo group and 18% in the rFVIIa groups combined. A subsequent study of 841 patients by the same investigators also showed a reduction in growth of the hematoma with rFVIIa, but in contrast to the initial study, no improvement in mortality or functional outcome occurred.¹²⁵ Studies of traumatic ICH have yielded similar findings. In a retrospective study by Stein and coworkers¹²⁶ of 63 patients with severe traumatic brain injury and coagulopathy at admission, 29 patients who received rFVIIa were compared with 34 patients who received FFP. Time to surgical intervention was less in the rFVIIa group; however, there was no difference between the groups at discharge with respect to neurologic outcome or mortality. In a prospective, dose escalation study of factor VII in patients with traumatic ICH, Narayan and colleagues¹²⁷ found no differences in mortality rates or ICH volume in the placebo and rFVIIa groups. A

reasonable conclusion to the use of rFVIIa in ICH is that although it may limit the size of the ICH, there does not appear to be any relevant effect on clinical outcomes and therefore it should not be considered for routine use in this setting.¹²⁸

Trauma

Several investigators have examined the use of factor VII in the setting of trauma. A study by Boffard and coworkers¹²⁹ in 2005 enrolled 301 ED patients with major trauma who required at least 8 units of PRBCs. The treatment group received three doses of rFVIIa immediately after the eighth unit of blood had been given. The doses were repeated at hours 1 and 3. The primary outcome measured was the total transfusion requirement and subgroup analysis was performed for blunt and penetrating trauma. For blunt trauma, there was a small decrease in the transfusion requirement (7.0 units in the treatment group versus 7.5 in the placebo group) and a decrease in the number of patients needing massive transfusion (14% of the treatment group versus 33% of the placebo group). In the penetrating trauma group the differences were not statistically significant. In the entire cohort, no differences were found in mortality at 48 hours or 30 days in comparison to placebo. Thromboembolic events were uncommon (4%) and did not differ between the treatment and placebo groups. Raobaikady and colleagues¹³⁰ evaluated a group of 48 patients with traumatic pelvic fracture who were scheduled for surgical repair. Patients were randomized to a dose of 90 µg/kg of rFVIIa or placebo at the time of first incision. No significant difference was found in the primary outcome measure of transfusion requirement. Other groups have found that the administration of factor VII can favorably affect the subsequent need for other blood products, specifically PRBCs, cryoprecipitate, and platelets; however, mortality is not significantly affected.^{131,132} A 2008 Cochrane review of seven trials involving 1214 individuals (687 patients receiving rFVIIa) concluded that there is no advantage or disadvantage of rFVIIa over placebo in any of the studied outcomes.¹³³ A more recent article by Hauser and colleagues also demonstrated that fewer units of blood needed to be transfused in trauma patients who received rFVIIa; however, they similarly found that there was no decrease in mortality in these patients when compared to placebo.¹³⁴ At the time of this writing, rFVIIa cannot be recommended as a general hemostatic agent in trauma patients.

Factor VIII Concentrate Human Antihemophilic Factor

Factor VIII extracted from pooled human plasma produces a concentrated stable product with a shelf life of up to 2 years. Significantly more concentrated than cryoprecipitate and available for home use, factor VIII concentrate was a major breakthrough in the treatment of hemophilia. Unfortunately, the presence of viruses in the donor pool contributed to the high prevalence of hepatitis and HIV infection in hemophiliacs who used earlier versions of this product. Newer products (Alphanate [Grifols Biologicals, Los Angeles, CA], Hemofil [Baxter Healthcare Corporation, Deerfield, IL], Humate-P [CSL Behring GmbH, Marburg, Germany], Koate-DVI [Kedrion Biopharma Inc., Fort Lee, NJ], Monarc-M [Baxter Healthcare Corp.], and Monoclate-P [CSL Behring LLC, Kankakee, IL]) are produced with one or more methods to reduce viral contamination. These methods have markedly reduced the risk for viral transmission, especially lipid-encapsulated viruses

(HIV, HBV, HCV). To date there have been no reports of transmission of these viruses with the newer preparations.

Recombinant Antihemophilic Factor

Since the gene for production of factor VIII was discovered in 1984, research into recombinant genetics has aimed to provide a safer product that will theoretically be more readily available and less expensive to produce. Two recombinant DNA-derived factor VIII preparations (Recombinate [Shire Pharmaceuticals Lexington, MA], Kogenate [Bayer Pharma AG, Berlin, Germany]) were approved by the FDA in 1993. More recent introductions include Bioclate (Baxter Healthcare Corp.), Helixate, Helixate FS (CLS Behring) and Kogenate FS (Bayer Pharma). These genetically engineered products have hemostatic activity equivalent to that of plasma-derived factor VIII and minimal risk for viral contamination. Because some of these products are prepared from human albumin and other animal proteins, there is a potential for transmission of viruses. Products such as Helixate FS and Kogenate FS are prepared without human albumin, which should eliminate the possibility of viral contamination. Though costlier, they are a better choice for young patients with a newly diagnosed condition who have not already been exposed to hepatitis or HIV.¹³⁵

Factor VIII Concentrate

Administration of 1 unit of factor VIII concentrate per kilogram of body weight should increase factor VIII activity by 2%. The dosage should be individualized according to the severity of bleeding, the known deficiency of factor VIII activity, and the presence of factor VIII antibodies. Factor VIII levels should be increased to 20% to 40% of normal levels for minor bleeding (e.g., small joint), 40% to 60% for moderate bleeding (e.g., large joint, neck, oral cavity), and 60% to 100% for life-threatening bleeding (e.g., intracranial, intraabdominal, pharyngeal).

Antibodies develop in up to 15% of factor VIII recipients. Administration of massive doses of factor VIII has proved to be beneficial in overwhelming the endogenous antibody response. In addition, immunosorbent techniques to remove the antibody have met with some success. The general use of immunosuppressants and plasmapheresis has also had limited success. In patients with inhibitors, rFVIIa and factor VIII inhibitor-bypassing activity (FEIBA) have proved to be very useful and effective hemostatic agents.

Long-Acting Factor VIII

A long-lasting antihemophilic factor has recently been approved for use in adults and children with hemophilia A. It is a fusion of factor VIII bound to the Fc region of human immunoglobulin G1 (IgG1), which binds to the neonatal Fc receptor. This means that it is not degraded as fast as regular factor VIII and lasts longer in circulation. The trade name for this new preparation is Eloctate (Biogen Idec, Inc, Cambridge, MA).

Factor VIII Inhibitor-Bypassing Activity

FEIBA is a product derived from pooled human plasma that contains factors II, IX, and X, each mainly nonactivated, and factor VII mainly in the activated form. It promotes coagulation by bypassing the need for factors VIII and IX. FEIBA is vapor heated to achieve greater than 10 logs of reduction in all target viruses and its safety profile is favorable.¹³⁶ FEIBA is used to treat bleeding episodes in hemophilic patients with antibodies to factor VIII and is generally efficacious in this

role.¹¹² Adverse reactions include headache, fever, chills, flushing, nausea, vomiting, and an occasional allergic reaction. The risk for thrombotic complications exists, especially in patients with liver and heart disease or those who are pregnant or breastfeeding.

1-Deamino-(8-D-arginine)-Vasopressin

A synthetic analogue of pituitary vasopressin, 1-deamino-(8-D-arginine)-vasopressin (DDAVP) has been found to stimulate the release of von Willebrand's factor from vascular endothelium.¹³⁷ Although a synthetic analogue of the natural hormone vasopressin, DDAVP administration has no impact on hemodynamics. vWF carries factor VIII in the blood and leads to a rise in factor VIII levels in some mild hemophiliacs.¹³⁷ Treatment of mild hemophiliacs with 0.3 mg/kg intravenously over a 15-minute period has been recommended when avoidance of the inherent risks of the factor VIII concentrate is desired. DDAVP has also been used in patients with mild von Willebrand's disease, congenital platelet dysfunction, acquired platelet dysfunction due to uremia, or intake of drugs such as acetylsalicylic acid, clopidogrel, and other antiplatelet agents. Responsiveness to DDAVP varies from patient to patient.

Factor IX Concentrate

Factor IX is prepared from pooled human plasma and is available as a lyophilized powder (AlphaNine SD [Grifols Inc., Los Angeles, CA] Mononine [CSL Behring]). Factor IX is also available in recombinant technology as BeneFix (Wyeth Pharmaceuticals Inc., Philadelphia, PA).

Historically, the use of factor IX concentrate has carried a very high risk for transmission of viral hepatitis. However, improved donor screening and new methods of viral reduction have substantially reduced the risk for transmission of viruses. As with factor VIII concentrate, the risk for transmission of HIV and hepatitis is very low with current human-derived products. Recombinant factor IX is not derived from human products and carries no risk for viral transmission.

Factor IX is indicated for the treatment of bleeding episodes in hemophilia B patients with a severe deficiency of factor IX. Administration of 1 unit/kg body weight will increase the factor IX concentration by approximately 1%. High levels of factor IX are not required to control bleeding. Levels should be increased to 15% to 25% of normal for mild to moderate bleeding and to 25% to 50% of normal for more serious bleeding or before major surgery.

Prothrombin Complex Concentrate

PCC is a plasma-derived concentrate of nonactivated clotting factors II, VII, IX, and X. These preparations undergo a process of viral inactivation to reduce the risk for viral transmission. PCCs are divided into two groups: three-factor preparations and four-factor preparations. This nomenclature can be confusing because both preparations contain four factors; however, the three-factor preparations have very low amounts of factor VII, whereas the four-factor preparations contain clinically relevant amounts. Some PCC products also contain protein C and protein S. These are added to balance the procoagulant effect of the concentrated clotting factors. The two most commonly available three-factor products are Profilnine SD (Grifols Inc.) and Bebulin VH (BDI Pharma, Inc., Columbia, SC). Four-factor preparations have been used in Europe for many years. The first four-factor PCC was approved in April 2013 by the FDA for use in the United States, specifically for

the reversal of warfarin-related coagulopathy. The product is called Kcentra (CSL Behring) in the United States and Beriplex P/N (CSL Behring) in Europe.¹³⁸ In addition to factors II, VII, IX and X, Kcentra contains proteins S and C and heparin.

In the ED, PCCs can play a very important role in the reversal of anticoagulation from warfarin (see hereafter). One concern with these preparations is a possible prothrombotic effect. A systematic review of 14 studies (460 patients) found only seven thrombotic complications: three strokes, two myocardial infarctions, and two deep venous thromboses. This translates to a 1.5% risk for clotting with PCC administration.¹³⁹ Two more recent reviews comparing four-factor PCCs to FFP in the reversal of warfarin-induced coagulopathy found similar rates of thrombotic events in both groups.^{140,141}

Warfarin-Induced Coagulopathy: Reversal Strategies

Elevated INRs may be encountered fortuitously or in patients with trauma or serious medical conditions. Guides to approaching and treating such patients are found in Table 28.4. Reflex reversal of an elevated INR should be avoided, especially in the absence of bleeding. Even minor bleeding can be tolerated in lieu of losing the beneficial effects of anticoagulation in selected patients (e.g., those with mechanical heart valves, left ventricular assist devices [LVADs], or active clots). In the presence of significant trauma or serious hemorrhage, however, any warfarin effect should be reversed.

Warfarin works as a vitamin K antagonist by inhibiting vitamin K epoxide reductase, decreasing available vitamin K, and thereby blocking synthesis of the active forms of the vitamin K-dependent coagulation factors II, VII, IX and X, along with proteins S and C. The factors that are made under the influence of warfarin are biologically inactive. Over a few days, the body's remaining stores of active factors are used up and replaced by the inactive forms creating a coagulopathy. Because protein S and C synthesis is relatively quickly blocked, the antithrombotic effect of these proteins is likewise curtailed, creating a transient hypercoagulable state while the warfarin is slowly developing its anticoagulation effects.

There are two parts to warfarin reversal: sustained reversal via the administration of vitamin K and "immediate" reversal using agents described in the following section.

Vitamin K₁ (Phytonadione)

The first step in the reversal of warfarin is to replete active vitamin K by administering vitamin K according to the recommended dosing and route guidelines outlined in Table 28.5. This provides a sustained reversal effect. Vitamin K can be given either orally or intravenously. Oral use is universally safe and should be used when possible. The IV preparation can be given orally to titrate small amounts, if needed. Although IV administration has been implicated in anaphylactoid-like systemic reactions, the incidence of these reactions is very small and should not preclude its use when the oral route is unavailable. Additionally, administration of the IV dose over at least 20 minutes may help to mitigate such reactions. Some institutions may elect to extend default administration times to 30 to 60 minutes as a further precautionary measure. The best treatment for a systemic reaction to intravenous administration of vitamin K is unknown, but general supportive measures for anaphylactoid reactions seem to work well. Because of erratic absorption patterns, subcutaneous administration of vitamin K is no longer recommended.¹⁴² Tablets are available in only 5-mg strength.

TABLE 28.5 Summary and Dosage of Reversal Agents for Warfarin^a

AGENT	DOSE	NOTES
Vitamin K	1–10 mg PO or IV	SC delivery is no longer used Reduction in the INR begins within 1–2 hr when given IV with peak effects seen in 12–14 hr. Oral doses generally have onset of effect in 6–10 hr with a peak effect in 24–48 hr.
Prothrombin Complex Concentrate 3-Factor (Profilnine), 4-Factor (Kcentra ^b)	Strategy 1: INR- and weight-based dosing INR 2–4: 25 IU/kg by IV push INR ≥4–6: 35 IU/kg by IV push INR >6: 50 IU/kg by IV push Strategy 2: INR-based dosing INR <5: 500 units; INR ≥5: 1000 units Strategy 3: Fixed dose 1500 IU	Multiple dosing strategies INR-based dosing is most effective with 3-factor preparations. Absolute dosing strategies should not be used with 3-factor PCCs. Any of the 3 strategies can be used with 4-factor PCCs. These authors' institution uses strategy 1: weight- and INR-based dosing.
aPCC (FEIBA)	INR <5: 500 units; INR >5: 1000 units	May be more thrombogenic than nonactivated PCC and should be reserved for use when 4-factor PCC is not available

^aMost of the dosing is off-label and is derived from various studies using these agents for unapproved conditions. Other dosing regimens may exist.

^bFDA approved for the reversal of warfarin-related bleeding.

aPCC, Activated prothrombin complex concentrate; FEIBA, factor VIII inhibitor-bypassing activity; INR, international normalized ratio; IV, intravenous; PCC, prothrombin complex concentrate; PO, oral; SC, subcutaneous.

Reduction in the INR begins within 1 to 2 hours when vitamin K is given intravenously, with peak effects seen in 12 to 14 hours. Oral doses generally have an onset of effect in 6 to 10 hours, with a peak effect in 24 to 48 hours. Correction to within the normal range is generally achieved in these time frames if hepatic function is normal and a sufficiently large dose is given.¹⁴³ Reversal of anticoagulation with vitamin K can be sustained for several days, making reanticoagulation with warfarin difficult. This is often referred to as *warfarin resistance*. This situation can happen with a patient on warfarin who has an artificial valve or an LVAD and has an acute GI bleed. Temporary reversal of anticoagulation may be necessary awaiting definitive correction of the GI bleeding source, followed by the rapid reintroduction of anticoagulation to protect the valve or LVAD. In these cases it may be desirable to withhold the vitamin K while attempting to achieve a short-term reversal with FFP or PCC.

The next step in the rapid correction of an elevated INR is to replace the missing clotting factors (II, VII, XI, and X). Traditionally, FFP has been used for this purpose. FFP is effective but requires a significant volume and takes time to thaw and prepare for administration. PCCs have been used in Europe and other parts of the world for many years to reverse undesirable warfarin effects. Studies have demonstrated the effectiveness of PCCs in normalizing elevated INRs within 15 minutes after administration without the complication of excessive volume or a delay in time to administration.^{144–146}

Fresh Frozen Plasma

FFP in doses of 10 to 15 mL/kg (with a minimum starting dose of 4 units) seems to effectively reverse coagulopathy, as measured by a decreasing INR. Issues related to volume expansion and the time required to obtain FFP have been discussed earlier. If PCCs are not readily available, FFP should

be administered as quickly as possible in the coagulopathic, bleeding patient. Good judgment must be used when deciding to wait for the type and crossmatch, thawing, and administration of FFP in a critically sick, bleeding patient who requires transfer to another facility that can provide definitive treatment for the source of bleeding.

Prothrombin Complex Concentrates

Studies comparing the use of PCCs and FFP have failed to show significant benefits with regard to survival.¹²³ The rapidity of administration, low volume required, and quick correction of the INR are compelling reasons to choose PCCs over FFP when managing an acutely bleeding patient. Dosing ranges for PCCs have varied. One study suggested a standard absolute dose for patients with an elevated INR (500 units for INR <5 and 1000 units for INR >5).¹⁴⁷ This study used four-factor preparations only available outside the United States; the same authors found suboptimal reversal effects with three-factor preparations in this fixed-dosing regimen. Other studies have suggested using “unit/kg” dosing, with the amount varying according to the degree of INR elevation.^{146,148} In a recent article, Klein and colleagues suggested using a fixed dose of 1500 international units (IU) of four-factor PCC. In their study, the authors evaluated 39 patients and found a high rate of successful INR reversal with no thrombotic adverse events within 7 days of PCC administration.¹⁴⁹

Recombinant Factor VII (NovoSeven)

Another strategy to reverse warfarin-related coagulopathy is to bypass the need for the missing factors by creating a very large thrombin burst (e.g., by directly activating factor X). rFVIIa has been used off-label for this purpose. Although rapid normalization of the INR is achieved, sustained correction requires additional doses because of the short half-life of rFVIIa.

TABLE 28.6 Correction of the International Normalized Ratio in Warfarin-Anticoagulated Patients

REVERSAL AGENTS	ADVANTAGES	DISADVANTAGES
PCC United States: Profilnine SD, Bebulin VH (3-Factor PCC), Kcentra ^a (4-Factor PCC)	<ol style="list-style-type: none"> 1. Onset within 10 min 2. Low risk for viral contamination 3. Effectively and immediately decreases INR 	<ol style="list-style-type: none"> 1. The Bebulin VH product (but not Profilnine) contains heparin—this would not be appropriate when heparin-induced thrombocytopenia is suspected. 2. Kcentra is a 4-factor PCC, FDA approved for the reversal of warfarin anticoagulation. It contains factors II, VII, IX, X; proteins C and S; albumin; and heparin. 3. Clotting events have been reported. 4. Duration of 12–24 hr may be an advantage or disadvantage. The coadministration of vitamin K will prevent a rebound of anticoagulation. 5. There is no significant evidence that the use of PCCs is more effective than FFP or that it improves clinical outcomes.
Activated PCC (FEIBA)	<ol style="list-style-type: none"> 1. Onset within 10 min 2. Effective and rapid lowering of an elevated INR 	<ol style="list-style-type: none"> 1. May be more thrombogenic than nonactivated PCCs 2. There is no significant evidence that the use of PCCs (activated or nonactivated) is more effective than FFP or that they improve clinical outcomes.
rFVIIa	<ol style="list-style-type: none"> 1. A recombinant product does not carry risks associated with blood products. 2. Onset within 10 min 3. Storage at room temperature 	<ol style="list-style-type: none"> 1. New data suggest that although the INR may be reversed in warfarin anticoagulation, clinical bleeding is not significantly affected. It is NOT recommended for the reversal of warfarin coagulopathy. 2. Some clotting events have been reported, especially at doses >1 mg. 3. Cost: approximately \$1200 for a 1-mg dose: 90 µg/kg in a 70-kg patient, ≈ \$7560 4. Short duration of 6 hr
FFP	<p>Cost: approximately \$65/unit 15 mL/kg with 250 mL/unit in a 70-kg adult = \$273. Clinician familiarity. Available everywhere</p>	<ol style="list-style-type: none"> 1. High volume of fluid may be undesirable for heart failure 2. Slow onset 3. Frozen—must be thawed over a 30-min period 4. Risk for TRALI 5. Its use is rapidly being replaced by the use of PCCs.

^aFDA approved for the reversal of warfarin-related bleeding.

FDA, Food and Drug Administration; FEIBA, factor VIII inhibitor-bypassing activity; FFP, fresh frozen plasma; INR, international normalized ratio; PCC, prothrombin complex concentrate; rFVIIa, recombinant factor VIIa; TRALI, transfusion-related acute lung injury.

Although the INR can be corrected rapidly, some studies have called into question the effects of rFVIIa on actual clinical reversal of bleeding.^{150,151} Additionally, outcome studies have failed to demonstrate a significant mortality benefit in patients with ICH on warfarin who received rFVIIa.¹²⁸ At present, there is not enough data to support the routine use of rFVIIa to reverse warfarin-associated bleeding.

FEIBA

FEIBA has also been studied as a potential reversal strategy for warfarin-induced bleeding. One study found FEIBA to be effective using an INR-based dosing strategy (500 units if the INR was <5 and 1000 units if the INR was ≥5).¹⁵² Although effective in reversing the INR, activated PCC carries the risk of being more thrombogenic than nonactivated PCCs. With the four-factor PCC agent Kcentra now approved by the FDA for reversal of warfarin-associated bleeding, FEIBA should only be considered when a four-factor PCC is not available. A comparison of FFP, PCC, and factor VII is provided in Table 28.4. Dosing of agents used to reverse warfarin can be

found in Table 28.5. Table 28.6 lists advantages and disadvantages of these reversal agents.

Reversal of the Novel Anticoagulants (NOACS)

With the introduction of new anticoagulants, direct factor Xa inhibitors (rivaroxaban [Xarelto, Janssen Pharmaceuticals Inc., Titusville, NJ], apixaban [Eliquis, Bristol-Myers Squibb Company, Princeton, NJ], edoxaban [Savaysa, Daiichi Sankyo Inc., Parsippany, NJ]) and direct factor II inhibitors (dabigatran [Pradaxa, Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, CT]), there are concerns about reversal during an acute bleeding episode. Because these inhibitors act at key points in the coagulation cascade, they may be difficult to reverse.

Direct Factor II Inhibitors (Dabigatran)

Although dabigatran is removed by dialysis, such intervention is rarely practical in an acutely bleeding patient. Until the fall of 2015, recommendations for dabigatran reversal were largely based on case reports, animal models, and human volunteer studies. At the time, no reversal agent had been approved

specifically for direct factor II inhibitors. In cases of life-threatening bleeding in patients receiving direct factor II inhibitors, the off-label use of PCC, FEIBA, or activated factor VIIa (or any combination) were all tried. FEIBA seemed to reverse the effects of dabigatran in healthy volunteers, whereas nonactivated PCCs appeared to have little effect.¹⁵³ This led the American Society of Hematology to recommend FEIBA as the first-line agent for life-threatening bleeding from dabigatran.

Idarucizumab (PraxBind [Boehringer Ingelheim Pharmaceuticals Inc.]), a monoclonal antibody fragment to dabigatran, was introduced in the fall of 2015. It has an affinity for dabigatran that is 350 times higher than that of thrombin.¹⁵⁴ In a phase I trial of healthy volunteers, idarucizumab rapidly and effectively corrected abnormal coagulation test results without significant adverse events.¹⁵⁵ In a 2015 uncontrolled trial of patients on dabigatran with a serious bleeding event or the need for an urgent procedure, idarucizumab reversed the effects of dabigatran in minutes in 88% to 98% of the patients studied. Importantly, the effectiveness of idarucizumab in this study was measured by reversal of abnormal clotting parameters, not by clinical cessation of bleeding.¹⁵⁴ There is currently no evidence that the reversal of dabigatran with idarucizumab will lead to improved patient outcomes. Notwithstanding, in the absence of a specific and clearly safe alternative, patients on dabigatran with life-threatening bleeding should be considered potential candidates for idarucizumab treatment. Definitive recommendations for the use of idarucizumab await additional studies.

The fibrinogen level should be checked in patients with dabigatran-associated bleeding. If fibrinogen is less than 200 mg/dL, two pools of cryoprecipitate should be given.

Dosing for agents used to reverse bleeding in patients on NOACs is listed in [Table 28.7](#).

Direct Factor Xa inhibitors (Rivaroxaban, Apixaban, Edoxaban)

Direct factor Xa inhibitors also present a challenge to reversal in the setting of acute hemorrhage. A variety of strategies using rFVIIa, PCC, and FEIBA have been tried in the treatment

of these patients. In an ex vivo study of healthy volunteers, rFVIIa reversed abnormal coagulation studies in patients who were given rivaroxaban.¹⁵⁶ rFVIIa failed, however, to reverse active bleeding in a rivaroxaban animal model. At the present time, rFVIIa is not recommended as a reversal agent for direct factor Xa inhibitors.

In contrast, FEIBA was effective in reversing abnormal coagulation studies in rivaroxaban-treated healthy volunteers and seemed to be effective at reversing bleeding in two animal models.^{157–159} As a result, FEIBA is an acceptable agent to reverse the effects of direct Xa inhibitors. Four-factor PCCs also seem effective at reversing abnormal coagulation parameters in healthy humans taking these medications.¹⁶⁰ Although the effectiveness is suggested in animal bleeding models, there have been no studies evaluating the effect of PCCs on clinical bleeding in humans receiving factor Xa inhibitors. According to the Hemostasis and Thrombosis Research Society, the use of four-factor PCCs seems to be a reasonable approach to reversing the effects of direct Xa inhibitors.¹⁶¹ The risks and benefits must be thoroughly weighed when choosing to reverse anticoagulation with agents that could cause thrombosis.

A 2015 study published in the *New England Journal of Medicine* (NEJM) looked at a novel reversal agent, andexanet alfa.¹⁶² This drug, which is scheduled for release in the fall of 2016, is capable of reversing the effect of all direct factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban) and indirect factor Xa inhibitors (low-molecular-weight heparins and fondaparinux). Andexanet alfa acts as an inactive factor Xa decoy that binds both direct and indirect factor Xa inhibitors and makes them unavailable to inhibit native factor Xa. In humans, the drug has been shown to reverse markers of anticoagulation, including anti-factor Xa activity. The NEJM study had two different arms; each looked at andexanet alfa reversal of either apixaban or rivaroxaban compared to a placebo. Both arms of the study first looked at a bolus dose of andexanet alfa and then a bolus followed by a continuous 2-hour infusion. The end point was measurement of anti-factor Xa activity and thrombin generation. In the apixaban group (33 participants), anti-factor Xa activity was reduced by 94% in the andexanet alfa-treated group ($n = 24$) compared to 21% among those who received a placebo ($n = 9$). Thrombin generation was fully restored in 100% of the treatment group and 11% of the placebo group. In the rivaroxaban group (41 participants) a 92% reduction in anti-Xa activity was seen in the andexanet alfa-treated group ($n = 27$), compared to 18% in the placebo group ($n = 14$). Thrombin generation was 96% restored. In this small study, there were no serious adverse events and no cases of inappropriate thrombosis.¹⁶² Larger studies are currently underway to further evaluate the effectiveness and safety of andexanet alfa.

Although the theoretical benefit of a safe and specific reversal agent such as andexanet alfa seems promising, there are no data as yet to show that there will be any actual beneficial effects or improved outcomes in human patients.

Dosing for agents used to reverse bleeding in patients on anti-Xa agents can be found in [Table 28.8](#).

COLLECTION AND STORAGE OF BLOOD PRODUCTS

Whole blood is collected from donors into 500-mL plastic bags containing 63 mL of citrate-phosphate-dextrose with a

TABLE 28.7 Summary and Dosage of Reversal Agents for Anti-Factor II Agents

AGENT	DOSE	NOTES
FEIBA	25–100 units/kg (50 units/kg is used by many institutions for this indication)	May be more thrombogenic than nonactivated PCC
Idarucizumab	5 g, provided as 2 separate vials each containing 2.5 g/50 mL	The only FDA-approved antidote to dabigatran-related bleeding
Cryoprecipitate	2 pools	If fibrinogen is <200 mg/dL, give 2 pools cryoprecipitate

FDA, Food and Drug Administration; FEIBA, factor VIII inhibitor-bypassing activity; PCC, prothrombin complex concentrate.

TABLE 28.8 Summary and Dosage of Reversal Agents for Anti-Factor Xa Anticoagulants

AGENT	DOSE	NOTES
4-Factor PCC (Kcentra)	25–50 units/kg	Not to exceed 5000 units Repeat doses beyond 50 units/kg are not recommended. FDA-approved agent for warfarin reversal This is generally considered the preferred agent at this time for reversing anti-Xa inhibitors. Another reversal agent for anti-Xa inhibitors (andexanet alfa) should be FDA approved in mid to late 2017.
aPCC (FEIBA)	25–100 units/kg 25 units/kg is used by many institutions for this specific indication.	If still clinically significant bleeding, consider redosing, but no sooner than 6 hr.

FDA, Food and Drug Administration; FEIBA, factor VIII inhibitor-bypassing activity; PCC, prothrombin complex concentrate.

resultant hematocrit of 35% to 40%. Immediately after collection, sophisticated techniques permit separation of the whole blood into various components and fractions. Blood components such as FFP, PRBCs, granulocytes, and platelets are prepared from a single donor, separated, and transfused as single units. Minor blood fractions, including albumin, γ -globulin, cryoprecipitate, and fibrinogen, are often pooled from multiple donors. Within 24 hours, blood is essentially devoid of normally functioning platelets and some clotting factors, especially the labile factors V and VIII. Separation into individual components permits specialized storage and transfusion techniques designed to optimize the survival and availability of each component.

As is true of whole blood, PRBCs can be stored for up to 21 days, although newer preservatives such as ADSOL (adenine, dextrose, saline, mannitol, and water) may allow 49-day storage. Red cell viability decreases approximately 1% per day. Storage of blood contributes to a variety of other derangements or “storage lesions.” Cell metabolism continues during storage and causes a mild acidosis. This acidosis is buffered effectively by the bicarbonate derived from the metabolism of citrate, assuming normal hepatic function. Even with massive transfusions, acidosis is more often the result of disruption of normal physiologic function than the storage of blood products themselves. Levels of 2,3-DPG decrease during storage, thereby shifting the oxygen-hemoglobin dissociation curve to the left. This shift is of small clinical significance because 2,3-DPG levels are usually normal in transfusion recipients within 24 hours of infusion. Potassium commonly leaks from red cells during storage because of a less efficient sodium-potassium adenosine triphosphatase-dependent pump. Most of the potassium is either absorbed by the remaining blood cells, excreted by the kidneys, or shifted back into the cells as a result of the alkalosis produced by metabolism of citrate in the preservative. Hyperkalemia may be of particular importance in newborns and patients with renal impairment.

ORDERING OF BLOOD

When it has been decided that a patient needs a transfusion and the patient’s condition is stable enough, ask the patient or relatives about any previous transfusion reactions and whether the patient abides by any religious prohibitions to transfusion.

Ordering a type and crossmatch procedure on a blood product implies that the decision has already been made to administer a transfusion. Draw blood from the patient (\approx 2 mL for every unit of blood product to be crossmatched) and put it into a red-topped, nonanticoagulated tube. The tube must not contain a serum separator gel. The label should be signed by the individual drawing the blood sample. This identifying signature will be used in the blood bank’s crossmatching procedures. The individual blood components are discussed in the following sections. A summary of the dosages and characteristics of each component is provided in Table 28.2. A “type and hold” or “type and screen” (no crossmatch) request alerts the blood bank to the possibility that a blood product will be required for the patient so that appropriate units can be acquired and kept on hand. A type and crossmatch procedure takes 45 minutes and restricts a unit of blood to a specific patient. In the ED, a crossmatch procedure should be considered for a blood product only if the adult patient: (1) manifests shock, (2) has symptomatic anemia (usually associated with a hemoglobin level $<$ 10 g/dL) in the ED, (3) has a documented loss of 1000 mL of blood, or (4) requires a blood-losing operation immediately (e.g., thoracotomy).¹⁶³ A type and hold can safely be requested for all other situations in which a blood transfusion is considered possible during the patient’s care; a desirable ratio of units crossmatched to units transfused can thus be achieved. Hooker and colleagues¹⁶⁴ found that the empirical trigger of prehospital hypotension (systolic blood pressure $<$ 100 mm Hg) was a useful discriminator for ordering early crossmatched blood.

The number of units requested for a crossmatch procedure is determined by the size of the patient, the response of the patient to the injury and subsequent emergency treatment, and the presence of ongoing blood loss (e.g., arterial or massive GI bleeding).

Red cell preparations for transfusion are not routinely tested for the presence of sickle hemoglobin. Donors with sickle trait are not excluded, and blood with sickle trait can be safely given to almost every patient because occlusion of blood flow caused by intravascular sickling would occur only in extreme conditions of acidity, hypoxia, or hypothermia, which are unlikely to be compatible with life. Nonetheless, when a transfusion is being performed in infants and patients with known sickle cell anemia, the blood bank should be alerted, and a “sickle preparation”

should be requested for donor blood to avoid the infusion of blood with sickle trait into such patients. Patients receiving multiple transfusions for sickle cell disease are at increased risk for alloimmunization. Directed donation may be helpful to decrease this risk.^{165,166}

Blood Request Forms

Proper identification of the patient and the intended unit of blood is critical. Transfusion of an incorrect unit is a potentially fatal error. Most transfusion reactions are attributable to clerical error, and the vast majority of such errors occur at the bedside (e.g., not in the blood bank).¹⁶⁷ Just before administering the blood, the nurse or clinician (or both) must check the identity of the numbered labels. In addition, the blood bank laboratory slip must identify the patient by name and number and contain the identification number of the unit of blood.

Usual procedures require a separate blood bank request form for each unit of RBCs or whole blood ordered. A number of units of FFP, cryoprecipitate, and platelet concentrates may be ordered on one form with proper identification (depending on individual blood bank procedures).

Blood Products for Jehovah's Witnesses

There are approximately 1.2 million Jehovah's Witnesses in the United States. Based on the religious belief that the Bible prohibits blood or blood product transfusion (Acts 15:28-29), devout Jehovah's Witnesses do not accept transfusions of whole blood, packed cells, white blood cells, platelets, plasma, or autologous blood.¹⁶⁸ Since 1961, willing acceptance of a blood transfusion by an unrepentant member has been grounds for expulsion from the religion.^{169,170} An individual's decision to abandon the teachings of the church and accept blood products can lead to congregational disciplinary actions, including *disfellowshipping*, a term for formal expulsion and shunning. Some members may permit the infusion of albumin, clotting factor solutions, plasma expanders, or intraoperative autotransfusion.¹⁷¹ Although no guidelines for the administration of blood products to Jehovah's Witnesses are absolute, certain recommendations can be made. Even though a transfusion may be necessary to save a patient's life and would otherwise be considered standard care, administration of blood or blood products in the face of refusal can legally be considered battery. In an awake and otherwise competent adult, courts have ruled that clinicians cannot be held liable if they comply with a patient's directive and withhold lifesaving blood administration after refusal of transfusion when specific and detailed information of the consequences of such an omission in treatment are provided. The issue becomes clouded when patients are incompetent, unconscious (most Jehovah's Witnesses carry cards informing medical personnel of their religious beliefs), or minors.

In the absence of specific directives to the contrary, it is prudent to administer blood products to patients who are unconscious, judged to be incompetent adults, or minors.¹⁷² Explicit documentation of the intent of the clinician to preserve life, coupled with an accurate description of discussion of the issue with the patient or the family and clarification of the patient's mental capacity is mandatory. Furthermore, emergency legal assistance (e.g., court orders, appointment of a temporary guardian) should be sought immediately with rapid judicial resolution.¹⁷³ Various clinical techniques to maximize oxygen delivery and minimize oxygen consumption should be used.

Examples include limited blood drawing, the use of high-dose erythropoietin and nutritional support with aggressive iron supplementation, hypothermia, volume expansion, sedation, oxygen, and the use of synthetic hemoglobin substitutes.^{174,175} Hyperbaric oxygen therapy can dissolve sufficient oxygen to sustain life in the absence of hemoglobin and may be another option when blood cannot be used.¹⁷⁶⁻¹⁷⁸ It can be used in a pulsed fashion (3 to 4 hr/day) to reduce the oxygen debt until hemoglobin can rise to adequate levels.

ADMINISTRATION OF BLOOD PRODUCTS

IV Transfusions

Do not open a unit of blood unless a free-flowing IV access line has been established in a large-bore vein. Use a 14- to 16-gauge IV catheter if possible, both to minimize hemolysis and to ensure rapid infusion of fluid for the treatment of hypovolemia or hypotension. When a large quantity of blood must be given rapidly, administer it by means of a high-flow infusion system if possible. The purpose of a large-bore infusion line is defeated if blood is piggybacked with an 18- to 20-gauge needle through a side port in the infusion tubing. For an elective transfusion, however, blood may be given through a smaller lumen. Combining hemodilution (250 mL of saline with 1 unit of PRBCs) and pressurization can safely increase the flow rate through 20- and 22-gauge catheters severalfold.¹⁷⁹ No significant hemolysis occurs when small (21-, 23-, 25-, and 27-gauge) short needles are used for the transfusion of fresh blood or packed cells in infants and children and when the maximum rate of infusion is less than 100 mL/hr.¹⁸⁰ For rapid infusion, however, connect the blood administration tubing directly to the infusion catheter. Monitor the infusion site for infiltration, infection, or local reactions.

If the patient already has a suitable IV line in place, flush the system with a solution of normal saline before administering the blood. Do not use other IV fluids because of the risk for hemolysis or aggregation (e.g., with 5% dextrose in water).^{181,182} Do not place any medications in the unit of blood or infusion line for the same reasons.

Errors associated with blood transfusions have serious consequences and frequently result in severe transfusion reactions and death. The Joint Commission on Accreditation of Healthcare Organizations has set forth guidelines in an attempt to reduce these errors, including the following:

- Training personnel in procedures and recognition of reactions.
- Revising staffing models.
- Redesigning methods to identify patients, attain patient and blood verification, gain consent, and process multiple samples. It was strongly suggested that room numbers be discontinued as a method of identifying patients and use of a unique identification band be considered for patients receiving blood.
- Enhancing technical and computer support of the process.
- Discontinuing the use of refrigerators for multiple blood units.

Many EDs have moved to a two-nurse mandate for checking patient and blood unit identities before administration. As the risk for infectious complications associated with transfusion medicine gradually declines, medical errors have supplanted them as the most serious cause of transfusion mishaps.¹⁸³

Intraosseous Transfusions

Although IV administration is by far the most common route of blood and blood component therapy, IO administration appears to be safe and effective. Administration rates via an IO route are generally slower (on average 21 mL/min versus 35 mL/min by the IV route) but appear to be metabolically and hemodynamically equivalent.¹⁸⁴ In animal models, no evidence of fat embolism and lung or kidney inflammation was noted after IO-PRBC infusion. Administration of IO liposome-encapsulated hemoglobin (one of the forms of HBOC therapy) is also effective and may have additional advantages over the IV route.¹⁸⁵ Similarly, limited studies on the administration of other blood products via the IO route have been promising.¹⁸⁶

Filters

Infuse all blood and blood products through an appropriate filter, such as those supplied in-line in blood administration tubing sets. In the past, filtration was required merely to keep the IV line from becoming blocked by clots. Adverse consequences from infusing unfiltered blood products have since been recognized. Debris consisting of clots and aggregates of fibrin, white blood cells, platelets, and intertwined RBCs (ranging in size from 15 to 200 μm) accumulates progressively during the storage of blood. The usual filter, made of a single layer of plastic with multiple 170- μm pores, traps larger particles yet allows the rapid infusion of 2 to 3 units of blood before flow is obstructed. Purified components of blood plasma can be safely administered through a filter with pores as fine as 5 μm .

It has been suggested that microaggregates of debris that can pass through a 170- μm filter may in part contribute to the syndrome of “shock lung” seen after the transfusion of many blood units in patients suffering from severe trauma and hemorrhage. Some clinicians therefore recommend using a microaggregate blood infusion filter with a mesh pore size of 40 μm when multiple units of blood are administered to trauma victims, patients with compromised pulmonary function, and neonates. Microaggregate filters tend to become blocked, impede the rate of infusion more quickly, and are not commonly required in the emergency setting.¹⁸⁷ A significant number of platelets are removed by microaggregate filters, and some clinicians advise against using these filters when platelet packs are infused. Others believe that although platelets are removed with the microaggregate filters, the trapped platelets can be removed with a saline flush without any significant loss.¹⁸⁸

Replace standard filters after 2 to 3 units of blood product have been administered. Change microaggregate filters after each unit.

Rate of Infusion

One unit of whole blood can be safely administered to a hypotensive patient at a rate of at least 20 mL/kg per hr. In the setting of hypovolemic shock and continued hemorrhage, there is no limit to the transfusion rate. Multiple units may be transfused simultaneously, even under pressure. Use of a rapid transfuser device can assist in the rapid administration and warming of blood (Fig. 28.3). In stable patients, administer 1 unit of whole blood (500 mL) over approximately a 2-hour period (3 to 4 mL/kg per hr). After this time RBCs begin to

Figure 28.3 Use of a rapid transfuser allows transfusion rates up to 300 mL/min via a 14-gauge peripheral intravenous line. All fluids administered via the rapid transfuser will be warmed to approximately 37°C.

lose metabolic activity. In addition, the unit of blood, which is an excellent culture medium, is likely to become contaminated if bacteria and fungi are allowed to grow at room temperature. Give packed cells at approximately the same rate. Give plasma products more rapidly; in a patient without cardiovascular compromise, administer FFP at a rate faster than 15 to 20 min/unit because the coagulant activity begins to deteriorate rapidly after thawing. In patients with severe anemia and congestive heart failure, administer a rapidly acting diuretic, such as furosemide at the onset of transfusion to prevent circulatory overload.

If a transfusion of blood must be interrupted or delayed for any reason, return the remainder of the blood unit to the blood bank. Refrigerators in the ED or on the hospital unit should not be used to store blood products unless they are specifically equipped and authorized to do so.

For patients in hemorrhagic shock, administer blood through two large-bore catheters, at different sites if necessary. Usually, gravity provides a sufficient pressure gradient if the unit is raised above the patient to increase the rate of infusion when the clamps are wide open. Using a pressure pump makes the infusion quicker.¹⁸⁹ Do not use a standard sphygmomanometer cuff wrapped around a unit of blood to create increased infusion pressure because the nonuniform application of pressure could burst the plastic bag containing the blood component.

If desired, dilute PRBCs with normal saline (0.9% without dextrose) before infusion simply by opening the clamps on the upper tubes of the Y-infusion set and leaving the lower (recipient end) clamps closed. Although it is generally agreed that LR solution should not be mixed with blood because of possible clot formation, multiple studies have challenged this belief

and results have shown that small amounts of LR solution (up to 150 mL) are safe in the clinical setting.^{190,191} Furthermore, larger volumes of LR solution have not been found to produce microaggregate clots in laboratory settings when using AS-3–preserved PRBCs, a typical additive nutritive solution containing sodium chloride, sodium citrate, sodium phosphate, citric acid, dextrose, and adenine.¹⁹²

Diluting blood, while increasing its volume, will allow more rapid infusion by decreasing blood viscosity, which is dependent on hematocrit. Alternatively, add approximately 200 mL of normal saline directly to the bag of PRBCs to bring the hematocrit in the blood bag to approximately 45%.

Rewarming

Blood is stored at approximately 4°C to maintain cellular integrity and prevent the growth of microorganisms. Blood products usually passively warm to 10°C by the time that they are administered to the patient unless administered under pressure. The adverse effects of hypothermia on cardiac conduction and flow rates are evident when rapid administration of a large volume of blood is performed without prewarming.

Various mechanisms have been used to warm blood to 35°C to 37°C. An ideal blood warmer should allow liberal flow rates while preventing thermal hemolysis of blood cells. Commonly used devices include those with bath coils that allow a plastic tube to reside in a closely regulated warm water bath and dry heat devices that allow blood to circulate through flat, thin bags sandwiched between aluminum blocks that contain electric heating elements. Both devices have relatively low flow rates and suboptimal thermal clearance.⁶ Immersion of blood bags in warm water baths is safe but is considered imprecise and slow. Despite some evidence of their safety, the use of microwave heating devices is not recommended by the Association of Blood Banks because of concerns of hemolysis.¹⁹³ Herron and colleagues¹⁹⁴ advocated keeping PRBC temperature below 50°C because they noted significant hemolysis beginning at 51°C to 53°C.

Rapid admixture warming is a promising alternative technique.¹⁹⁵ Mix the unit of whole blood with an equal amount of normal saline that has been preheated to 60°C to 70°C. Once mixed, administer the product to the patient; this gives a resultant delivery temperature of approximately 35°C. This technique combines dilution of blood product and warming into one step. Regardless of the rewarming technique used, warming refrigerated blood to body temperature decreases its viscosity twofold to threefold and avoids venous spasm, thus facilitating transfusion.

Monitoring

During the first part of the transfusion of any blood product, carefully monitor the patient for evidence of a transfusion reaction. Look for signs and symptoms such as hives, chills, diarrhea, fever, pruritus, flushing, abdominal or back pain, tightness in the chest or throat, and respiratory distress. A potentially life-threatening acute hemolytic transfusion reaction in a patient who has previously received transfusions may differ clinically from a minor allergic reaction only by its effects on the patient's pulse and blood pressure. Treat an allergic reaction (hives, itching) to leukocytes or plasma proteins by administering an antihistamine (but not in the blood infusion line), and stop the transfusion.

Stop the transfusion immediately when the following signs are encountered: an increase in pulse rate, a decrease in blood pressure, respiratory symptoms, chest or abdominal discomfort, or a sensation of “impending doom.” Administer normal saline to maintain blood pressure and urine output. Send samples of urine and blood to the laboratory to verify the presence of free hemoglobin. In addition, send the blood bank a clotted sample of blood to reassess for the presence of an immune reaction. If the blood bank concludes that the reaction is a nonhemolytic allergic response, premedicate with antihistamines (diphenhydramine or hydroxyzine) and antipyretics before the next transfusion. Alternatively, use washed cells.

If a hemolytic transfusion reaction is suspected, treat the patient vigorously and promptly.¹⁹⁶ Most morbidity and mortality are due to hypotension and shock, with subsequent cardiovascular instability, renal insufficiency, respiratory manifestations, or hemorrhagic complications of disseminated intravascular coagulation. Infuse crystalloid or vasopressors to treat the hypotension directly, if required. Determine the volume and rate of infusion by blood pressure response. Treat symptomatically with acetaminophen, a warming blanket, antihistamines, and inhaled or subcutaneous β -agonists for bronchospasm or subglottic edema.

If an acute hemolytic transfusion reaction occurs, alkalinize the urine with IV sodium bicarbonate to prevent the precipitation of free hemoglobin. Force diuresis with mannitol to maintain urine output at 50 to 100 mL/hr. The benefit of alkalization and diuresis in preventing acute renal failure is uncertain, although the use of these techniques is commonly advocated.¹⁹⁷ After shock is controlled, assess hemostasis, respiratory function, renal function, and cardiac function to help direct therapy for complications; disseminated intravascular coagulation may require the administration of plasma, platelets, or fibrinogen, and acute tubular necrosis may complicate fluid management.

Delayed, or “late,” hemolytic transfusion reactions may occur days or even weeks after the transfusion of RBCs. Such reactions are characterized by falling hemoglobin levels, jaundice, hemoglobinemia, and indirect hyperbilirubinemia.¹⁹⁸ This complication is usually self-limited and is not life-threatening. Therapy is symptomatic, but future attempts at crossmatching for transfusions may be difficult because of the presence of RBC antibodies. Individuals thus affected should wear identification tags or bracelets to alert medical personnel that previous transfusion reactions have occurred.

On completion of a transfusion, make an entry in the patient's record to indicate the type and volume of the transfusion and the presence or absence of any reaction. The progress note, the transfusion record sheet, or the transfusion laboratory slip can be used for this purpose and should be signed and dated by the clinician, in accordance with hospital policies.

Emphasize to the patient and family how critically important any blood transfusion is to the patient's care. Suggest that the family consider arranging for replacement donations of units of blood to afford future patients the luxury of an ample, available supply of blood products.

Conclusion

Some general guidelines and caveats regarding the transfusion of blood products in the setting of acute blood loss are outlined in [Box 28.2](#).

BOX 28.2 Caveats Regarding Transfusion of Blood Products in the Setting of Acute Blood Loss

The total volume of blood circulating in the body is approximately 7% of ideal body weight in adults and 8%–9% in children. A 70-kg adult, therefore, has a total blood volume of approximately 5 L.

DEFINITION OF MASSIVE BLOOD LOSS

Loss of total blood volume (10 units in a 70-kg adult) in 24 hr or loss of 50% of total blood volume over a 3-hr period.

GENERALIZED GUIDE TO TRANSFUSION OF RBCS³

Rarely transfuse if the hemoglobin level is >10 g/dL; usually transfuse if the level is <6 g/dL. In general, the aim is to keep the hemoglobin level at approximately 7–8 g/dL and the hematocrit approximately 30%–35% to sustain hemostasis and oxygen delivery.^b

In critically ill patients, a restrictive transfusion policy of administering RBCs if the hemoglobin level drops below 7 g/dL and maintaining levels in the 7–9 g/dL range is at least as beneficial as more liberal criteria, except perhaps for patients with acute coronary ischemia.

GENERAL GUIDE TO PLATELET TRANSFUSION

Aim for a platelet count of 50,000/mL³ or higher in actively bleeding patients^c, but lower thresholds may be safe, especially in the absence of bleeding.

FFP

Fibrinogen levels may fall to a critical level (<1 g/dL) after 150% has been lost. Other labile clotting factors fall to 25% activity after approximately 200% blood loss. Transfusing 1 unit of FFP per every 5–6 units of RBCs has been traditional teaching, but decisions are best based on coagulation profiles. Preliminary evidence indicates that an FFP/RBC ratio of 1:1 may be more beneficial in patients with exsanguinating hemorrhage.

CRYOPRECIPITATE^d

If FFP does not raise fibrinogen levels to more than 1 g/dL, consider cryoprecipitate. Use in the ED is supported, but not mandated.

PROTHROMBIN COMPLEX CONCENTRATES^d

Profilnine SD and Bebulin VH are both 3-factor PCCs. They contain insignificant amounts of factor VII. Kcentra is a 4-factor PCC. FEIBA (factor VIII inhibitor-bypassing activity) contains factor VII, mostly in the activated form and factors II, IX, and X in the mostly nonactivated form.

RECOMBINANT FACTOR VIIA^d

No strict guidelines or proven benefits exist. May consider if:

1. No heparin/warfarin effect remains.
2. Surgical control of bleeding is not possible.
3. Bleeding continues despite adequate replacement of other coagulation factors (FFP, platelets, cryoprecipitate).
4. Acidosis is corrected.

Use in the ED is supported but not mandated, nor proven to be clinically effective.

^aDepends on the rate of blood loss and underlying medical condition. RBC transfusion is probably required with 30% to 40% blood volume loss.

^bRBCs can contribute to hemostasis by their effect on platelet margination and function. ^cThis level can be anticipated by the time that the patient has received 2 blood volumes of fluid or RBC transfusions, but substantial variations exist.

^dUse in the ED is supported but not mandated.

ED, Emergency department; FFP, fresh frozen plasma; INR, international normalized ratio; RBCs, red blood cells.

Anesthetic and Analgesic Techniques

CHAPTER 29

Local and Topical Anesthesia

Douglas L. McGee

Local anesthetic agents are important tools used in the everyday practice of emergency medicine. This chapter describes the mechanism of action, the nuances of clinical use, and the adverse reactions to anesthetics that are commonly used in the emergency department (ED). Detailed technical guidance for the performance of topical and infiltrative local anesthesia is provided.

BACKGROUND

The first local anesthetic was cocaine, an alkaloid in the leaves of the *Erythroxylon coca* shrub from the Andes Mountains. Early Incan society used cocaine for invasive procedures, including cranial trephination. In 1884, Koller¹ used topical cocaine in the eye and was credited with the introduction of local anesthesia into clinical practice. In the same year, Zenfel used a topical solution of alcohol and cocaine to anesthetize the eardrum, and Hall² introduced the drug into dentistry. In 1885 Halsted³ demonstrated that cocaine blocked nerve transmission, thereby laying the foundation for nerve block anesthesia. The search for alternatives to cocaine led to synthesis of the benzoic acid ester derivatives and the amide anesthetics used today. It was not until the 1960s that detailed understanding of the physiochemical properties, mechanism of action, pharmacokinetics, and toxicity of these agents emerged.

PHARMACOLOGY AND PHYSIOLOGY

Chemical Structure and Physiochemical Properties

Most useful local anesthetic agents share a basic chemical structure:

Aromatic segment—Intermediate chain—Hydrophilic segment

Subtle variations in this basic structure determine each agent's main physiochemical properties: the negative log of dissociation constant (pK_a), the partition coefficient (a measurement of lipid solubility), and the degree of protein binding. Each of these properties determines the drug's potency, onset, and duration of action. However, physiochemical properties are not the sole determinant of clinical activity; other factors influence the drug's effect. The intermediate chain between the aromatic and the hydrophilic segments is either an amino-ester or an amino-amide; these chemical structures form the basis for the two main classifications of local anesthetics. Common ester-type agents include procaine, chlorprocaine, cocaine, and tetracaine. Common amide-type agents include articaine, lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. Different biochemical pathways metabolize each class. Esters are hydrolyzed by plasma pseudocholinesterase. Cocaine, an ester, is also partly metabolized by N-demethylation and nonenzymatic hydrolysis. Individuals with pseudocholinesterase deficiency may have a greater potential for cocaine toxicity if large doses are used, although this has not been an issue when cocaine is used clinically as an anesthetic. Amides are metabolized in the liver by enzymatic degradation. Local anesthetics are poorly soluble weak bases combined with hydrogen chloride to produce the salt of a weak acid. In solution, the salt exists both as uncharged molecules (nonionized) and as positively charged cations (ionized). The nonionized form is lipid soluble, which enables it to diffuse through tissues and across nerve membranes. The ratio of nonionized to ionized forms depends on the pH of the medium (vial solution or tissue milieu) and on the pK_a of the specific agent. The pK_a is the pH in which 50% of the solution is in the uncharged form and 50% is in the charged form. When the pH of the solution or tissue is less than the pK_a , more of the drug is ionized. When the pH increases, more of the drug is in the nonionized form. Because the nonionized form of drug can diffuse through tissues and nerves, manipulating the pH of the solution can alter a drug's diffusion properties.

Local anesthetics are available in single-dose vials or ampules and in multidose vials, with and without epinephrine. Most solutions have a pH higher than 5. Multidose vials contain methylparaben (MPB), an antibacterial preservative. Local anesthetics premixed with epinephrine also contain an antioxidant (sodium bisulfite or sodium metabisulfite) to prevent deactivation of the vasoconstrictor. These solutions must be adjusted to a more acidic pH, approximately 3.5 to 4.0, to maintain the stability of epinephrine and its antioxidant. These properties as they relate to the amide group are depicted in [Table 29.1](#).

TABLE 29.1 pH and Additives of Amide Local Anesthetics

SOLUTION CONTENT	pH (RANGE)	PRESERVATIVE (METHYLPARABEN)	ANTIOXIDANT
Plain, single dose	4.5–6.5	–	–
Plain, multidose	4.5–6.5	+	–
Commercial epinephrine, single dose	3.5–4.0	–	+
Commercial epinephrine, multidose	3.5–4.0	+	+
Prepared epinephrine, single dose	4.5–6.5	–	–

Nerve Structure and Impulse Transmission

Functional and Structural Components of a Peripheral Nerve

The functional nerve unit includes the nerve axon and its surrounding Schwann cell sheath. The Schwann cell (Fig. 29.1) may surround several unmyelinated axons or a single myelinated nerve fiber and form a myelin sheath. Junctions between sheaths along the axon, called *nodes of Ranvier*, contain sodium channels necessary for depolarization. As myelin sheath thickness increases from autonomic to sensory to motor fibers, the nodes of Ranvier are spaced farther apart. The most important structure affecting transmission of nerve impulses is the axon membrane (Fig. 29.2). The membrane consists of a double layer of phospholipids into which are embedded protein molecules that serve as channels containing pores for the movement of ions in and out of the cell. Most pores have a filter, or gate, that controls ion-specific movement and a sensory mechanism that opens or closes the gate. Bundles of nerve fibers (Fig. 29.3) are embedded in the endoneurium, which is made of collagen fibrils, and they are surrounded by a cellular layer, the perineurium. The perineurium functions as a diffusion barrier and maintains the composition of extracellular fluid around the nerve fibers. Surrounding the entire structure is the outer layer of a peripheral nerve, the epineurium, which is composed of areolar connective tissue.

The Nerve Impulse and Transmission

The inside of a nerve fiber, or axoplasm, is negative (-70 mV) at rest in comparison to the outside. This resting potential is the net result of the differences in ionic concentration on each side of the axonal membrane and the forces that tend to maintain that difference. Specifically, there is a surplus of sodium extracellularly and potassium intracellularly. The sodium channel

Figure 29.2 Axon Membrane. ECF, Extracellular fluid; ICF, intracellular fluid. (Reproduced with permission from Wildsmith JAW: Peripheral nerve and local anesthetic drugs, *Br J Anaesth* 58:692, 1986.)

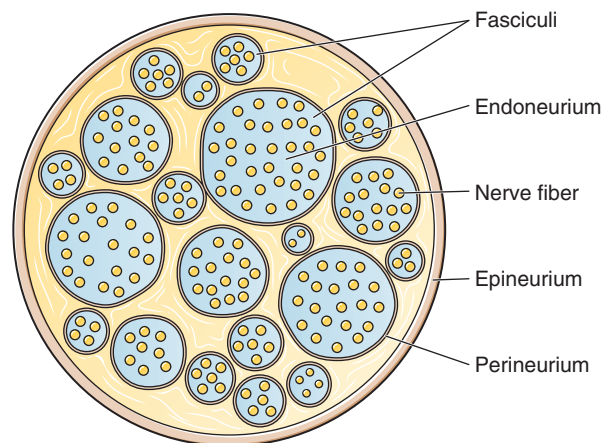

Figure 29.3 Cross-Section of a Peripheral Nerve. (Reproduced with permission from Wildsmith JAW: Peripheral nerve and local anesthetic drugs, *Br J Anaesth* 58:692, 1986.)

is closed, thereby preventing these ions from moving along their concentration gradient (out \rightarrow in). Although potassium can leave the cell to follow its concentration gradient (in \rightarrow out), the need to maintain electrical neutrality inside the cell prevents it from completely doing so. Potassium is in equilibrium between the concentration gradient and the electrochemical gradient, thus creating the negative resting potential.

The sodium channel opens when a nerve is stimulated. Sodium ions enter slowly at first until a critical threshold is reached. They then enter the cell rapidly, along the electrochemical and concentration gradients, and cause depolarization. The influx of sodium is halted when the membrane potential reaches +20 mV, but potassium continues to move out of the cell and repolarizes it until the resting potential is reached. When the excitation process has been completed and the nerve cell is electrically quiet, the relative excess of sodium inside the cell and potassium outside the cell is readjusted by the adenosine triphosphate–dependent sodium–potassium pump.

Depolarization of a portion of the nerve causes a current to flow along the adjacent nerve fiber. This current makes the membrane potential less negative and actuates the sensor to open the next sodium channel. The action potential cycle is repeated, thereby propagating the impulse. Nerve conduction is essentially unidirectional because the sodium channel is not only closed but inactivated as well, and delayed closure of specific potassium channels prevents the critical threshold from being reached in the segment just depolarized. Impulses travel continuously down the axon in unmyelinated nerve fibers. In myelinated fibers, current flows from node to node and depolarizes intervening segments at once. This saltatory conduction causes a faster rate of impulse transmission in myelinated fibers.

Mechanism of Action

How local anesthetic agents block nerve conduction depends on the active form of the agent and the specific physiologic and cellular activity.

The Active Form

Anesthetic solutions contain uncharged and charged forms. The concentration of the uncharged form increases in more alkaline milieus. Only this uncharged lipid-soluble form can cross tissue and membrane barriers. Once the uncharged drug is through a barrier, it reequilibrates into uncharged and charged forms in a proportion dependent on the prevailing pH. Because local anesthetics are more effective in alkaline solutions, it was originally thought that the uncharged form was responsible for conduction blockade. Alkaline solutions are currently believed to be more effective because of increased penetration through tissue barriers, but it is the cationic charged form that is responsible for the actual neuronal blockade.

The Physiologic and Cellular Basis for Neuronal Blockade

Prevention of sodium influx across the nerve membrane forms the physiologic basis for conduction blockade. Local anesthetics slow sodium influx, thereby decreasing the rate of rise and amplitude of depolarization. If sufficient anesthetic is present and the firing threshold is not reached, the action potential is not formed. With no action potential, no impulse is transmitted and conduction is blocked, which results in local anesthesia.

How anesthetic agents prevent sodium influx is still not completely understood. It is believed that the cationic charged form blocks the action potential from inside the membrane; the agent enters the sodium channel from the axoplasmic side and binds to a receptor.^{4,5} This “specific receptor” theory is well accepted and is considered the predominant mechanism in preventing influx of sodium. However, this theory cannot account for the action of benzocaine and other neutral com-

pounds or the uncharged base forms of the common local anesthetics.

In summary, when a local anesthetic (other than benzocaine) surrounds the perineurium, it equilibrates into its uncharged and charged forms based on tissue pH and pK_a . In a more alkaline environment, a greater proportion of the uncharged form is present. The uncharged lipid-soluble form penetrates tissue, nerve sheath, and nerve membrane to gain access to the axoplasm and reequilibrates into both charged and uncharged forms. The charged form enters the sodium channel, decreases movement of sodium into the cell, and halts nerve transmission. The uncharged base is also involved in sodium channel blockade, but the exact nature of this mechanism is unknown.

Activity Profile During Neuronal Blockade

A local anesthetic’s onset, potency, duration, and ability to produce a differential blockade in mixed nerves are a function of its physiochemical properties, the physiologic environment, and to some extent, manipulation by the clinician.

Onset of Action

The pK_a of an anesthetic is the primary physiochemical factor that determines its onset of action. Increased tissue penetration and a shortened onset of action are found in drugs with a lower pK_a because more of the lipid-soluble uncharged form is present (Tables 29.2 and 29.3). Although in isolated nerve fibers the onset of action directly parallels pK_a , other physiochemical factors also influence drug activity. For example, prilocaine and lidocaine have the same pK_a , but lidocaine’s onset is faster because of its enhanced ability to penetrate through nonnerve tissue.

The site of administration also influences the onset of action. Onset times are prolonged as the amount of interspersed tissue or the size of the nerve sheath increases because of the greater distance that the agent must travel to reach its receptor. The pattern of onset for large nerves is determined by the structural arrangement of its fibers. Peripheral (mantle) fibers are blocked before core fibers. Because mantle fibers innervate more proximal regions, nerve blockade proceeds in a proximal to distal progression.

TABLE 29.2 Activity Profile With a Primary Physiochemical Determinant

AGENT	ONSET: pK_a	POTENCY: LIPID SOLUBILITY	DURATION: PROTEIN BINDING
Tetracaine	Slow	8	Long
Procaine	Slow	1	Short
Chlorprocaine	Fast	1	Short
Lidocaine	Fast	2	Moderate
Mepivacaine	Fast	2	Moderate
Prilocaine	Fast	2	Moderate
Bupivacaine	Moderate	8	Long
Etidocaine	Fast	4–6	Long

TABLE 29.3 Physicochemical Properties of Selected Local Anesthetics

AGENT	TYPE	SITE OF METABOLISM	pK ^a	LIPID SOLUBILITY (PARTITION COEFFICIENT)	PROTEIN BINDING (%)
Tetracaine	Ester	Plasma	8.5	High (4.1)	76
Procaine	Ester	Plasma	8.9	Low (0.02)	6
Chloroprocaine	Ester	Plasma	8.7	Low (0.14)	—
Lidocaine	Amide	Liver	7.9	Medium (2.9)	64
Mepivacaine	Amide	Liver	7.6	Medium (0.8)	78
Prilocaine	Amide	Liver	7.9	Medium (0.9)	55
Bupivacaine	Amide	Liver	8.1	High (27.5)	95
Etidocaine	Amide	Liver	7.7	High (141.0)	94

Note: a common way to remember the class of anesthetic (amide versus ester) is that all amides have the letter “i” appearing twice in the generic name. The others are esters. Cocaine, not listed in this table, is also an ester.

Adding sodium bicarbonate to raise the pH of the anesthetic solution (a technique that decreases pain on injection) yields a higher concentration of the uncharged lipid-soluble form and decreases onset time. Increasing the total dose by using a higher concentration of the same volume or a greater volume of the same concentration also shortens onset time. For most procedures performed in the ED, the time of onset of most agents is short enough that manipulation to achieve shorter times is unnecessary.

Potency

The lipid solubility of an anesthetic is a primary physicochemical factor determining potency. The drug’s partition coefficient, not the concentration of the lipid-soluble form determined by the pK_a or pH, confers its lipid solubility. Because the nerve membrane is lipid, lipophilic anesthetics pass more easily into the cell and few molecules are needed to block conduction (see Tables 29.2 and 29.3).

The degree of vasodilation produced by the anesthetic also affects potency because vasodilation promotes vascular absorption, thereby reducing the amount of locally available drug. Lidocaine is more lipid soluble than prilocaine or mepivacaine, but it produces more vasodilation. Although lidocaine is twice as potent as prilocaine or mepivacaine *in vitro*, it is equipotent *in vivo*. Though not a primary reason for its use, epinephrine increases the depth of anesthesia by producing vasoconstriction and making more molecules available to the nerve. Drugs more readily absorbed by fat have reduced potency. Increased concentration also increases potency. Choosing an anesthetic for its potency is not usually necessary for any given site because the commercially available concentration of an agent may be manipulated to make most drugs equianesthetic. For example, lidocaine, being one fourth as potent as bupivacaine, is usually used at four times the concentration (1% to 2% vs. 0.25% to 0.5%, respectively). For different sites and techniques, different concentrations and volumes of a given agent are needed to produce adequate blockade.

Duration

The degree of protein binding of an anesthetic primarily determines its duration of action. Agents that bind more tightly to the protein receptor remain in the sodium channel longer

(see Tables 29.2 and 29.3). Like potency, the duration of action is reduced by the vasodilation produced by local anesthetics. Prilocaine, which is less protein bound than lidocaine, has a longer duration of action because of its lesser degree of vasodilation. The duration of action also varies with the mode of administration. It is shorter when agents are applied topically.

The duration of action may be prolonged by several methods. Increasing the dose, usually by increasing the concentration, prolongs the duration to limits imposed by toxic effects. Raising the pH of the anesthetic solution has also been shown to prolong duration.^{6,7} The most practical way to increase duration is to use solutions that contain epinephrine.⁸ Epinephrine causes vasoconstriction, decreases systemic absorption, and allows more drug to reach the nerve. The effect of epinephrine varies according to the agent. Anesthetics that intrinsically produce more vasodilation (e.g., procaine, lidocaine, mepivacaine) benefit more from epinephrine’s vasoconstrictive action. The long-acting, highly lipid-soluble agents (e.g., bupivacaine, etidocaine) are less affected because they are substantially taken up by extradural fat and released slowly. In fact, lidocaine with epinephrine may be effective for as long as bupivacaine without epinephrine. Generally, most ED procedures can be accomplished quickly before the anesthesia wears off regardless of which drug is selected. Choose agents with a long duration of action when the procedure is lengthy or if postoperative analgesia is desired.

TOPICAL ANESTHESIA

Local anesthetic agents may be applied topically to mucous membranes, intact skin, and lacerations. There are sufficient differences among these sites to merit a separate discussion of each one. Topical anesthesia of the eye is discussed in Chapter 62.

Mucous Membranes

Agents and Uses

Effective anesthesia of the intact mucous membranes (not intact skin) of the nose, mouth, throat, tracheobronchial tree,

esophagus, and genitourinary tract may be provided by several anesthetics (Box 29.1). Tetracaine, lidocaine, and cocaine are the most effective commonly used agents (Table 29.4 and Box 29.1). Benzocaine (14% to 20%) is commonly used for intraoral or pharyngeal anesthesia (Fig. 29.4). The anesthesia produced is superficial and does not relieve pain that originates from submucosal structures. The onset of action may be slow, which limits its usefulness in urgent situations (such as passing a nasogastric tube). Agents applied topically can be absorbed systemically, and concentrated topical agents can cause toxicity.

Tetracaine solution is an effective and potent topical agent with a relatively long duration of action. It is used in

concentrations from 0.25% to 1% with a recommended maximum adult dose of 50 mg. In overdose, it has the disadvantage of severe cardiovascular toxicity without any preceding central nervous system (CNS) stimulatory phase.

Lidocaine is also an effective topical agent that is marketed in a variety of forms (solutions, jellies, and ointments) and concentrations (2% to 10%). The 10% form is most effective, and minimal topical anesthesia is achieved with less potent concentrations. Lidocaine is commonly used as the 2% viscous solution prescribed for inflamed or irritated mucous membranes of the mouth and pharynx. Patient misuse of viscous lidocaine, by repeated self-administration, can lead to serious toxicity. Topical lidocaine provides an adequate duration for most procedures, with the maximum safe dose being 250 to 300 mg.

Cocaine is an effective, but potentially toxic topical agent that is applied to the mucous membranes of the upper respiratory tract. Although it is an ester, hepatic metabolism occurs, as does hydrolysis by plasma pseudocholinesterase. Absorption is enhanced in the presence of inflammation. Cocaine is the only anesthetic that produces vasoconstriction at clinically useful concentrations, hence its popularity for treating epistaxis.

BOX 29.1 Common Local and Topical Anesthetics Used in the ED

- Benzocaine spray will produce transient anesthesia of the mucous membranes. Rarely, it can precipitate methemoglobinemia in standard doses. Anbesol (Pfizer Inc., New York, NY) is a popular over-the-counter benzocaine anesthetic for dental problems, such as teething. Topical anesthesia of mucous membranes can be obtained by applying a gel mixture of 10% lidocaine, 10% prilocaine and 4% tetracaine (Profound, Steven's Pharmacy Costa Mesa, CA, www.stevensrx.com) and is preferred by editors.
- EMLA cream (lidocaine and prilocaine) will produce anesthesia of intact skin, but it must be in place for approximately 60 minutes to provide significant benefit.
- ELA-Max, now known as LMX4 (Ferndale Laboratories Inc, Ferndale, MI), is another topical lidocaine preparation with a more rapid onset of action.
- “Magic mouthwash” contains equal parts of diphenhydramine elixir, Maalox (Novartis, East Hanover, NJ), and 2% viscous lidocaine. Each 5-mL teaspoon contains less than 50 mg of lidocaine. It is swished, held in the mouth for 1 to 2 minutes, and expectorated.
- Lidocaine (2%) may be used intraorally, but repeated use may produce systemic toxicity, especially in children. Each 5-mL teaspoon contains 100 mg of lidocaine. It should not be swallowed but, instead, expectorated after holding it in the mouth for a few minutes. Viscous lidocaine is not useful for acute pharyngitis. Systemic narcotics are preferred if the pain is severe.

ED, Emergency department; EMLA, eutectic mixture of local anesthetics.

Figure 29.4 Topical anesthetics can provide effective anesthesia of intact mucous membranes. Here, Hurricaine spray (Beutlich Pharmaceuticals, Bunnell, FL) (benzocaine 20%) is used before incision and drainage of a peritonsillar abscess. A rare side effect of topical benzocaine is methemoglobinemia.

TABLE 29.4 Practical Agents for ED Use: Mucosal Application

AGENT	USUAL CONCENTRATION (%)	Maximum Dosage ^a		ONSET (min)	DURATION (min)
		Adult (mg)	Pediatric (mg/kg)		
Tetracaine	0.5	50	0.75	3–8	30–60
Lidocaine	2–10	250–300 ^b	3–4 ^b	2–5	15–45
Cocaine ^c	4	200	2–3 ^b	2–5	30–45

^aThese are conservative figures; see text for explanations.

^bThe lower dosage should be used for a maximum safe dose when feasible.

^cThe 10% cocaine solution is best avoided because of minimal additional clinical benefit and the potential for coronary vasoconstriction in patients with coronary artery disease.

ED, Emergency department.

This major advantage is offset by its susceptibility to abuse and toxic potential. The toxic effects are due to direct stimulation of the CNS and blockade of norepinephrine reuptake in the peripheral nervous system. Cocaine should not be administered to patients who are sensitive to exogenous catecholamines or who are taking monoamine oxidase (MAO) inhibitor antidepressants. Clinical manifestations of toxicity include CNS excitement, seizures, and hyperthermia. Central and peripheral effects of hypertension, tachycardia, and ventricular arrhythmias may also be seen. Acute myocardial infarction has been reported after topical application.⁹ Cocaine is commonly used as a 4% solution with a maximum safe dose of 200 mg (2 to 3 mg/kg). A 10% solution is available, but this concentration adds little to the topical effect while enhancing the potential for toxicity. Coronary vasoconstriction may occur with doses as low as 2 mg/kg applied to the nasal mucosa. Although the clinical effect of this vasoconstriction is usually benign and without electrocardiographic changes, topical cocaine should be used cautiously in patients with known or suspected coronary artery disease. Dyclonine offers advantages over other topical anesthetic agents. It is a ketone derivative without an ester or amide linkage and may be used in patients who are allergic to the common anesthetics. Extensive experience with the topical preparation has shown it to be effective and safe.¹⁰ Dyclonine is marketed in 0.5% and 1% solutions, often in sore throat preparations, with a maximum adult recommended dose of 300 mg.

Benzocaine is an ester that is marketed in its neutral form in 14% to 20% preparations (Cetacaine [Cetylite Industries, Inc., Pennsauken, NJ], Americaine [Celltech Pharmaceuticals, Rochester NY], Hurracaine) (see Fig. 29.4). Its low water solubility prevents significant penetration of the mucous membranes, thus reducing systemic toxicity if applied to intact mucosa. However, it is not a potent anesthetic and has a brief duration of action. It is more allergenic than other topical agents. Benzocaine is usually dispensed in an admixture with other therapeutic ingredients and is clinically effective only at relatively high (>14%) concentrations. Benzocaine is available as a nonprescription gel and liquid (6.3% to 20% Anbesol [Pfizer Inc., New York, NY], for example) and is used for a variety of maladies, including ear pain, mouth pain, and teething. It is commonly used by dentists to produce mucosal anesthesia before intraoral nerve blocks (see Chapter 30). Adriani and Zepernick¹⁰ recommended this agent for lubricating catheters, airways, endotracheal tubes, and laryngoscopes and reported only one adverse reaction (methemoglobinemia) in their experience with approximately 150,000 patients. Methemoglobinemia occurs rarely after mucosal absorption of benzocaine used repeatedly for teething infants and after standard doses of benzocaine sprays used in endoscopic procedures.¹¹

An excellent topical preparation is a combination of lidocaine, prilocaine, and tetracaine, especially useful for dental mucosa anesthesia. Topical gel mixtures of 2.5% lidocaine and 2.5% prilocaine (eutectic mixture of local anesthetics [EMLA]) are commonly used on intact skin but have also been used on mucous membranes. EMLA is more effective than 20% benzocaine when applied to the oral mucosa before needle injection for dental anesthesia. One study demonstrated that pain was reduced more quickly with EMLA than with benzocaine when applied to the buccal mucosa.¹²

As with infiltrated anesthesia, toxic reactions to topically applied anesthetics correlate with the peak blood levels achieved and not necessarily with the dose administered. Systemic

absorption of a topical agent is more rapid, with a higher level being achieved than with the same dose given by infiltration. The total dose of a topical anesthetic should be considerably less than that used for infiltration at a given site. Fractionating the total dose into three portions administered over a period of several minutes effectively reduces peak blood levels. Inadvertent suppression of the gag reflex, combined with difficulty swallowing, may lead to aspiration, an important potential adverse reaction to topical anesthesia of the nose, mouth, and pharynx. Infections from drug solutions in multidose vials for topical anesthesia of the larynx and trachea have not been substantiated.

Technique and Precautions

A commonly used “magic mouthwash” for the topical treatment of painful gingivostomatitis in children is often prescribed by emergency clinicians and pediatricians. There has been little scientific study of the preparation and it is not available commercially, but it has been used safely for decades. It consists of equal parts viscous lidocaine (2%), Maalox as a binder, and diphenhydramine elixir. Corticosteroids or nystatin is often added when the mixture is used to treat chemotherapy-induced mucositis.¹³ However, a 2004 review found no evidence that magic mouthwash is effective in treating this condition.¹⁴ The creamy mixture is swished around the mouth and expectorated, or painted on specific lesions with a cotton swab. Packing an area with a cotton ball soaked with this mixture is another option. Repeated doses or swallowing of the elixir can produce systemic toxicity, so careful instruction should be given to limit use of the solution to every few hours. This combination would be theoretically less toxic than simply using topical lidocaine.

Emergency clinicians often prescribe 2% viscous lidocaine (20 mg/mL) for patients with pharyngitis, stomatitis, dental pain, or other inflammatory or irritative lesions in the oropharynx. Although this intervention is widely used and generally safe, the common misconception that topical anesthesia is totally innocuous may result in poor patient instructions and serious consequences. Topical lidocaine is helpful for painful mouth lesions, but is of little practical value for acute pharyngitis, for which systemic analgesics are usually a better option. Seizures and death from topical lidocaine have been reported when excessive repeated doses have been administered.^{15,16} Toxic blood levels may occur because the anesthetic effect of viscous lidocaine lasts for only 30 to 60 minutes and patients with recurrent pain may either ignore or be ignorant of the safe dosing interval of 3 hours and medicate themselves more frequently. Patients tend to increase each dose to obtain greater relief, and inflammation may increase systemic absorption. In addition, painful oral lesions may last for several days.

Children are at higher risk for the rare toxicity of oral lidocaine. When compared with adults, children may exhibit increased lidocaine absorption, decreased clearance, and a longer half-life.¹⁷ Continued medication use allows lidocaine and its major metabolites monoethylglycinexylidide (MEGX) and glycinexylidide (GX) to accumulate. Both MEGX and GX are produced from the hepatic metabolism of lidocaine and are excreted in urine. They possess anesthetic and antiarrhythmic activity and have the potential for CNS toxicity. Although these metabolites are less potent than lidocaine, their elimination half-lives are considerably longer. Several investigators regard MEGX and GX to be the cause of CNS toxicity with prolonged topical use of lidocaine.¹⁶ The length of time

that viscous lidocaine is retained in the mouth and whether the excess is expectorated or swallowed also affect the blood level produced. Expectorating the medication after swishing it in the mouth produces much lower blood levels than when it is swallowed. It seems logical that the most hazardous mode of administration would be to retain the solution in the mouth “until absorbed.”

Clearly explain the proper way to use viscous lidocaine and inform patients not to dose themselves *ad libitum*. Note that a 2% solution contains 20 mg/mL, or 100 mg per standard teaspoon (5 mL). The recommended maximum adult dose is 300 mg (15 mL of a 2% solution) no more frequently than every 3 hours. When possible, instruct the patient to decrease the dose by using direct cotton swab application. When gargled or swished in the mouth, limit application time to 1 to 2 minutes, and instruct the patient to expectorate excess solution. Limit use to 2 or 3 days, especially if swallowing the solution is necessary to obtain relief. Prescribe lower doses for patients at risk for decreased clearance (see later section on **Systemic Toxic Reactions**). Doses for children are prescribed at 3 mg/kg. Because infants cannot expectorate well, do not use viscous lidocaine for minor oral irritation and teething. Recommend that no food be eaten for 1 hour after application because anesthesia of the oropharynx can interfere with swallowing and cause aspiration. Special note should be made of the over-the-counter availability of benzocaine, commonly used for toothaches and teething. A gel or liquid (Anbesol, Pfizer) is available in 6.3% to 20% formulations. When used repeatedly in the oral cavity on irritated tissue, systemic toxicity, including methemoglobinemia, may occur.

Lidocaine 4% solution can be atomized with a standard nebulizer device commonly used for delivering asthma medications and inhaled by the patient before insertion of a nasogastric tube. This method effectively anesthetizes the nasopharyngeal and oropharyngeal tissues, thereby easing the pain of tube insertion.^{18,19} Lidocaine (4%) and cocaine (4%) atomized by a single-use mucosal atomizer, compared with lidocaine gel (4%), demonstrated equal reductions in nasal pain scores during the insertion of a nasogastric tube in healthy study participants, although they indicated that overall discomfort was less with lidocaine gel injected into the nose.²⁰

Intact Skin

Agents and Uses

The stratum corneum provides a cutaneous barrier that prevents the commonly marketed aqueous solutions (acid salts) from producing anesthesia, but saturated solutions of the bases of local anesthetics are effective on intact skin. When applied topically to abraded skin, most anesthetic agents produce peak blood levels similar to those resulting from infiltration in 6 to 10 minutes.

Lidocaine Cream and Patch

In 1974, Lubens and coworkers²¹ used 30% lidocaine cream, saturated on a gauze pad and adherent to an elastic patch, for a myriad of procedures including minor operative procedures (e.g., excision of lesions, incision and drainage of abscesses), lumbar puncture, venipuncture, and allergy testing. Today, lidocaine is available in a 5% patch, and remains one of the most commonly used topical compounds. Recent literature regarding its effectiveness, however, has been mixed. In a study by Cheng, a lidocaine patch applied at the site of rib fractures

in patients taking oral pain medication decreased pain scores when compared to a placebo patch.²² In contrast, a meta-analysis of 251 patients in 5 trials compared lidocaine patches to placebo patches for acute or postoperative pain, but failed to conclusively demonstrate that a lidocaine patch decreases pain intensity, reduces opioid consumption, or reduces hospital length of stay.²³

EMLA Cream, ELA-Max, and Tetracaine Base Patch

Various topical anesthetics have been suggested to decrease the pain of venipuncture or injections and to provide topical anesthesia for painful skin abrasions and lesions. These agents have been studied extensively and are safe, but they are not practical in many ED settings because of their slow onset of action and inadequate efficacy. However, their activity profiles make them more applicable than 30% lidocaine cream to emergency medicine. Tetracaine base is available as a solution, a gel, and a patch preparation. It is effective in crossing the lipid-rich barrier of the stratum corneum because it is highly lipophilic. EMLA was approved in the United States in 1992. It contains 2.5% lidocaine and 2.5% prilocaine in a unique oil-and-water emulsion, yielding 5% EMLA. The mild lipophilic and hydrophilic properties of the component drugs are greatly increased when mixed together, thereby allowing absorption through intact skin. ELA-Max and ELA-Max5, now known as LMX 4 and LMX 5 respectively (Ferndale Laboratories Inc, Ferndale, MI), are topical lidocaine anesthetic creams with a more rapid onset of action than EMLA cream. ELA-Max is a 4% concentration, and 5% ELA-Max is marketed as an anorectal cream that may benefit patients undergoing painful rectal procedures. Neither product has prilocaine, as is found in EMLA cream, and neither has US Food and Drug Administration approval for pain relief before painful injections or intravenous (IV) insertion, but both have such potential.²⁴

Tetracaine base seems to offer the advantage of being able to achieve effective anesthesia with a shorter application time and a longer duration.²⁵ For tetracaine and EMLA preparations, onset, depth of anesthesia, duration, and blood levels vary directly with application time, use on thinner or inflamed skin, and larger doses.²⁶ These preparations exhibit a reservoir effect.²⁷ The drug is deposited in the stratum corneum and continues to diffuse along its concentration gradient, even after it is removed from the skin.

Tetracaine base, lidocaine cream, and EMLA can be useful in the ED for providing anesthesia for many procedures: venous cannulation, venipuncture, or any needle insertion, including preinfiltration anesthesia and lumbar puncture; a variety of minor surgical procedures; and anesthetizing the tympanic membrane and external auditory canal. EMLA has also been used effectively for débridement of ulcers.²⁸ EMLA cream applied to wound edges prior to local wound infiltration with 1% lidocaine decreased the pain of laceration repair compared with infiltrative anesthesia alone.²⁹

EMLA and 5% lidocaine cream are equally effective in reducing the pain of IV insertion.³⁰ Luhmann and colleagues³¹ demonstrated that 5% lidocaine cream applied for 30 minutes under an occlusive dressing was as effective as infiltrated buffered lidocaine before IV catheter insertion in children. Obviously, infiltrative administration of buffered lidocaine requires skin puncture, but its onset of anesthesia is almost immediate. When time is not an issue, topical creams may be an acceptable alternative to infiltrated anesthesia or no anesthesia at all. Approximately a 60-minute interval after application is required

for these preparations to provide optimal topical analgesia to the intact skin for such procedures as venipuncture. Early cutaneous placement of these agents (e.g., over common IV sites while the patient is being triaged) is important for practical ED use.

Ethyl Chloride and Trichloromonofluoromethane and Dichlorodifluoromethane (Fluori-Methane) Sprays

These topical agents are often used for limited skin incisions (e.g., drainage of small abscesses), trigger point injections, joint aspiration, or injection of bursitis or tendinitis. These agents evaporate quickly from the skin and cool it to the point of freezing. Anesthesia is effective and immediate, but drawbacks include its short duration (only up to 1 minute), potential pain on thawing, and possibly lowered resistance to infection and delayed healing. Highly volatile ethyl chloride spray is flammable. Ethyl chloride has been studied in children to reduce the pain of venipuncture, but the results are mixed.^{32,33} Given their short duration of action and the time needed to perform pediatric venipuncture, these preparations have limited use for this purpose.

Technique

Lidocaine Cream

This 30% cream is saturated on a gauze pad that is adherent to an elastic patch and placed over the area to be injected or incised.²¹ The high concentration of anesthetic and an occlusive patch are needed to achieve effective skin penetration. The duration of action varies with the application time. A 45-minute application time is needed for most procedures. To achieve a topical anesthetic duration of 30 minutes, a 2-hour application is necessary.

Tetracaine Base Patch and EMLA Cream

Because both agents demonstrate a reservoir effect, anesthesia may increase or begin many minutes after removal of the drug. A precise description of application times and duration is not possible. Tetracaine base requires a minimum of 20 to 30 minutes of application time to produce several hours of anesthesia. EMLA requires an application time of 1 to 2 hours for a reported duration of 30 minutes to several hours. Occlusive dressings seem to increase penetration of EMLA whenever the cream is used. Patches are more convenient and cause no loss of effectiveness.

EMLA dosing is based on the amount of cream applied, not on the amount of anesthetic. Each gram of EMLA cream contains 25 mg of lidocaine and 25 mg of prilocaine. Dosages are given in grams of cream, not milligrams of anesthetic. In general, apply EMLA as a thick layer over intact skin under an occlusive dressing for approximately 1 hour before a procedure. Application of a thick layer approximates to 1 to 2 g/10 cm². For minor procedures such as needle insertions, apply 2.5 g of EMLA over 20 to 25 cm² for at least 1 hour. For more painful procedures, apply approximately 2 g of cream per 10 cm² for at least 2 hours. The maximum application area (MAA) determines the appropriate total dose applied. Base the MAA on the patient's weight as follows: up to 10 kg, MAA = 100 cm²; 10 to 20 kg, MAA = 600 cm²; more than 20 kg, MAA = 2000 cm².

Ethyl Chloride and Fluori-Methane Sprays

Collect all the equipment required and make all preparations needed to immediately perform the desired procedure. Invert

the bottle 25 cm from the skin and spray a stream along the proposed incision site until the area turns white and hard. Make the incision or local anesthetic injection immediately or during actual spraying of the agent for optimal results because the effect is fleeting. Some clinicians use these vapocoolant sprays to decrease the pain of injection of a more traditional local anesthetic such as lidocaine.

Iontophoresis

Anesthetic agents may be drawn into the skin without needles by electrical current applied through electrodes in a process called *iontophoresis*. Lidocaine with epinephrine administered via iontophoresis provides adequate anesthesia before venipuncture in pediatric patients and is superior to EMLA in providing cutaneous anesthesia.³⁴⁻³⁷ Iontophoresis is not widely used in emergency medicine but may be another alternative to applied anesthetic agents.

Microneedle Pretreatment

Recently developed technology known as microneedle pretreatment may improve the efficacy of cutaneously applied topical anesthetics. A functional microarray of fine needles painlessly perforates the stratum corneum to facilitate the penetration of applied medications without using traditional needle injections. A 2010 study demonstrated that perforation of the skin of healthy volunteers with a microneedle to which dyclonine was applied resulted in decreased time to anesthesia and a greater degree of pain reduction than did application of dyclonine to nonperforated skin.³⁸ Microneedling followed by the application of EMLA prior to facial laser resurfacing, and lidocaine 2.5%/prilocaine 2.5% prior to full face fractional microneedling for atrophic acne scars was superior to either topical anesthetic applied alone.^{39,40} This emerging technology may improve the practical application of anesthetics to intact skin in the ED.

Jet Injection

Jet injection of anesthetic through intact skin may overcome some of the limitations imposed by the cutaneous application of anesthetics without needle infiltration. A jet injector is a device containing carbon dioxide gas that rapidly forces a plunger to expel the drug through a small orifice applied over intact skin. Medication penetrates the epidermis to a depth of 5 to 8 mm in 0.2 second and causes the drug to be rapidly dispersed through the skin. Safety is improved because no needles are used to penetrate the skin. Several studies have demonstrated that jet injection of anesthetics provides more rapid anesthesia than topical application of anesthetic agents and is preferred by patients over no anesthesia at all for painful procedures such as laceration repair, lumbar puncture, IV insertion, and arterial blood gas sampling.⁴¹⁻⁴⁵

Complications

General adverse reactions to anesthetic agents are discussed in the Complications section later in this chapter.

Tetracaine base is quite safe, with a low blood concentration after proper use. In one study, cutaneous erythema developed at the site of application in approximately 25% of patients.²⁷ This vasodilatory effect may actually be an advantage when starting IV lines or performing venipuncture. EMLA is also quite safe. Although it has a high rate of local skin reactions, they are mild and transient, with disappearance 1 to 2 hours after removal of the cream. Despite the reported successful

use of EMLA cream on skin ulcers, Hansson and associates²⁸ and Powell and coworkers⁴⁶ described an increase in bacterial growth, infection, and inflammation when used in experimental wounds. Methemoglobinemia resulting from the metabolites of prilocaine may occur with EMLA.²⁶ The risk for clinically significant methemoglobinemia seems remote when EMLA is used properly. It is contraindicated in any infant younger than 3 months and in infants between 3 and 12 months of age who are currently taking methemoglobinemia-inducing drugs (nitrites, sulfonamides, antimalarials, phenobarbital, and acetaminophen). The risk for adverse effects is increased in patients with anemia, respiratory or cardiovascular disease, and deficiencies in glucose-6-phosphate dehydrogenase or methemoglobin reductase. Prolonged inhalation of ethyl chloride spray may produce general anesthesia, coma, or cardiorespiratory arrest. Ethyl chloride is also flammable, thus precluding its use with electrocautery.

Topically applied anesthetics are often covered with an occlusive dressing to contain the medication. Covering the medication with an occlusive dressing may dramatically increase drug absorption and the amount of metabolites. Oni and associates demonstrated that 4% lidocaine cream applied to volunteers with an occlusive dressing resulted in three times the level of serum lidocaine and double the level of MEGX when the same dose was applied to volunteers without occlusion.⁴⁷ Use caution when occluding topical anesthetics over intact skin because markedly elevated serum levels of the drug may be reached.

Lacerations

Background

In 1980, Pryor and colleagues⁴⁸ reported their experience with a topical anesthetic solution (tetracaine-adrenaline-cocaine [TAC]) for wound repair. The original formula, used in most subsequent studies, consists of a solution of 0.5% tetracaine, 1:2000 epinephrine (adrenaline), and 11.8% cocaine. Traditionally, anesthesia is produced by firmly applying a solution-saturated gauze pad or cotton ball directly to the laceration for 10 minutes. The resulting loss of cutaneous sensation is centered about the area of application. Gel formulations of topical wound anesthesia (TWA) with alternative mixtures of agents promise to improve the ease and safety of topical anesthetic solutions for wound repair in the ED. Advantages of TWA include painless application, no distortion of wound margins, good hemostasis, and good patient and parental acceptance in the pediatric age group.

Indications and Contraindications

Use of TWA is generally restricted to young children with wounds less than 5 cm in length, in whom the delay in application of an anesthetic is acceptable and proper application can be ensured (Fig. 29.5). TWA containing vasoconstricting agents is not generally used in structures without a collateral blood supply (e.g., digits, tip of the nose, pinna of the ear, penis), although there is no evidence that this is unsafe. When some wound preparation is desired before anesthesia, remove large

Figure 29.5 Topical Wound Anesthesia **A**, The topical anesthetic (in this case, lidocaine-epinephrine-tetracaine gel) is applied to a cotton ball or gauze pad. **B**, The anesthetic is held in place with an occlusive dressing such as Tegaderm. **C**, After a 30-minute application period, vasoconstriction of local tissue can be readily observed (*arrow*), and effective anesthesia has been achieved. **D**, Local wound repair, including additional infiltrative anesthesia if necessary, can proceed with little if any patient discomfort.

debris and clotted blood to allow the appropriate application of TWA and then finish wound preparation once the wound is properly anesthetized.

TWA appears to be less effective on the trunk and extremities than on the face and scalp and less effective than lidocaine infiltration in these areas. The 10- to 20-minute onset time may be unacceptable in a busy ED.⁴⁹ Two other often mentioned drawbacks may be more theoretical than real. Vasoconstrictor-induced higher infection rates (see later section on **Complications**) have not been clearly demonstrated. The argument that the necessary 10-minute application period is time-consuming and takes valuable nursing time is partially offset by using the child's caretaker or adhesive paper tape alone to hold the solution in place. It is not necessary for anyone to "hold" the medicine in place when gel is used.

Some EDs still stock topical anesthetic gels that contain cocaine. Cocaine use is complex because of cost and federal regulations requiring storage in a locked cabinet and maintenance of separate written records of its use. In view of the evidence that mixtures without cocaine are efficacious, avoid the potential complications related to cocaine that do not have the potential for abuse that cocaine does. The practicality of cocaine-containing TWA has also been questioned.⁵⁰

Agents and Effectiveness

TAC and Related Mixtures

Three clinical trials directly compared TAC with infiltrated lidocaine. Without specifying wound location, Pryor's group⁴⁸ found equal anesthetic effect. Complete anesthesia with TAC was achieved in 82% to 86% of patients as compared with 83% to 92% for subcutaneous lidocaine. The remaining patients obtained partial anesthesia. Hegenbarth and associates⁵¹ and Anderson and coworkers⁵² demonstrated results similar to those of Pryor's group.⁴⁸ Hegenbarth and associates found TAC to be equal to lidocaine only on the face and scalp and inferior to it at other locations. In contrast, other studies have confirmed excellent rates of effectiveness, especially on the face and scalp.⁵³⁻⁵⁷ TAC is more effective than its component drugs alone. On the face and scalp, TAC was found to be superior to tetracaine alone, although on nonfacial areas, both produced equally poor results.⁵³ TAC was found to be more effective than cocaine alone and more effective than a tetracaine-epinephrine solution in the same dosage ratio.^{55,58}

In 1990, Bonadio and Wagner⁵⁶ showed that an epinephrine-cocaine solution (1:2000 epinephrine and 11.8% cocaine) was equal to TAC in effectiveness. Bonadio and Wagner⁵⁴ also found that half-strength TAC (0.25% tetracaine, 1:4000 epinephrine, 5.9% cocaine) achieved excellent results in patients with dermal lacerations of the face, lip, and scalp. Smith and Barry⁵⁹ compared three strengths of TAC and found equal effectiveness among them; they recommended the lowest-strength cocaine formulation (1% tetracaine, 1:4000 epinephrine, 4% cocaine). Ernst and colleagues⁶⁰ found similar effectiveness to TAC when a slightly different lidocaine-epinephrine-tetracaine (LET) solution (4% lidocaine, 1:2000 epinephrine, 1% tetracaine) was used.

TAC has also been compared with EMLA when placed in a wound for 60 minutes before wound repair. In a study of 32 wounds, supplemental anesthesia was required less often with EMLA.⁶¹ The non-cocaine-containing formulations are generally considered less toxic and have advantages in terms of reduced cost and avoidance of controlled substance precautions during storage.

LET and Related Solutions

Many variations of mixtures that do not contain cocaine have been studied; these include LET, lidocaine-epinephrine, tetracaine-phenylephrine, tetracaine-lidocaine-phenylephrine, bupivacaine-norepinephrine, and prilocaine-phenylephrine. Schilling and associates⁶² found that a LET solution (4% lidocaine, 1:1000 epinephrine, 0.5% tetracaine) was as effective as TAC. LET gel preparations are at least as effective as LET solutions.⁶³ Singer and Stark⁶⁴ determined that EMLA or LET gel placed in a wound on initial evaluation and before infiltration with lidocaine reduced the pain of infiltration, thereby allowing an essentially painless injection of lidocaine. Gauze soaked with lidocaine 2% without vasoconstrictive agents placed in a wound was not effective in eliminating the need for infiltrative anesthesia prior to suturing.⁶⁵

Technique and Dosage

Because the topical mixtures noted earlier (especially TAC) are not innocuous anesthetics, pay close attention to the technique of application and the recommended maximum dose. There is no uniformly accepted application technique, composition of components, or concentration of components.

Generally, apply topical solutions such as TWA to the wound in a gravity-dependent position and carefully fill the wound cavity. After 3 minutes, place a single 2 × 2-cm gauze pad or cotton ball saturated with TWA on the wound. Tape or hold the pad firmly in place for 15 to 20 minutes. The person holding the gauze should wear latex examination gloves to minimize the risk for cutaneous absorption of the solution. The average dose of TWA mixture for most wounds is 2 mL.

Gaufberg and coauthors⁶⁶ described "sequential layer application" (SLA) of topical lidocaine with epinephrine (TLE) to deeper wounds that might not typically be amenable to the use of TWA. Cotton soaked with TLE was applied to the wound surface and 2 mm of surrounding skin for 10 to 15 minutes and then removed. A second similarly soaked piece of cotton was packed deeper into the wound for 10 to 15 minutes. Deep wounds were treated with a third piece of TLE-soaked cotton placed deeper into the wound. Anesthesia was presumed when 3 mm or more of pallor was seen on all wound margins. The group receiving lidocaine by SLA was compared with a group receiving infiltrated 2% buffered lidocaine with epinephrine. Both groups experienced a similar degree of anesthesia during suturing. Mean time to anesthesia with SLA was 29 minutes versus 5 minutes for the infiltration group. Despite the longer time in the SLA group, the authors argued that the additional time is worthwhile because the painful injection, risk for hollow-bore needle injury, and tissue distortion with infiltration were eliminated. If time permits, the SLA technique may be useful for wounds that would have otherwise required infiltrated anesthesia.

Hegenbarth and associates⁵¹ estimated the maximum safe dose of full-strength TAC to be 0.09 mL/kg based on the known maximal safe dose of infiltrated tetracaine, the mucosal application of cocaine, and an estimate of absorption of solution onto the applicator. The key to safety is to avoid TAC on mucosal surfaces or areas in which sniffing or swallowing may accidentally occur. Topical mucosal anesthesia is discussed elsewhere in this chapter.

Prepare an epinephrine-cocaine gel by adding 0.15 g of methylcellulose to 1.5 mL of epinephrine-cocaine solution. Stir the mixture thoroughly for a minute or two until a gel consistency is obtained. After sterile preparation, place the

wound in a gravity-dependent position and apply the gel with a cotton-tipped swab to coat the entire wound cavity and margins. Allow the wound to stand for 15 to 20 minutes and thoroughly wash the wound cavity to remove the gel. In Bonadio and Wagner's study,⁵⁷ the average dose used was 0.35 mL of gel containing only 40 mg of cocaine. Again, other agents are equally efficacious and safer; select these over cocaine-containing mixtures whenever possible.

Complications

Most adverse events associated with TWA occur with mixtures that contain cocaine. Lidocaine toxicity is a well-recognized, adverse event when higher doses are used (see later section on [Systemic Toxic Reactions](#)), but lidocaine toxicity has not been reported with TWA mixtures.

Mucosal application may rarely lead to significant systemic toxicity; fatalities have been reported after application. Even after nonmucosal TAC use, cocaine levels appear in the blood and cocaine metabolites appear in the urine in the majority of patients,^{67,68} but tetracaine does not. Gel formulations of TAC tend to stay in the wound and thus reduce the risk of solution runoff onto mucosal surfaces. There is no need to use a gauze pad to apply the medication in a gel formulation or to hold it in place. Because the entire applied dose will stay in the wound, a lower dose can be used. Gel also provides more uniform application to tissues, which improves the anesthetic effect. In tissues containing end-arteries, ischemia caused by vasoconstrictors may occur. Avoid TAC on the digits, the tip of the nose, the penis, and the pinna of the ear. Use TAC with caution on patients with coronary artery disease, uncontrolled hypertension, seizures, or peripheral vascular disease. Patients with decreased plasma cholinesterase levels are theoretically at increased risk for systemic toxic effects, but this potential risk is of little clinical concern.

INFILTRATION ANESTHESIA

Background

Injection of an anesthetic agent directly into tissue before surgical manipulation is known as *infiltration anesthesia* (Fig. 29.6). Field block anesthesia is also considered a form of infiltration anesthesia, particularly as the agents, concentrations, and recommended maximum dosages are the same. To create a field block, inject a field of anesthetic around the operative site. Make the injection proximal to or surrounding the area that you plan to manipulate. Combine infiltrative anesthesia with procedural sedation (see [Chapter 33](#)) to reduce anxiety or motion.

Indications and Contraindications

Infiltration anesthesia is indicated when good operative conditions can be obtained with this technique. It may be used for the majority of minor surgical procedures, such as excision of skin lesions and suturing of wounds. Infiltration anesthesia is considered quicker and safer than nerve block and general anesthesia. Local infiltration can provide hemostasis, both by direct distention of tissue and by the concurrent use of epinephrine.

A disadvantage of local infiltration over nerve blocks is that a relatively large dose of the drug is needed to anesthetize a

Figure 29.6 Infiltration anesthesia for incision and drainage of a pilonidal abscess. Minimize pain by using a small needle (ideally 30-gauge if injecting through intact skin or 25- to 27-gauge if going through the cut edges of a wound), buffering the anesthetic with sodium bicarbonate, warming the anesthetic to body temperature, and injecting slowly in the subdermal plane.

TABLE 29.5 Maximum Allowable Volume (Adults)

AGENT	CONCENTRATION (%)	MAXIMUM ^a SAFE DOSE (mg)	MAXIMUM VOLUME (mL)
Lidocaine	0.5 (5 mg/mL) ^b	300	60
	1 (10 mg/mL)	300	30
Bupivacaine ^c	0.25 (2.5 mg/mL)	175	70
Lidocaine-epinephrine	0.5 (5 mg/mL)	500	100
	1 (10 mg/mL)	500	50
Bupivacaine-epinephrine	0.25 (2.5 mg/mL)	225	90

^aThese are quite conservative figures for infiltration anesthesia; see text for explanation.

^bAlso see [Table 29.9](#). A 0.5% solution is 0.5 g/100 mL = 500 mg/100 mL = 5 mg/mL. A 1% solution is 1 g/100 mL = 1000 mg/100 mL = 10 mg/mL.

^cSome physicians recommend 400 mg as the maximum safe dose for bupivacaine.

relatively small area. For extensive wounds, the amount of anesthetic required may risk systemic toxicity. The maximum allowable volume can be increased by adding epinephrine, using a lower concentration of the anesthetic agent, or both ([Table 29.5](#)). When large volumes are anticipated and a nerve block is anatomically feasible, the nerve block is preferred. Avoid using infiltration for large procedures in small children and in apprehensive patients, especially those with previous adverse reactions to the medications (whether vasovagal or otherwise). Local infiltration distorts the tissues that will be incised or repaired, which makes it undesirable in areas requiring precise anatomic alignment (e.g., some lip repairs).

Choice of Agent

The local anesthetic agents most frequently used for infiltration are 0.5% to 1% lidocaine, 0.5% to 1% procaine, and 0.25% bupivacaine (Table 29.6). Higher concentrations are of no additional benefit. Lidocaine is most commonly used because of its excellent activity profile, low allergenicity, low toxicity, user familiarity, and ready availability. Procaine is useful for patients who are allergic to amide anesthetics. Some clinicians prefer bupivacaine because of its prolonged duration. Bupivacaine may also be preferred when postoperative analgesia is desired, for prolonged procedures, for dental anesthesia, or even for short procedures that may be interrupted in a busy ED.

A comparison of equianesthetic doses of lidocaine and bupivacaine for infiltration anesthesia (Table 29.7) revealed that the duration of action is the major difference between the two agents. For the majority of ED procedures it is not necessary to extend the duration of anesthesia beyond 1 hour, which makes plain lidocaine a logical anesthetic choice. However, patients experience a moderate amount of pain after repair of a laceration when the lidocaine wears off in approximately 1 hour.⁶⁹ Bupivacaine reduces the pain after repair of lacerations for at least 6 hours. This benefit of a prolonged duration of anesthesia must be weighed against the hazards of injury to the mucous membranes or an unprotected limb or

the annoyance of prolonged numbness in patients who have undergone simple surgical procedures.

A prolonged duration of anesthesia can also be achieved by adding epinephrine, sodium bicarbonate, or both to lidocaine. Epinephrine provides excellent wound hemostasis and slows systemic absorption. This latter property decreases the peak blood level, reduces the potential for a toxic reaction, and allows a greater volume of agent to be used for extensive lacerations. The major disadvantage of epinephrine is theoretical damage to host defenses, but it is generally clinically inconsequential (Box 29.2). Bicarbonate added to the anesthetic just before injection decreases the pain of administration. Bupivacaine, if used with due caution, is safe and easy to use. The deciding factors are many, but some logical choices are as follows:

- For a wound with excessive bleeding, use lidocaine with epinephrine and sodium bicarbonate.
- For an apprehensive patient, use lidocaine with sodium bicarbonate.
- For anticipated prolonged postprocedure pain, use bupivacaine.

Equipment

The pain of injection is reduced with the use of small-gauge needles. Ideally, a 30-gauge needle is used if the injection is

TABLE 29.6 Practical Agents for Emergency Department Use: Local Infiltration

AGENT	USUAL CONCENTRATION (%)	Maximum Dosage ^{a,b}		ONSET (min)	DURATION ^c
		Adult (mg)	Pediatric (mg/kg)		
Procaine	0.5–1.0	500 ^d (600)	7 (9)	2–5	15–45 min
Lidocaine	0.5–1.0	300 (500)	4.5 (7) ^e	2–5	1–2 hr
Bupivacaine	0.25	175 (225)	2 (3) ^f	2–5	4–8 hr

^aThese are quite conservative figures; see text for explanation.

^bThe higher maximum dose for solutions containing epinephrine appears in parentheses.

^cThese values are for the agent alone; they can be extended considerably with the addition of epinephrine.

^dSome authorities recommend up to 1000 mg or 14 mg/kg for procaine.

^eSome authorities recommend up to 7 mg/kg of plain lidocaine in children older than 1 year.

^fBecause of lack of clinical trial experience, drug companies do not recommend the use of bupivacaine in children younger than 12 years, but bupivacaine is commonly used without problems in children.

TABLE 29.7 Comparison of 1% Lidocaine and 0.25% Bupivacaine: Infiltration Anesthesia

	LIDOCAINE	BUPIVACAINE	ADVANTAGE
Onset	2–5 min	2–5 min	Equal
Effectiveness (equianesthetic dose)	Excellent	Excellent	Equal
Duration	1–2 hr	4–6 hr	B
Infection potential	No	No	Equal
Administration pain	Less	More	L
Maximum volume ^a —plain lidocaine	Less	More	B
Maximum volume—epinephrine	Less	More	B
Toxic potential	Less cardiotoxic; equal CNS	More cardiotoxic; equal CNS	L

^aSee Table 29.6 for volume and concentration comparison.

B, Bupivacaine; CNS, central nervous system; L, lidocaine.

BOX 29.2 Epinephrine Use**ADVANTAGES**

1. Prolongs the duration
2. Provides hemostasis
3. Slows absorption:
 - Decreases the agent's toxic potential
 - Allows an increased dose
4. Increases the level of blockade

DISADVANTAGES

1. Impairs host defenses—increases the incidence of infection^a
2. Delays wound healing^a
3. Do not use for:
 - Areas supplied by end-arteries
 - Patients “sensitive” to catecholamines
4. Toxicity—catecholamine reaction^b

^aBased on laboratory studies and is of unknown clinical importance.

^bFor example, in patients taking monoamine oxidase inhibitors.

made through skin. If the injection is made through the cut edges of the wound, a 25- to 27-gauge needle suffices. A small-gauge needle slows the rate of injection and reduces the rate and pain of tissue distention. A 10-mL syringe is recommended both for its ease of handling and for the relatively slow rate of injection that it allows.

Technique

Once an agent has been chosen, proper administration technique minimizes pain, prevents spread of bacteria, and avoids intravascular injection. Buffering, temperature manipulation, and careful infiltration also reduce the pain of injection.

Buffering

Raising the pH of an anesthetic by adding sodium bicarbonate decreases pain dramatically, whereas lowering the pH by adding epinephrine increases pain. Buffering is probably the best way to reduce the pain of local anesthetic injections, and its routine use is highly recommended. It is probable that pH is not the sole factor in producing pain because the pain produced by various agents does not correlate strictly with the pH. Sodium bicarbonate probably works by increasing the ratio of nonionized to ionized molecules, which either renders the pain receptors less sensitive or causes more rapid diffusion of solution into the nerve and a shorter time to the onset of anesthesia.

To alkalinize lidocaine, add 1 mL of sodium bicarbonate (8.4%, 1 mmol/mL) to every 10 mL of anesthetic solution. As the pH of the solution is raised, the anesthetic becomes unstable and has a decreased shelf life. It was initially recommended that buffered lidocaine be prepared just before use to avoid precipitation and degradation, but buffered lidocaine retains its effectiveness for 1 week and refrigeration may further increase its shelf life.^{70,71} Bicarbonate may be combined with plain lidocaine for both infiltrative anesthesia^{72,73} and digital nerve blocks.⁷⁴ In one volunteer study, sodium bicarbonate was effectively combined with lidocaine and epinephrine.⁷¹

Sodium bicarbonate can be added to bupivacaine, but the solution tends to precipitate as the pH rises. The clinical effect of such precipitation is unclear, but if it occurs, it is probably prudent to use another solution prepared with less buffer.

Precipitation varies directly with the concentration of bupivacaine and the time since mixture.⁷⁵ Cheney and coworkers⁷⁶ showed that 0.05 mL of 8.4% sodium bicarbonate (measured in a tuberculin syringe) could be mixed with 10 mL of 0.5% bupivacaine without precipitation. The goal of using bupivacaine is to prolong the duration of anesthesia; this effect can also be accomplished somewhat by using buffered lidocaine (plain or with epinephrine).

In view of the amount of published literature demonstrating that adding sodium bicarbonate to lidocaine before infiltrative anesthesia reduces the pain of injection without adverse effects, lidocaine should almost always be buffered when infiltrated in the ED; there is no practical reason to avoid the addition of bicarbonate.

Temperature Manipulation

Warming an anesthetic to body temperature (37°C to 42°C) reduces the pain of infiltration,^{77,78} but warming may not reduce injection pain as much as buffering with sodium bicarbonate does. Bartfield and colleagues⁷⁹ found that lidocaine warmed to 38.9°C was more painful than room-temperature buffered lidocaine during intradermal injection. Brogan and associates,⁸⁰ using lidocaine warmed to 37°C, found the warmed lidocaine and room-temperature buffered lidocaine to be equivalent during wound infiltration. Neither study found a synergistic effect with combined warming and buffering. Martin and coworkers⁸¹ found that warmed (37°C) lidocaine was no less painful than buffered lidocaine. Anesthetic solutions can be warmed in a baby food warmer with thermostat temperature control or in an IV solution warmer. Warming is not believed to adversely affect the shelf life of the local anesthetic.

Locally cooling the area to be infiltrated may provide additional pain relief. Leff and colleagues⁸² demonstrated that patients receiving local infiltrative anesthesia for repair of an inguinal hernia had less pain when the incision area was cooled before infiltration. Patients were randomized to two groups and had a 1000-mL bag of saline placed over the inguinal area for 5 minutes. One group used saline bags at room temperature, the other group used saline bags cooled to 4°C. A significant decrease in pain perception was found in the group in which the inguinal area was cooled before lidocaine infiltration. Cooling of wounds in the ED before infiltration has not been studied.

Injection

The pain from injection of local anesthetics is primarily a result of skin puncture (which can be minimized with small-gauge needles) and subcutaneous injection. Although patients fear the needle, there is little perceived pain merely from the needle's presence in subcutaneous tissue. Place the injection in subdermal tissue to minimize needle puncture pain and the tissue distention that occurs with intradermal placement. Place the needle “up to the hub” and inject while withdrawing along the just-created subdermal tunnel to minimize tissue distention. After an initial injection, instead of totally withdrawing the needle from the tissue, redirect it along another path to lessen the number of skin punctures. Slowly inject the smallest volume necessary to reduce pain. Hamelin and coworkers demonstrated that blinded volunteers receiving digital nerve block with 2 mL of lidocaine and epinephrine (1 : 100,000) experienced less pain when the solution was injected over 60 seconds rather than over 8 seconds.⁸³

Because the patient barely feels a needle placed subcutaneously and skin puncture is often quite painful, make all wound

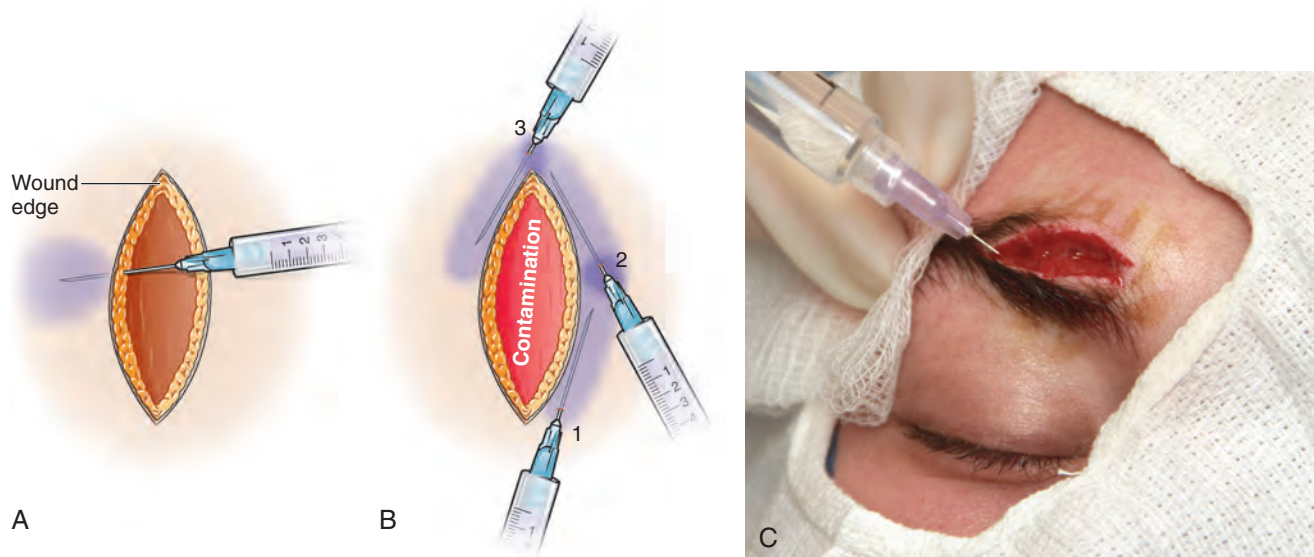

Figure 29.7 **A**, Except in the setting of gross contamination, wounds should be anesthetized by inserting the needle through the cut edges, not through the intact skin. Patients often will not feel a 25-gauge or smaller needle passed into subcutaneous tissue when it is advanced slowly through the cut edge. However, pain generally occurs with distention of tissue by the anesthetic, and hence injection should be slow and deliberate. **B**, If a wound is grossly contaminated, the anesthetic may be introduced through the intact skin. The operator should limit the number of needlesticks. The needle is first introduced at a point in line with the wound and beyond the wound edge (1), and while the anesthetic is slowly injected, the needle is advanced to include one entire side of the wound (if possible) to a point well past the opposite end of the wound. If the needle is not long enough to encompass the entire wound, the skin is painlessly punctured at a midway point that has already been anesthetized (2). The other side may be anesthetized by passing the needle through the area already infiltrated by the first injection (3) to make the skin puncture painless. A 3.8-cm (1.5-inch) 27-gauge needle is a good choice. **C**, Inject local anesthetic through subcutaneous tissue, not intact skin.

injections through the wound edge and not through the skin (Fig. 29.7).^{84,85} Spread of infection beyond the wound margin has not been demonstrated clinically with this technique. Some clinicians choose to inject the anesthetic through intact skin in patients with a grossly contaminated wound. Bierman⁸⁶ described a technique of patient distraction by applying light pressure to alternate sides of the wound with one's fingers and repeated ambiguous questioning about feeling the light pressure rather than the ongoing wound injection. Ask school-aged children to count backward or to say the "ABCs" to distract them during injection. Inject 1% lidocaine through intact skin with the needle bevel facing upward because this is less painful than injecting with the needle bevel facing downward.⁸⁷

To prevent a systemic toxic reaction, avoid giving an intravascular injection. For infiltration anesthesia with a small-gauge needle, however, aspiration is usually unnecessary unless the injection is deeper than the subcutaneous area or the area to be injected contains many large vessels.

SPECIAL CONSIDERATIONS

Hematoma Block

▶ Hematoma block (Video 29.1) has been used for many years to provide anesthesia for fracture reduction, particularly of the distal end of the forearm and hand (Fig. 29.8). Its popularity has waned somewhat because of the fear (unproven and theoretical) of introducing infection at the fracture site and its limited efficacy. Although several studies have shown hematoma block

Figure 29.8 Hematoma block. This technique is useful for reducing fractures of the distal end of the forearm and hand. Here it is being used before reduction of a distal radius (Colles) fracture. To perform the block, slowly inject 5 to 15 mL of plain 1% lidocaine into the fracture cavity and around the adjacent periosteum. It may require 10–15 minutes for anesthesia to occur.

to be safe, the anesthesia that it provides is not as good as that provided by a Bier block (see Chapter 32). Nevertheless, there are several reasons to consider this technique.^{88,89} The procedure is simple and quick to perform and does not require additional personnel. There is no need to wait for an anesthesiologist. A

lower dose of the anesthetic agent is required for a hematoma block than for a Bier block (see [Chapter 32](#)). A hematoma block is particularly useful when a Bier block and general anesthesia are contraindicated.

Prepare the skin over the fracture site with antiseptic solution and insert the needle into the hematoma, as confirmed by aspirating blood. Slowly inject 5 to 15 mL of plain 1% lidocaine or 5 to 10 mL of plain 2% lidocaine into the fracture cavity and around the adjacent periosteum. Larger fractures require larger volumes of local anesthetic. Adequate anesthesia occurs in approximately 5 to 10 minutes and may last for several hours. A common error is to attempt the procedure too soon after injection. Do not perform this procedure through dirty skin or with open fractures.

Intraarticular Anesthesia and Analgesia

Findings from the history and physical examination of an acutely traumatized joint, such as the knee, often underestimate the severity of the injury. Instillation of 5 mL of 1% lidocaine after joint aspiration may help relieve pain and facilitate an examination, but its use is not routinely recommended.⁹⁰ As spasm and apprehension are often not relieved by local anesthesia, the information gained from this maneuver does not usually influence the ED treatment plan. Intraarticular anesthesia of the knee has no effect on gait pattern or joint proprioception.⁹¹ Postprocedure weight bearing may be allowed without fear of producing or increasing injury if otherwise indicated. Intraarticular anesthesia may enhance elbow use after aspiration of a hemarthrosis associated with a radial head fracture.⁹² The technique of administration is analogous to arthrocentesis (see [Chapter 53](#)). Intraarticular lidocaine has been effective in facilitating reduction of a shoulder dislocation. Animal experiments have demonstrated chondrotoxicity when local anesthetics are continuously infused into a joint.^{93,94} Although continuous joint infusion of anesthetic may be harmful when used in a postoperative setting, there is no evidence that a single injection of intraarticular anesthetic in the ED is harmful.

Morphine may be injected directly into joints for postoperative pain relief and potentially provide prolonged analgesia after reduction of fractures. Theoretically, there are local opioid receptors in joints that are capable of being stimulated by rather small doses of morphine to provide relief for up to 24 hours with a single dose. There may also be some systemic absorption of the intraarticular morphine that contributes to analgesia, but adverse systemic opioid effects are not seen with this technique. Data are sparse on the exact mechanism and optimal doses. A period of 3 to 6 hours may be required for analgesia to reach its maximum effect. In a systematic review, Gupta and colleagues concluded that postoperative intraarticular morphine injected into the knee joint at doses of 2 to 4 mg provides analgesia for up to 24 hours.⁹⁵ There is a wide variability in efficacy, which may be dose related. Though studied primarily for postoperative use after knee surgery, a similar concept may be intuitively applied to traumatic joint pain, but this has not been studied adequately.

Intrapleural Anesthesia

Indications

Intrapleural anesthesia introduces a local anesthetic into the pleural space (i.e., between the parietal and visceral pleura) through an epidural catheter. The anesthetic can also be

introduced through a previously placed chest tube. The technique can provide relief for several conditions, primarily postthoracotomy pain, postcholecystectomy pain, and most importantly for emergency clinicians, posttraumatic chest pain (e.g., rib fractures, pneumothorax, hemothorax). This procedure is not only useful for pain relief but also facilitates turning, coughing, and deep breathing. Several studies have demonstrated improved respiratory mechanics when intrapleural anesthesia is used.^{96,97} Though not unanimous, most studies show that intrapleural anesthesia is effective in providing analgesia.^{98,99} Concern has been raised that intrapleural anesthesia may create a level of anesthesia below the umbilicus and make posttraumatic abdominal examinations unreliable. Until this issue is clarified, it seems prudent to rule out intraabdominal injury before intrapleural anesthesia is used.¹⁰⁰

Technique

If a chest tube is in place, it is preferable to inject anesthetic into the pleural space through the chest tube. Clamp the tube for 10 to 15 minutes to allow the anesthetic to diffuse. When the tube cannot be taken off suction or if no tube is present, inject the local anesthetic percutaneously.¹⁰¹ With the patient in the lateral position (with the affected side up), place a 16-gauge Tuohy needle 8 to 10 cm from the posterior midline in the eighth intercostal space. Angle the needle 30 to 40 degrees with respect to the skin and aim medially, with the bevel up and directed just above the rib. After perforating the posterior intercostal membrane (felt as a distinct resistance), remove the stylet and attach a well-wetted, air-filled glass syringe to the Tuohy needle. Advance the needle until it enters the pleural space, which is denoted by the plunger being drawn down the syringe as a result of the negative pressure created during inspiration. Remove the syringe and introduce an epidural catheter 5 to 6 cm into the pleural space. Remove the Tuohy needle, obtain a chest radiograph to confirm proper position, and secure the catheter.

The most commonly used anesthetic and dose is 20 mL (0.3 mL/kg) of 0.5% bupivacaine. A dose repeated every 8 hours is safe and effective.¹⁰² Alternatively, infuse 0.25% bupivacaine at 0.1 to 0.2 mL/kg per hour after a bolus has been administered.⁹⁶ The solution presumably diffuses from the pleural space “back” through the parietal pleura and the intercostal muscle to reach the intercostal spaces, where it blocks the intercostal nerves. The level of anesthesia can extend from T2 to T12 and involve the skin, chest, abdominal wall, and potentially the viscera if the visceral afferent fibers are blocked at the sympathetic chain in the paravertebral gutter.

Though not yet a consistently proven or a completely standardized technique, intrapleural anesthesia offers promise for patients and is a valuable procedure for the emergency clinician to master.

COMPLICATIONS

Local Anesthetic Effect on Wounds

Wound Healing

Local anesthetics produce cytotoxic effects on cell structure and function in a dose- and time-related manner. These effects, at doses well below those used clinically, involve fibroblasts more than nervous tissue. Local anesthetics impair mitochondrial function and fibroblast proliferation and hasten apoptosis in

vitro; the clinical relevance of these effects to the ED use of local anesthetics is likely to be minimal.^{103,104} Collagen synthesis is inhibited by lidocaine and bupivacaine.¹⁰⁵ Morris and Tracey¹⁰⁶ found that lidocaine in increasing concentrations progressively reduces the tensile strength of wounds. Epinephrine added to 1% and 2% concentrations of lidocaine further reduced tensile strength, but when epinephrine was added to distilled water or to 0.5% lidocaine, it had little effect. Several conclusions may be clinically relevant. Although it may delay the onset of anesthesia, 0.5% lidocaine solution, without epinephrine, may be best for maintaining wound strength.

Eriksson and associates¹⁰⁷ found that lidocaine reduces the inflammatory response in wounds by decreasing the number of white cells and their metabolic activity. Although an inflammatory response may be beneficial in a contaminated wound, it can be detrimental in a sterile wound because of tissue toxicity created by the release of superoxide anions, lysosomal enzymes, thromboxanes, leukotrienes, and interleukins. The clinical relevance of this is unknown. None of the concerns mentioned earlier should prohibit the use of standard anesthetics or epinephrine when their use is otherwise indicated.

Wound Infection

Though not generally appreciated, it has long been known that local anesthetics possess antimicrobial activity in vitro. Lidocaine and procaine demonstrate concentration-dependent inhibition of culture growth of most gram-negative organisms.¹⁰⁸⁻¹¹⁰ Gram-positive isolates are also significantly affected by lidocaine and, to a lesser extent, by procaine. Lidocaine inhibits the growth of common nosocomial pathogens, including *Enterococcus faecalis*, *Escherichia coli*, *Pseudomonas aeruginosa*, and several strains of methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci.¹¹⁰ Administering anesthetics before obtaining material for culture, including injecting a joint before arthrocentesis, may give false-negative culture results. To avoid this problem, if possible inject the skin at the injection site and along the needle tract but not into the actual joint space until after a synovial fluid specimen has been obtained for culture. Berg and coworkers¹¹¹ demonstrated that lidocaine administered before tissue biopsy of chronic wounds did not affect the culture results when the exposure time before culture was less than 2 hours. This effect is also significant when anesthetic ointments are applied before culture. EMLA cream applied before culture demonstrates powerful antimicrobial properties.¹¹¹ Furthermore, it has been shown that adding sodium bicarbonate to lidocaine greatly enhances its inhibitory effect on bacteria.¹¹² Although local anesthetics can interfere with culture testing, several studies have shown that local anesthetics, by themselves, do not appear to alter the incidence of wound infection.^{113,114}

Epinephrine appears to exert a deleterious effect on host defenses, at least in animal models. Studies of infiltrated and topically applied epinephrine solutions in contaminated animal wounds show an increased potential for infection.^{113,114} Epinephrine-induced vasoconstriction may contribute to tissue hypoxia, retard the killing of *S. aureus* by leukocytes, and reduce leukocyte migration into the tissue.¹¹⁵ Most clinical studies using topical anesthetics with vasoconstrictor properties (e.g., TAC mixtures) do not demonstrate a significant rise in infection rates.^{48,51,52,57} The concerns mentioned earlier should not prohibit the use of epinephrine for wound preparation when its use is otherwise appropriate.

Local Injuries

Injury may result from the direct application of an anesthetic agent to a nerve or from passage of a needle through soft tissue structures. Factors implicated in transient or persistent neuropathy include acidic solutions, additives, the agent itself, needle trauma, compression from hematomas, and inadvertent injection of neurolytic agents. Born¹¹⁶ described a series of 49 wrist and metacarpal blocks with bupivacaine in which significant neuropathy developed in eight patients. He postulated that damage occurred from trapping the drug in a confined space and recommended that whenever bupivacaine is used in this situation, it should be low in concentration and volume. Infection, hematomas, and broken needles are other local problems that can be avoided by using proper technique. Erroneous needle placement can also produce complications such as pneumothorax during a brachial plexus or intercostal block.

Use of Epinephrine With Local Anesthetics

Epinephrine in conjunction with local anesthetics prolongs the duration of anesthesia and produces a temporary hemostatic effect, but its inclusion in digital block solutions has traditionally been discouraged because of the belief that it can lead to ischemia and necrosis. Areas of special concern include the digits, penis, tip of the nose, and earlobe. Although tissue ischemia and sloughing have been reported with concentrations of 1:20,000, current practice involves concentrations in the range of 1:100,000 to 1:200,000 and the use of submaximal doses. Several authors suggest that epinephrine-containing solutions can be safely injected into the fingers without adverse sequelae.¹¹⁷⁻¹²⁰

A study of more than 3000 cases of elective injection of low-dose epinephrine ($\leq 1:100,000$) into the hand and fingers failed to identify a single case of digital tissue loss, and phentolamine (Regitine, Novartis Pharmaceuticals Corp., East Hanover, NJ) was not required to reverse vasoconstriction.¹¹⁷ Of 1111 procedures reported by Chowdhry and coauthors¹²¹ involving digital blocks with 1% lidocaine plus epinephrine (1:100,000) at a dose ranging between 0.5 and 10 mL (average, 4.3 mL), no patient in the epinephrine group exhibited digital ischemia or experienced nerve injuries or unusually delayed wound healing. Current data support the use of epinephrine, when correctly applied, for the performance of digital blocks of the fingers and toes.

The use of phentolamine, which produces postsynaptic α -adrenergic blockade, is recommended for clinically significant vasoconstrictor-induced tissue ischemia. This medication is usually given by local infiltration, in the area where epinephrine has been injected, at a dose of 0.5 to 5.0 mg diluted 1:1 with saline. If local infiltration is ineffective because of tension within a tissue compartment or if the area of vasoconstriction is large, give phentolamine by the intraarterial route.¹²²

Systemic Toxic Reactions

Although systemic toxic reactions occur in only 0.1% to 0.4% of patients after the administration of local anesthetics, they are the most frequent serious adverse reactions encountered (Table 29.8).¹²³ After the administration of a local anesthetic, some of the drug reaches its intended target and some is absorbed quickly into the systemic circulation. Peak blood levels are generally produced within 30 minutes. Many vagal reactions, nonspecific anxiety reactions, and sensitivity to preservatives

^aAnxiety reaction, including hyperventilation syndrome.

^bDenotes common and significant reactions.

^cVasovagal syncope occurs with the patient upright; any loss of consciousness in the recumbent position implies a severe toxic or anaphylactic reaction.

^dAlthough apprehension is classically associated with anxiety and vasoconstrictor reactions, milder toxic and allergic reactions may cause patient apprehension.

have been attributed to “allergies” or to systemic toxicity to local anesthetics. Patients may also demonstrate systemic reactions to hidden allergens that may mimic a systemic reaction, such as anaphylactic reactions to the latex in surgical gloves.

High Blood Levels

Systemic toxic reactions result from high blood levels of local anesthetic. Several factors are important in producing high blood levels, including the site and mode of administration, rate of administration, dose and concentration, addition of epinephrine, specific drug, clearance, maximum safe dosage, and inadvertent intravascular injection.

Site and Mode of Administration

In comparing the routes of administration for a given dose, the intravascular route produces the highest levels, followed by topical mucosal application and then infiltration. The more vascular the site, the more systemic absorption that occurs and the higher the level obtained. The following blocks are arranged in decreasing order of systemic absorption: intercostal, caudal, epidural, brachial plexus, and subcutaneous. It follows that the site of administration is an important variable in determining the safe dose of an anesthetic. For example, 400 mg of lidocaine may produce a nontoxic blood level with subcutaneous abdominal wall infiltration but produce a toxic level when used for an intercostal nerve block.

Rate of Administration

A more rapid IV injection will produce a higher blood level than a slower injection. A single topical application leads to a higher level than a dose that is fractionated over time.

Dose and Concentration

The larger the total dose, the higher the peak blood level. It is uncertain whether increasing the concentration while maintaining the total dose by decreasing the volume affects the serum level.

Addition of Epinephrine

Epinephrine produces vasoconstriction and reduces systemic absorption, thereby resulting in lower peak blood levels. Occasionally, the apprehension, tachycardia, or palpitations induced by epinephrine can be incorrectly interpreted by both the clinician and patient as an “allergic” reaction.

Specific Drugs

The more potent agents are more toxic on a milligram-to-milligram basis. Because anesthetics are used in equipotent doses (e.g., 1 mg of bupivacaine vs. 4 mg of lidocaine), they are approximately equitoxic. The blood levels achieved by a particular agent depend on the agent’s absorption, distribution, and clearance from the circulation. Agents with high lipid solubility and lower protein binding (etidocaine > bupivacaine > lidocaine > mepivacaine) tend to become sequestered in tissue and have slower absorption and lower blood levels. Agents with a greater volume of distribution or faster clearance (etidocaine > lidocaine > mepivacaine > bupivacaine) also produce lower blood levels. Together, these effects produce margins of safety for each anesthetic, with etidocaine having the greatest safety margin, followed by bupivacaine, which is equal to or better than lidocaine.

Esters are difficult to measure in blood because of their rapid hydrolysis by pseudocholinesterase. As a group, toxicity

is inversely proportional to the rate of hydrolysis. Tetracaine is slowly hydrolyzed and is most toxic. Chloroprocaine is quickly hydrolyzed and is the least toxic. Procaine falls between the two.

Clearance

The liver metabolizes amides, with the clearance rate being a function of hepatic blood flow and the extraction capacity of the liver. Decreased hepatic blood flow, produced by norepinephrine, propranolol, or general anesthesia, slows clearance and potentially raises drug blood levels. Decreased drug extraction, associated with congestive heart failure, cirrhosis, or hypothermia, may produce a higher blood level. Hypovolemia, which decreases hepatic flow, does not raise blood levels because it causes an offsetting decrease in absorption.

Decreased clearance of esters and an increased risk for toxicity occur in patients with either low levels or an atypical form of pseudocholinesterase. Low levels occur in various disease states, including severe liver disease and renal failure, and in pregnancy. Atypical pseudocholinesterase is an inherited trait, and its presence reduces the hydrolysis rate of procaine to a greater extent than low levels do.

There are significant differences between pediatric and adult drug distribution and metabolism. Neonates exhibit both reduced levels of pseudocholinesterase and reduced hepatic metabolism, thus increasing the risk for toxicity. In older children, the effects of increased hepatic metabolism and a relatively larger volume of distribution increase their tolerance for higher doses.

Because lidocaine is metabolized in the liver by cytochrome P-450 enzymes, drugs that inhibit these enzymes may slow lidocaine clearance and increase the risk for lidocaine toxicity. Although the effect of ciprofloxacin and erythromycin on infiltrated lidocaine has not been studied, these drugs decrease the metabolism of lidocaine and increase the concentration of its major metabolites when lidocaine is injected intravenously.¹²⁴⁻¹²⁶ The clinical effect of this previously discussed phenomenon is unknown and probably of little consequence in ED wound care.

Maximum Safe Dosage

The maximum safe dose of a drug may be defined as the dose that produces a blood level of the drug just below the toxic level (Table 29.9). One maximum dose of an anesthetic agent appropriate for all patients and all conditions cannot be stated. A maximum safe dose cannot be based solely on the weight of a patient. In an adult, peak blood levels do not correlate well with weight because the volume of drug distribution is relatively constant.^{127,128} As an approximation, Arthur and McNicol¹²⁹ recommended that maximum dosages for children be based on weight. Plain lidocaine may be used in doses of up to 4.5 mg/kg, and the addition of epinephrine allows a maximum dose of 7 mg/kg. Bupivacaine is not recommended for children younger than 12 years, although it is commonly used without adverse consequences. Furthermore, the dose should be modified according to the site and mode of administration.

Maximum safe doses as stated on package inserts should be used only as guidelines because most of them are derived from animal experiments and are based on absorption data only. Levels vary with the site of administration, use of a vasoconstrictor, and to some extent, the health of the patient. Levels can often be exceeded safely when the drug is admin-

TABLE 29.9 Calculation of Anesthetic Doses

Anesthetic solutions are marketed with the drug concentration expressed as a percentage (e.g., bupivacaine 0.25%, lidocaine 1%). To ascertain the strength of a solution in milligrams per milliliter, consider the following:

A 1% solution is prepared by dissolving 1 g of drug in 100 mL of solution.

Therefore 1 g/100 mL = 1000 mg/100 mL = 10 mg/mL.

Note: To calculate the strength from the percentage quickly, simply move the decimal point one place to the right, as follows:

0.25% = 2.5 mg/mL e.g., bupivacaine

0.5% = 5 mg/mL e.g., tetracaine

1% = 10 mg/mL e.g., lidocaine

2% = 20 mg/mL e.g., viscous lidocaine

4% = 40 mg/mL e.g., cocaine

5% = 50 mg/mL e.g., lidocaine ointment

20% = 200 mg/mL e.g., benzocaine

When combined in an anesthetic solution, epinephrine is usually in a 1:100,000 or a 1:200,000 dilution. For example:

1:100,000 concentration of epinephrine = 1 g/100,000 mL = 1000 mg/100,000 mL =

1 mg/100 mL or 0.01 mg/mL.

1 mL of 1:1000 epinephrine = 1 mg.

0.1 mL of 1:1000 epinephrine in 10 mL of anesthetic solution = 1:100,000 dilution = 0.01 mg/mL.

0.1 mL of 1:1000 epinephrine in 20 mL of anesthetic solution = 1:200,000 dilution = 0.005 mg/mL.

Some examples detailing epinephrine content:

	1:100,000	1:200,000
5 mL	0.050 mg	0.025 mg
10 mL	0.100 mg	0.050 mg
20 mL	0.200 mg	0.100 mg

Therefore 50 mL of 1% lidocaine with epinephrine 1:200,000 contains 500 mg of lidocaine and 0.25 mg of epinephrine.

istered accurately. Drugs may be toxic even within the “safe range” when inadvertently injected intravenously.

Inadvertent Intravascular Injection

Most toxic reactions are caused by inadvertent intravascular injection of anesthetics whose doses were calculated for their intended extravascular sites. For example, lidocaine, 300 mg, is a safely infiltrated dose that would probably cause toxicity if directly injected into the bloodstream.

Anesthetics that are injected intravascularly must pass through the lungs before they reach other organs. Lung tissue sequesters a significant amount of drug, which lowers the arterial

blood concentration. Anesthetics that bypass the lungs, in cases of inadvertent injection into the carotid or vertebral arteries or in patients with intracardiac right-to-left shunts, can produce CNS toxicity at low doses. Intraarterial injections into subcutaneous end-arteries about the head or neck are capable of retrograde flow into the cerebral circulation if the injection pressure exceeds arterial pressure. Because the blood volume in the brain is only approximately 30 mL at any given moment, even 1 mg of lidocaine injected into the carotid artery can theoretically produce toxic concentrations. Patients with low cardiac output or hypovolemia and preferential cerebral blood flow may suffer enhanced CNS toxicity.

Host Factors

Four factors tend to lower the body's systemic tolerance to local anesthetic agents: hypoxia, acid-base status, protein binding, and concomitant drug use.

Hypoxia

It was initially thought that an overdose of a local anesthetic produces CNS stimulation and subsequent intracellular hypoxia, which then became the key precipitant for all toxic manifestations of the drug. It is now known that hypoxia may enhance anesthetic toxicity but is not the primary factor.

Acid-Base Status

Although studies of metabolic alkalosis have produced conflicting results, acidosis, particularly respiratory acidosis, can increase toxicity. The elevated CO₂ produced by respiratory acidosis crosses the blood-brain barrier, where it may act directly on the receptor and indirectly by lowering intracellular pH. The lower pH causes more of the drug to ionize, thereby furthering the block in the sodium channel and increasing the potential for toxicity.

Protein Binding

The concentration of unbound drug relates more closely to toxic effects than does the total drug concentration (bound plus unbound) as measured in the blood. The amount of α -acid glycoprotein (AAG), the major plasma protein responsible for binding local anesthetics, is considerably decreased in neonates in comparison to adults. Arthur and McNicol¹²⁹ implied that the low AAG levels in neonates are responsible for the increased toxic potential. Tucker and colleagues¹³⁰ listed several disease states that alter AAG levels and protein binding but questioned whether they lead to changes in free drug concentration in vivo.

Concomitant Drugs. For years, barbiturates were used to prevent and treat local anesthesia-induced seizures. Barbiturates were found to worsen anesthetic-induced apnea and cardiovascular depression. CNS depressants are used with caution when concern exists for local anesthetic toxicity. CNS stimulants have been shown to increase anesthetic-induced excitability and are avoided. Mixtures of local anesthetics have an additive effect on toxicity. If two drugs are used at half strength, they produce the same degree of toxicity as though each were used alone at normal strength. As discussed previously, drugs that slow metabolism by inhibiting hepatic enzymes may increase the risk for toxicity.

Recognition of CNS Toxicity

The earliest manifestation of systemic toxicity is CNS stimulation resulting from blockade of inhibitory synapses. CNS

depression follows and is produced by direct depression of the medulla, although hypoxia may play a role. The signs and symptoms are dose related. Potential signs and symptoms of CNS toxicity, in progressing order, are numbness of the tongue, light-headedness, tinnitus, visual disturbances, muscle twitching, convulsions, coma, and apnea. Drowsiness, commonly seen with lower doses of lidocaine, is not associated with bupivacaine or etidocaine. Tetracaine may produce apnea or cardiovascular toxicity without CNS manifestations.

Recognition of Cardiovascular Toxicity

Moderate blood concentrations of local anesthetics produce slight increases in cardiac output, heart rate, and arterial pressure because of the effects of direct peripheral vasodilation and CNS stimulation. At concentrations generally well above CNS toxicity levels, local anesthetics cause direct myocardial depression, hypotension, and bradycardia, perhaps leading to cardiovascular collapse. These agents also slow electrical conduction and lead to reentry phenomena and various supraventricular and potentially lethal ventricular dysrhythmias, especially with bupivacaine and etidocaine.

Prevention of Toxicity

Knowledge of factors contributing to toxicity guides preventive measures. Avoid esters in patients with an atypical form or a quantitative deficiency of pseudocholinesterase. Use amides with caution in patients with severe liver disease or congestive heart failure. Pay attention to maximum safe dosages based on the site, technique, use of epinephrine, and patient status. Add epinephrine when possible to decrease the rate of drug absorption at vascular sites. Reduce the drug concentration by saline dilution to increase the volume for administration when a large area must be infiltrated. Frequently aspirate in areas of high vascularity, even though a negative aspiration may not prevent IV administration.¹³¹ Slow infiltration is safer and less painful.

Treatment of Systemic Toxicity

Local anesthetics should not be administered without the ability to recognize and treat a toxic reaction, including having all necessary equipment and drugs readily available and being knowledgeable in their use. Despite taking all possible precautions, toxic reactions still occur, and close observation of the patient allows early detection and treatment.

Providing proper oxygenation and ventilation at the earliest sign of a reaction is the cornerstone of treatment. Encourage patients who are alert to moderately hyperventilate to lower the pressure of carbon dioxide (PCO₂) and raise the seizure threshold. Intubation with high-flow oxygen and hyperventilation is performed for patients who cannot adequately ventilate. Initiate IV access and monitor vital signs and cardiac rhythm closely.

Seizures are generally self-limited but are treated if they persist or prevent adequate ventilation. Because respiratory depression secondary to toxicity may follow, low-dose lorazepam or an ultrashort-acting barbiturate (thiopental or sodium methohexital) is preferred. Intubate the patient to ensure an effective airway and prevent further lactic acidosis if the seizures persist. If toxicity is caused by an ester, especially if there is an associated pseudocholinesterase problem, succinylcholine will compete with the anesthetic for the pseudocholinesterase and may increase the toxicity of both compounds.

Treat hypotension and bradycardia with fluids, leg elevation, α - and β -agonists (epinephrine, ephedrine, or dopamine), or atropine as the need dictates. Although lidocaine (with diazepam pretreatment) has been shown to be effective for bupivacaine-induced ventricular dysrhythmias, strong theoretical and experimental evidence indicates that bretylium is more effective.^{132,133} However, until bretylium becomes available again, amiodarone is a reasonable alternative. High doses of atropine and epinephrine can be successful in correcting pulseless idioventricular rhythm. Cardiopulmonary resuscitation is instituted when necessary.

Intravenous Lipid Emulsion

Animal studies, case reports/small series, and personal opinion have advocated the use of 20% lipid emulsion intravenously as a remarkable antidote to resuscitate bupivacaine- and mepivacaine-related cardiac arrest, a situation that is usually fatal (see <https://lipidrescue.com>). Rosenblatt and associates¹³⁴ described the IV injection of 100 mL of 20% Intralipid (Baxter Healthcare Corp., Deerfield, IL; formulation used for hyperalimentation) followed by an infusion (0.5 mL/kg per min over a 2-hour period) and related this intervention to successful resuscitation in a scenario that appeared hopeless. Picard¹³⁵ considers lipid emulsion a “crucial antidote” that should be available when local anesthetics are used for peripheral nerve blocks. A large collaborative workgroup of leading toxicologists recommends Intralipid (Baxter) infusion during cardiac arrest associated with bupivacaine but strikes a neutral posture for cardiac arrest due to other local anesthetics.¹³⁶ Lipid emulsion therapy is typically administered intravenously but bupivacaine-induced toxicity is reversed in rats when lipid emulsion is administered by the intraosseous route.¹³⁷ Intraosseous infusion may be a reasonable alternative to IV infusion when IV access is not available, though this route of administration in humans is of unproven benefit. Lipid emulsion therapy in otherwise hopeless situations of cardiac arrest secondary to local anesthetic overdose is supported (Box 29.3). It appears prudent and intuitive to initiate this antidote before cardiac arrest when significant local anesthetic toxicity is identified.

BOX 29.3 Preliminary Strategies for Lipid Emulsion Rescue Therapy in Patients With Severe Local Anesthetic Toxicity

Intravenous lipid emulsion (ILE) is available as Liposyn II (Hospira, Inc., Lake Forest, IL) (20%) or Intralipid (Baxter Healthcare Corp., Deerfield, IL) (20%).

Protocol: Infuse 20% ILE intravenously. Administer a bolus injection of 1.5 mL/kg^b over a period of 1 to 2 minutes. It may be repeated 1 to 3 times every 5 minutes. Follow with a continuous infusion at 0.25 mL/kg per min for 30 to 120 minutes.

Increase the rate of infusion to 0.5 mL/kg per min in patients with declining blood pressure.

^aCan be extrapolated to other toxins. Continue other resuscitative efforts, including cardiopulmonary resuscitation.

^bFor the initial dose, withdraw 100 mL from a 500-mL bag/bottle and inject with a syringe. Then attach to an infusion pump.

Allergic Reactions

Allergenic Agents

True allergic reactions are rare and account for only 1% to 2% of all adverse reactions, but they are important to recognize because of their serious potential. Ester solutions (procaine, tetracaine) that produce the metabolite para-aminobenzoic acid (PABA) account for the majority of these reactions. Amide solutions (lidocaine, bupivacaine) are rarely involved, and usually the preservative MPB, which is structurally similar to PABA, is responsible. Although pure esters and pure amides do not cross-react, amides may appear to do so if multidose vials containing MPB are used. Patients may manifest an allergic response on first contact with a local anesthetic because of previous sensitization to these agents. MPB is found in creams, ointments, and various cosmetics, and PABA is an ingredient in many sunscreen preparations. Patients who are latex sensitive may have an allergic reaction incorrectly attributed to the local anesthetic.

Cell-mediated delayed reactions manifesting as dermatitis are rare; it is immediate hypersensitivity that most concerns the emergency clinician. A spectrum of signs and symptoms may occur, from rhinitis and mild urticaria to bronchospasm, upper airway edema, or anaphylactic shock. Onset may be immediate and occur even during administration of the agent. Treat anaphylaxis in the usual manner.

The more frequent problem facing emergency clinicians is a patient who claims to have a past history of allergy to local anesthetics. Most patients assume that any adverse reaction to a local anesthetic procedure is an allergy. Because allergy is rarely the cause, a careful history and a review of previous records, if available, are crucial in evaluating these patients. Procaine, trade name Novocaine (Hospira, Inc, Lake Forest, IL), was commonly used in dentistry, and many patients who experienced many types of reactions in the dentist's office, rarely true allergy, state they are allergic to Novocaine. Procaine is no longer used in dental practice, but it is the local anesthetic in intramuscular penicillin preparations (procaine penicillin G).

Attempts to uncover the actual cause of the past reaction and the specific agent involved are often fruitless. Ask about the exact signs and symptoms, technique of administration, amount of drug used, and how the patient was treated. If an allergic reaction cannot be ruled out and the drug previously used is known, use an agent from the other class (whether amide or ester). Lidocaine from a dental cartridge does not contain MPB, and if this were the allergenic source, an ester agent could be used. However, if lidocaine from a multidose vial is implicated, do not use an ester because MPB may cross-react with PABA. In this case, it may be safer to use an amide without MPB or to choose an alternative (see later). In most cases the allergen is an ester, and the patient can safely be given an amide without MPB. Single-dose ampules of 1% lidocaine without MPB, readily obtainable from a resuscitation cart, can be used for this purpose.

Uncertainty often exists regarding the specific agent involved, and the clinician must choose an alternative approach to local anesthesia. If the wounds are extensive and the risk is acceptable, procedural sedation (see Chapter 33) or general anesthesia may be used. Conversely, if minimal pain is expected and the procedure is short (e.g., one or two sutures or staples in the scalp), no anesthesia may be required. These methods may be useful, but the degree of anesthesia produced is frequently not sufficient. Antihistamines injected into a wound have been used successfully for many years and represent a good alternative. Local anesthetic efficacy is found in varying degrees with all

antihistamines. Ketamine anesthesia may be a useful alternative in some situations and is commonly used in children.

Diphenhydramine and Benzyl Alcohol

Several studies have demonstrated that 1% diphenhydramine (Benadryl, Johnson & Johnson, New Brunswick, NJ) is as effective as 1% lidocaine for infiltrative anesthesia.¹³⁸⁻¹⁴⁰ As long as diphenhydramine is not used at concentrations greater than 1%, potential problems of skin necrosis or significant sedation are rare. Dilute the standard 5% parenteral form to a 1% concentration for subcutaneous injection (1 mL of drug to 4 mL of saline). The duration of action of diphenhydramine is shorter than that of lidocaine but appears to be adequate for most procedures. The injection pain of diphenhydramine exceeds that of lidocaine but can be diminished by reducing the concentration to 0.5%. At this lower concentration, the effectiveness of this agent on facial wounds is lost.¹⁴¹ The addition of epinephrine to 0.5% diphenhydramine results in a more painful solution with a shorter duration of action than a standard buffered lidocaine with epinephrine solution.¹⁴² Benzyl alcohol (0.9%) with epinephrine (1 : 100,000) compares favorably with diphenhydramine as an effective local anesthetic. This appears to be a useful alternative to diphenhydramine when lidocaine cannot be used but is of shorter duration than diphenhydramine.¹⁴³⁻¹⁴⁵

Skin Testing

Skin testing and progressive subcutaneous challenge doses deserve special mention because they appear to be logical and well-studied approaches. However, intradermal skin testing with local anesthetics is controversial and often of no practical benefit in the ED. False-positive results are frequently produced by local release of histamine in response to needle trauma, tissue distention, or preservatives in the solution.¹⁴⁶ In addition, a high incidence of false-negative results can occur. It is questionable whether these low-molecular-weight drugs or their allergenic metabolites are ever capable of eliciting positive responses.¹⁴⁷ Other disadvantages of skin testing include its time-consuming nature and potential hazard when even minute traces of an allergen may precipitate a serious reaction. Subcutaneous challenge testing in graduating doses has been advocated and may well eliminate many false responses, but it does not eliminate the problems of time and hazard. Swanson,¹⁴⁸ recognizing that allergy to pure lidocaine is extremely rare, recommended 0.1 mL as a single intradermal skin test. Although his approach eliminates the time disadvantage, intradermal placement can still produce false responses. It would seem more reasonable to give this test dose subcutaneously while exercising due caution in the unlikely event that a patient exhibits a serious reaction.

Summary of Anesthetic “Allergy” Management

Generally speaking, the optimal approach to a patient with a presumed anesthetic allergy is to determine the specific anesthetic agent associated with a presumed allergic reaction and then use a preservative-free agent from the other class (see earlier discussion). If the agent is unknown, use an antihistamine or give 0.1 mL of preservative-free lidocaine as a subcutaneous test dose and proceed with the full dose if no reaction occurs within 30 minutes. Given the studies mentioned earlier, prudent choices would seem to be diphenhydramine (Benadryl, Johnson & Johnson) or benzyl alcohol. Epinephrine (1 : 100,000) can be added to both these drugs to prolong the duration of action. Ketamine anesthesia is also an alternative.

Catecholamine Reactions

Anxiety and vasoconstrictor (epinephrine) reactions are discussed together because each produces similar manifestations caused by elevated catecholamine levels. These relatively common disorders are difficult to distinguish from each other and are not generally serious.

Excess catecholamine levels produce tachycardia, palpitations, hypertension, apprehension, tremulousness, diaphoresis, tachypnea, pallor, and on occasion, anginal chest pain. Thus, catecholamine excess may resemble the CNS stimulation phase of local anesthetic toxicity.

Catecholamine reactions are not usually caused solely by exogenous epinephrine because if it is used in its optimal concentration (1 : 200,000), the maximum safe dose (0.25 mg) is rarely exceeded. However, many patients produce significant endogenous catecholamines because of anxiety about the anesthetic approach or upcoming procedure. In this case, even the addition of small amounts of epinephrine could trigger a catecholamine reaction. Therefore patient preparation includes proper explanation and reassurance to decrease anxiety. Exercise caution with patients who have hyperthyroidism, hypertension, or atherosclerotic cardiovascular disease, although these conditions do not contraindicate the judicious use of epinephrine-containing anesthetics. Do not give epinephrine-containing anesthetics to patients taking MAO inhibitors.

Treatment of a catecholamine reaction includes stopping further drug administration, observing the patient closely, and administering α - or β -antagonists or benzodiazepine agents, if necessary, to combat severe reactions.

Vasovagal Reactions

It is not standard to monitor patients (cardiac, pulse oximetry) during routine local anesthesia procedures. Vasovagal reactions are, however, common, especially in dental procedures (reported incidence, 2% to 3%), during which the patient is generally in an upright position. To limit vasovagal reactions related to local anesthesia in the ED, do not draw up medication in a syringe in front of the patient, and inject only when the patient is supine (Figs. 29.9 and 29.10). The patient initially experiences anxiety when a triggering event, commonly the

Figure 29.9 Drawing up local anesthetic with a syringe and needle in front of the patient may lead to anxiety and a vasovagal reaction. Avoid this potential complication by simply performing this task out of view of the patient.

Figure 29.10 **A**, What’s wrong in this picture? Almost everything! The patient is sitting upright and directly observing the procedure. This may lead to a vasovagal event, and should he fall from the bed, significant injury may occur. Additional problems include improper positioning of the overhead light (behind the physician’s back), lack of privacy (open curtain and door), equipment tray placed too far away, and a hunched-over posture of the physician. **B**, A much better approach. Note that the patient is supine, the bed is raised, the light and equipment tray are in a better position, the curtain is closed, and a family member is present (but sitting to avoid a “bystander vagal event”) to distract the patient during the procedure. The clinician could also be seated for comfort.

sight or sensation of needle insertion, causes loss of sympathetic tone and an increase in vagal tone. The resultant hypotension and bradycardia may lead to syncope. Address the patient’s anxiety and administer the injections with the patient recumbent as useful preventive measures. Cardiac monitoring may help identify the onset of vagally induced bradycardia when suggested by the past history. Lay the patient supine and elevate the legs. Rarely, atropine is required. Should a patient lose consciousness while in a recumbent position, consider diagnoses other than vasovagal syncope, although significant bradycardia and even complete heart block may accompany a vagal reaction in a supine patient.

SUMMARY

Emergency medicine cannot be practiced without the use of local anesthetic agents. Their effectiveness when applied topically or by infiltration makes them extremely adaptable to many clinical circumstances. A working knowledge of commonly used agents is necessary to ensure the safe administration of these medications. Aim specific efforts at maximizing the drugs’ anesthetic effects while minimizing the pain of administration and risk for toxicity.

Regional Anesthesia of the Head and Neck

Ryan M. Spangler and Michael K. Abraham

Emergency physicians encounter patients with dental pain, facial lacerations, and other injuries of the head on a regular basis. The assessment of these injuries can be both time consuming and painful. Thankfully, regional anesthesia for these conditions is easy to instill, reliable, and safe. Techniques such as nerve blocks can be used for patient comfort during repair of lacerations of the face, ear, forehead, and, particularly, the lips. A block avoids direct infiltration into the actual laceration, which preserves the anatomy in these delicate areas and thus allows better cosmetic repair.

Nerve blocks can also be used to give patients with dental pain almost immediate relief. They can be used to treat dentalgia caused by infection, fracture, or dry socket. They decrease the need for narcotic drugs. The ability of an emergency physician to master these blocks leads to fast and efficient patient care as well as improved patient satisfaction (Table 30.1).

ANATOMY OF THE TRIGEMINAL NERVE (CRANIAL NERVE V)

Sensation to the face and head region is supplied primarily by cranial nerve V (CN V), which is also known as the trigeminal

nerve, due to its three large branches: V1, the ophthalmic nerve; V2, the maxillary nerve; and V3, the mandibular nerve (Fig. 30.1A). This is the largest of the 12 cranial nerves, originating at the upper portion of the pons. CN V contains motor neural fibers that control the muscles of mastication. This chapter focuses on its sensory function (see Fig. 30.1B).

The ophthalmic nerve, V1, courses through the cavernous sinus and exits through the supraorbital fissure. It then gives off three branches: the frontal, lacrimal, and nasociliary (see Fig. 30.1C). These nerves and their branches innervate the eye, orbit, forehead, and portions of the nose.¹

The maxillary nerve, V2, exits through the foramen rotundum and gives off several branches, including the infraorbital nerve and the posterior, middle, and anterior superior alveolar nerves (see Fig. 30.1C). These nerves innervate the face, lip, maxillary teeth, and mucosa.¹

The mandibular nerve, V3, exits through the foramen ovale into the infratemporal fossa. It then splits into many branches that supply the dura and muscles of mastication (motor function), as well as the buccal branch and the auriculotemporal, lingual, and inferior alveolar branches (see Fig. 30.1C). These branches supply sensation to the skin on the side of the head, the auricle of the ear, the tongue, the mucosa and skin of the cheek, the mandibular teeth, and the lower lip.¹

EQUIPMENT FOR FACIAL NERVE BLOCKS

The equipment needed to perform facial nerve blocks is very minimal, and should be available in any emergency department (ED) (Review Box 30.1). Medications include common anesthetics such as lidocaine or bupivacaine, with or without epinephrine. The practitioner should always be aware of the maximum doses of anesthetic agents being utilized, although most blocks will require much less than the maximum dosing. Standard 25- to

Regional Anesthesia of the Head and Neck

Indications

Anesthesia of the teeth for dental pain
Anesthesia of the soft tissues of the face

Contraindications

Lack of patient cooperation
Inability to perform the procedure without passing through an infected area
Anticoagulated patients (e.g., warfarin)

Complications

Local anesthetic toxicity if maximum amounts are exceeded
Failure to obtain anesthesia
Allergy to local anesthetic
Infection extending to the deep spaces of the head and neck because of injecting through an infected area
Hematoma
Failure to aspirate blood
Intravascular injection of epinephrine
Needle breakage (rare)
Needlestick of the operator

Equipment

Review Box 30.1 Regional anesthesia of the head and neck: indications, contraindications, complications, and equipment.

TABLE 30.1 Nerve Blocks and Indications

NERVED BLOCKED OR AREA INJECTED	AREA ANESTHETIZED
Supraperiosteal infiltration	Individual teeth
Posterior superior alveolar nerve	Second and third molars and partial anesthesia of first molar
Middle superior alveolar nerve	First and second premolars, as well as partial anesthesia of first molar
Anterior superior alveolar nerve	Central incisor to the canine
Infraorbital nerve	Midface region, skin of lateral nose, lower eyelid, and MSA and ASA regions
Inferior alveolar nerve	All ipsilateral mandibular teeth, lower lip, and chin
Mental nerve	Mucosa and skin of lower lip and chin
Scalp block	Skin of the scalp within the blocked area
Greater and lesser occipital nerve	Occipital region of the scalp
Ophthalmic nerve	Skin of the forehead and scalp (as far back as lambdoid suture), upper eyelid

ASA, Anterior superior alveolar; MSA, middle superior alveolar.

27-gauge needles are recommended. Using a smaller needle can lead to false-negative aspiration in the case of an arterial puncture. Some of the equipment listed in [Review Box 30.1](#) might not be necessary for all blocks, and some can be substituted. For instance, a tongue depressor is recommended for use as a retractor, but any other acceptable instrument or even a finger can be used for this purpose.

GENERAL RECOMMENDATIONS

Some general recommendations apply to nearly all types of blocks ([Fig. 30.2](#)). These procedures have very few contraindications. One of them involves infected tissue: the needle should never be inserted through infected tissue because this approach could result in inoculation of deep tissue with bacteria. In addition, patients with an allergy to the anesthetic agent should not undergo these procedures unless an alternative agent is available. Although not an absolute contraindication, coagulopathy might present a higher risk for hematoma and bleeding complications, so, as for any procedure, the risks should be considered and might outweigh the benefits.

When performing many of these blocks, inserting the needle with the bevel facing toward the bone allows the anesthetic to be injected as close to the nerve or bone as possible and

increases the likelihood that the procedure will be successful. During and after injection, particularly when working in areas near the lip, slight exterior pressure and massage not only help the anesthetic diffuse to its target but also help prevent ballooning of the lip or facial tissue. Finally, it is generally recommended that the full length of the needle should not be inserted into the mucosa when performing an intraoral injection, so that it can be retrieved if it breaks.

Application of a topical anesthetic before insertion of the needle is not a necessary step prior to inducing any of the intraoral blocks, but it can increase patient comfort ([Fig. 30.3](#)). To apply a topical anesthetic, first dry the tissue with gauze and then apply a topical mucosal anesthetic, for instance, viscous lidocaine. Another technique is to soak a piece of gauze with the anesthetic and then place it over the dry mucosa. Spray anesthetics such as cetacaine are popular and effective alternatives to lidocaine-soaked gauze.

Supraperiosteal Injection

Indication

Supraperiosteal injection is generally used to achieve anesthesia of individual maxillary teeth, but it can be used for any tooth. This block works well if the anesthesia is needed for only one or two teeth, and it can be very helpful to alleviate pain associated with a simple toothache. As noted previously, care should be taken to avoid inserting the needle through any infected tissue.

Anatomy

The nerves for each individual tooth enter at the apex of that tooth and are protected by the bone supporting the tooth. Supraperiosteal injection is designed to anesthetize a single tooth ([Fig. 30.4A](#)).

Approach

Begin by applying a topical anesthetic, as previously described. Once the anesthetic has had time to take effect, retract the lip until the tissues are taut (down and out for maxillary teeth and up and out for mandibular teeth). Insert the needle at the mucobuccal fold, with the bevel facing the tooth. The needle needs to be inserted only a few millimeters (see [Fig. 30.4B](#)). Intraarterial injection is unlikely in this block, but you should aspirate prior to slowly injecting 1 or 2 mL of anesthetic. Apply slight pressure and massage as previously discussed. Because the anesthetic needs to penetrate the bone, a few minutes are needed for anesthesia to occur.

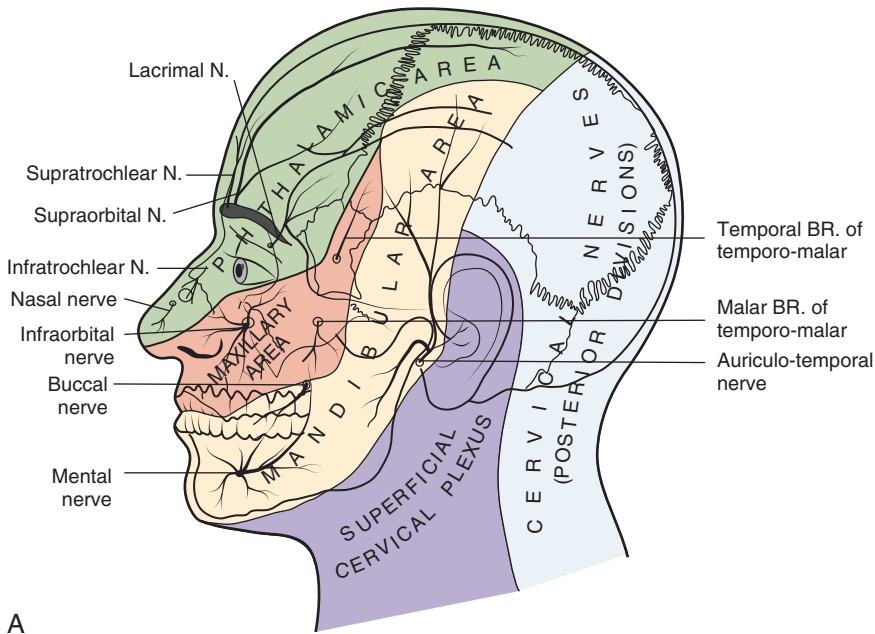

Complications

Complications with this injection are very rare. The risk of inoculating deeper tissues with bacteria is possible if the injection goes through infected tissue. Anesthesia can fail if the injection is too high, too low, or too far away from the nerve.

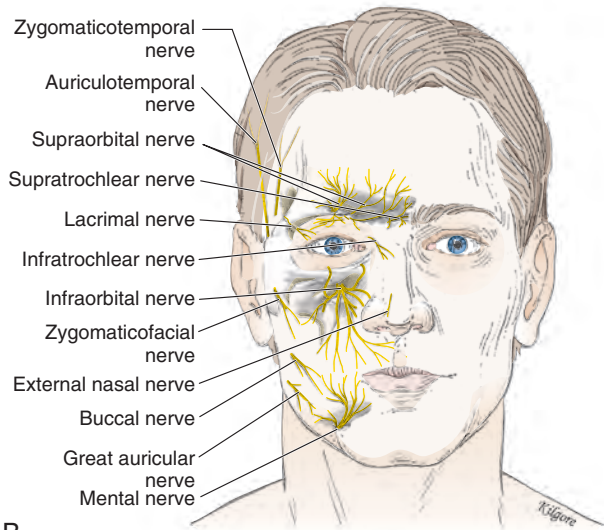

Posterior Superior Alveolar Nerve Block

Indication

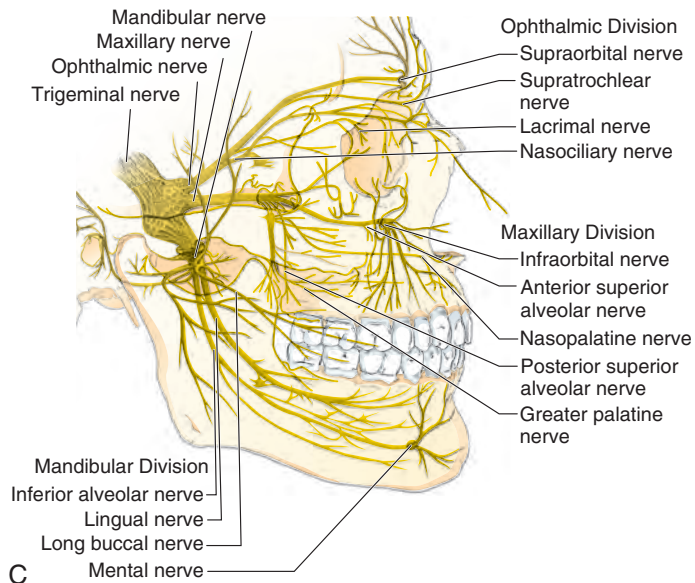

The posterior superior alveolar nerve (PSAN) block can be used to provide anesthesia for the first through the third maxillary molars. However, it is likely that only partial anesthesia of the first molar will be achieved due to its innervation with accessory nerves, particularly at the mesiobuccal root of this molar.

Head and Neck Regional Anesthesia: General Technique

1 Confirm relevant local anatomy (in this example, the infraorbital nerve block is depicted).

2 Retract the lip and dry the mucous membranes with gauze or a cotton pledget.

3 Apply a topical anesthetic, such as Benzo-Jel, on a cotton-tipped applicator (shown here), or use Hurracaine spray (not depicted).

4 Insert the needle, aspirate the syringe to exclude intravascular placement, and then inject the appropriate amount of local anesthetic (usually about 2 mL).

Figure 30.2 Head and neck regional anesthesia: general technique depicting the infraorbital nerve block.

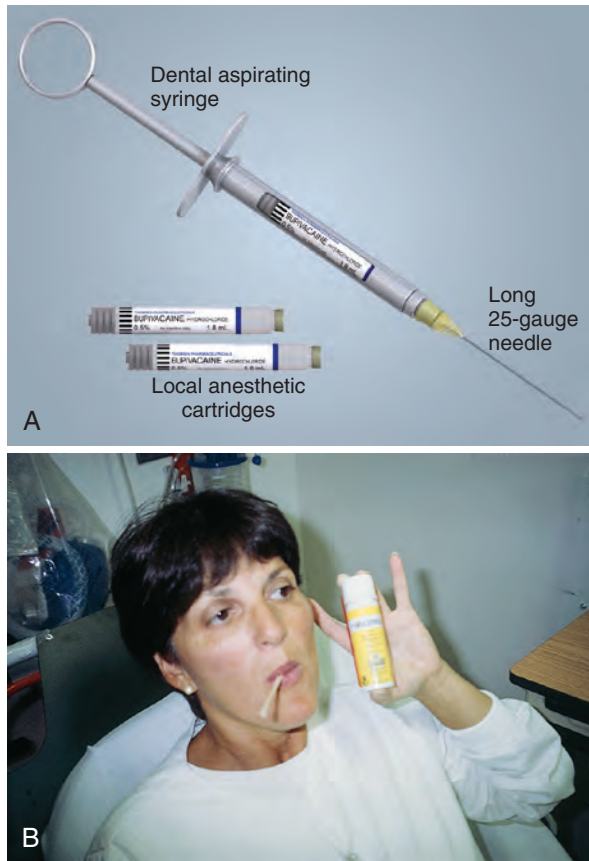

Figure 30.3 A, Local anesthesia: basic setup for intraoral application using an aspirating dental syringe. B, Topical mucosal anesthesia can make the injection nearly painless. Swab the gauze-dried mucosa with the topical agent or have the patient hold cotton swabs soaked in the agent, and wait for 1 to 3 minutes.

Anatomy

The PSAN branches from the maxillary branch of the trigeminal nerve and travels inferiorly just before the maxillary nerve enters the infraorbital groove. The nerve descends along the posterior lateral portion of the maxillary tuberosity and gives off branches to the second, third, and partially the first maxillary molars (Fig. 30.5A).

Approach

Two techniques for creating a PSAN block have been well described in the literature. The traditional method begins similar to the other blocks, that is, by applying a topical anesthetic to the mucosa. The insertion point for the needle is just distal to the root of the second molar, at the height of the mucobuccal fold (see Fig. 30.5B). For this block, because of the posterior and medial location of the nerve complex, insert the needle in an upward, inward, and posterior direction (toward the maxillary tuberosity), approximately 45 degrees in each direction.² Ultimately, the needle should be inserted approximately 15 mm and certainly no more than 25 mm. The operator should not feel any resistance while inserting the needle and should not encounter bone. If resistance or bone is felt, withdraw the needle nearly and then redirect it. Once the appropriate depth is reached, aspirate and, if negative, slowly inject 1 to 3 mL of anesthetic.

The second technique involves a curved 24-mm needle, to approach the posterior maxillary surface. Again, anesthetize the mucosa with a topical anesthetic. The insertion point for the needle is more posterior than the traditional approach, just distal to the third molar, at the corner of the posterior lateral portion of the maxilla and directed along the posterior maxilla. Insert the needle 10 to 12 mm from the initial insertion point along the posterior wall of the maxilla, and orient it just slightly medially. After aspirating, inject 1 to 3 mL of lidocaine.³

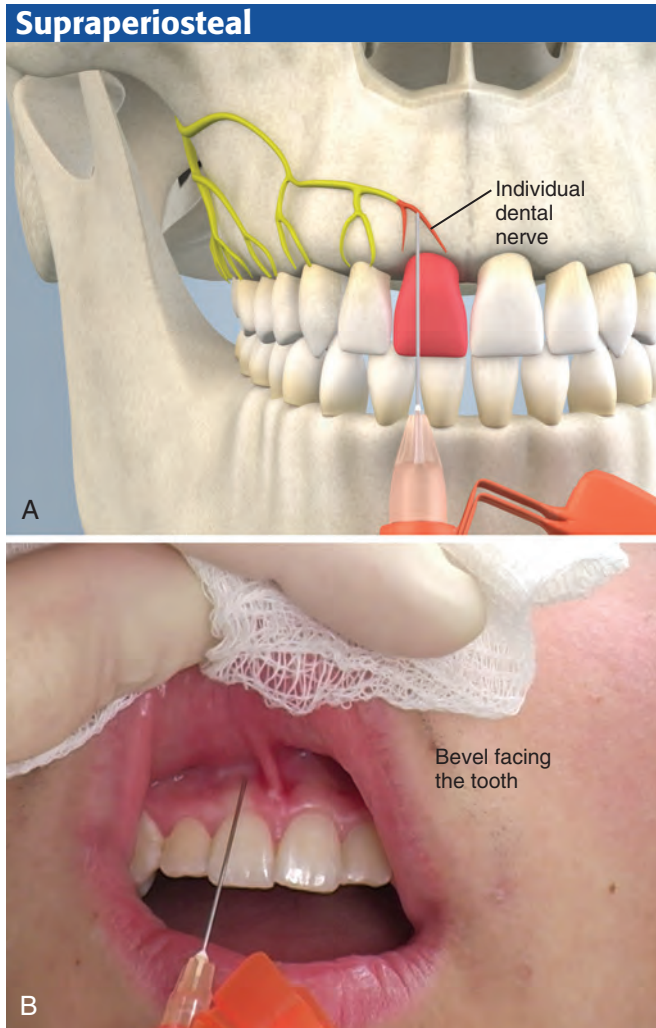

Figure 30.4 Supraperiosteal nerve block for anesthesia of an individual anterior tooth. **A**, Anatomy and distribution. **B**, Technique for supraperiosteal injection. Anesthetic should be deposited next to the periosteum, with the bevel of the needle facing the bone.

In a study of 200 patients undergoing extraction of the second and third molars, Thangavelu and colleagues achieved successful anesthesia with the curved needle technique in all cases at 10 minutes, with no complications.³ In contrast, after a randomized, controlled comparison of the straight-needle and bent-needle techniques, Singla and Alexander concluded that use of a straight needle was more successful in achieving anesthesia.²

Complications

Diplopia and a presentation resembling Horner syndrome (ptosis, enophthalmos, miosis), thought to be caused by diffusion of the anesthetic superiorly and medially to the orbital nerves, were reported in a case series.⁴ Isolated fourth cranial nerve (trochlear) palsy has also been reported and seems to be very rare.⁵ All these complications were temporary. Visual disturbances are uncomfortable and disturbing for patients but do not appear to be permanent.

The pterygoid plexus can be damaged by a needle that is too long; therefore the use of shorter needles is recommended.

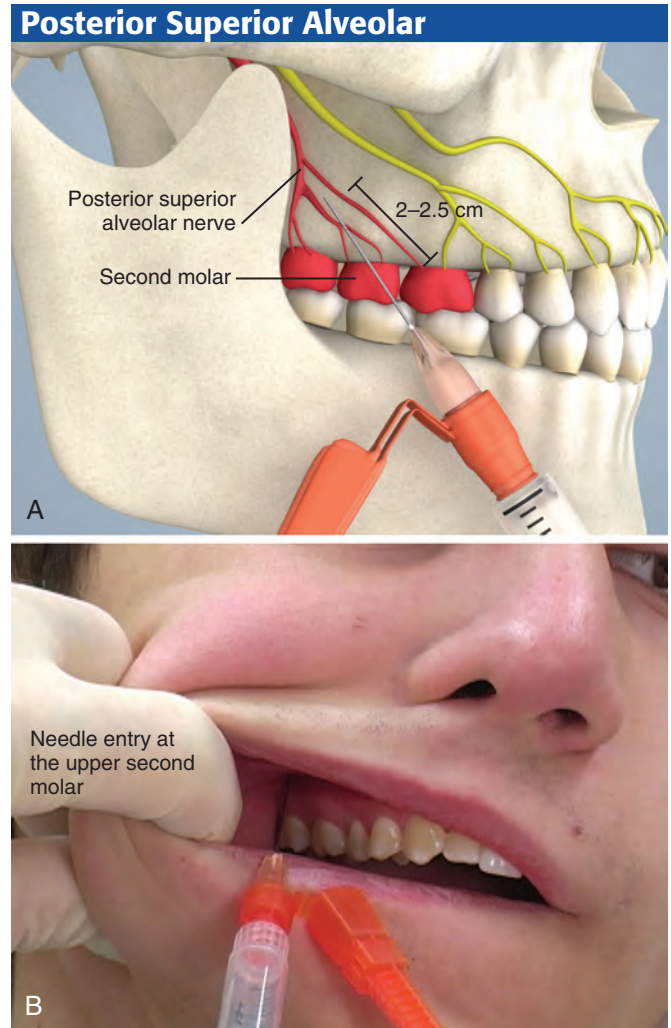

Figure 30.5 Posterior superior alveolar nerve block for anesthesia of the upper posterior molars. **A**, Anatomy and distribution. **B**, Technique. Insert the needle at the upper second molar and direct it upward, inward, and backward to the maxillary tuberosity, 15–25 mm.

Based on a literature review, Singla and Alexander recommended insertion to approximately 15 mm; however, this is lower than many recommendations and up to 25 mm, no deeper, may be required. The further the needle is inserted, the greater the risk of complications.²

Middle Superior Alveolar Nerve Block

Indication

The middle superior alveolar nerve (MSAN) block can be used to anesthetize the lateral upper lip and the first and second premolars simultaneously, as well as the mesiobuccal root of the first molar. This technique can be especially useful if the lateral lip is not anesthetized by an infraorbital nerve block.

Anatomy

The MSAN descends posteriorly to anteriorly along the lateral maxillary wall as an extension of the maxillary nerve. The landmark needed for this procedure is the junction between the first molar and the second premolar (Fig. 30.6A). A subset

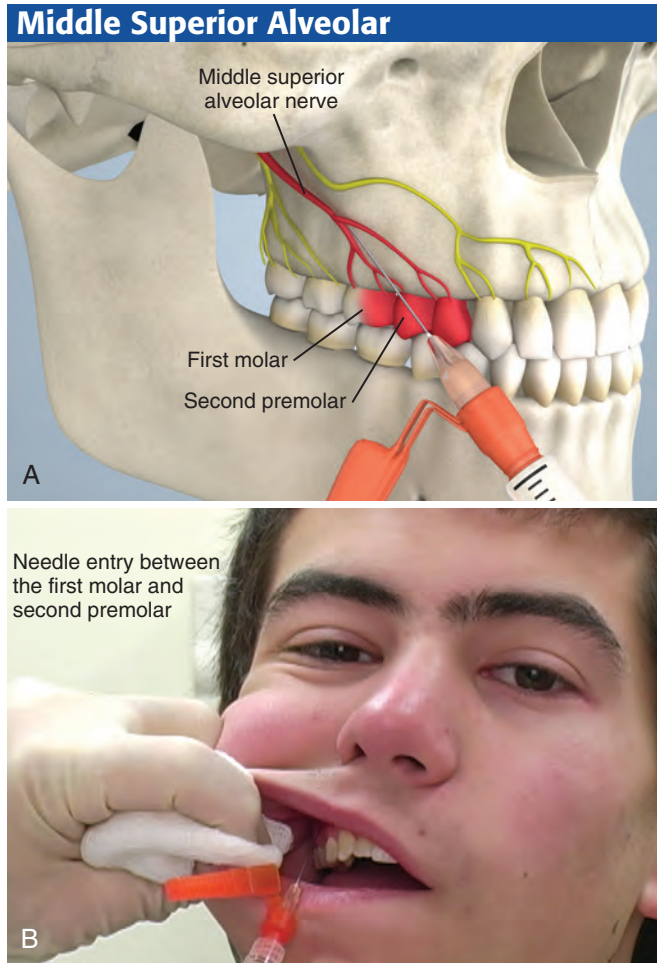

Figure 30.6 Middle superior alveolar nerve block for anesthesia of the upper middle teeth. **A**, Anatomy and distribution. **B**, Technique. Insert the needle between the second premolar and the first molar, directing it at a 45-degree angle. For an alternative similar nerve block, see [Fig. 30.8](#).

of patients have an anatomic variant in which the MSAN does not exist.¹

Approach

Begin as you would for any of the other intraoral block procedures, by applying topical anesthetic. Retract the upper lip and pull the tissues taut. Direct the needle toward the intersection of the first molar and the second premolar at the mucobuccal fold, and insert it 5 to 10 mm at a 45-degree angle posteriorly, with the bevel facing the bone, in an effort to place as much anesthetic near the nerve as possible (see [Fig. 30.6B](#)). Slowly inject 1 to 3 mL of anesthetic while massaging the tissue.

Complications

Complications of this procedure are few: they are the same complications inherent to all procedures, such as bleeding. Because this is an area with low vascularity, hematoma formation and arterial aspiration are rare. For patients with the anatomic variation of absence of the MSAN, this block will obviously fail, so an infraorbital nerve block, an anterior superior alveolar

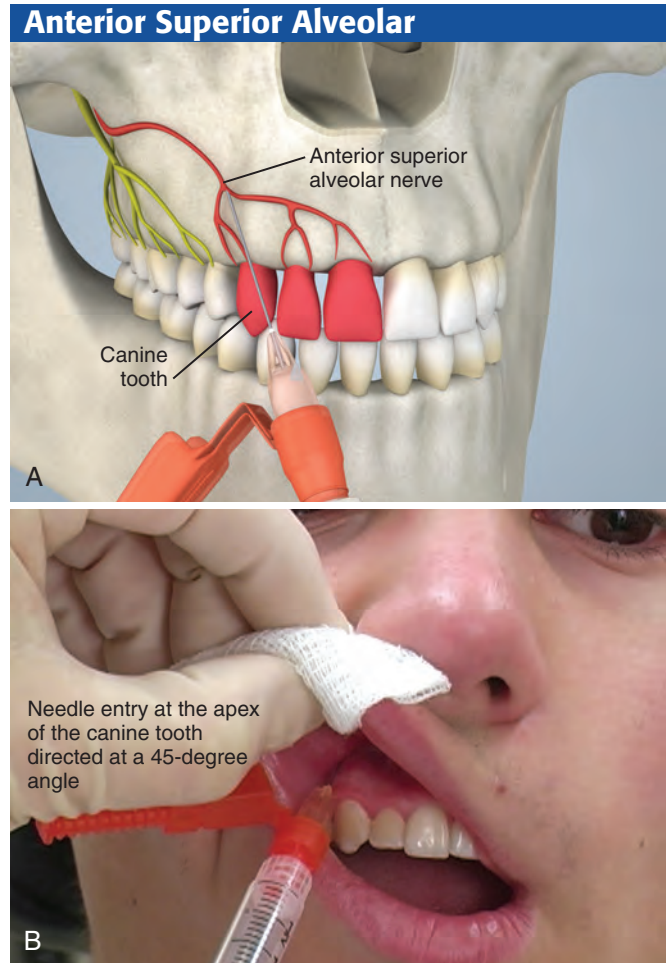

Figure 30.7 Anterior superior alveolar nerve block for anesthesia of the front teeth. **A**, Anatomy and distribution. **B**, Technique. Insert the needle at the apex of a canine tooth and direct it at a 45-degree angle.

nerve (ASAN) block, or a PSAN block will be necessary, depending on the region needing anesthesia.

Anterior Superior Alveolar Nerve Block

Indication

Depending on the area of injury or pain, multiple areas of the maxilla might require anesthesia. If anesthesia from the central incisor to the canine is required, the ASAN can be blocked.

Anatomy

The ASAN is a distal branch from the infraorbital nerve. As the infraorbital nerve travels down the anterior maxilla, it gives off the ASAN, which travels to innervate the area from the central incisors to the canine of the ipsilateral side. The landmark needed is the apex of the canine ([Fig. 30.7A](#)).

Technique

Begin by applying a topical anesthetic, as for the blocks described previously. Then, at the height of the mucosal reflection toward the apex of the canine, insert the needle at a 45-degree angle, to a depth of 5 mm (see [Fig. 30.7B](#)). Inject 1 to 2 mL of anesthetic slowly.

Complications

Complications associated with this procedure are rare, unless the needle is inserted too far. The infraorbital nerve could be blocked, depending on the final depth of the needle. The block could be unsuccessful if the needle insertion is too superficial for the anesthetic to reach the nerve.

Anterior Middle Superior Alveolar Block

Indications

This approach is indicated when anesthesia is needed from the central incisor to the bicuspid. It can be used for greater palatine anesthesia as well as nasopalatine, anterior superior alveolar (ASA), and middle superior alveolar (MSA) nerve coverage, with the goal of avoiding multiple injections and avoiding anesthetizing the lip unnecessarily by incidental infiltration of anesthetic into the surrounding soft tissue.

This block uses the palatal nutrient pores to distribute anesthesia through the palate to the ASA and the MSA simultaneously. Small pores in the palate allow diffusion of the anesthetic after injection into the palate.

Approach

All the blocks described earlier in this chapter began on the buccal surfaces to anesthetize the maxillary teeth. The injection for the anterior middle superior alveolar block is placed through the hard palate at the intersection of an imaginary line dividing the premolars at a point halfway between the midpalatine crest and the free gingival margin (Fig. 30.8).⁶ The anesthetic must be injected very slowly—no faster than 0.5 mL/min for 4 to 5 minutes—to avoid pain and discomfort and to allow diffusion. Lee and colleagues found that computer-assisted delivery of the anesthetic was more successful than the traditional clinician-controlled approach, due to the slow pace that is necessary.⁷

Complications

Few complications are associated with this injection because of low vascularity in the area involved. The main challenges

Figure 30.8 For the anterior middle superior alveolar nerve block, inject anesthetic through the hard palate at the intersection of an imaginary line dividing the premolars at a point halfway between the midpalatine crest and the free gingival margin (arrow).

presented by this approach are pain, the time needed for the injection, and the time until the block takes effect. As noted previously, Lee and colleagues had greater success with computer-assisted delivery of the anesthetic (which is not available in most EDs) than with administration by a clinician, but failure rates were still high for both techniques, suggesting that this block is not reliable for inducing anesthesia.⁷

Infraorbital Nerve Block

Indications

The ability to induce an infraorbital nerve block is a necessary skill for an emergency medicine provider. This block can be achieved with an intraoral or extraoral approach. It anesthetizes the midface from the lateral upper lip to the lower eyelid, including the nasal skin but not the mucosa (Fig. 30.9A). This block is helpful in wound care and abscess drainage.

Anatomy

The infraorbital nerve is the terminal branch of the mandibular branch of the trigeminal nerve. The second division exits the cranium from the foramen rotundum and ultimately enters the face through the infraorbital canal. The infraorbital foramen is located on the inferior border of the infraorbital ridge on a vertical (sagittal) line with the pupil when the patient stares straight ahead (see Fig. 30.9B). The middle and superior alveolar nerves are also in close proximity to the main trunk of the infraorbital nerve near the foramen.

Intraoral Approach

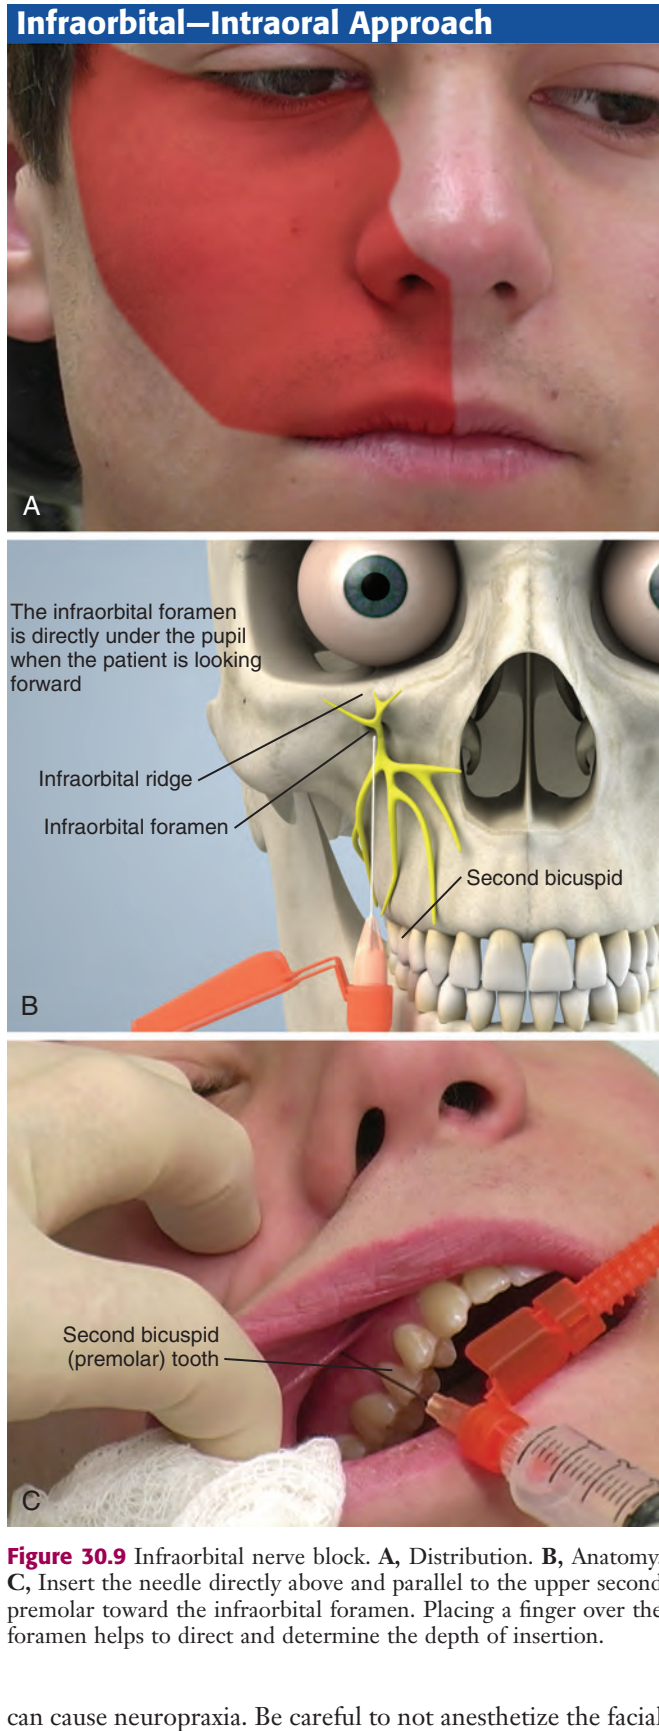

Due to the location of the foramen, an intraoral approach is preferred. Provide local anesthetic to the buccal and gingival mucosa, as previously described. Place one finger extraorally on the foramen. This has two purposes: it gives the practitioner a tangible feeling of the needle, and the pressure will help direct the deposited anesthetic from pushing upward into the lower eyelid. Retract the cheek and enter the mucosa above the second premolar. Aim the needle toward the infraorbital foramen, approximately 2 cm from the mucosal surface, taking care not to enter the foramen (see Fig. 30.9C). Once the needle is in the proper position, inject 2 to 3 mL of anesthetic and gently massage the tissue overlying the area to promote distribution of the anesthetic. The alternative method is to perform a field block, which is less precise and anesthetizes a larger area. This technique can be used if the patient has no palpable landmarks or if a wider area of anesthesia is necessary.

Extraoral Approach

The infraorbital foramen can also be approached from an extraoral route (Fig. 30.10). This approach requires external preparation of the skin. Use the same landmarks as those used to locate the infraorbital foramen as described in the intraoral approach. The needle can be felt as it passes through the skin, the subcutaneous tissue, and the quadratus labii superioris muscle. After injection, firmly massage the infiltrated tissue for 10 to 15 seconds. It is usually visibly swollen. Place a finger under the eye to limit edema.

Complications

If the needle is angled posteriorly, it might enter and anesthetize the orbit. The risk of such positioning can be limited by placing the finger on the foramen and palpating the needle below the orbital rim. Injection into, as opposed to near, the foramen

can cause neuropraxia. Be careful to not anesthetize the facial artery and vein, which could lie on either side of the nerve. Do not use epinephrine, as its injection would cause vasoconstriction of the facial artery. If severe blanching occurs, apply warm compresses to the patient's face immediately.

Figure 30.10 Infraorbital nerve block, external approach. While injecting, place a finger under the eyelid to minimize lid swelling.

Inferior Alveolar Nerve Block

Regional anesthesia of the inferior alveolar nerve (IAN) should be in every emergency provider's armamentarium. Dental complaints have been the cause of an increasing number of ED visits. If the pain or an injury involves the mandibular teeth or the lower lip and chin, the IAN block will be a useful tool. Examples of its application are for facial or dental trauma, dry socket, periapical abscess, and pericoronitis. The IAN block provides anesthesia to all the teeth on that side of the mandible and desensitizes the lower lip and chin via blockade of the mental nerve. The IAN can be anesthetized using the classic approach, the Gow-Gates technique, or Akinosi-Vazirani methods.

Anatomy

The IAN is the largest of the branches of the mandibular nerve (V3). It provides sensation to all the lower teeth and lip; the central incisors, lateral incisors, and the buccal aspect of the molar teeth may also receive sensory innervation. The nerve descends, covered by the external pterygoid muscle, and passes between the ramus of the mandible and the sphenomandibular ligament to enter the mandibular canal. It is accompanied by the inferior alveolar artery and vein, proceeds along the mandibular canal, and innervates the teeth. At the mental foramen, the nerve bifurcates into an incisive branch, which continues forward to supply the anterior teeth. It gives off a side branch, the mental nerve, which exits from the mental foramen to supply the skin.

Approach

The patient can be seated either in a chair or upright with the head firmly against the back of the stretcher, so that when the mouth is opened, the body of the mandible is parallel to the floor. The easiest approach for the provider is with the patient seated or slightly reclined. Depending on the practitioner's handedness and comfort level, the best approach is to be positioned on the contralateral, or opposite, side of the nerve you are trying to block, as this will give better visual access to the targeted area. The best approach to regional

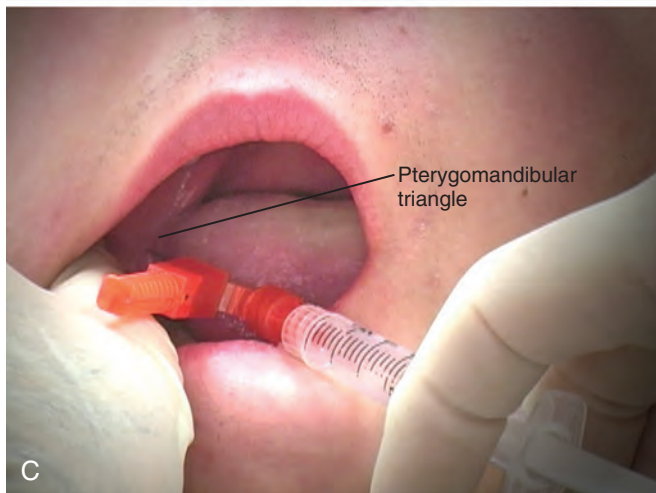

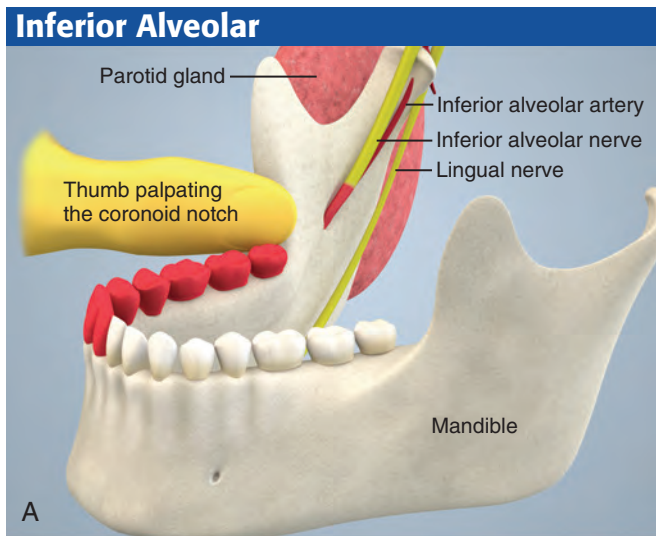

Figure 30.11 Inferior alveolar nerve block for anesthesia of all the lower teeth on one side. **A**, Anatomy and distribution. Identify the anterior border of the mandibular ramus (coronoid notch) with the thumb. **B**, Approach. **C**, Technique. Also see [Fig. 30.12](#).

anesthesia is to use a topical anesthetic over the approach area to increase patient compliance. Place a gauze pad soaked with topical lidocaine in the area of the IAN while preparing the rest of the supplies, or use a cotton swab with viscous lidocaine. Despite the use of topical anesthesia, be ready for an unexpected

Figure 30.12 To compensate for difficulty in obtaining the correct approach with a straight needle for the inferior alveolar nerve block, bend a 25-gauge, 1½-inch needle with the needle guard.

quick jerk of the head when an anxious patient first feels the needle.

To begin the technique, palpate the retromolar fossa with the index finger or thumb. With this maneuver, the greatest depth of the anterior border of the ramus of the mandible (the coronoid notch) can be identified ([Fig. 30.11A](#)). With your thumb in the patient's mouth, resting in the retromolar fossa, and your index finger placed externally behind the ramus at the same height as the thumb, retract the tissues toward the buccal (cheek) side, and then visually locate the pterygomandibular triangle (see [Fig. 30.11C](#)). This technique also moves your finger safely away from the tip of the needle.

When topical anesthesia has been achieved, hold the syringe parallel to the occlusal surfaces of the teeth, angled so that its barrel lies between the first and second premolars on the opposite side of the mandible (see [Fig. 30.11B](#)). Failing to achieve the required angle is the most common reason for failure of this nerve block. If a large-barrel syringe is used, the corner of the mouth might hamper efforts to obtain the proper angle; therefore a 5- or 10-mL syringe with a 25-gauge needle should be sufficient. If you have difficulty achieving the necessary angle, you can carefully bend the 25-gauge needle approximately 30 degrees ([Fig. 30.12](#)). This modification presents the risk of needle fracture and its inherent risks; an alternative is to use one of the other blocks described in the following sections. Puncture inside the pterygomandibular triangle at a point 1 cm above the occlusal surface of the molars. If the needle enters too low (e.g., at the level of the teeth), the anesthetic will be deposited over the bony canal and prominence (lingula) that house the mandibular nerve and not over the nerve itself.

The needle can be felt as it passes through the ligaments and the muscles covering the internal surface of the mandible. Stop when the needle has reached bone, which signifies contact with the posterior wall of the mandibular sulcus. You must feel bone with the needle. Failure to do so generally results from directing the needle toward the parotid gland (too far posteriorly) rather than toward the inner aspect of the mandible, which will anesthetize portions of the facial nerve. Withdraw the needle slightly and aspirate. Deposit approximately 1 to 2 mL of the anesthetic. Three to 4 mL could be required if

the needle position is suboptimal. In children, the angulation is not parallel to the occlusal surfaces of the teeth, so the barrel of the syringe should be held slightly higher because the mandibular foramen is lower.

One of the benefits of an IAN block is its ability to affect the other nerves in relative proximity. For example, one can anesthetize the lingual nerve, which innervates the anterior two thirds of the tongue, by placing several drops of anesthetic solution in that area while slowly withdrawing the syringe and needle. This technique consistently blocks the lingual nerve because of the proximity of the two nerves. The area that is anesthetized can also be extended by blocking the long buccal nerve by injecting 0.5 cc of anesthetic just distal and buccal to the last mandibular molar. Supplementing the IAN block with both lingual and buccal nerve blocks helps anesthetize any aberrant fibers that are innervating the teeth. Shortly after a successful injection, the patient will report tingling in the lower lip; however, 3 to 5 minutes is usually required to achieve complete anesthesia.

Complications

This nerve block reportedly has a 15% to 20% failure rate. As with any block, the complications are mainly related to deposition of the anesthetic in inadvertent areas; for the IAN block, misplacement most commonly affects the parotid gland, anesthetizing the facial nerve. This is a relatively benign complication that causes temporary facial paralysis (similar to Bell's palsy). It affects the orbicularis oculi muscle, making the patient unable to close the eyelid. Should this occur, protect the eye with an eye patch or tape until the local anesthetic has worn off (2 to 3 hours for 1% lidocaine). The duration of this complication is elongated to 3 to 6 hours if anesthesia is induced with bupivacaine (perhaps longer if it is used in combination with epinephrine).

Gow-Gates Block

Because the IAN block is frequently unsuccessful, other techniques have been developed to facilitate anesthesia in this region. The Gow-Gates and Akinosi-Vazirani techniques for regional anesthesia can augment or replace the IAN block. Introduced in the 1970s, the Gow-Gates mandibular block is an acceptable technique for achieving mandibular anesthesia, especially if traditional approaches fail (Fig. 30.13A).⁸ It involves the deposition of anesthetic at the lateral aspect of the anterior condylar head, in an attempt to anesthetize the trunk of the mandibular branch of the trigeminal nerve as it exits the foramen ovale (see Fig. 30.13B).

Approach

The key to this technique is patient compliance because the patient has to be able to open his or her mouth wide enough to allow the angle of approach that is necessary to achieve this block (see Fig. 30.13C). The optimal plane is parallel to an imaginary line drawn from the corner of the mouth to the intratragal notch. This is different from the plane used with the classic IAN block. Place a finger inferior to the tragus of the ear as the landmark for the lateral aspect of the anterior condyle (which is now sitting at the eminence). Insert the needle opposite the second molar with the barrel of the syringe between the opposite lower premolars and the corner of the mouth (similar to the inferior alveolar approach). With this plane maintained, advance the needle until it reaches the

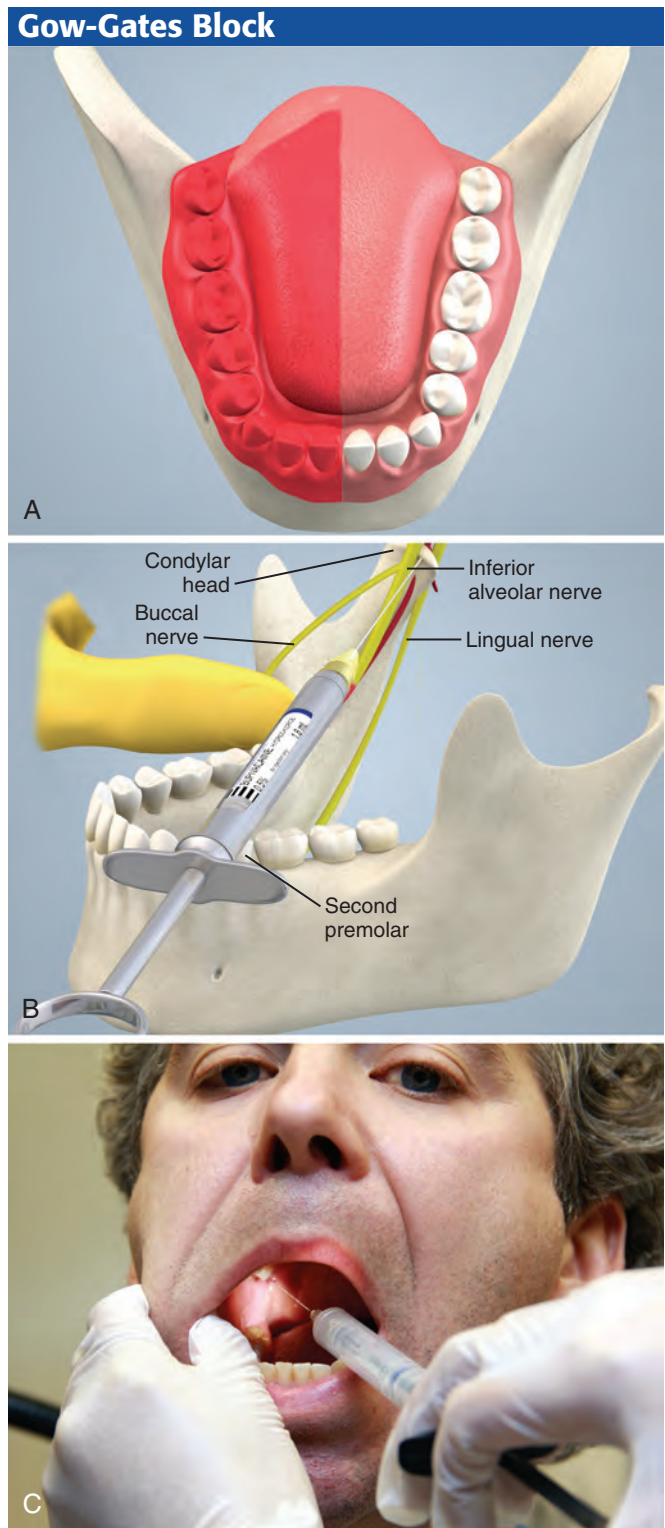

Figure 30.13 Gow-Gates block. **A**, Distribution. **B**, Anatomy and approach. Angle the needle from the opposite premolar toward the condylar head. **C**, Technique. Note the angle across and up toward the condylar head. Placing a finger at the condylar head can help to identify landmarks. (Adapted from Norton NS: Mandibular injections. In *Netter's head and neck anatomy for dentistry*, Philadelphia, 2007, WB Saunders, 2007 Elsevier Inc, pp 572–574.)

condylar neck. The goal is to head below the insertion of the lateral pterygoid muscle, and it uses extraoral landmarks (tragus of the ear and corner of the mouth).⁹ Withdraw the needle, aspirate, and inject 1 to 2 mL of anesthetic.^{8,9}

Complications

The positive vascular aspiration rate with the Gow-Gates procedure is reported to be 1.6%, compared with 3.5% to 22% for the conventional IAN block technique.⁶ If the needle is directed more toward the medial aspect of the anterior condylar process, it will be in the proximity of the pterygoid plexus of veins and the sympathetic plexus of the internal carotid artery. If the sympathetic plexus is anesthetized, the patient will experience a temporary version of Horner syndrome.

Akinosi-Vazirani Block

The Akinosi-Vazirani block can be used to anesthetize the IAN, including its mental and lingular nerve branches. A benefit of this block is that it can be performed when the patient's mouth is closed. This can be very helpful for the emergency physician because the condition necessitating the block can cause trismus, so opening the mouth wide enough for the classic or Gow-Gates techniques might not be possible.

Approach

With the patient's mouth closed, distract the buccal surface from the teeth, which will allow palpation of the bony landmarks. The main difference with this procedure and the IAN or Gow-Gates block centers on the fact that you do not want to hit bone with the needle; instead, you are aiming for the pterygomandibular space. The syringe should be positioned at the height of the gingival junction of the maxillary teeth and parallel to the occlusal surfaces of the teeth (Fig. 30.14). If bone is contacted, simply redirect the needle slightly toward the teeth, which should allow you to enter the desired space. The temporalis muscle is also in this area, and care should be taken to not inject the anesthetic into it.

Figure 30.14 General approach to the Akinosi-Vazirani nerve block technique.

Mental Nerve Block

The mental nerve block is an easy and useful form of regional anesthesia and should be considered for all lower lip laceration repairs, especially those involving the vermilion border (Fig. 30.15). The mental nerve can be blocked with a complete IAN block or alone where it exits the mental foramen. An intraoral or extraoral approach can be used. An isolated block of the mental nerve is achieved by infiltrating local anesthetic where the nerve exits its bony foramen on the mandibular surface.

Anatomy

The mental nerve is a continuation of the IAN and innervates the mucosa and skin of the lower lip on the ipsilateral side of the mandible, with limited crossover of midline fibers. The nerve emerges from the mental foramen below the second premolar (Fig. 30.16 A and B). Generally, the foramen will be just medial to the pupil of the eye (when the patient stares straight ahead) along a sagittal plane.

Approaches

Like the infraorbital nerve, the mental nerve block can be performed via an intraoral or extraoral approach. As the area being anesthetized is very sensitive and limiting scarring is a priority, the intraoral approach should be used when possible. Before using either approach, identify the mental foramen by palpation approximately 1 cm inferior and anterior to the second premolar. As with the IAN block, packing a gauze pad soaked in viscous lidocaine into the gingival sulcus while preparing the remainder of the supplies is a good way to ensure topical anesthesia. Approach the mental foramen at approximately a 45-degree angle with a 1.3-cm (½-inch), 25- or 27-gauge needle on a 3-mL syringe, and infiltrate the area adjacent to the foramen with 1 to 2 mL of local anesthetic (see Fig. 30.16C). Avoid inserting the needle into the mental nerve foramen because the injection of liquid into that site can produce neuropraxia. Infiltrate around the foramen to provide anesthesia of the lower lip and soft tissue of the chin. For lacerations over the midline of the lip, administer anesthetic over the mental foramina bilaterally. This practice anesthetizes the crossover fibers and will ensure midline anesthesia.

Figure 30.15 A mental nerve block is ideal for a complicated lower lip laceration, because it will not distort the local tissue or the vermilion border. See Fig. 30.16.

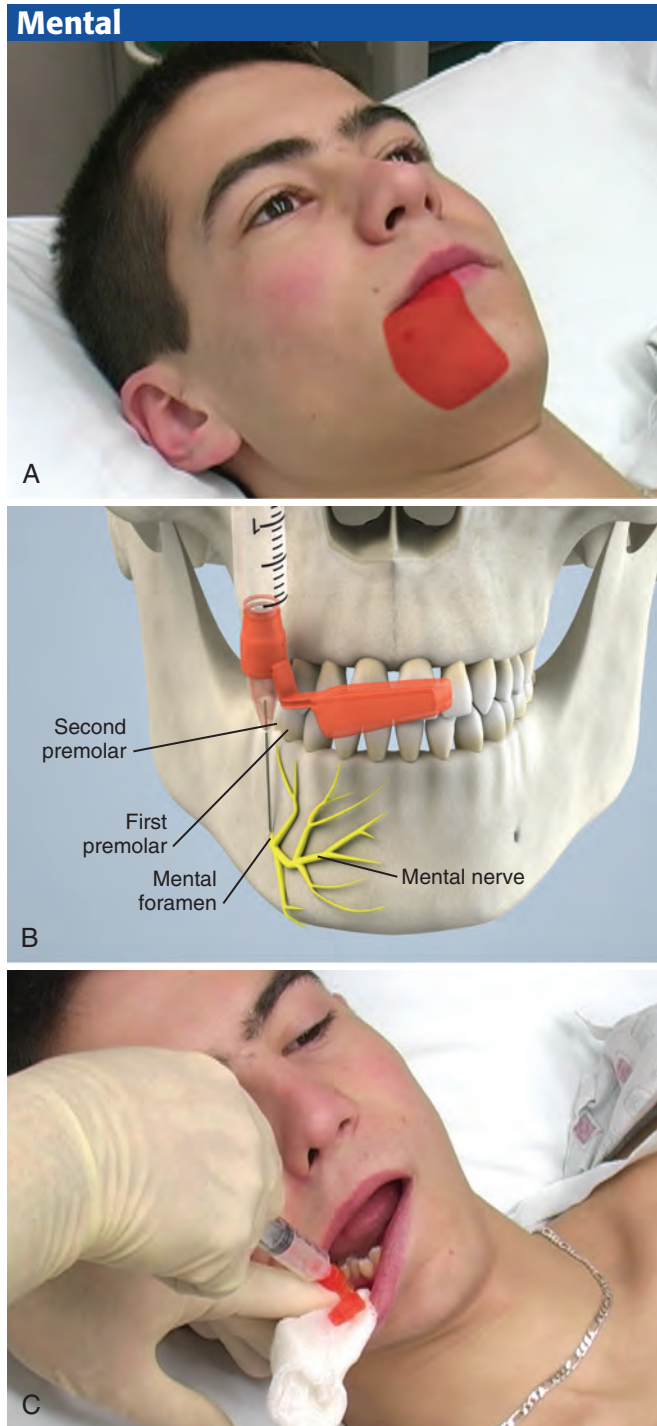

Figure 30.16 Mental nerve block. **A**, Distribution. **B**, Anatomy and approach. The mental foramen is found inferior to the second premolar. **C**, Technique. Insert the needle toward the mandibular foramen, inferior to the second premolar. Palpate the mental foramen with a finger, if necessary, to aid needle direction and depth, but keep the finger well away from the needle.

Complications

The main complication of the mental nerve block stems from damaging the mental nerve where it exits the foramen, by direct needle trauma or pressure from the injection, causing neuropraxia.

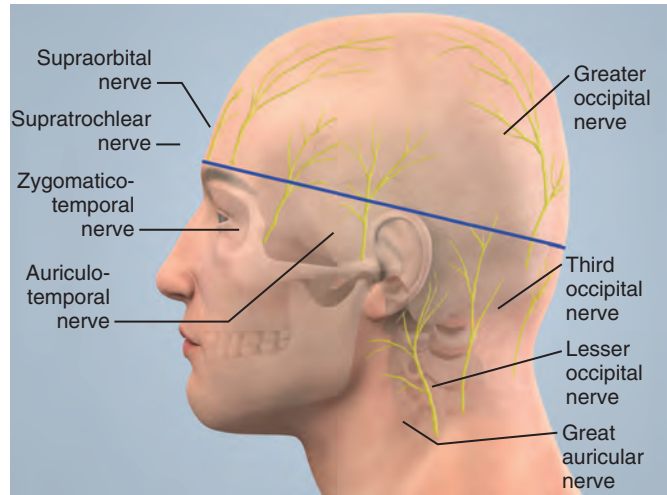

Figure 30.17 Origin of the sensory nerve supply to the scalp. Nerves above the *blue line* become superficial and converge toward the vertex of the scalp.

Figure 30.18 Topographic anatomy of the scalp. Generously infiltrating this area in a fanlike motion will block multiple sensory nerves.

Scalp Anesthesia

Scalp blocks provide surgical anesthesia for repair of lacerations, drainage of superficial abscesses, and exploration and débridement of wounds. In general, the larger nerves innervating the scalp are blocked best when they are induced near the exit of the nerve from the skull. This is because the nerves branch and spread superficially very quickly, so it becomes difficult to achieve regional anesthesia.

Anatomy

As shown in Fig. 30.17, the scalp receives its nerve supply from branches of the trigeminal nerve (CN V) and the cervical plexus. The forehead is supplied by the supraorbital and supratrochlear nerves, both of which are branches of the ophthalmic division of the trigeminal nerve. The temporal region receives its nerve supply from the zygomaticotemporal nerve (a V2 branch nerve) and the temporomandibular and auriculotemporal nerves (V3 branch nerves). The posterior aspect of the scalp is innervated by the great auricular and the greater, lesser, and least (third) occipital nerves. The nerves that supply the posterior aspect of the scalp originate from the cervical plexus.

Topographically, the nerves and vessels of the scalp are located in subcutaneous tissue above the epicranial aponeurosis (Fig. 30.18). From this level, they divide into small branches

that extend to the deeper layers (epicranium and periosteum).^{10,11} The scalp is a very vascular structure, so take care to provide hemostasis with vasoconstrictive agents while simultaneously monitoring the systemic effects of the chosen agents.

Approaches

A complete scalp block can be accomplished by individually blocking each nerve that supplies the scalp, but this approach is time-consuming, difficult, and rarely necessary. Because the nerves on the scalp are located superficially, especially above the eyebrows to the vertex of the skull, a local anesthetic can be used around the wound's edges in most cases. Injection of local anesthetic to deeper levels is necessary only if bone is to be removed. Injection of a local anesthetic only in the deeper layers without subcutaneous infiltration results in an unsuccessful block and a greater amount of bleeding during surgical intervention.

In preparation for the procedure, clip hair or use sterile petroleum gel to slick hair away from the injured area. Prepare the skin with an antiseptic solution, and raise a skin wheal at any point along the skin with a 1.3-cm ($\frac{1}{2}$ -inch), 25-gauge needle. Insert a 7.6-cm (3-inch), 22-gauge needle through the skin wheal and into the subcutaneous tissue. Advance it along the scalp circumferentially to surround the wound. Inject 0.5% to 1% lidocaine or 0.125% to 0.25% bupivacaine with epinephrine (1:200,000). Use epinephrine, unless there is a contraindication to it, to provide vasoconstriction and prevent excessive blood loss and absorption of local anesthetic. The total dose of the local anesthetic should not exceed the recommended dose for that particular agent. The first 10 to 15 minutes after the injection is the most critical period to monitor for local anesthetic toxicity.

Greater and Lesser Occipital Nerve Block

This relatively simple block may be useful in the ED for treating occipital neuralgia and tension headaches. For occipital neuritis, a long-acting corticosteroid such as methylprednisolone (20 to 40 mg) can be combined with a local anesthetic (see Chapter 52).

Anatomy

The posterior aspect of the head is supplied by the posterior rami of the cervical nerves. Two important branches of these nerves are the greater and lesser occipital nerves. The greater occipital nerve becomes superficial on each side at the inferior border of the obliquus capitis inferior muscle and runs superiorly toward the vertex over this muscle. The nerve is located medial to the occipital artery. The lesser occipital nerve is located approximately 2.5 to 3.5 cm lateral and 1 to 2 cm caudal to the greater occipital nerve (Fig. 30.19A).

Approach

It is not usually necessary to shave or clip the scalp before performing greater and lesser occipital nerve blocks. The greater occipital nerve is best blocked at the nuchal line, which extends from the middle of the external occipital protuberance to the mastoid process. The nuchal line is located between the insertion sites of the trapezius muscle and the semispinalis muscles. At this site, the greater occipital nerve is just medial to the occipital artery.

First, palpate the occipital artery. Next, attach a 3.8-cm, 23- to 25-gauge needle to a syringe containing 5 mL of local

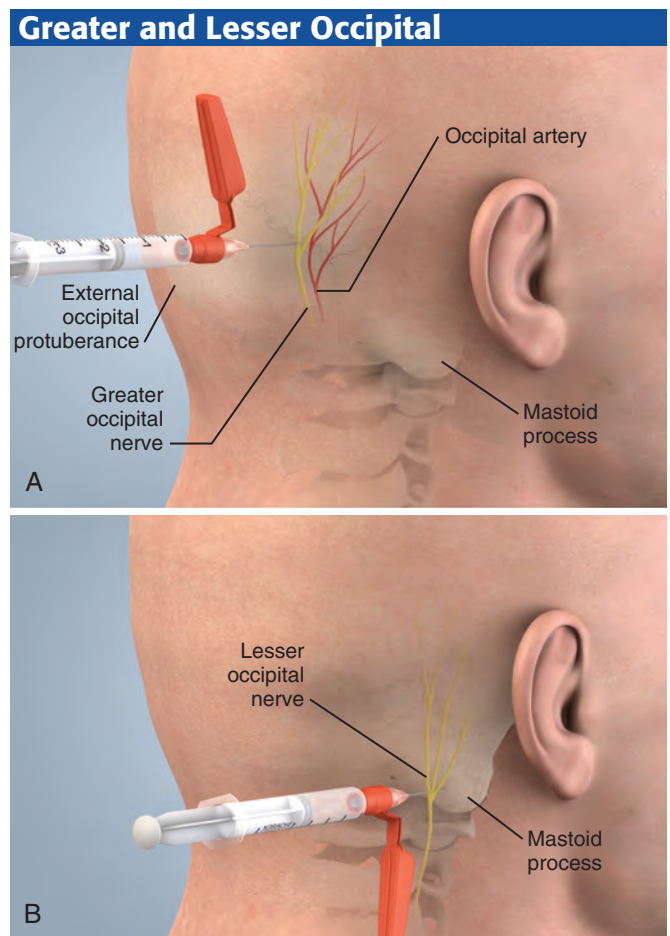

Figure 30.19 Occipital nerve blocks. **A**, Block the greater occipital nerve on a line 3 cm lateral to the external occipital protuberance and the base of the occipital bone. **B**, Block the lesser occipital nerve by injection of 2 to 3 mL of anesthetic solution along the posterior border of the mastoid process of the temporal bone.

anesthetic. Insert the needle into the skin (see Fig. 30.19B). After obtaining paresthesia at the vertex, inject 5 mL of local anesthetic solution. Block the lesser occipital nerve with a fanlike injection of a local anesthetic solution, 2.5 to 3.5 cm lateral and 1 cm caudal to the point described for the greater occipital nerve.

This procedure is not usually associated with any complications. Intraarterial injections can be avoided by careful aspiration.

Ophthalmic (V1) Nerve Block

The lateral and medial branches of the supraorbital, supra-trochlear, and infratrochlear nerves can be blocked by percutaneous local injection at the point where they emerge from the superior aspect of the orbit. Anesthesia of the forehead and scalp is achieved as far posteriorly as the lambdoid suture. This block can be used for débridement or topical treatment of burns or abrasions and for delicate lacerations of the upper eyelid. It is also ideal for removing small pieces of glass embedded in the forehead from a windshield injury (Fig. 30.20). Although this block is used infrequently, it is easily performed and not associated with serious side effects. It should be

Figure 30.20 An ophthalmic (V1) nerve block (supraorbital and supratrochlear nerves) would be ideal for this patient with extensive forehead and upper eyelid lacerations from a windshield injury, and for exploration for foreign bodies. Additionally, an infraorbital (V2) block could be used to provide anesthesia for repair of the maxillary laceration.

considered when anesthesia of the forehead or the anterior aspect of the scalp is desired.

Anatomy

The subtle supraorbital notch, which is in line with the pupil (when the patient is staring straight ahead), can be palpated along the superior orbital rim (Fig. 30.21B). This landmark is the site of injection for blockade of the supraorbital nerves. The supratrochlear nerve is found 0.5 to 1.0 cm medial to the notch. This nerve innervates the midline and should be blocked bilaterally for wounds or procedures that require midline anesthesia. The infratrochlear nerve is not usually blocked but is found in the most medial aspect of the superior orbital rim.

Approach

With the patient in the supine position, hold a finger or a roll of gauze firmly under the orbital rim to avoid ballooning of anesthetic into the upper eyelid and raise a skin wheal over the lateral border of the upper orbital ridge. This should be approximately 0.5 cm from the supraorbital notch. Extend a 3.8-cm, 23- to 25-gauge needle attached to a syringe containing 5 mL of local anesthetic. Inject 1 to 3 mL of anesthetic in the area medial to the supraorbital notch (see Fig. 30.21C), and continue to withdraw the needle. Place another 1 to 2 mL of anesthetic in the area of the supraorbital notch as well. This effectively places a line of anesthetic solution along the orbital rim laterally to medially to ensure a block of all the branches of the ophthalmic nerve. Paresthesia in the form of an electric shock sensation over the forehead indicates a successful block.

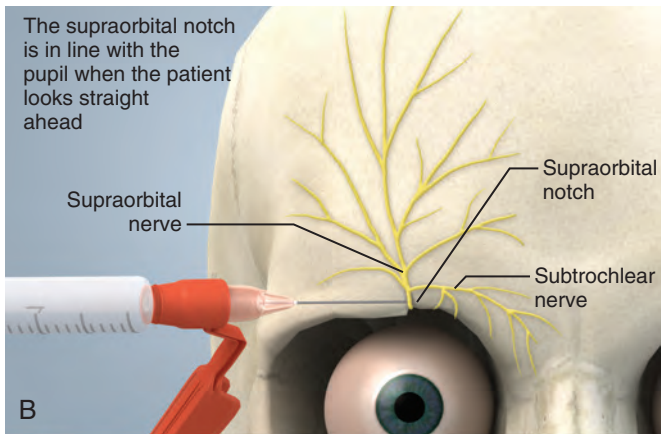

Complications

Hematoma formation or swelling of the eyelid may occur but requires only local pressure to limit expansion. Occasionally, ecchymosis of the periorbital region will appear the next day, and the patient should be warned of this possibility.

Supraorbital

C

Figure 30.21 Supraorbital/supratrochlear nerve block, branches of V1. **A**, Distribution. **B**, Anatomy and approach. **C**, Technique. Insert the needle laterally and advance medially to include the supratrochlear nerve. Aspirate and then inject while withdrawing the needle across the canal. Extra anesthetic can be inserted directly over the supraorbital notch. Placing a finger inferiorly to the orbital rim can prevent eyelid swelling, and aid in landmark identification. This nerve block will include the upper eyelid.

CONCLUSION

Nerve blocks about the head and neck are relatively painless when induced carefully and slowly after topical mucosal anesthesia (for intraoral approaches) or local skin anesthesia

(for extraoral blocks and approaches). They can alleviate patient apprehension, minimize wound margin misalignment, and contribute to better patient outcomes. The blocks should be considered in all cooperative patients who require regional anesthesia in the head and neck.

Regional Anesthesia of the Thorax and Extremities

John J. Kelly and Jason Younga

Virtually every peripheral nerve can be blocked at some point along its course from the spine to the periphery (Videos 31.1 to 31.14), but digital nerve blocks (e.g., fingers and toes) are more commonly used than proximal blocks. Other common applications include femoral blocks for fractures of the femur, ankle blocks for foot injuries and infections, intercostal blocks for rib fractures, and wrist blocks for injuries to the palm.

The preparation, technique, choice of anesthetic, precautions, and complications are similar for all nerve blocks and are described in general in the following sections. The clinician is encouraged to use the same basic techniques and precautions for all nerve blocks. Specific precautions unique to a particular nerve block are included with the description of that block. Obvious precautions, such as aspiration before injection when the needle is in close proximity to a vascular structure, are not restated to avoid redundancy.

GENERAL CONCEPTS

Indications

For most lacerations and injuries seen in the emergency department (ED), local infiltrative anesthesia is adequate and more efficient than using a nerve block (see [Chapter 29](#)). Patients who require extensive repair and anesthesia of the entire extremity are often referred to a specialist, who may prefer to examine an unanesthetized limb. A nerve block is indicated when it will provide advantages over other techniques. Scenarios in which this requirement is met include the following:

- When distortion from local infiltration hampers closure (e.g., facial wounds) or compromises blood flow (e.g., fingertip)
- When anesthesia is required over a large area and multiple injections would be painful or when the large amount of anesthetic needed for local infiltration exceeds the recommended dose
- When a nerve block is the most efficacious form of treatment, such as an intercostal block for treating a rib fracture in a patient with chronic obstructive pulmonary disease (COPD)
- When local infiltration of the wound would be more painful than a regional nerve block, such as in the plantar surface of the foot or the palm of the hand
- When the block is performed to decrease pain during reduction of a finger or toe dislocation
- When extensive limb surgery or manipulation is required (e.g., extensive tendon repair) and other options are not available

Preparation

A brief history, including drug allergies (particularly to local anesthetics), medications, and systemic illnesses, should be

taken from the patient. Peripheral vascular, heart, and liver disease may increase the risk for severe complications. Therefore information about the existence of these diseases should also be sought.

Instructions

Explain the procedure to the patient, including the pain of needle insertion, paresthesias, and possible complications that may occur. Discuss the potential need for additional anesthetic or alternative procedures if the nerve block fails. Be sure that the patient understands that the additional administration of an anesthetic is part of the normal procedure rather than an attempt to correct an improperly performed nerve block. It is not standard to obtain written informed consent for nerve blocks performed in the ED.

Equipment

For most nerve blocks performed in the ED, the following equipment is required: latex gloves, an antiseptic solution (e.g., chlorhexadine), a 10-mL syringe, an 18-gauge needle for drawing the anesthetic from the vial, and a 3.75-cm, 25- or 27-gauge needle for the nerve block. Note that the needle sizes given in text are general recommendations, but for the majority of blocks, a 25-gauge needle is ideal. In addition, keep standard resuscitation equipment for advanced cardiac life support readily available any time that local anesthetic agents are given.

Choice of Anesthetic

Factors influencing the choice of anesthetic agent for nerve blocks are similar to those for local infiltration (see [Chapter 29](#) for extensive discussion). In general, most nerve blocks are done for the repair of painful traumatic injuries that are likely to cause pain long after the repair is completed. In such cases, select the anesthetic with the longest duration of action to maximize the patient's analgesia. Buffering the anesthetic is strongly encouraged to lessen the pain of infiltration (see [Chapter 29](#)). For most of the blocks described in this chapter, buffered 0.25% bupivacaine is suggested as the anesthetic of choice, but equal volumes of 1% lidocaine with epinephrine can be substituted to provide faster onset of relief. The use of epinephrine on end-organ areas has traditionally been discouraged (e.g., tip of the nose, peripheral ear pinna, distal end of the penis), although the theoretical risk is unsubstantiated in clinical practice. Literature from 2010 describes the use and confirms the safety of lidocaine with epinephrine (1:100,000 concentration) for digital blocks.¹ It would be prudent to avoid epinephrine-containing anesthetics in injuries involving vascular compromise or for those patients with peripheral artery disease. Higher concentrations of lidocaine ($\leq 2\%$) or bupivacaine (0.5%) are commonly used for large nerves. Ropivacaine is another anesthetic with a rapid onset and a long duration of action (several hours). It has been reported to have fewer cardiotoxic and central nervous system effects than bupivacaine.^{2,3} Take care to avoid exceeding the recommended dosages of the anesthetic chosen.

Positioning the Patient

When possible, perform nerve blocks with the patient in the supine position to minimize the vasovagal syncope that may

occur when the patient is in an upright position. When drawing up the anesthetic from the vial, hide this anxiety- and fear-inducing portion of the procedure from the patient.

Preparation of the Area to Be Blocked

To limit the incidence of infection, prepare the field in aseptic fashion before needle puncture. Allow the antiseptic solution to dry fully to achieve its maximal antibacterial effect. Sterile drapes and gloves are not routinely required but may be considered in addition to aseptic skin preparation for the initiation of blocks that (1) are close to large joints, vessels, and nerves; (2) are located in inherently contaminated areas of the body (e.g., groin, perineum); or (3) require simultaneous palpation of the underlying structures while injecting.

Choosing the Nerves to Block

Successful anesthesia requires appropriate knowledge of the relevant anatomy. Most areas to be anesthetized have overlapping sensory innervation and therefore require two or more nerves to be blocked. In addition, the cutaneous distribution of the various peripheral nerves differs slightly from patient to patient. Use a liberal margin of error when determining which nerves supply the desired area of anesthesia.

Locating the Nerve

When locating a nerve to be blocked, approach it from a site with easily identifiable anatomic landmarks. The best sites are those with good structural landmarks (e.g., prominent bones or tendons) immediately next to the nerve. For example, the four digital nerves are reliably found at the 2, 4, 8, and 10 o'clock positions around and just superficial to the proximal phalanx, whereas the median nerve lies between the palpable palmaris longus and flexor carpi radialis tendons at the proximal wrist crease. Nerves that course adjacent to easily palpable arteries, such as in the axilla and groin, are also easy to locate and are good sites for performing nerve blocks. Nerves that do not have adjacent structural or vascular landmarks are much more difficult to block.

Blocking nerves with good structural or vascular landmarks is straightforward: palpate the landmarks and follow the course of the nerve in relation to these landmarks. After visualizing the anatomy in the mind's eye, insert the needle in close proximity to the nerve.

Blocking nerves with poor landmarks, such as the radial nerve at the elbow, requires skill, practice, and some degree of luck. To increase the likelihood of successfully blocking these nerves, consider using ultrasound-guided techniques (see [Ultrasound Box 31.1](#)).

Nerve Stimulator

A nerve stimulator is commonly used by anesthesiologists but has never gained popularity among emergency clinicians. Nevertheless, it helps locate nerves that do not have adjacent structural or vascular landmarks, which greatly increases the chances of successfully blocking these nerves.

Ultrasound

Use of ultrasound to identify injection sites for peripheral nerve blocks has gained popularity. Ultrasound has been used successfully to locate and block nerves in the neck (e.g.,

interscalene, axillary, and brachial plexus), lower extremity (e.g., femoral and saphenous nerve blocks), upper extremity (e.g., radial, ulnar, and median nerve blocks at the elbow and forearm), and the lumbar plexus.⁴⁻⁷ Ultrasonographic guidance negates the effects of anatomic variability, provides real-time needle guidance, and allows the operator to visualize the "spread" of local anesthetic. The use of ultrasound is associated with superior success rates with fewer attempts, less time to perform the block, and fewer complications compared to anatomic nerve blocks or use of nerve stimulators.⁸

There are two basic ultrasound techniques used to facilitate nerve blocks; the *in-plane* and *out-of-plane* techniques. Using the in-plane technique, the needle is inserted at the side of the probe and advanced toward the target. With this technique, the entire needle is visualized as it traverses the plane of ultrasound. With the out-of-plane technique, the needle enters the skin away from the probe and is aimed at the plane of sound. As the needle moves toward the target, only the needle tip is visualized. Detailed descriptions of ultrasound-guided nerve blocks can be found later in this chapter (see [Ultrasound Box 31.1](#)).

Paresthesia

A common technique to ensure that the tip of the needle is in close proximity to the nerve is to elicit a paresthesia. Touching and mechanically stimulating the nerve with movement of the needle tip produces a tingling sensation or jolt known as a *paresthesia*, and it is felt along the distribution of the nerve. In practice, the jolt of a true paresthesia is often difficult to distinguish from the "ouch" of a pain-sensitive structure. When blocking proximal nerves at the elbow or axilla, the paresthesia travels far enough away from the injection site that it can be reliably distinguished from locally induced pain. Paresthesias at the level of the hand and wrist are more difficult to distinguish from pain. In both cases, paresthesia is a subjective feeling that requires intelligent and cooperative patients to understand what they are expected to feel and to remain relaxed and attentive so that they can distinguish an "ouch" from a jolt. Before the procedure, a simple explanation of what the patient should or may feel will facilitate cooperation. Although eliciting paresthesias is generally reliable in demonstrating that the needle is close to its target, some authors believe that it may theoretically increase the rate of complications as a result of mechanical trauma or intraneural injection.⁹⁻¹¹ Once the paresthesia is elicited, it is important to withdraw the needle 1 to 2 mm before injecting the anesthetic. If a paresthesia persists, stop the injection and reposition the needle.

Injecting the Anesthetic

Strive to ensure that the anesthetic agent is not inadvertently injected into a vessel or nerve bundle. In practice, a misplaced intravascular injection is usually of minimal consequence, but small amounts of epinephrine may cause systemic symptoms such as tachycardia or anxiety. Intraarterial injection, theoretically, is more dangerous than intravenous injection. Either way, aspirate the syringe to check for blood before injection. If no blood is aspirated, inject the anesthetic while observing the extremity for blanching, which suggests intravascular injection. If blanching occurs, reposition the needle before further injection.

Nerve bundle injection has the potential to cause nonspecific nerve injury. Severe pain or paresthesia during injection or

resistance to depressing the plunger suggests the possibility of intraneural placement of the needle. If any of these problems occur, immediately stop injecting and reposition the needle.

The onset and duration of anesthesia are both greatly influenced by how close the injected anesthetic is to the nerve. Onset occurs within a few minutes if the anesthetic is in immediate proximity to the nerve. Onset takes longer or may not occur at all if the anesthetic must diffuse more than 2 to 3 mm, which underscores the importance of locating the nerve before the injection.

More anesthetic is required if it must diffuse a long distance to the nerve. A range of suggested volumes of anesthetic is given with each nerve block description. For blocks in which a definite paresthesia is elicited or a nerve stimulator or ultrasound is used, the minimal recommended amount of anesthetic suffices. For blocks of smaller nerves, paresthesias are often not easily elicited, and the anesthetic must be injected in the general vicinity of the nerve. For these blocks or when doubt exists about the proximity of the needle to the nerve, larger amounts of anesthetic are recommended. This point cannot be emphasized strongly enough. The difference between a successful and an unsuccessful block may be merely an additional 2 mL of anesthetic. When in doubt, err on the high side of the recommended dosage. When blocking large nerves, many clinicians also opt for 2% lidocaine rather than the 1% solution.

With most blocks, the onset of anesthesia occurs in 2 to 15 minutes, depending on the distance that the anesthetic must diffuse to the nerve and the type of anesthetic used. Wait 30 minutes before deciding that a block is unsuccessful.

Complications and Precautions

Complications may result from peripheral nerve blocks but are rare in clinical practice. Most cannot be prevented by even perfect technique. General precautions include measures to minimize nerve injury, intravascular injection, and systemic toxicity. No actual statistics exist on the complication rate from nerve blocks performed by emergency clinicians, but they are extremely rare in clinical practice. Theoretically, infrequently performed blocks, blocks that require high doses of anesthetic, and blocks close to major vascular structures are more likely to have complications.

Nerve Injury

Nerve injury is rare but can occur secondary to (1) chemical irritation from the anesthetic, (2) direct trauma from the needle, or (3) ischemia as a result of intraneural injection. Overall, the incidence of serious neuronal injury is rare and occurs in 1.9 per 10,000 blocks.¹² Given that placement of a nerve block is a blind procedure, nerve injuries do not necessarily represent an error in technique.

Chemical neuritis from the anesthetic is the most common nerve injury.^{10,11} The patient may complain of pain and varying degrees of nerve dysfunction, including paresthesia or motor or sensory deficit. Most cases are transient and resolve completely. Supportive care and close follow-up are the mainstays of treatment. Emergency clinicians should not exceed the recommended doses and concentrations of anesthetic (Table 31.1). In general, buffered lidocaine 1% or 2% or buffered bupivacaine 0.25% or 0.5% is safe for nerve blocks performed in the ED.

Direct nerve damage can be minimized by proper needle style, positioning, and manipulation. Use a short, beveled needle

TABLE 31.1 Recommended Volumes of Anesthetic for Various Nerve Blocks

and keep the bevel parallel to the longitudinal axis of the nerve. Sharp pain or paresthesia indicates that the needle is close to or in the nerve. Avoid excessive needle movement when the tip of the needle is in contact with the nerve. If a 25-gauge needle is used, physical damage to a nerve should be minimal, even when directly touched by the tip of the needle. A 27-gauge needle is theoretically attractive, but its small size may limit aspiration testing and it may bend or break when attempting to block deep nerves.

Intraneural injection may rarely cause nerve ischemia and injury. Elicitation of a paresthesia or severe pain suggests that the needle has made contact with the nerve. When a paresthesia is elicited, withdraw the needle 1 to 2 mm before injecting the anesthetic. If the paresthesia occurs during injection, stop the injection and reposition the needle. Most neurons are

surrounded by a strong perineural sheath through which the nutrient arteries run lengthwise. Injection directly into a nerve sheath may increase pressure within the nerve and compress the nutrient artery. Impaired blood flow results in nerve ischemia and subsequent paralysis. Intraneural injection is often heralded by severe pain, which worsens with further injection and may radiate along the course of innervation. The operator may notice difficulty depressing the plunger of the syringe. If the tip of the needle is in proper position, slow injection of the anesthetic should be minimally painful, and the anesthetic should go in without resistance.

Intravascular Injection

Intravascular injection may rarely result in both systemic and limb toxicity. Inadvertent intravascular injection produces high blood levels of the anesthetic. Exercise care when administering large amounts of anesthetic in close proximity to large blood vessels.

Intraarterial injection of anesthetics with epinephrine may cause peripheral vasospasm and further compromise injured tissue. Intravascular anesthetic is not toxic to the limb itself, although it may produce transient blanching of the skin by displacing blood from the vascular tree. Epinephrine, however, can cause prolonged vasospasm and subsequent ischemia if it is injected into an artery. This is especially worrisome when anesthetizing areas with little collateral circulation, such as the toes, fingers, penis, and tip of the nose. Severe epinephrine-induced tissue blanching or vasospasm may be reversed with local or intravascular injection of phentolamine (see extensive discussion in [Chapter 29](#)).

Vasospasm associated with the epinephrine in anesthetic solutions is rare, but experience in related clinical situations can help guide therapy. Roberts and Krisanda used a total of 5 mg of phentolamine infused intraarterially to reverse arm ischemia following 3 mg of epinephrine inadvertently administered into the brachial artery during cardiac resuscitation.¹³ Accidental injection of epinephrine from an Epi-Pen (Mylan, Canonsburg, PA) will produce an area of vasoconstriction. This is usually self limited and requires no intervention, but it may take a few hours to be complete. However, digital ischemia from inadvertent epinephrine autoinjection (Epi-Pen) has been successfully treated both by proximal “digital block” with 2 mg of phentolamine and by local infiltration at the ischemic site with 1.5 mg of phentolamine.^{14,15}

The route of phentolamine administration should be guided by the clinical situation. Phentolamine must reach the site of vasospasm. Local infiltration may be effective for ischemia in a single toe or finger, whereas arterial injection has the advantage of delivering the medication directly to the arteries exhibiting spasm. For larger areas of involvement or in instances in which local infiltration is ineffective, use intraarterial injection. A dose of 1.5 to 5 mg appears to be effective in most cases,^{13–15} although a total of 10 mg may be used for local infiltration. Phentolamine, 5 mg, can be mixed with 5 mL of either normal saline or lidocaine. The small volume of the distal pulp space may limit the volume of the infiltration dose to 0.5 to 1.5 mL in the fingertip. Larger volumes and dosages can be used with proximal infiltrations. For intraarterial infusion of the radial artery at the wrist or the dorsalis pedis at the ankle, dosages of 1.5 to 5 mg of phentolamine are suitable. Slow infusion or graded dosages of 1 mg may provide enough phentolamine to reverse the ischemia without excessive systemic effects such as hypotension.

Hematoma

Hematoma formation may result from arterial puncture, particularly during blocks in which a major blood vessel is being used as a landmark to locate the nerve (e.g., axillary or femoral artery). Direct pressure for 5 to 10 minutes usually controls further bleeding. Use of small-gauge needles (e.g., 25- to 27-gauge) also helps minimize bleeding from a punctured artery. A minor coagulopathy is not a contraindication to a nerve block.

Infection

Infection is rare and can be minimized by following aseptic technique and using the lowest possible concentration of epinephrine. Injection should be made through noninfected skin that has been antiseptically prepared. Injection through a site of infection may spread the infection to adjacent tissues, fascial planes, and joints.

Systemic Toxicity

The incidence of systemic toxicity with local anesthetics has diminished significantly in the past 30 years. Interestingly, peripheral nerve blocks have been reported to have the highest incidence of systemic toxicity.¹² Allergic reactions account for only 1% of untoward reactions (see [Chapter 29](#)).¹⁶

Limb Injury

Injury to the anesthetized limb can result if the patient is permitted to use the limb, is advised to use heat or cold application, or performs wound care before the anesthesia has worn off. With major nerve blocks, do not release the patient from the ED until sensation and function have returned.

With minor blocks, the patient may be sent home but should be properly cautioned. Advise the patient to avoid ischemia-producing compression dressings (e.g., elastic bandages) because the anesthetized area may not sense impending problems.

SPECIFIC NERVE BLOCKS

Intercostal Nerve Block

Blocking the intercostal nerves produces anesthesia over an area of their cutaneous distribution ([Fig. 31.1](#)) and provides considerable temporary pain relief for patients with rib contusions or fractures. Rib fractures are typically quite painful and cause the patient to try to splint respirations to avoid excessive movement of the injured site. The resulting hypoventilation, atelectasis, and poor expectoration may cause hypoxia or lead to pneumonia. This is particularly true in patients with preexisting pulmonary disease and minimal respiratory reserve, in whom further impairment of function may cause significant respiratory compromise.

Theoretically, anesthetizing injured ribs eases pain and facilitates deep breathing and coughing. Unfortunately, no controlled studies have compared intercostal blocks and oral analgesics in patients with the types of rib fractures that are commonly managed on an outpatient basis. However, studies do suggest that intercostal blocks may be superior to analgesics in patients who have undergone thoracotomy.^{17–19} In these studies, those receiving intercostal nerve blocks had better results on pulmonary function tests, greater oxygenation, and earlier ambulation and discharge than did those receiving opioid analgesics.^{17–19}

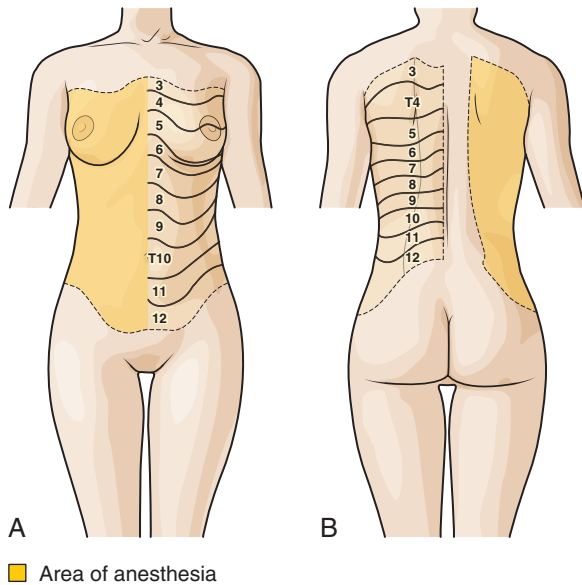

Figure 31.1 A and B, Intercostal nerve block: area of anesthesia and cutaneous distribution of the intercostal nerves.

There are several arguments against the routine use of intercostal nerve blocks in the ED. First, rib fractures are often tolerated well by young patients, who usually require minimal oral analgesics. Second, these blocks have a relatively short duration of action. The typical duration of action of a long-acting anesthetic with epinephrine is 8 to 12 hours. However, it should be noted that patients often experience partial analgesia for up to 3 days, a period that cannot be attributed to direct action of the anesthetic on the nerve. Perhaps the anesthesia reduces muscle spasm and the associated cycle of pain.

Finally, a wrongly perceived high incidence of pneumothorax and unsuccessful blocks deters many clinicians from performing intercostal nerve blocks in the ED. The true incidence of pneumothorax after intercostal nerve blocks is very low and not significant enough to prohibit the procedure. Moore reported that in more than 10,000 individual rib blocks performed, the incidence of pneumothorax was less than 0.1%.²⁰ However, Shanti and associates reported that the incidence of pneumothorax was 1.4% for each individual intercostal nerve blocked.²¹ If more than one nerve requires blockade, the incidence of pneumothorax may be greater. The suggested approach to discussing intercostal blocks is to give patients the facts with regard to the duration of analgesia and possible complications and then allow them to decide on the method for themselves. Frequently, they prefer oral analgesics initially but may return for further relief of pain, at which time they are more amenable to a nerve block.

Anatomy

Each thoracic nerve exits the spine through the intervertebral foramen, which lies midway between adjacent ribs (Fig. 31.2A). It immediately gives off the posterior cutaneous branch, which supplies the skin and muscles of the paraspinal area. The intercostal nerve then continues around the chest wall and gives off lateral cutaneous branches at the midaxillary line. These branches are the sensory supply to the anterior and posterior lateral chest wall.

The intercostal nerve runs with the vein and artery in the subcostal groove. The vein and artery lie *above the nerve* and

are somewhat protected by the rib during a nerve block. Posteriorly, the nerve is separated from the pleura and lungs by the thin intercostal fascia. When blocking the nerve in the posterior aspect of the back, particular care must be taken to avoid puncture of the thin fascia and underlying lung. Fortunately, most rib fractures occur in the anterior or lateral portion of the rib and can be blocked in the posterior axillary line, where the internal intercostal muscles lie between the nerve and the lung's pleura and provide a buffer for minor errors in needle placement. Note that blocking the nerve in this area will anesthetize the entire course of the intercostal nerve because it is blocked before the cutaneous branches are given off.

Technique

To achieve adequate analgesia for most rib fractures, the lateral cutaneous branch needs to be anesthetized. Therefore perform blocks between the posterior axillary and midaxillary line at a point proximal to the origin of this branch (see Fig. 31.2A, *arrow*). Explain the procedure and its benefits and its risks, including potential pneumothorax, systemic toxicity, and ineffective block, before proceeding.

Use buffered 0.25% bupivacaine in a 10-mL syringe with a 3.75-cm, 25-gauge needle. Prepare the area to be injected in the usual aseptic manner. Use the index finger of the nondominant hand to retract the skin at the lower edge of the rib cephalad and pull it up and over the rib (see Fig. 31.2B). With the syringe in the opposite hand, puncture the skin close to the tip of the finger that is retracting the skin over the rib. Keep the syringe at an 80-degree angle to the chest wall with the needle pointing cephalad, and rest the hand holding the syringe on the chest wall for stability. In this position, the depth of needle penetration is well controlled. Slowly advance the needle until it comes to rest on the lower border of the rib. The bone should be felt through the tip of the needle.

At this point, release the skin retracted over the rib. As the skin returns to its natural position, the shaft of the needle will become perpendicular to the chest wall and the tip of the needle will be at the inferior margin of the rib. Shift the syringe from the dominant hand to the index finger and thumb of the nondominant hand. Rest the middle finger of the same hand against the shaft of the needle and exert gentle pressure on the shaft to “walk” the needle off the lower edge of the rib. Again, keep the palm of the hand planted firmly on the chest wall to ensure control of the needle. With the help of the dominant hand, slowly advance the needle 3 mm. Aspirate to be sure that the needle has not penetrated a blood vessel, and then inject 2 to 4 mL of anesthetic while carefully moving the needle in and out 1 mm to ensure that the compartment containing the nerve between the internal and external intercostal muscles is penetrated. This may also serve to minimize intravascular injection. Repeat the procedure on the two ribs above and below to ensure that the overlapping innervation from adjacent nerves is blocked.

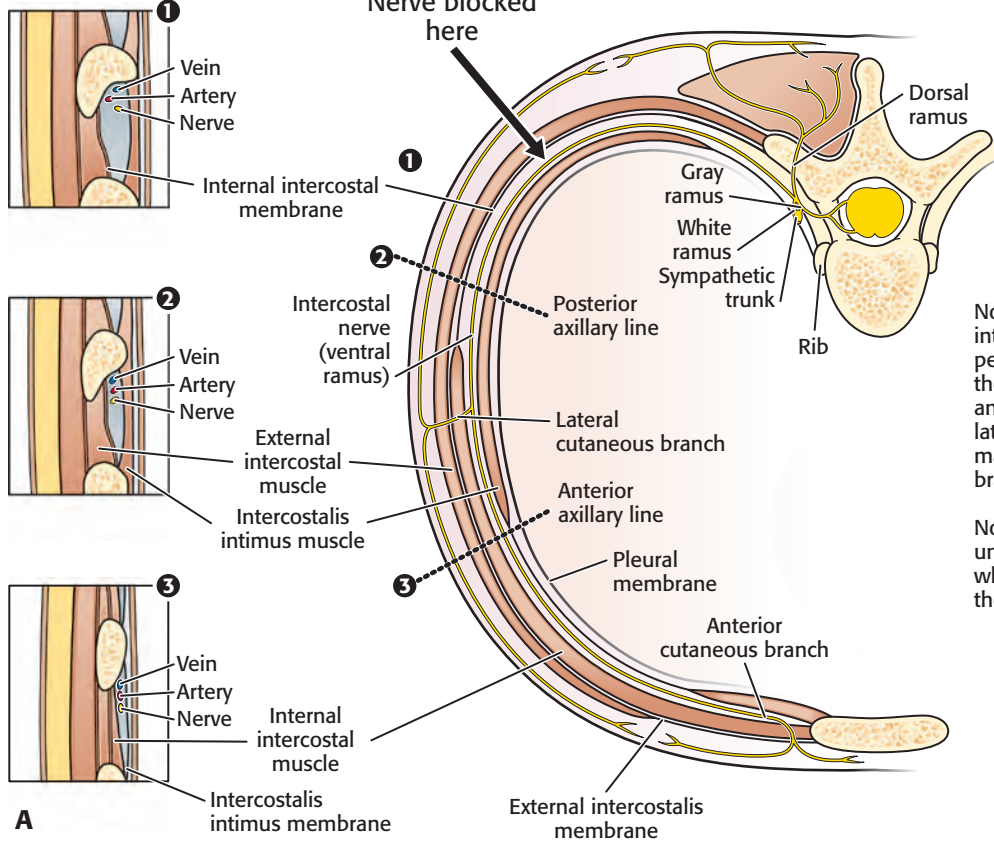

Although the procedure just discussed seems extensive, it takes 1 to 2 minutes to perform once the operator is familiar with the technique, and three to five intercostals can be blocked in 10 minutes total.

Precautions

Initially place the needle at the lower edge of the rib. If it contacts the rib above this point, it cannot be walked off the lower edge of the rib at the proper angle. If it is inserted too low, over the intercostal space, it may be advanced through

Intercostal Nerve Block

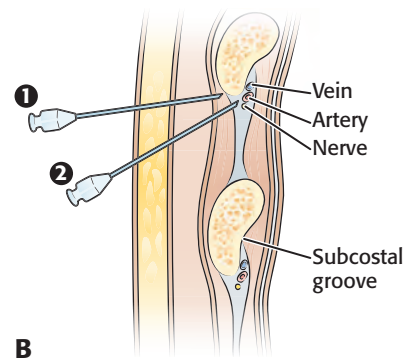

Anatomy

Note the posterior area where the intercostal block is usually performed (*arrow* at the angle of the rib/posterior axillary line); the anesthetic will also block the lateral cutaneous, lateral mammary, and anterior cutaneous branches.

Note that the vein and artery lie under the inner portion of the rib, which offers them protection from the anesthetizing needle.

Technique

B

The anesthetizing needle is advanced until it touches the rib, an obvious sensation to the operator. The needle is walked down the inferior portion of the rib until it is felt to drop off the bone. The needle is advanced a few millimeters and a generous amount of the anesthetic is deposited (2 to 4 mL per rib). Penetration too deep risks pneumothorax.

Method of retracting the skin and the proper needle insertion site for an intercostal block. See text for details.

Figure 31.2 Intercostal nerve block: anatomy and technique. (Adapted from Chung J: Thoracic pain. In Sinatra RS, Hord AH, Ginsberg G, et al, editors: *Acute pain*. St. Louis, 1991, Mosby.)

the pleura and into the lung before the operator realizes that it is too deep. Before inserting the needle, it is always prudent to estimate the depth of the bone. If the bone is not encountered by this depth of insertion, reevaluate the position of the needle. Even after the needle has been properly walked off the edge of the rib, take care to not puncture the pleura and lung. The depth of the intercostal groove in which the nerve runs is 0.6 cm posteriorly and diminishes to 0.4 cm anteriorly.

Because the incidence of pneumothorax is low, a chest radiograph is not routinely required after this procedure. Observe asymptomatic patients for 15 to 30 minutes and instruct them to return if problems arise. If the patient has symptoms of pneumothorax (e.g., cough, a change in nature of the pleuritic pain, or shortness of breath), obtain a chest film before discharge.

If the clinician inadvertently causes a pneumothorax, treatment depends on its size. Many pneumothoraces from this procedure are small and require no specific intervention. Those smaller than 20% may be observed for 6 hours.²² During this time, administer a high concentration of oxygen to help decrease the size of the pneumothorax. If the pneumothorax does not enlarge, the patient may be released home with arrangements for close follow-up. Needle or catheter aspiration of larger pneumothoraces may be all that is needed. A chest tube is necessary if this method fails (see [Chapter 10](#)).

Nerve Blocks of the Upper Extremity

The upper extremity is supplied by the brachial plexus. The nerve roots and its branches—primarily the median, radial, ulnar, and musculocutaneous nerves—can be blocked at the level of the interscalene muscles, axilla, elbow, wrist, hand, or fingers. Nerve blocks at the axilla and elbow are seldom used in the ED, but interscalene nerve blocks are becoming more popular.^{23,24} Nerve blocks of the wrist are performed occasionally before painful procedures or for repair of injuries to the hand. Metacarpal and digital blocks are used frequently to treat fractures, lacerations, and infections of the fingers.

Interscalene Nerve Block

An interscalene nerve block anesthetizes the nerve roots from the upper (C5 and C6) and middle (C7) trunks of the brachial plexus, providing anesthesia to the shoulder and proximal arm. The lower trunk of the brachial plexus (C8 and T1) is blocked approximately 40% of the time, resulting in inconsistent anesthesia to the medial aspects of the forearm and hand (i.e., the territory supplied by the ulnar nerve). In the ED, an interscalene nerve block may be ideal for shoulder dislocations or complex lacerations of the upper extremity.^{23,24}

Anatomy and Technique

The brachial plexus is formed by the ventral rami of the lower cervical and upper thoracic nerve roots and supplies cutaneous and muscular innervation to the shoulder and proximal arm. The trunks of the brachial plexus pass between the anterior and middle scalene muscles where they can be blocked at the level of the cricoid cartilage (i.e., C6) ([Fig. 31.3](#)).

To perform an interscalene block, position the patient supine with the head turned away from the side of the block. Identify the sternal notch, the sternal and clavicular heads of the sternocleidomastoid muscle, and the clavicle. The anterior and middle scalene muscles lie posterior to the clavicular head of the sternocleidomastoid muscle at the level of the cricoid

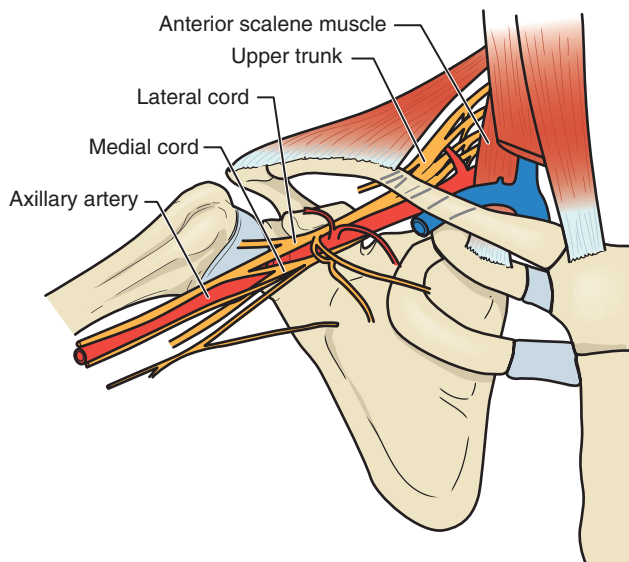

Figure 31.3 Anatomy of the brachial plexus.

cartilage (C6). The safest and most successful technique used to perform an interscalene block utilizes ultrasound guidance and is described in detail later in this chapter (see [Ultrasound Box 31.1](#)).

Complications

Interscalene nerve blocks using typical volumes of local anesthetic frequently cause diaphragmatic paralysis by blocking the phrenic nerve. This may result in dyspnea, hypoxemia, or hypercapnia that may not be tolerated by patients with underlying pulmonary dysfunction (e.g., COPD). Using smaller volumes of local anesthetic will reduce the incidence of phrenic nerve palsy, but it will also reduce the likelihood of a successful block. Spread of local anesthetic to surrounding neural tissue may cause a Horner syndrome from stellate ganglion block or hoarseness from a recurrent laryngeal nerve block. Epidural and total spinal anesthesia have also been reported. Rarely, pneumothorax due to the proximity of the pleura may occur.

Nerve Blocks at the Elbow

The median, ulnar, and radial nerves can be blocked at the elbow to provide anesthesia to the distal end of the forearm and hand ([Fig. 31.4](#)). For most injuries extensive enough to require a nerve block at the elbow, all three nerves must be blocked for successful anesthesia because of the variable and overlapping innervation of the forearm. Furthermore, injuries to the proximal and middle aspects of the forearm may require additional circumferential subcutaneous field blocks of the lateral, medial, and posterior cutaneous nerves.

Ulnar Nerve: Anatomy and Technique ([Fig. 31.5A](#))

The ulnar nerve can be palpated in the ulnar groove on the posteromedial aspect of the elbow between the olecranon and the medial condyle of the humerus. This nerve supplies innervation to the small finger, the ulnar half of the ring finger, and the ulnar aspect of the hand.

With the elbow flexed, insert buffered 0.25% bupivacaine via a 3.75-cm, 25-gauge needle 1 to 2 cm proximal to the ulnar groove and advance the needle parallel to the course of the nerve. The tip of the needle should come to rest close to the proximal end of the groove. Do not block the nerve in the

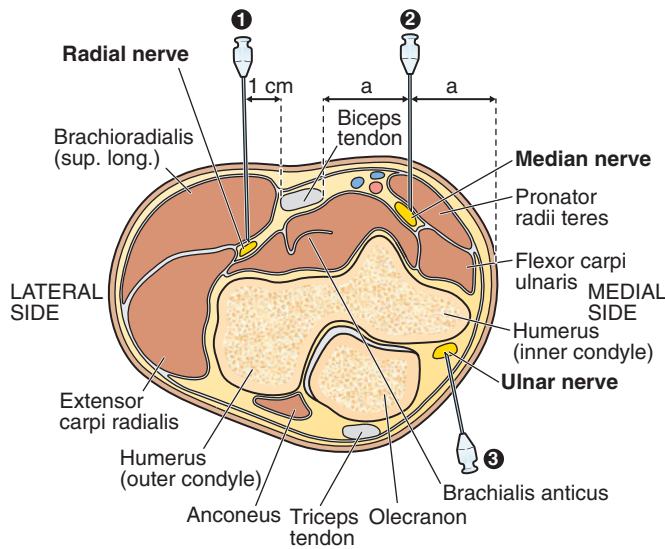

Figure 31.4 Cross section of the elbow looking cephalad, right arm. The radial nerve (1), median nerve (2), and ulnar nerve (3) are demonstrated.

groove, where it is prone to damage. For similar reasons, a paresthesia may be elicited but is not vigorously sought. If a paresthesia occurs during injection, slightly reposition the needle to avoid intraneural injection. Although an elbow ulnar nerve block is common, many clinicians prefer to block the ulnar nerve at the wrist to limit the risk for injury. Once the tip of the needle is positioned properly, deposit 5 to 10 mL of anesthetic. The use of ultrasound can aid in blocking the ulnar nerve at the elbow and mid forearm (see [Ultrasound Box 31.1](#)).^{25–27} If a nerve stimulator is used, flexion of the small and ring fingers signals proximity to the nerve.

Radial Nerve: Anatomy and Technique (See [Fig. 31.5B](#))

The radial nerve and sensory branch of the musculocutaneous nerve run together in the sulcus between the biceps and brachioradialis muscles on the anterolateral aspect of the elbow. The block produces anesthesia of the lateral dorsum of the hand and the lateral aspect of the forearm.

Palpate the sulcus in which the nerve runs between the sharp border of the biceps muscle and the medial border of the brachioradialis muscle in the antecubital fossa just proximal to the skin crease of the elbow. Having the patient flex the elbow to 90 degrees and isometrically contract and relax these muscles will help define their borders. Puncture the skin with a 3.75-cm, 25-gauge needle halfway between the muscles, or 1 cm lateral to the biceps tendon, at a point 1 cm proximal to the antecubital crease and inject 5 to 15 mL of anesthetic. Because of poor landmarks and the depth of the radial nerve at the elbow, a nerve stimulator greatly facilitates the search for the nerve, which, when stimulated, produces extension of the fingers and wrist. In addition, the use of ultrasound may improve success rates of radial nerve blocks at the elbow and forearm (see [Ultrasound Box 31.1](#)).^{25–27}

Median Nerve: Anatomy and Technique (See [Fig. 31.5C](#))

The median nerve runs medial to the brachial artery in the anteromedial aspect of the elbow. Block of this nerve

anesthetizes the index, middle, and radial portion of the ring finger and the palmar aspect of the thumb and lateral part of the palm.

Palpate the brachial artery in the flexed arm at the elbow just proximal to the antecubital crease and medial to the prominent biceps tendon. Once the anatomy is defined and marked in the flexed arm, extend the arm to 30 degrees and insert buffered 0.25% bupivacaine via a 3.75-cm, 25-gauge needle slightly medial to the artery and perpendicular to the skin to the depth of the artery, approximately 2 to 3 cm, and inject 5 to 15 mL of anesthetic. As with the radial nerve blocks, the use of ultrasound may improve success rates of median nerve blocks at the elbow and forearm (see [Ultrasound Box 31.1](#)).^{25–27} A nerve stimulator can also facilitate the process and produces flexion of the wrist and index finger. Most commonly, median nerve blocks are performed at the wrist.

Nerve Blocks at the Wrist

The median, ulnar, and radial nerves may be blocked at the wrist to provide anesthesia to the hand. Most extensive injuries and procedures for which a wrist nerve block could be used can also be managed by local infiltration or a digital block. When compared with direct infiltration, wrist block anesthesia may have a slow and unreliable onset and can require more time to take effect if all three nerves are to be blocked. There are several circumstances, however, in which wrist nerve blocks are more advantageous than other types of blocks or anesthesia.

Diffuse lesions that may be difficult to anesthetize with local infiltration can easily be anesthetized with a wrist block. Deep abrasions with embedded debris, commonly the result of “road burn” from bicycle and motorcycle crashes, can be cleaned and débrided painlessly after a nerve block at the wrist. Hydrofluoric acid burns, which require treatment with numerous subcutaneous injections of calcium gluconate, and thermal burns that require extensive débridement are better tolerated after a wrist nerve block. Wrist blocks are also advantageous in a severely swollen and contused hand, in which small amounts of anesthetic injected locally may increase tissue pressure and produce further pain. Finally, deep lacerations of the palm are very painful to anesthetize with local infiltration and will also benefit from a wrist block.

When compared with nerves in the axilla and elbow, the nerves in the wrist are more easily located anatomically and can be blocked more reliably. All three nerves lie in the volar aspect of the wrist near easily palpated tendons. A nerve stimulator is not necessary, but may be useful in locating the nerves, particularly when one is learning how to perform these blocks.

The anatomy and technique for blocking each nerve follow. Note that the median nerve lies in the midline and deep to the fascia and the ulnar and radial nerves lie on their respective sides and have branches that wrap around dorsally. Blocking all three nerves at the wrist requires a block that when viewed end-on, roughly resembles a horseshoe straddling a horseshoe stake ([Fig. 31.6](#)).

Median Nerve: Anatomy and Technique ([Fig. 31.7A](#))

In the wrist, the median nerve lies just below the palmaris longus tendon or slightly radial to it between the palmaris longus and flexor carpi radialis tendons. Both tendons are easily palpated, but the palmaris longus may be absent in up to 20% of patients, in which case the nerve is found

Nerve Blocks at the Elbow

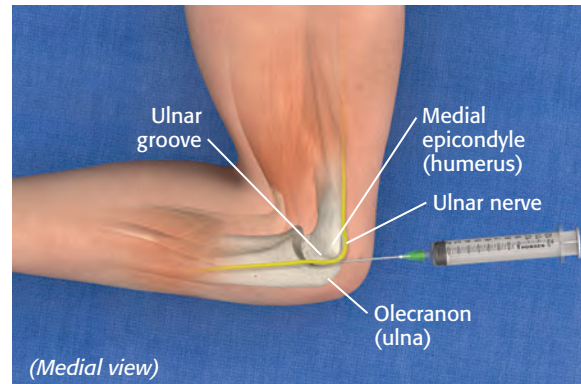

Ulnar Nerve

Distribution

A

Anatomy and Technique

(Medial view)

With the elbow flexed, insert the needle 1 to 2 cm proximal to ulnar groove, and advance toward the groove parallel to the course of the nerve. Deposit 5 to 10 mL of anesthetic.

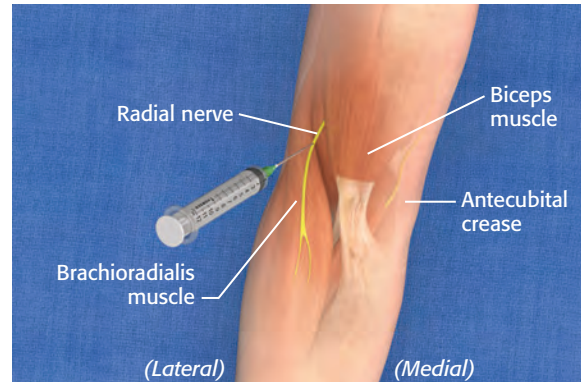

Radial Nerve

Distribution

B

Anatomy and Technique

(Lateral)

(Medial)

Insert the needle on the volar surface of the elbow, 1 cm proximal to the antecubital crease, midway between the brachioradialis and biceps muscles. Deposit 5 to 15 mL of anesthetic.

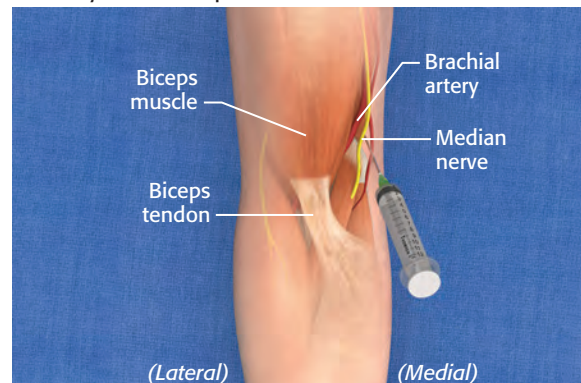

Median Nerve

Distribution

C

Anatomy and Technique

(Lateral)

(Medial)

Palpate the brachial artery in the flexed arm, proximal to the antecubital crease and medial to the biceps tendon. Then with arm flexed at 30 degrees, inject 5 to 15 mL of anesthetic slightly medial to the artery.

Figure 31.5 Nerve blocks at the elbow.

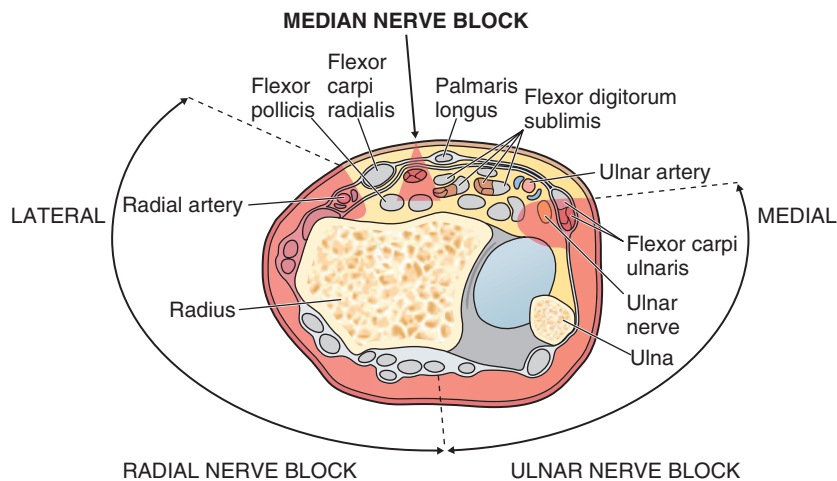

Figure 31.6 Cross section of the wrist looking cephalad, right wrist. The *arrow* points to the (covered) median nerve. The shaded triangle depicts the area infiltrated with anesthetic. Note the relatively superficial position of the median nerve, just radial to the palmaris longus.

approximately 1 cm in the ulnar direction from the flexor carpi radialis tendon. The nerve lies deep to the fascia of the flexor retinaculum, but at a depth of 1 cm or less from the skin. The superficial position of the median nerve at the wrist is emphasized because a major cause of failure of this block is to instill the anesthetic too deep.

The palmaris longus tendon is located by having the patient make a fist with the wrist flexed against resistance (Fig. 31.8). Insert buffered 0.25% bupivacaine via a 3.75-cm, 25-gauge needle perpendicular to the skin on the radial border of the palmaris longus tendon just proximal to the proximal wrist crease. Advance the needle slowly until a slight “pop” is felt as the needle penetrates the retinaculum and a paresthesia is produced. If no paresthesia ensues, it may be elicited in a more ulnar direction under the palmaris longus tendon. If a paresthesia is still not elicited, deposit 3 to 5 mL of anesthetic in the proximity of the nerve at a depth of 1 cm under the tendon. Although the nerve is surprisingly close to the skin, it is better to err slightly on the deep side of the retinaculum and continue depositing anesthetic as the needle is withdrawn because the retinaculum is an effective barrier to a successful nerve block from superficially injected anesthetic.

Radial Nerve: Anatomy and Technique (See Fig. 31.7B)

The radial nerve follows the radial artery into the wrist but gives off sensory nerve branches proximal to the wrist. These branches wrap around the wrist and fan out to supply the dorsal and radial aspect of the hand.

Nerve block here requires an injection in close proximity to the artery and a field block that extends around the dorsal aspect of the wrist. Insert buffered 0.25% bupivacaine via a 3.75-cm, 25-gauge needle immediately lateral to the palpable artery at the level of the proximal palmar crease. At the depth of the artery, inject 2 to 5 mL of anesthetic. Distribute an additional 5 to 6 mL of anesthetic subcutaneously from the initial point of injection to the dorsal midline. Withdraw the needle and reposition it to complete the block. Withdrawing the needle and repositioning it to a site that has already been anesthetized help decrease the discomfort of numerous

needlesticks. Ultrasound can also be used at the level of the wrist to identify the precise location of the radial artery.²⁷

Ulnar Nerve: Anatomy and Technique (See Fig. 31.7C)

The ulnar nerve follows the ulnar artery into the wrist, where they both lie deep to the flexor carpi ulnaris tendon. The flexor carpi ulnaris tendon is easily palpated just proximal to the prominent pisiform bone by having the patient flex the wrist against resistance. At the level of the proximal palmar crease, the artery and nerve lie just off the radial border of the flexor carpi ulnaris tendon; however, the nerve lies between the tendon and the artery and deep to the artery, which makes it difficult to approach the nerve from the volar aspect of the wrist without involving the artery.

A nerve block of the ulnar nerve can be carried out by two different approaches: lateral and volar. The lateral approach may be easier because of the reason stated previously. For the lateral approach, insert buffered 0.25% bupivacaine via a 3.75-cm, 25-gauge needle on the ulnar aspect of the wrist at the proximal palmar crease and deposit a wheal of anesthetic horizontally under the flexor carpi ulnaris tendon. Then direct the needle toward the ulnar bone at a point deep to the flexor carpi ulnaris tendon and inject 3 to 5 mL of anesthetic solution as the needle is withdrawn. Like the radial nerve, cutaneous nerves branch off the ulnar nerve, wrap around the wrist, and supply the dorsum of the hand. Block these branches by subcutaneously injecting 5 to 6 mL of anesthetic from the lateral border of the flexor carpi ulnaris tendon to the dorsal midline. Another advantage of the lateral approach is that the dorsal branches can be blocked from the same injection site. As mentioned with the radial nerve, ultrasound can easily identify the ulnar artery at the level of the distal radius and ulna.²⁷

Nerve Blocks of the Digits

The digital nerve block is one of the most useful and most used blocks in the ED. Indications for choosing it include repair of finger lacerations and amputations, reduction of fractures and dislocations, drainage of infections, removal of fingernails, and relief of pain (e.g., from a fracture or burn).

Nerve Blocks at the Wrist

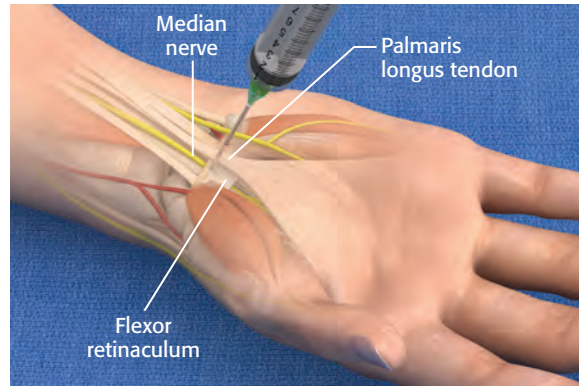

Median Nerve

Distribution

A

Anatomy and Technique

Locate the palmaris longus tendon. Insert the needle on the radial side of the tendon just proximal to the volar wrist crease. Feel for a "pop" as the needle penetrates the retinaculum, and inject 3 to 5 mL of anesthetic.

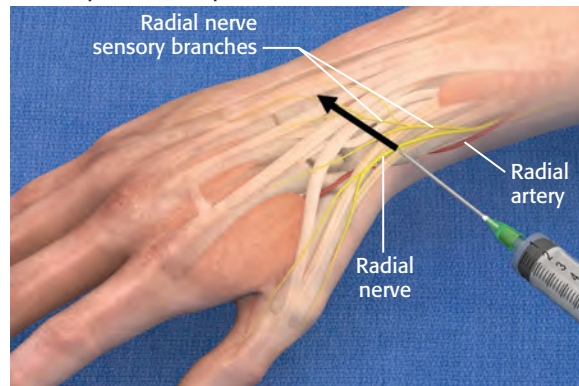

Radial Nerve

Distribution

B

Anatomy and Technique

First inject 2 to 5 mL of anesthetic immediately lateral to the radial artery at the level of the proximal palmar crease (not shown). Then inject another 5 to 6 mL from the initial injection point to the dorsal midline.

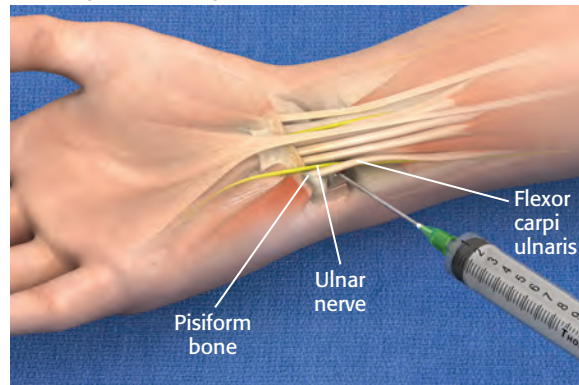

Ulnar Nerve

Distribution

C

Anatomy and Technique

Insert the needle on the ulnar aspect of the wrist at the proximal palmar crease, under the flexor carpi ulnaris tendon. Inject 3 to 5 mL of anesthetic. Next, deposit 5 to 6 mL of anesthetic from the lateral border of the flexor carpi ulnaris to the dorsal midline (not shown).

Figure 31.7 Nerve blocks at the wrist.

Figure 31.8 The palmaris longus tendon is found by having the patient make a tight fist and flex the wrist. This tendon may be absent in some patients.

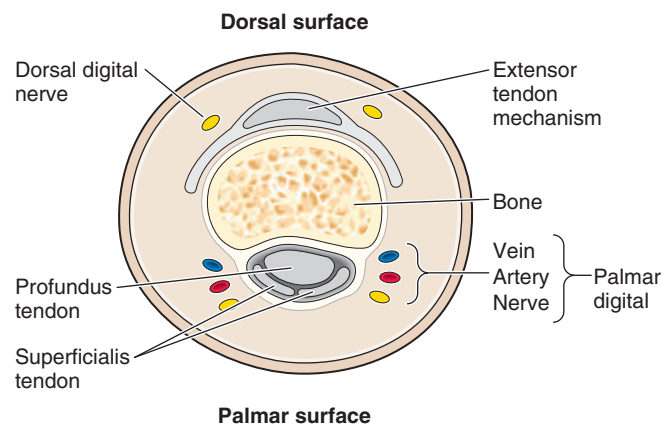

Figure 31.9 Schematic cross section of the phalanx demonstrating the relationship of the nerves to the bone. Note that each finger has four digital nerves and that the digital artery and vein run parallel to and near the palmar branches.

A digital block is superior to local infiltration in most circumstances. Wound infiltration may be a problem in a finger that has tight skin and can accept only a limited volume of anesthetic. Injection of anesthetic into this restricted space increases tissue pressure, thereby impairing capillary blood flow and causing pain. Fibrous septa in the fingertips also restrict the space available for the injected substance and even limit the spread of small amounts of anesthetic.

Anatomy

Each finger is supplied by two sets of nerves. These nerves, the dorsal and palmar digital nerves, run alongside the phalanx at the 2 and 10 o'clock positions and the 4 and 8 o'clock positions, respectively (Fig. 31.9).

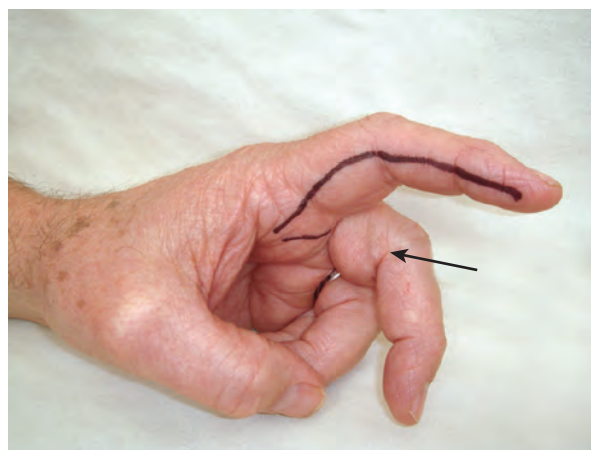

Figure 31.10 Each finger has four digital nerves: two palmar and two dorsal. The palmar nerves travel in a line connecting the top of the skin creases made by flexing the proximal interphalangeal and distal interphalangeal joints (*black line*). The nerves are more palmar than is often appreciated and are almost adjacent to the flexor tendon, so injecting the true lateral portion of the finger may miss the nerve. If the anesthesia needle is inserted at the tip of the skin creases (*arrow*) the nerve will be blocked.

The principal nerves supplying the finger are the palmar digital nerves (also called the common digital nerves). These nerves originate from the deep volar branches of the ulnar and median nerves, where they branch in the wrist. The palmar digital nerves follow the artery along the volar lateral aspect of the bone, one on each side, and supply sensation to the volar skin and interphalangeal joints of all five digits (Fig. 31.10). In the middle three fingers, these nerves also supply the dorsal distal aspect of the finger, including the fingertip and nail bed. Although many clinicians routinely block both sets of digital nerves, in the presence of normal anatomy, only the volar (palmar) branches must be blocked to obtain adequate anesthesia of the middle three fingers distal to the distal interphalangeal joint.

The dorsal digital nerves originate from the radial and ulnar nerves, which wrap around to the dorsum of the hand. They supply the nail beds of the thumb and small finger and the dorsal aspect of all five digits up to the distal interphalangeal joints. Unlike the middle three fingers, which require blocking of only the two volar (palmar) digital nerves, all four nerves are usually blocked in the thumb and fifth finger, particularly to obtain anesthesia of the fingertip and nail bed (Fig. 31.11).

Technique

The digital nerves can be blocked anywhere in their course, including sites in the finger, in the web space between the fingers, and between the metacarpals in the hand. There are a variety of approaches to the nerves, including the dorsal and palmar approaches and the web space approach. Each has its merits, and the technique is similar at each level.

The dorsal approach has the advantage of thinner, less pain-sensitive skin than encountered with volar approaches. The hand can be held firmly and flat on the table to prevent withdrawal. The disadvantage is that two injections are needed with this approach to block both volar digital nerves.

The dorsal approach can be used in the dorsum of the hand at the metacarpals, just proximal to the finger webs at the proximal end of the proximal phalanx or distal to the web

Figure 31.11 For the index, middle, and ring fingers, the volar digital nerves provide sensation not only to the volar surface of the fingers but also to the dorsal surface distal to the distal interphalangeal joints. Thus, to obtain anesthesia of the distal portion of these three fingers, only the volar nerves need be blocked. Note that for the thumb and little finger, *both* the dorsal and volar nerves need to be blocked to obtain distal anesthesia.

space. Clinical situations may dictate which site to use; however, given equal circumstances, the preferred site is just proximal to the finger web. Here, the nerve's location is more consistent than in the hand, and there is more soft tissue space to accommodate the volume of injected anesthetic than there is in the distal end of the finger. Digital block at the web space is more efficacious in onset and requires less time to achieve anesthesia than does a metacarpal block done proximal to the metacarpophalangeal joint.²⁸

A digital block requires aseptic injection technique, and usually only alcohol pad preparation is performed. Sterile gloves and drapes are not necessary, although examination gloves are recommended. The onset of anesthesia occurs in 1 to 15 minutes and it lasts for 20 minutes to 6 hours, depending on the anesthetic agent used. Either short-acting buffered 1% lidocaine or long-acting buffered 0.25% bupivacaine may be used. Avoid the use of epinephrine containing local anesthetics.

The clinician must first decide whether two or four digital nerves require blocking (see earlier discussion). As noted previously, the authors recommend performing the block from the dorsal surface where the skin is thinner, easier to penetrate, and less sensitive than skin on the volar surface. Insert a 3.75-cm, 25- or 27-gauge needle at the web space, just distal to the knuckle at the lateral edge of the bone (Fig. 31.12A). Once the tip of the needle is subdermal, it usually contacts the bone. At this point, create a skin wheal by injecting 0.5 to 1 mL of anesthetic without epinephrine. This serves to block the dorsal digital nerve and provide anesthesia at the injection site. Pass the needle lateral to the bone and toward the palmar surface until the palmar skin starts to tent slightly. Withdraw the needle 1 mm and inject 0.5 to 1.5 mL of anesthetic. This procedure is repeated on the opposite side of the finger. The result is a circumferential band of anesthetic at the base of the finger. Firm massage of the injected area for 15 to 30 seconds enhances diffusion of the anesthetic through the tissue to the nerves.

A variation of the dorsal approach is performed as follows. After injecting one side of the finger, pull the needle back

slightly (without removing it) and redirect it across the top of the digit to anesthetize the skin on the opposite side (see Fig. 31.12B). Completely withdraw the needle and reinsert it at the site that was just anesthetized, and continue the method as described earlier. The presumed advantage of this method is that it minimizes the pain of the second skin puncture. However, because this technique requires the needle to be placed across the dorsal aspect of the finger, it increases the risk for extensor tendon puncture and trauma.

The palmar and web space approaches can be used most successfully for the middle three fingers when only a single puncture is required to block both volar nerves. This technique takes advantage of the anatomic fact that only the volar digital nerves must be blocked to obtain anesthesia of the total finger (except the proximal dorsal surface). If the thumb or fifth finger must be anesthetized, the dorsal branches must also be blocked to obtain anesthesia of the fingertip and fingernail area (see Fig. 31.11).

The palmar approach requires an injection in the palm, which is more painful than an injection in the dorsal skin. Insert the needle directly over the center of the metacarpal head and slowly inject the anesthetic as the needle is advanced to the bone (see Fig. 31.12C). At this point, withdraw the needle 3 to 4 mm and redirect it slightly to the left and right of center to block both digital nerves without withdrawing the needle. To be successful, a palpable soft tissue fullness should be appreciated. The technique requires 4 to 5 mL of anesthetic.

With the web space approach, hold the patient's hand with your thumb and index finger over the dorsal and volar surface of the metacarpal head, respectively. Use your third finger to separate the patient's fingers to expose the web space while your fourth and fifth fingers support the patient's finger being anesthetized (see Fig. 31.12D). Insert the needle into the web space and inject 1 mL of anesthetic. Slowly advance the needle until it is next to the lateral volar surface of the metacarpal head and inject additional anesthetic. Withdraw the needle slightly and redirect it across the midline of the metacarpal head to the opposite digital nerve. Use the index finger to palpate "a fullness" as the anesthetic is injected. Again, firm massage of the injected area for 15 to 30 seconds enhances diffusion of the anesthetic through the tissue to the nerves. When needed, redirect the needle to the adjacent finger without withdrawing it to block both fingers with a single puncture (Fig. 31.13).

Alternative Techniques Jet Injection Technique

Jet injection for a digital nerve block can be used effectively and is less painful than standard needle techniques.²⁹ The technique described by Ellis and Owens uses 0.15 mL of 1% lidocaine delivered by a jet injector at 2600 psi.²⁹ Make three injections in the lateral aspect of the proximal phalanx: the first, midway between the volar and dorsal surfaces; the second, dorsal to this; and the third, volar. Administer a combined total of 0.45 mL to each side of the phalanx at the 2, 3, and 4 o'clock positions and the 8, 9, and 10 o'clock positions in relation to the bone.

Advantages of jet injection are a less painful injection and avoidance of "needle phobia," particularly in children. Potential disadvantages include lacerations, which may occur with tangential injection. Holding the injector perpendicular to the skin avoids this problem. Thick skin associated with older age,

manual labor, and male gender may require larger volumes of anesthetic.

Transthecal Digital Block Technique

A transthecal block is performed by making a single injection into the flexor tendon sheath, which produces rapid and complete finger anesthesia. It was first described by Chiu in 1990, who noted rapid finger anesthesia after injection treatment of a trigger finger.³⁰ Cadaver studies suggest that the injected fluid diffuses out of the tendon sheath and around the phalanx and all four digital nerves.

Palpate the flexor tendon in the palm proximal to the metacarpophalangeal joint. Introduce a 25-gauge needle attached to a 3-mL syringe at a 45-degree angle and advance it toward the tendon sheath while maintaining constant slight pressure on the plunger of the syringe (Fig. 31.14). When the sheath has been entered, the anesthetic should flow freely. If it does not, it is presumed that the tendon has been entered. If this happens, withdraw the syringe slowly (while keeping slight pressure on the plunger) until anesthetic flows smoothly and easily. Inject a total of 2 mL of anesthetic solution (smaller volumes should be used in children). After the needle is

Digital Nerve Blocks

Dorsal Approach

1. Insert the needle at the web space, just distal to the knuckle at the edge of the bone. Once the needle tip is subdermal, inject 0.5 to 1 mL of anesthetic to block the dorsal digital nerve.

2. Advance the needle along the bone toward the palmar surface until the palmar skin begins to tent. Inject another 0.5 to 1 mL of anesthetic to block the volar digital nerve.

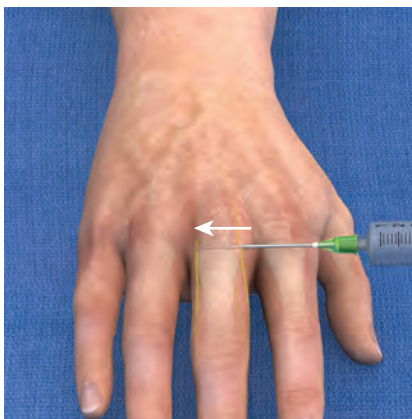

3. Repeat steps 1 and 2 on the opposite side of the finger. The result is a circumferential band of anesthesia around the base of the finger. Firmly massage the area for 30 seconds to enhance diffusion of the anesthetic.

A

Dorsal Approach—Alternative Method

1. Block both the dorsal and volar digital nerves on one side of the finger as described above. *Do not* fully remove the needle after blocking the volar nerve.

2. *Without removing the needle*, redirect it across the top of the finger to anesthetize the skin on the opposite side. After injecting the opposite side, remove the needle.

3. Insert the needle at the site that was anesthetized in step 2, and block the other side of the finger. The presumed benefit of this technique is that it minimizes pain at the second skin puncture site.

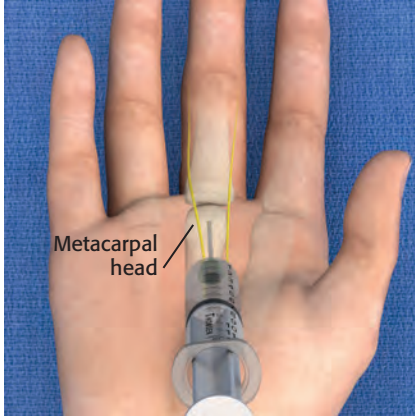

B

Figure 31.12 Digital nerve blocks.

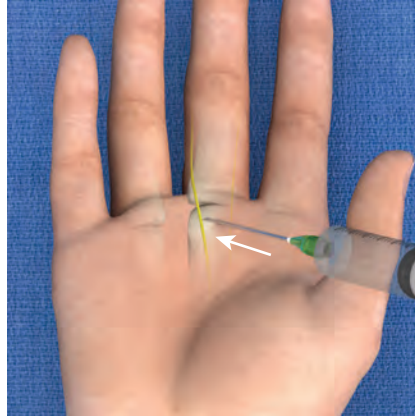

Continued

Digital Nerve Blocks, Cont'd

Palmar Approach

1. Insert the needle directly over the center of the metacarpal head and slowly inject anesthetic while advancing the needle to the bone.

2. Withdraw the needle 3 to 4 mm (without completely removing it) and slightly angle it to the right or left of center to block one of the volar digital nerves.

3. Repeat on the other side of the digit. To be successful, a palpable soft tissue fullness should be appreciated. Usually 4 to 5 mL of anesthetic is required.

C

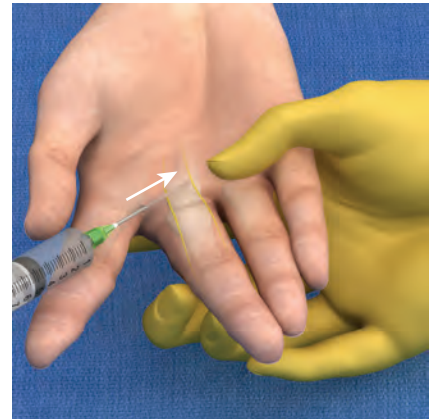

Web-Space Approach

1. Hold the patient's hand with your thumb and index finger over the metacarpal, and spread the fingers to expose the web space.

2. Insert the needle into the web space and inject 1 mL of anesthetic. Slowly advance the needle until it is next to the volar surface of the metacarpal head and inject additional anesthetic.

3. Withdraw the needle slightly and redirect it across the midline of the metacarpal head to the opposite digital nerve. Inject additional anesthetic at this location. You will be able to feel the tissue distention by the anesthetic with your thumb, but be careful to avoid passing the needle through the skin and puncturing your thumb.

D

Figure 31.12, cont'd

removed, apply pressure over the tendon proximally to facilitate distal spread. The average onset of anesthesia is 3 minutes.³¹

The advantage of this technique is a single injection. However, Hill and colleagues found the technique to be “clinically equal” to traditional digital blocks.³² Other authors have stated that the traditional digital block is easier to perform and produces less pain during and after injection.³³ Theoretically, the technique may increase risk for injury to the tendon.

Complications and Precautions

The injection should go in smoothly, without resistance during injection. Although the finger is forgiving of transient pressure

from excessive anesthetic, if the injection site becomes excessively tense, digital perfusion may be compromised. Even if epinephrine-containing solutions are used for a digital block in otherwise healthy individuals without peripheral vascular disease, it is unlikely that serious ischemic injury will occur.³⁴ Significant vasoconstriction generally lasts less than 60 minutes, within the time interval for which an ischemic tourniquet can safely be used in the same area.³⁵ However, if the entire digit remains blanched for more than 15 minutes, it is prudent to reverse the α -agonism of epinephrine with phentolamine (see Chapter 29). Using a pulse oximeter on the affected finger may help quantitate the degree of ischemia.³⁶

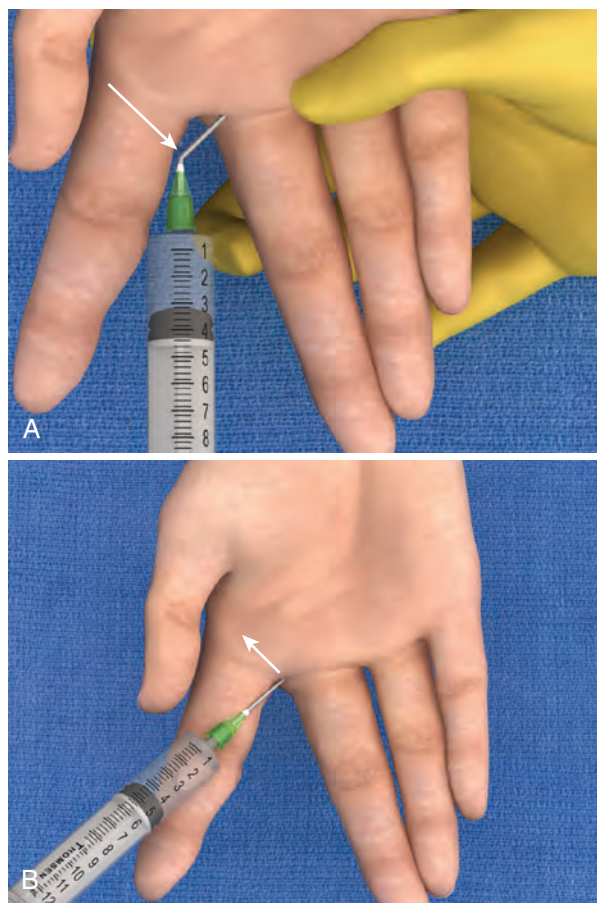

Figure 31.13 Web space block techniques. Both volar digital nerves are blocked with one injection. **A**, For a metacarpal head block from the palmar surface, bending the needle 30 to 45 degrees allows easier access to the digital nerves without the syringe getting in the way. Make sure the needle is advanced far enough to block the side opposite the needle entrance, in this case to where the gloved thumb is positioned. **B**, Adjacent fingers can be blocked with only one needle puncture in the web space. After blocking the middle finger, withdraw the needle slightly, and without exiting the skin, redirect it to the metacarpal head of the index finger (*arrow*).

Figure 31.14 Transthecal block. The flexor tendon sheath is entered volarly just proximal to the metacarpophalangeal joint. With the use of a 25-gauge needle on a 3-mL syringe, the fluid should flow easily. Inject 2 to 3 mL of anesthetic and apply pressure to the proximal end of the tendon sheath.

The small size of the digital arteries and nerves makes intravascular or intraneural injection less likely. Inadvertent intravascular injection may cause digital ischemia from vasospasm or displacement of blood out of the capillary bed by the anesthetic. Blanching of the finger as the anesthetic is injected suggests intravascular injection. If this is observed, immediately discontinue the injection. Usually, the ischemia is transient and self-resolving, and serious complications are rare. Massage or topical application of nitroglycerin paste may be attempted if the ischemia persists.³⁷

Commonly, the digital nerve is lacerated or damaged by the initial injury to the finger. Careful evaluation using two-point discrimination should be performed to determine the extent of nerve injury before blocking the nerve. Even if nerve injury is questionable, it should be documented in the chart, and the patient should be advised of the injury before the nerve block. Careful evaluation and patient education should prevent misconceptions about the cause of the nerve injury. Although most isolated digital nerve injuries are not debilitating, they heal slowly and can be annoying to the patient. Digital nerve injury proximal to the distal interphalangeal joint may be repaired surgically. Nerve repair may be undertaken immediately when specialty consultation is available or be delayed after initial simple closure.

Nerve Blocks of the Lower Extremity

In the lower extremities, nerve blocks can be performed in the groin (e.g., femoral nerve block), ankles, popliteals, metatarsals, and toes. Femoral nerve block is the least often performed but is an effective method for providing analgesia to ED patients with femoral neck fractures. Ankle, metatarsal, and digital blocks are used frequently to treat ingrown toenails, foreign bodies, fractures, and lacerations of the forefoot and toes.

Femoral Nerve Block (Three-In-One Block)

A femoral nerve block provides significant analgesia to the proximal end of the femur and complete analgesia to the femoral shaft. It has been used to supplement anesthesia for a variety of surgical procedures on the anterior aspect of the thigh and knee and to provide postoperative analgesia after hip surgery. In the ED, this block is primarily used to provide analgesia for patients with hip fractures.^{38–40} It can be especially helpful in the management of elderly patients and those with respiratory compromise or poor pulmonary reserve, in whom high doses of opiate analgesics may be problematic.³⁸

The three-in-one nerve block may be used to block the femoral, obturator, and lateral femoral cutaneous nerves with a single injection. The femoral nerve runs down the thigh in a fascial sheath that is continuous with the nerve sheath that contains all three nerves more proximally. If a large amount of local anesthetic is injected into this sheath, it will track proximally, medially, and laterally and thereby block all three nerves and provide more complete analgesia of the femoral neck and hip joint. The technique for performing both a femoral and three-in-one nerve block is identical except that the three-in-one block requires a larger volume of local anesthetic (25 to 30 mL vs. 20 mL).

Because the femoral and three-in-one nerve blocks are technically similar and associated with the same potential complications, and the fact that the three-in-one nerve block provides better analgesia of the femoral neck and hip joint, it

would seem logical to choose the three-in-one over the femoral nerve block for these patients. In clinical practice, however, the lateral femoral cutaneous nerve is less likely to be blocked than the femoral nerve, and the obturator nerve is frequently left unblocked despite proper technique.⁴¹ Nevertheless, because of potentially better analgesia obtained with the three-in-one nerve block and no clinically significant downside in comparison to a femoral nerve block, the remainder of the section will focus on performing the three-in-one nerve block.

Anatomy (Fig. 31.15A)

The femoral nerve is formed from the posterior branches of L2-L4 and is the largest branch of the lumbar plexus. The nerve emerges from the psoas muscle and descends between the psoas and iliacus muscles. It passes under the inguinal ligament in the groove formed by these muscles lateral to the femoral artery and divides into anterior and posterior branches. The anterior branches innervate the anterior aspect of the thigh, and the posterior branches innervate the quadriceps muscle and continue below the knee as the saphenous nerve to provide sensory innervation from the medial side of the calf to the medial malleolus.

The lateral femoral cutaneous nerve arises from the second and third lumbar nerve roots. The nerve emerges from the lateral border of the psoas muscle and travels under the iliac fascia, across the iliac muscle, and under the inguinal ligament

1 to 2 cm medial to the anterior superior iliac spine. It branches into anterior and posterior branches 7 to 10 cm below the anterior superior iliac spine. The anterior branch innervates the skin over the anterolateral aspect of the thigh to the knee, whereas the posterior branch of the nerve innervates the lateral part of the thigh from the greater trochanter to the middle of the thigh.

The obturator nerve arises from the anterior divisions of L2-L4. It descends through the fibers of the psoas muscle and emerges from its medial border near the brim of the pelvis. It then passes behind the common iliac arteries and runs along the lateral wall of the lesser pelvis, above and in front of the obturator vessels to the upper part of the obturator foramen. Here, it enters the thigh through the obturator canal and divides into an anterior and a posterior branch. The obturator nerve is responsible for sensory innervation of the skin of the medial aspect of the thigh and motor innervation of the abductor muscles of the lower extremity.

Technique (See Fig. 31.15B)

Place the patient in a supine position and prepare the skin overlying the femoral triangle in the usual fashion. Palpate the femoral artery 1 to 2 cm distal to the inguinal ligament and inject a subcutaneous wheal of local anesthetic 1 to 2 cm lateral to this point. Keep the nondominant hand on the femoral artery throughout the remainder of the procedure. Insert a

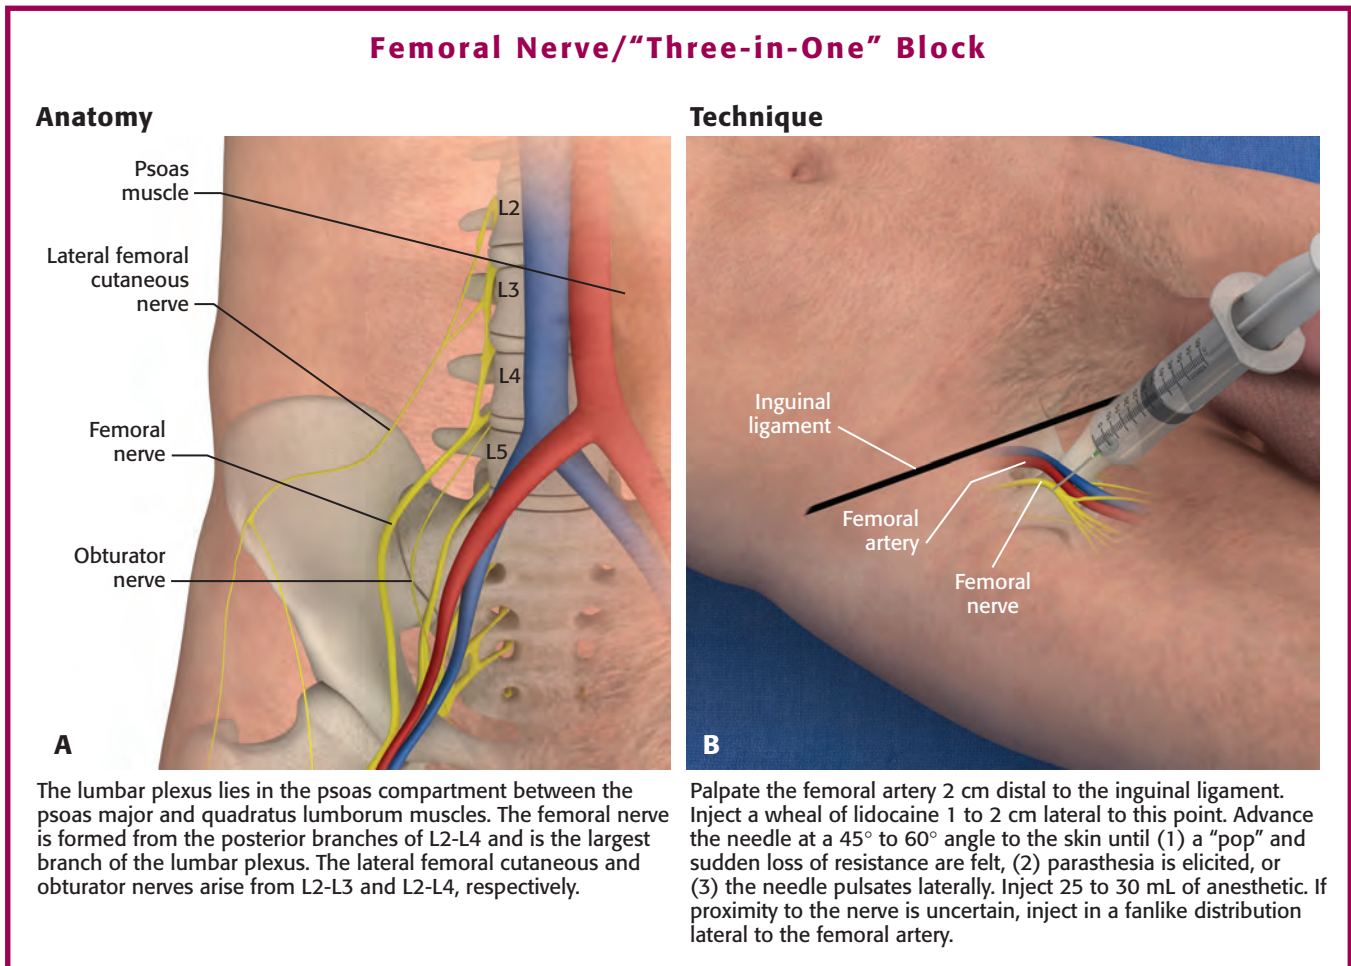

Figure 31.15 The femoral nerve/“three-in-one” block.

3.75-cm, 25- to 22-gauge needle just lateral to the artery at a 45- to 60-degree angle to the skin. Slowly advance the needle cephalad until one of the following occurs: a “pop” with sudden loss of resistance (signifying penetration into the femoral nerve sheath) is felt, a paresthesia is elicited, or the needle pulsates laterally, which signifies a position adjacent to the femoral artery. Inject 25 to 30 mL of anesthetic. The block usually takes 15 minutes to take effect. If proximity to the nerve is uncertain (e.g., a pop is not appreciated, a paresthesia is not elicited, or the needle does not move with pulsation of the femoral artery), inject the anesthetic in a fanlike distribution lateral to the femoral artery in an attempt to anesthetize the nerve.

Some experts recommend applying finger pressure 2 to 4 cm below the injection site to help spread the local anesthetic proximally to the obturator and lateral femoral cutaneous nerves. However, an imaging study suggested that blockade occurs through lateral (lateral femoral cutaneous nerve) and medial (obturator nerve) spread of injected anesthetic.⁴²

The use of ultrasound can facilitate performance of a femoral and three-in-one nerve block; its use is described in detail later in this chapter (see [Ultrasound Box 31.1](#)).

Fascia Iliaca Block

The fascia iliaca block is an alternative to the femoral and three-in-one nerve blocks that more reliably blocks the lateral cutaneous femoral nerve. It has comparable effectiveness to the three-in-one nerve block, but is easier to perform because it does not depend on deposition of local anesthetic in close proximity to the nerves.^{43,44} Instead, it relies on diffusion of the anesthetic along the fascial plane to block the femoral and lateral cutaneous nerves. The fascia iliaca block can be performed using an anatomic approach or with ultrasound guidance.

Anatomy and Technique

The fascia iliaca block takes advantage of the fact that both the lateral cutaneous and femoral nerves lie deep to the fascia iliaca ([Fig. 31.16A](#)). To perform this block, draw an imaginary line between the anterior superior iliac spine and the pubic tubercle and divide the line into thirds. Insert a 3.75-cm, 25- to 22-gauge needle at a 45-degree angle 2 cm caudad to the junction of the lateral and middle thirds. Two distinct “pops” are felt as the needle passes first through the fascia lata and then the fascia iliaca. Once through fascia iliaca, carefully aspirate and then inject 30 to 40 cc of local anesthetic (see [Fig. 31.16B](#)). The anesthetic will diffuse in the plane under the fascia to anesthetize the femoral and lateral femoral cutaneous nerves.

Ultrasound can be used to help visualize the fascia lata and fascia iliaca and underlying structures. Its use is described later in this chapter (see [Ultrasound Box 31.1](#)).

Nerve Blocks of the Ankle

Nerve block of the five nerves of the ankle—the deep peroneal (anterior tibial), posterior tibial, saphenous, superficial peroneal (musculocutaneous), and sural nerves—provides anesthesia to the foot. Of all the nerve block techniques described, these are the most technically difficult and most prone to failure. Depending on the desired area of anesthesia, one or more of the five nerves are blocked. These blocks can be used during operative procedures and repair of injuries to the foot. They are particularly useful in providing anesthesia to the sole of the foot for repair of lacerations and removal of foreign bodies.

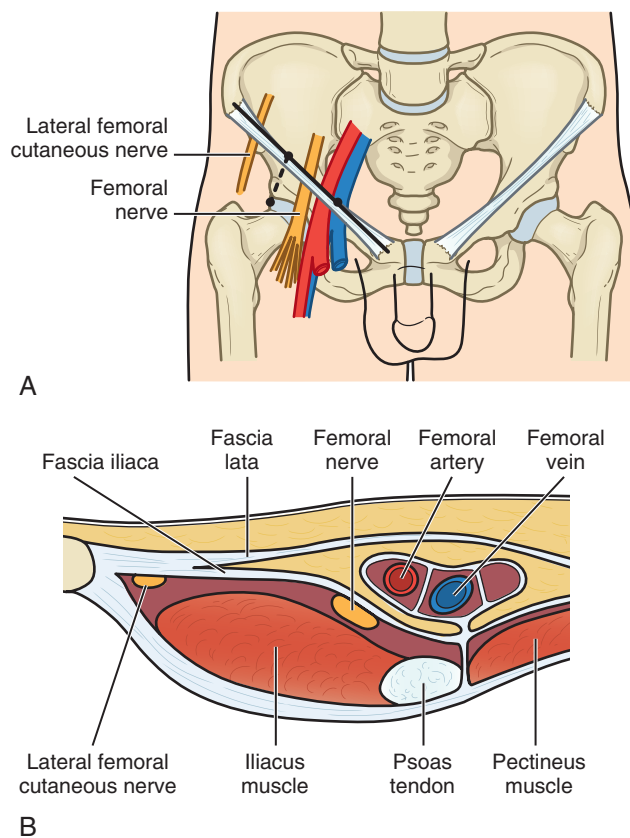

Figure 31.16 Fascia iliaca block. **A**, Anatomy. **B**, Technique.

A nerve block of the foot is better tolerated by the patient than local infiltration in all but the most minor procedures; it is the method of choice for treating injuries (e.g., lacerations, foreign bodies) of the sole. The skin of the sole is thicker and more tightly bound to the underlying fascia by connective tissue septa than is skin in other parts of the body. Puncturing this skin can be difficult and is always quite painful. The fibrous septa can limit the amount and spread of anesthetic. If large amounts of anesthetic are injected, the volume of injected substance quickly exceeds the space available, which can lead to painful distention of the tissue and circulatory compromise of the microvasculature. Local infiltrative anesthesia is adequate for treating minor injuries to the dorsum of the foot in which only small amounts of anesthetic are needed. However, for more extensive procedures such as incision and drainage, extensive wound care, and foreign body removal, an ankle block is better tolerated.

Anatomy

The foot is supplied by the five nerve branches of the principal nerve trunks. Three nerves are located anteriorly and supply the dorsal aspect of the foot. Two nerves are located posteriorly and supply the volar aspect.

The anteriorly located nerves are the superficial peroneal, deep peroneal, and saphenous nerves ([Fig. 31.17A](#)). The superficial peroneal nerve (also called the dorsal cutaneous or musculocutaneous nerve) actually consists of multiple branches that supply a large portion of the dorsal aspect of the foot. These nerves are located superficially between the lateral malleolus and the extensor hallucis longus tendon, which is

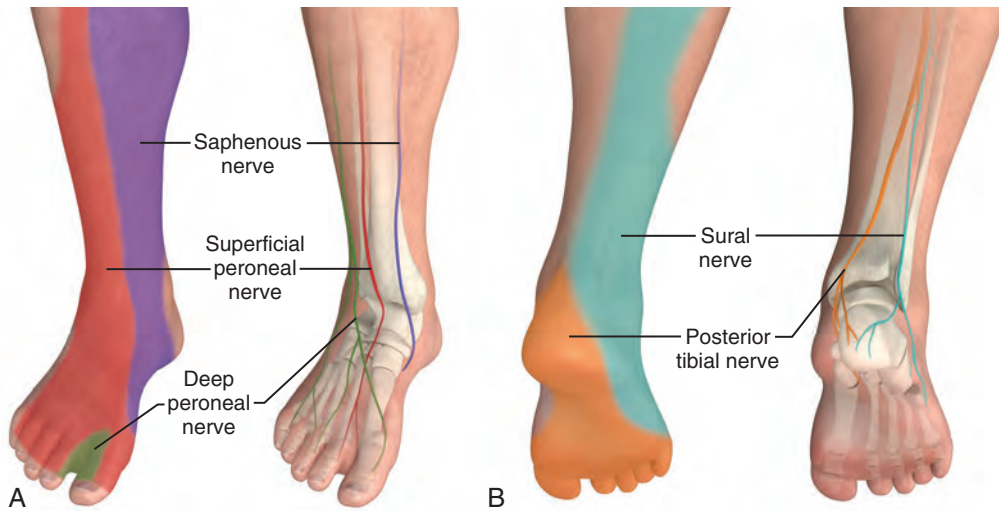

Figure 31.17 Anatomy and distribution of the sensory nerves of the lower part of the leg and foot.

easily palpated by having the patient dorsiflex the big toe. The deep peroneal nerve (also called the anterior tibial nerve) supplies the web space between the big and second toes. In the ankle, it lies under the extensor hallucis longus tendon. The saphenous nerve runs superficially with the saphenous vein between the medial malleolus and the tibialis anterior tendon, which is prominent when the patient dorsiflexes the foot. The saphenous nerve supplies the medial aspect of the foot near the arch.

The posteriorly located nerves are the posterior tibial and sural nerves (see Fig. 31.17B). The sural nerve runs subcutaneously between the lateral malleolus and the Achilles tendon and supplies the lateral border, both volar and dorsal, of the foot. The posterior tibial nerve runs with the posterior tibial artery, which can be palpated between the medial malleolus and the Achilles tendon. It lies slightly deep and posterior to the artery.

The posterior tibial nerve is one of the major nerve branches to the foot. After passing through the ankle, it branches into the medial and lateral plantar nerves, which supply sensation to most of the volar aspect of the foot and toes and motor innervation to the intrinsic muscles of the foot.

Technique

A complete nerve block of the foot requires blocking three subcutaneous nerves and two deeper nerves (Fig. 31.18). Once familiar with the anatomy, an experienced clinician can anesthetize all five nerves quickly by placing subcutaneous band blocks around 75% of the ankle circumference and two deep injections: one next to the palpable posterior tibial artery and the other under the extensor tendon of the big toe.

The five nerves of the foot are commonly blocked in combinations of two or more. Small procedures clearly within the distribution of one nerve may require only a single nerve block. However, overlap of the nerves' sensory distribution frequently necessitates blocking a number of nerves for adequate anesthesia. Nerve block of the sural and posterior tibial nerves together anesthetizes the bottom of the foot and is the most useful combination. Using anatomic landmarks, nerve blocks of the ankle have a 95% success rate, making ultrasound unnecessary in most cases.⁴⁵

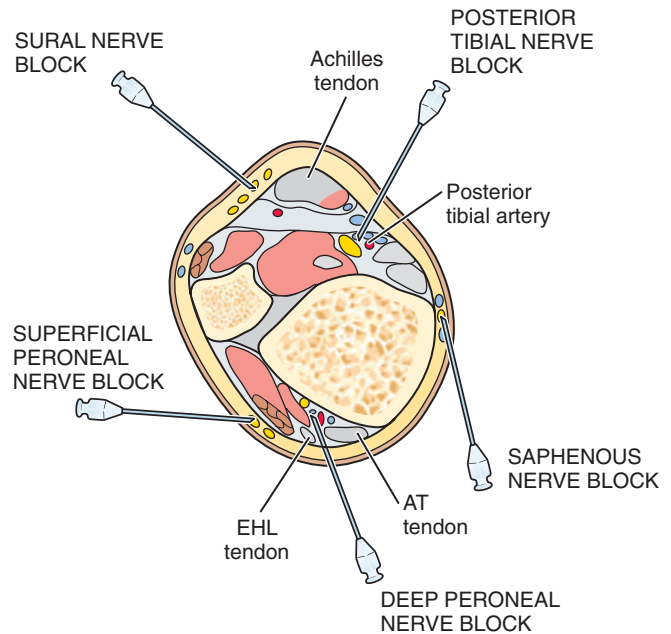

Figure 31.18 A complete nerve block of the foot requires blocking three superficial nerves (sural, saphenous, and superficial peroneal) and two deep nerves (posterior tibial and deep peroneal). *AT*, Anterior tibial; *EHL*, extensor hallucis longus.

Posterior Tibial Nerve (Fig. 31.19A)

Block the posterior tibial nerve in the medial aspect of the ankle between the medial malleolus and the Achilles tendon. Palpate the tibial artery just posterior to the medial malleolus. The injection site is 0.5 to 1.0 cm superior to this point. If the artery is not palpable, use a point 1 cm above the medial malleolus and just anterior to the Achilles tendon.

Insert a 3.75-cm, 25-gauge needle at a 45-degree angle to the mediolateral plane (the needle is almost perpendicular to the skin), just posterior to the artery. At the estimated depth of the artery (approximately 0.5 to 1.0 cm deep), wiggle the needle slightly to produce a paresthesia. If a paresthesia is

Nerve Blocks at the Ankle

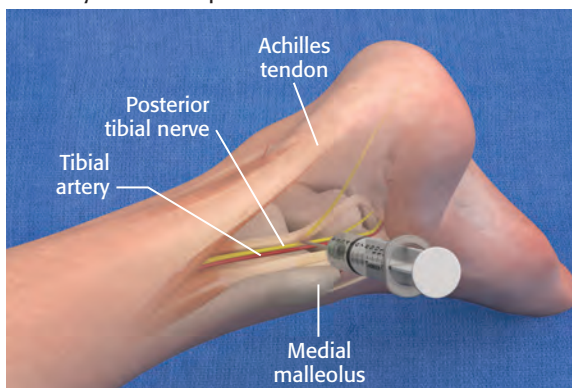

Posterior Tibial

Distribution

A

Anatomy and Technique

Palpate the tibial artery posterior to the medial malleolus. Insert the needle 1 cm superior to this point, perpendicular to the skin. At a depth of 1 cm, inject 3 to 5 mL of anesthetic. See text for additional details.

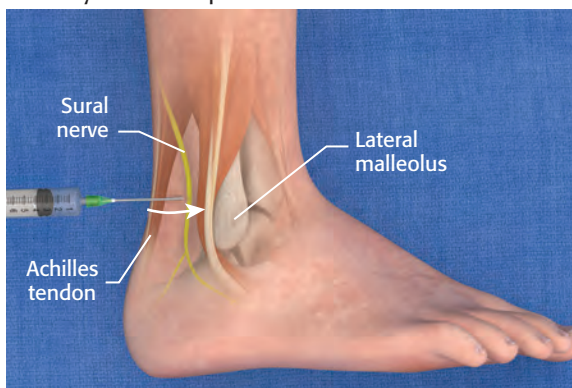

Sural Nerve

Distribution

B

Anatomy and Technique

Palpate the Achilles tendon and lateral malleolus. Inject 3 to 5 mL of anesthetic subcutaneously in a band between the Achilles tendon and lateral malleolus, about 1 cm superior to the malleolus.

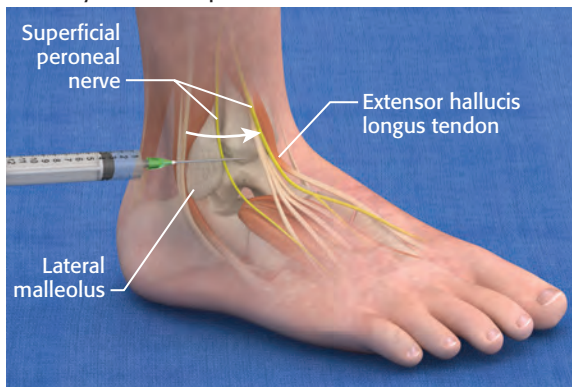

Superficial Peroneal

Distribution

C

Anatomy and Technique

Palpate the extensor hallucis longus tendon and the lateral malleolus. Inject 4 to 10 mL of anesthetic subcutaneously in a band between the tendon and the malleolus.

Figure 31.19 Nerve blocks at the ankle.

Nerve Blocks at the Ankle, Cont'd

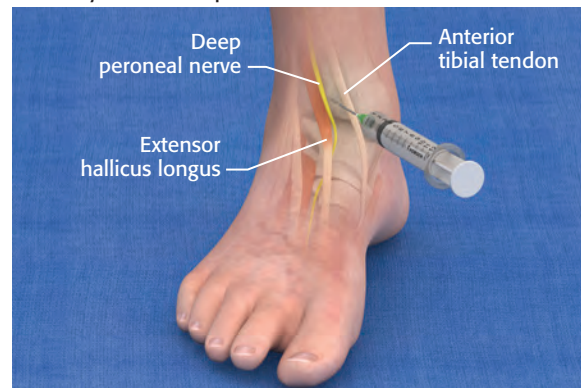

Deep Peroneal

Distribution

D

Anatomy and Technique

Palpate the extensor hallucis longus and anterior tibial tendons while the patient dorsiflexes the foot and big toe. Insert the needle at a level 1 cm superior to the medial malleolus, and direct it laterally under the EHL tendon until it strikes the tibia. Inject 3 to 5 mL of anesthetic.

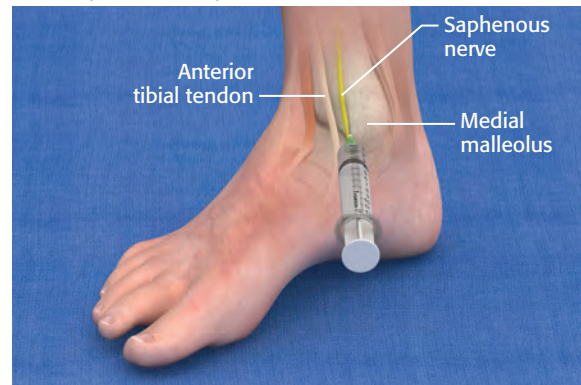

Saphenous

Distribution

E

Anatomy and Technique

First, inject 2 to 5 mL of anesthetic immediately lateral to the radial artery at the level of the proximal palmar crease (not shown). Then inject another 5 to 6 mL from the initial injection point to the dorsal midline.

Figure 31.19, cont'd

elicited, inject 3 to 5 mL of anesthetic. If no paresthesia is produced, advance the needle inward, again at a 45-degree angle, until it hits the posterior aspect of the tibia. Withdraw the needle approximately 1 mm and inject 5 to 7 mL of anesthetic while slowing withdrawing the needle another 1 cm. A rise in temperature of the foot, because of vasodilation from loss of sympathetic tone, may herald a successful block.

Sural Nerve (See Fig. 31.19B)

Block the sural nerve on the lateral aspect of the ankle between the Achilles tendon and the lateral malleolus. Inject 3 to 5 mL of anesthetic subcutaneously in a band approximately 1 cm above the lateral malleolus between the Achilles tendon and the lateral malleolus.

Superficial Peroneal Nerves (See Fig. 31.19C)

Block the superficial peroneal nerves on the anterior aspect of the ankle between the extensor hallucis longus tendon and the lateral malleolus by subcutaneously injecting 4 to 10 mL of anesthetic in a band between these landmarks.

Deep Peroneal Nerve (See Fig. 31.19D)

Block the deep peroneal nerve anteriorly beneath the extensor hallucis longus tendon. The injection site is 1 cm above the base of the medial malleolus between the extensor hallucis longus and anterior tibial tendons. Palpate the tendons by having the patient dorsiflex the big toe and foot, respectively. Create a lidocaine wheal at the injection site. Direct the needle approximately 30 degrees laterally and under the extensor

hallucis longus tendon until it strikes the tibia (at a depth of < 1 cm). Withdraw the needle 1 mm and inject 3 to 5 mL of anesthetic.

Saphenous Nerve (See Fig. 31.19E)

Block the saphenous nerve anteriorly between the medial malleolus and the anterior tibial tendon by injecting 3 to 5 mL of anesthetic subcutaneously between these landmarks.

Nerve Blocks of the Metatarsals and Toes

Like nerve blocks in the hand and fingers, nerve blocks in the foot and toes are commonly used in the ED. Indications for using these blocks include repair of lacerations, drainage of infections, removal of toenails, manipulation of fractures and dislocations, and otherwise painful procedures requiring anesthesia of the forefoot and toes.

Digital nerve blocks in the foot and toes are superior to local infiltration anesthesia for all but the most minor procedures. In the toes, the limited subcutaneous space does not accommodate enough injected material for adequate infiltrative anesthesia. Furthermore, the fibrous septa, which attach the volar skin to the underlying fascia and bone, limit the spread and volume of injected solutions. On the plantar surface, even small amounts of local infiltrate can cause painful distention and local ischemia of the tissues.

Anatomy

Each toe is supplied by two dorsal and two volar nerves, which are branches of the major nerves of the ankle. The dorsal digital nerves are the terminal branches of the deep and superficial peroneal nerves. The volar nerves are branches of the posterior tibial and sural nerves.

The location of the nerves in relation to the bones varies with the site of the foot. In the toes, the nerves lie at the 2, 4, 8, and 10 o'clock positions in close relationship to the bone. In the proximal part of the foot, the nerves run with the tendons and are not in close relationship with the bones (Fig. 31.20).

Technique

The digital nerves can be blocked at the metatarsals, interdigital web spaces, or toes. The bones of the foot can be palpated easily from the dorsum and are used as the landmarks for estimating the location of the nerves. Proximally, the nerves' relationship to the bones is less consistent, which makes definitive needle placement and successful block less reliable. In the toes, the position of the nerves is more consistent; however, minimal subcutaneous tissue space is available for the injected solution. At the web space, the nerves are located in close relationship to the bone, and ample space is available for injecting the anesthetic; hence, for most procedures the web space is the preferred site for a digital nerve block.

The technique for toe and metatarsal blocks is similar (Fig. 31.21). All four nerves supplying each toe are usually blocked because of their sensory overlap. Perform the block from the dorsal surface, where the skin is thinner and less sensitive. Start by placing a 1-mL skin wheal dorsally between the metatarsal bones. Advance the needle until the volar skin tents slightly, and inject 2 mL of anesthetic as the needle is withdrawn. Without removing it, redirect the needle in a different volar direction, and repeat the procedure. Deposit a total of 5 mL of anesthetic in a fanlike pattern in each metatarsal space. Again, because of sensory overlap, two or more spaces need to be anesthetized for each toe to be blocked.

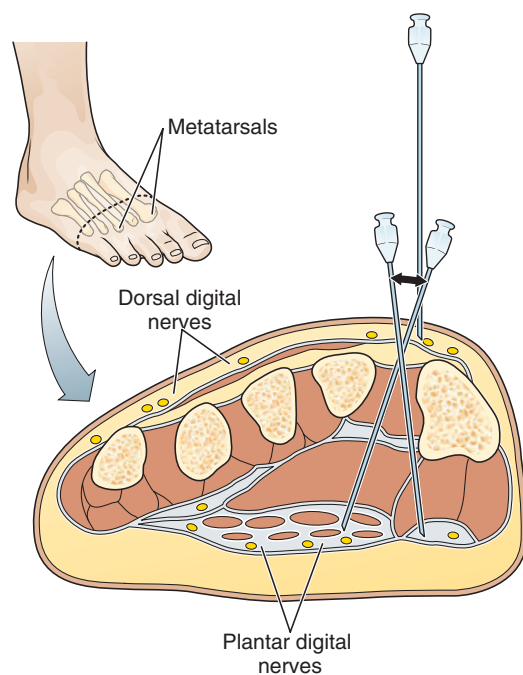

Figure 31.20 Anatomy and technique for a digital nerve block at the metatarsals.

For a web space block, select a site on the dorsum just proximal to the base of the toe. Insert a 3.75-cm, 27-gauge needle attached to a 10-mL syringe at the lateral edge of the bone and place a subcutaneous wheal between the skin and the bone with 0.5 to 1.0 mL of anesthetic. This serves to block the dorsal nerve and minimize pain at the needle insertion site. Advance the needle just lateral to the bone toward the sole until the needle tents the volar skin slightly. Withdraw the needle 1 mm and inject 0.5 to 1.0 mL of anesthetic. As the needle is withdrawn, inject another 0.5 mL to ensure a successful block. Repeat the procedure on the opposite side of the toe. In this manner, two columns of anesthetic are placed on each side of the toe in the area through which the four digital nerves run. A total of 2 to 4 mL of anesthetic is used. For blocks done in the toe itself, the procedure is the same, but smaller amounts of anesthetic (e.g., < 2 mL) are used because of the limited subcutaneous space and fear of vascular compression. Alternative techniques using a single injection site, as described for the finger, can be performed.

Complications and Precautions

Complications of lower extremity nerve blocks are similar to those associated with nerve blocks performed in the upper extremity and include intravascular injection, local anesthetic toxicity, nerve trauma, hematoma formation, and failure of the block.

The precautions that apply to the hand and fingers apply to the foot and toes. Ischemic complications can be avoided by paying attention to changes in the skin during the injection. Blanching heralds possible intravascular injection or vascular compression. If the skin blanches, halt the procedure and reevaluate the position of the needle and the amount and content of the injected solution. The total volume of anesthesia should not exceed the recommended amount. The literature

Figure 31.21 Nerve blocks of the toes.

ULTRASOUND BOX 31.1: Nerve Blocks of the Thorax and Extremities

by Christine Butts, MD

Regional nerve blocks are typically performed by identifying anatomic landmarks and blindly injecting anesthetic agents. Nerve stimulators may be used to identify larger nerves and ensure proper placement of anesthetics. However, these techniques are not infallible and improper placement of anesthetic may result. Additionally, some nerve blocks, such as the scalene block, may be avoided because of concern regarding adjacent anatomic structures. Use of ultrasound allows the clinician to identify the nerve in question, as well as to directly guide the application of anesthetic. Furthermore, nearby structures such as arteries or veins can be identified and avoided, thereby offering the operator greater confidence in performing more advanced blocks. Despite a limited number of randomized controlled trials, preliminary evidence seems to support the use of ultrasound, especially with regard to patient safety.¹

Although each nerve block will require a slightly different approach, similar principles apply. Use a high-frequency transducer (10 to

12 MHz or higher) to ensure the proper resolution and to identify the structures in question (Fig. 31.US1). Gather equipment as described earlier in this chapter. Sterile technique is not typically required for peripheral nerve blocks but should be used when accessing larger, more central structures such as the femoral nerve.

Peripheral nerves have a characteristic appearance when viewed by ultrasound and are usually easily identified, especially in the transverse orientation. They are hyperechoic (white) in appearance and are generally round or oval, although some may also appear more triangular (Fig. 31.US2). In larger nerves, the individual fascicles may be visible, especially when viewed with higher frequency. Nerve trunks (such as those used for scalene blocks) appear as rounded objects with a hypoechoic (darker gray) center (Fig. 31.US3). They may resemble blood vessels so take care to ensure that they are distinguished. This can be done by applying color flow Doppler and noting the absence of blood flow.

ULTRASOUND BOX 31.1: Nerve Blocks of the Thorax and Extremities—cont'd

Figure 31.US1 High-frequency transducer.

Figure 31.US2 Ultrasound image of a peripheral nerve (*arrow*), in this case the median nerve. Peripheral nerves are characterized by a brightly echogenic (*white*) texture and appear slightly fibrillar.

Figure 31.US3 Ultrasound image of a nerve trunk (*arrow*), in this case a brachial plexus trunk. Nerve trunks appear similar to vascular structures, with a hypoechoic (*light gray*) area surrounded by a hyperechoic (*white*) wall. Applying color flow will aid in distinguishing the two.

Figure 31.US4 Ultrasound image demonstrating movement of the transducer to place the target nerve away from the anticipated entry point of the needle. The path of the needle is approximated by the *arrow*.

Figure 31.US5 Introducing the needle along the long axis of the transducer. Use of this technique will allow the sonographer to directly follow the course of the needle as it travels toward the nerve.

Once the nerve has been visualized, the “in-plane” technique is often the most useful to guide the needle to the selected area. Place the transducer in the transverse or slightly oblique plane relative to the nerve. Adjust the transducer so that the nerve is further away from the entry point of the needle (Fig. 31.US4). This will ensure that when the needle is inserted under ultrasound guidance, it can be “followed” as it advances toward the nerve in question. Once the image has been obtained, introduce the needle from the end of the transducer (Fig. 31.US5). Again, the entry point should be away from the nerve. Once the needle tip or needle is seen on screen, advance it toward the nerve. Once the tip of the needle is seen adjacent to the nerve, inject anesthetic under direct ultrasound guidance. The best results are usually obtained by injecting anesthetic in a pattern that surrounds the nerve in a concentric manner. This can be achieved by injecting under ultrasound guidance and then repositioning the tip of the needle

ULTRASOUND BOX 31.1: Nerve Blocks of the Thorax and Extremities—cont'd

Figure 31.US6 Placement of the ultrasound transducer at the level of the thyroid cartilage.

under ultrasound guidance until the nerve has been surrounded. The needle can also be inserted from the midpoint of the transducer, although this technique may cause more difficulty in following the tip of the needle.

Detailed descriptions of the anatomy and technique of the individual nerve blocks can be found throughout this chapter. However, it is important to discuss the nerve blocks typically performed under ultrasound guidance because the landmarks differ slightly.

Interscalene Block

The interscalene nerve blocks focuses on the trunks of the brachial plexus, specifically C5, C6, and C7. Blocking these trunks will provide anesthesia to most of the shoulder and upper extremity and spare the medial aspects of the arm and hand (these are innervated by the C8 and T1 nerve roots). This block is ideal for shoulder dislocations or complex lacerations of the upper extremity.

The trunks can be found grouped together in the neck and are typically easily identified with ultrasound. Because a number of critical structures are located near these trunks, using ultrasound to guide the injection will offer the physician increased confidence in the procedure, as well as increased success in the block. Several methods are described in the literature for localizing the nerve trunks. One of the most straightforward is to use the surrounding anatomy. Begin by placing the transducer, in the transverse orientation, lateral to the trachea at the level of the thyroid cartilage (Fig. 31.US6). Move the transducer laterally until the internal jugular vein and carotid artery are visualized (Fig. 31.US7). Once these vessels are seen, continue moving the transducer slightly laterally until the muscle bellies of the anterior and middle scalenes are visible. The border between the muscles may be subtle; however, shifting the transducer to a slightly oblique plane may help to better distinguish the anatomy. The trunks of the brachial plexus will be seen as rounded structures lying between the muscle bellies (Fig. 31.US8). They typically have an echogenic (white) border with a hypochoic (dark gray) to anechoic (black) center. As noted previously, the nerve trunks can resemble blood vessels, so take care to evaluate the target structures before inserting the needle.

Figure 31.US7 Ultrasound at the level of the thyroid cartilage. The internal jugular (IJ) vein is seen as the large vascular structure. Lying just beneath it is the carotid artery (CA).

Figure 31.US8 A, Ultrasound at the level of the thyroid cartilage. The vascular structures are seen on the right of the image. **B**, The anterior and middle scalenes can be seen with the brachial plexus trunks lying between them (highlighted in the *second image*).

ULTRASOUND BOX 31.1: Nerve Blocks of the Thorax and Extremities—cont'd

Figure 31.US9 Image of the brachial plexus trunks again highlighted in red. In this image, the potential space in the sheath around the trunks is highlighted in blue. Placement of an anesthetic agent in this potential space ensures the intended effect on the nerve trunks with minimal spread to adjacent structures.

Once the nerve trunks have been identified, needle insertion can proceed as described earlier. Typically, 10 to 20 mL of anesthetic is sufficient to achieve blockade, provided that it is injected directly adjacent to the nerve trunks (in the potential space between the trunks and the anterior and middle scalenes) (Fig. 31.US9). Injecting relatively small volumes of anesthetic into this potential space will prevent “overflow” into the potential space anterior to the anterior scalene, where the phrenic nerve is found.

Forearm Nerve Blocks

Although blockade of the nerves that innervate the hand and wrist is typically performed at the wrist by using anatomic landmarks, it can also be performed under direct ultrasound guidance in the forearm. The median, radial, and ulnar nerves are easily identified with ultrasound, and direct visualized injection of anesthetic produces excellent results. Placing the transducer on the middle of the forearm in the transverse orientation will allow rapid identification (Fig. 31.US10). The median nerve is found in the center of the forearm, surrounded by the muscle belly. It is brightly echogenic (white) and usually has an oval or slightly triangular appearance (Fig. 31.US11). The radial nerve can be found toward the radial aspect of the forearm, adjacent to the radial artery and vein (Fig. 31.US12). The ulnar nerve is similarly found on the ulnar aspect of the forearm, adjacent to the ulnar artery and vein (Fig. 31.US13). The radial and ulnar nerves may appear smaller but have a similar echogenic, slightly triangular shape. Once the nerves have been visualized, the block can proceed as described previously.

Lower Extremity Blocks

The femoral nerve is easily blocked with ultrasound and gives anesthesia to the anterior thigh, knee, and hip joint. It is ideal for femur fractures and can be helpful in controlling pain in patients with comorbidities that make more aggressive systemic pain management difficult.

Figure 31.US10 Placement of the transducer over the middle of the forearm to localize the median nerve. The transducer can then be shifted slightly to the right or left to locate the ulnar and radial nerves.

Figure 31.US11 Ultrasound image of the median nerve. Although the median nerve does not travel with an associated artery, it is easily located in the middle of the forearm and is characterized by its triangular appearance. Its hyperechoic (white) structure is highlighted by the arrow in this image.

The femoral nerve is easily identified in the femoral triangle accompanying the femoral vein and artery. A high frequency linear transducer is best suited for identification of these structures in most patients and should be placed transversely (or at a slight oblique angle) at the level of the inguinal crease. The vascular structures should be sought first and if not immediately apparent, can be found by moving the transducer slightly medial and increasing the depth, as vascular structures may be deeper than expected. Typically, the vein is the largest and most medial vessel, and compresses with gentle pressure. The femoral artery is typically more round, thicker walled, and less compressible. It is typically lateral to the vein. The femoral nerve is usually seen as a triangular, hyperechoic (white)

ULTRASOUND BOX 31.1: Nerve Blocks of the Thorax and Extremities—cont'd

Figure 31.US12 Ultrasound image of the radial nerve with its accompanying vascular structures. In contrast to the median nerve, the radial nerve is smaller but can easily be identified by first locating the radial artery (*arrowhead*). The nerve can be identified as the echogenic (*white*) slightly triangular structure (*arrow*) beside the artery.

Figure 31.US13 Ultrasound image of the ulnar nerve with its accompanying vascular structures. In contrast to the median nerve, the ulnar nerve is smaller but can be easily identified by first locating the ulnar artery (*arrowhead*). The nerve can be identified as the echogenic (*white*) slightly triangular structure (*arrow*) beside the artery.

structure lateral to the femoral artery (Fig. 31.US14). The vessels and nerve are bounded superiorly by the fascial planes of the fascia lata.

Once the nerve has been identified, advance a needle using the in-plane technique to infiltrate anesthesia to the surrounding area. Take care to keep track of the needle tip at all times to avoid injecting medication into the artery or vein. An amount of 15 to 20 cc of anesthesia is usually sufficient to achieve anesthesia to the femoral

Figure 31.US14 Image of the femoral triangle as seen with a high frequency transducer. The femoral vein (*V*) is larger and more medial, adjacent to the more lateral and smaller artery (*A*). The femoral nerve is seen as a hyperechoic (*white*) triangle (*arrow*) lateral to the vascular structures. Overlying these three structures is the hyperechoic fascia lata.

nerve. If the nerve is not immediately identified, but the femoral artery and vein are clearly seen, injecting a small amount of anesthesia to the area lateral to the femoral artery may cause the nerve to become more visible. Once the needle tip penetrates the fascial plane created by the fascia lata and is near the area where the nerve would be expected, placement of a small amount (approximately 1 to 2 cc) of anesthetic may make the nerve more visible. This may make the physician more confident in placing larger amounts of medication.

A variation of the femoral nerve block, the 3-in-1 block, utilizes a larger volume of medication in an attempt to obtain a greater area of anesthesia. The 3-in-1 block gives anesthesia to the area supplied by the femoral nerve, but also to the lateral thigh (lateral femoral cutaneous nerve) and the medial thigh (obturator nerve). These three nerves arise from the lumbar plexus and travel proximally within the same fascial compartment. The 3-in-1 block proceeds as described previously, but utilizes a volume of 20 to 30 cc of medication.

To perform the fascia iliaca block using ultrasound guidance, insert the needle in-plane just inferior to the inguinal ligament and guide it under the fascia iliaca, which lies just superior to the vessels. After aspiration, inject 30 to 40 cc of local anesthetic.

The tibial and common peroneal nerves can be blocked in the popliteal fossa to provide anesthesia to the distal part of the calf, ankle, and foot. Both are easily identified in the popliteal fossa, where they exist as separate structures. The transducer should be placed transversely in the popliteal fossa, and the popliteal artery should be sought (Fig. 31.US15). It is easily identified as a pulsatile, rounded, anechoic structure. Once the artery has been identified, the tibial nerve can be found slightly superficial (“high and outside”) to the artery (Fig. 31.US16). As with other peripheral nerves, the tibial nerve appears as an echogenic, rounded structure. Once the tibial nerve has

Figure 31.US15 Placement of the ultrasound transducer in the transverse plane in the popliteal fossa to enable visualization of the tibial and peroneal nerves.

Figure 31.US17 Ultrasound image of the tibial and peroneal nerves. The peroneal nerve (*arrow*) is typically slightly more superficial than the tibial nerve (*arrowhead*).

Figure 31.US16 Ultrasound image of the tibial nerve (*arrow*) viewed in transverse orientation. The popliteal vein can be seen just below the nerve and serves as a landmark for locating the nerve.

been found, it should be followed slightly proximally until the common peroneal nerve is identified. It is similar in appearance to the tibial nerve but is seen more superficially (Fig. 31.US17). Once both nerves have been identified, apply anesthetic under direct ultrasound guidance as described earlier.

suggests that epinephrine-containing anesthetics are safe for digital nerve blocks,³⁰ but some clinicians opt for epinephrine-free alternatives because of the theoretical risk for ischemic complications (see subsection on Complications and Precautions and Chapter 29).

As with upper extremity nerve blocks, note any neural or vascular injuries before the injection. The close proximity of

these structures to the skin and bones means that they are frequently injured. Deficits, even if questionable, should be documented in the record and brought to the attention of the patient before performance of the nerve block.

Intravenous Regional Anesthesia*

James R. Roberts

Clinical use of intravenous regional anesthesia (IVRA) has been well established as a safe,¹⁻³ quick, and effective alternative to general anesthesia in selected cases requiring surgical manipulation of the upper and lower extremities. Though historically relegated to the operating room, the procedure is also readily applicable to outpatient use. Because of its reliability, safety, and ease of use, it is now commonly used in the emergency department (ED) and clinic. In the ED, the technique provides quick and complete anesthesia, muscle relaxation, and a bloodless operating field. The procedure is free from the troublesome side effects associated with other regional blocks, such as the axillary block. The procedure is easily mastered and has a very low failure rate; consistently good results can be expected. Although not a standard requirement of ED personnel, this technique can be safely used by trained ED clinicians, including physician's assistants and nurse practitioners, and does not have to be administered by an

*This chapter is modified with permission from Roberts JR: Intravenous regional anesthesia, *JACEP* 6:261, 1977.

anesthesiologist.³ The first practical use of analgesia associated with the intravenous (IV) injection of a local anesthetic agent was described by August Gustav Bier in 1908.⁴ Colbern has since proposed the eponym *Bier block* (Video 32.1).⁵ Although the procedure has been in existence for many years, the need for special equipment and a safe anesthetic agent limited its use. However, the Bier block has now gained wide acceptance as a safe and effective procedure, and several papers extol its virtues.⁶⁻⁹ Even though complications do exist, no reported fatalities directly attributable to use of the Bier block *with lidocaine* have been reported. In this chapter, the techniques and complications are discussed according to their application in the ED.

INDICATIONS AND CONTRAINDICATIONS

Indications for IVRA include any procedure on the arm or leg that requires operating anesthesia, muscle relaxation, or a bloodless field, such as reduction of fractures and dislocations, repair of major lacerations, removal of foreign bodies, débridement of burns, and drainage of infection (Fig. 32.1). IVRA is commonly used for extremity surgery, such as carpal tunnel surgery or tendon repair. The procedure may be carried out on any patient of any age who is able to cooperate with the clinician.

The only absolute contraindications are allergy to the anesthetic agent and, possibly, uncontrolled hypertension. Relative contraindications include severe Raynaud's disease, Buerger's disease, or a crushed or already hypoxic extremity in which further transient ischemia would be detrimental. Homozygous sickle cell disease is a theoretical contraindication, but few data exist on the treatment of patients with this condition.

Intravenous Regional Anesthesia

Indications

Procedures of the arm or leg that require operating anesthesia, muscle relaxation, or a bloodless field:

- Reduction of fractures and dislocations
- Repair of major lacerations
- Removal of foreign bodies
- Débridement of burns
- Drainage of infection

Contraindications

Absolute

- Allergy to anesthetic agent
- Uncontrolled hypertension

Relative

- Severe Raynaud's disease
- Buerger's disease
- Crushed or hypoxic extremity
- Procedures taking >90 minutes

Complications

- Lidocaine allergy (rare)
- Lidocaine toxicity
- Thrombophlebitis
- Tissue extravasation of anesthetic agent

Equipment

Review Box 32.1 Intravenous regional anesthesia: indications, contraindications, complications, and equipment. A double cuff tourniquet is shown. Not shown is a device required to provide continuous cuff pressure (see Fig. 32.2). Do not use a standard blood pressure cuff.

Figure 32.1 Intravenous regional anesthesia can be used in the emergency department for any procedure on an extremity that requires anesthesia, muscle relaxation, or control of hemorrhage, such as closed reduction of a displaced distal radius fracture like the one depicted here.

IVRA is best used for procedures requiring no more than 60 to 90 minutes of tourniquet time. Continuous cardiac or blood pressure monitoring is not standard and not required unless extenuating circumstances prognosticate potential cardiovascular problems. An uncooperative patient may delay the procedure rather than contraindicate it. The judicious use of standard ED sedation may facilitate the use of IVRA in an anxious or transiently uncooperative patient.

EQUIPMENT

The equipment required for IVRA consists of the following:

- 1% lidocaine (Xylocaine),* *without epinephrine*, to be diluted to a 0.5% solution (Note: 1% lidocaine = 10 mg/mL; hence 1 mL of 1% lidocaine = 10 mg.)
- Clonidine, a parenteral opioid such as fentanyl, or ketorolac if used as additives
- Sterile saline solution as a diluent
- 50-mL syringe/18-gauge needle
- Pneumatic tourniquet (single or double cuff) such as the Zimmer A.T.S. 2000 Automatic Tourniquet System (Zimmer Inc., Bloomfield, CN) (Fig. 32.2) (Note: Do not use a standard blood pressure cuff.)
- IV catheters (20- or 22-gauge) or a 21-gauge butterfly needle
- Elastic bandage/Webril padding
- 500 mL of 5% dextrose in water (D₅W) and IV extension tubing (optional)

PROCEDURE

The procedure should be explained to the patient in advance. Premedication with midazolam (Versed), diazepam (Valium), or an opioid (e.g., morphine, fentanyl) may be helpful but need not be used routinely. The only painful portions of the

*Commercial preparations with preservatives are commonly used. Lidocaine 0.5% is also available.

Figure 32.2 A digital-controlled double-cuff system by Zimmer (A.T.S. 2000, Zimmer Inc., Bloomfield, CN) allows safe intravenous regional anesthesia and the ability to lessen pain from the arterial tourniquet.

procedure are establishment of the infusion catheter and exsanguination. The procedure should not be done on patients who are persistently uncooperative, intoxicated, or obtunded or who have had a previous reaction to a local anesthetic.

The patient need not be free of oral intake for a specific period before the procedure, but it is prudent to delay the procedure if the patient has just eaten a large meal. As a precaution, a suggested option is a large-bore catheter and an IV line with D₅W in the unaffected extremity. General resuscitation equipment, including suction, anticonvulsant drugs, bag-valve-mask (BVM) apparatus, and oxygen, should be available. Continuous cardiac and blood pressure monitoring is not routine but may be used as an option depending on the clinician's assessment of the potential for cardiovascular events.

While the patient is being prepared, keep the lidocaine solution ready, but withhold it until the injured extremity is exsanguinated and the cuff is in place and inflated, as discussed later. The standard dose of lidocaine for the arm is 3 mg/kg. Inject it as a 0.5% solution (1% lidocaine mixed with equal parts sterile saline in a 50-mL syringe). Hence, for a 70-kg patient, infuse 210 mg of lidocaine (21 mL of 1% lidocaine) mixed with 21 mL of saline for a total volume in the infusing syringe of 42 mL of 0.5% lidocaine. Farrell and coworkers described a procedure termed the *minidose Bier block* in which 1.5 mg/kg of lidocaine is used and reported a 95% success rate.¹⁰ This lower dose may decrease the incidence of central nervous system side effects and is more desirable in the ED setting. Additional lidocaine may be infused if the initial dose is inadequate. Do not use lidocaine with epinephrine. Plain lidocaine is also available as a 0.5% solution and can therefore be used directly to avoid diluting the stronger solution. Some

prefer preservative-free lidocaine, but most clinicians use standard lidocaine with preservatives.

Apply a pneumatic tourniquet with cotton padding (to prevent ecchymosis) under the cuff proximal to the pathology. It is strongly advised that one not use a regular blood pressure cuff because these cuffs often leak or rupture and are not designed to withstand high pressure for any length of time. A specially designed portable double-cuff pneumatic system, such as that marketed by Zimmer Corporation, is ideal and preferred by the author.

Premix the anesthetic and saline solution in the syringe. Inflate the tourniquet and place a plastic catheter or a metal butterfly needle in a superficial vein as close to the pathologic site as possible, and securely tape it in place (Fig. 32.3, step 1). It is usually desirable to use a vein on the dorsum of the hand, but importantly, the injection site should be at least 10 cm distal to the tourniquet to avoid injection of anesthetic proximal to or under the tourniquet. Keep the hub on the catheter to avoid backbleeding, or attach the syringe to the butterfly tubing. This catheter will be the route of injection of the anesthetic agent. Anesthesia from a fingertip-to-elbow direction seems to occur irrespective of the site of infusion of the anesthetic, but selecting an injection location near the site of pathology may provide more rapid anesthesia at a lower dosage.

Deflate the tourniquet used to obtain IV access, and exsanguinate the extremity so that when the anesthetic agent is injected, it will fill the drained vascular system. Exsanguination may be accomplished by either of two methods. Simple elevation of the extremity for a few minutes may be adequate, but wrapping the extremity in a distal-to-proximal direction with an elastic or Esmarch bandage, while being careful to not dislodge the infusion needle, significantly enhances exsanguination (see Fig. 32.3, step 2). Wrapping may be painful, so this step can be eliminated if it causes too much anxiety for the patient. If the wrapping procedure is not done, the extremity should be elevated for at least 3 minutes. During the wrapping procedure, take care to not dislodge or infiltrate the infusion catheter.

With the extremity still elevated or wrapped, inflate the tourniquet to 250 mm Hg (or 100 mm Hg above systolic pressure). Place the arm by the patient's side, and remove the elastic exsanguination bandage (see Fig. 32.3, steps 3 to 5). In a child, inflate the tourniquet to 50 mm Hg above systolic pressure. In elderly obese patients with calcified peripheral vessels, arterial occlusion may not be achieved safely.¹¹ In the leg, cuff pressure of 300 mm Hg or approximately twice the systolic pressure measured in the arms is suggested.

With the tourniquet now inflated, slowly inject the 0.5% lidocaine solution into the infusion catheter at the calculated dose (see Fig. 32.3, step 6). Note that the solution is placed in the arm in which the circulation is blocked, not in the precautionary keep-open IV line on the unaffected side. At this point, blotchy areas of erythema may appear on the skin. This is not an adverse reaction to the anesthetic agent but merely the result of residual blood being displaced from the vascular compartment, and it heralds success of the procedure.

In 3 to 5 minutes, the patient will experience paresthesia or warmth beginning in the fingertips and traveling proximally, with final anesthesia occurring above the elbow, to the level of the tourniquet. Complete anesthesia ensues in 10 to 20 minutes, followed by muscle relaxation. Note that adequate analgesia may exist even if the patient can still sense touch and position and has some motor function. If the "minidose" technique (initial dose of 1.5 mg/kg of lidocaine) does not

provide adequate anesthesia, infuse an additional 0.5 to 1 mg/kg of diluted lidocaine at this time. As an example, for a 70-kg patient, an additional 0.5 mg/kg of lidocaine equals 35 mg lidocaine (3.5 mL of 1% lidocaine), and when the 1% lidocaine is diluted equally with saline, the final volume of the additional 0.5% lidocaine is 7 mL. Additional lidocaine was required in 7% of cases in one series in which the minidose regimen was used.¹⁰ The clinician should be patient, however, and wait a full 15 minutes before infusing additional lidocaine. Alternatively, if analgesia is slow or inadequate, an extra 10 to 20 mL of saline solution may be injected to supplement the total volume of solution to enhance the effect. Do not exceed a 3-mg/kg total dose of lidocaine. For obese patients, a maximum of 300 mg of lidocaine is suggested for the arm and no more than 400 mg for the leg. Data for very obese patients do not exist. Next, withdraw the infusing needle and tightly tape the puncture site to prevent extravasation of the anesthetic agent. Perform the surgical procedure or manipulation, including postreduction x-ray films and casting or bandaging (see Fig. 32.3, step 7).

On completion of the procedure, deflation of the tourniquet may be *cycled* to prevent a bolus effect of any lidocaine that may remain in the intravascular compartment. Deflate the cuff for 5 seconds and reinflate it for 1 to 2 minutes. Repeat this action two or three times. This is probably required only if the cuff has been inflated for less than 30 minutes. A single deflation is often performed if the cuff has been inflated for longer than this time.

If the tourniquet has been in place for less than 30 minutes, an increase in transient lidocaine-related side effects may be seen if cycled deflation has not been used because adequate tissue fixation of the lidocaine has probably not occurred. This may result in a higher peak plasma lidocaine level, with increased side effects. If the surgical procedure is completed rapidly and the 3-mg/kg limit of lidocaine has been infused, the tourniquet should remain inflated until 20 to 30 minutes has elapsed, and only then should it be deflated via the cycling technique. It is reasonable to use a 20-minute cutoff if the minidose technique is used or a total of 200 mg or less of lidocaine has been administered because this dose is equal to a commonly administered antiarrhythmic IV bolus.

Sensation returns quickly when the tourniquet is removed, and in 5 to 10 minutes the extremity returns to its pre-anesthetic level of sensation and function. Many patients describe a transient intense tingling sensation after cuff deflation. If the procedure takes longer than 20 or 30 minutes, many patients complain of pain from the tourniquet because it is not inflated over an anesthetized area. Use of a double-cuff tourniquet may alleviate the problem of pain under the cuff. A wide tourniquet cuff (14 cm) is less painful than a narrow tourniquet (7 cm) when the cuff is inflated 10 mm Hg above loss of the arterial pulse.¹² The reason for pain under the tourniquet is unknown, but this can be a limiting factor because most patients begin to feel significant discomfort after 30 minutes if only a single cuff is used. Tourniquet pain can be significantly reduced and tourniquet time extended by adding ketorolac to the lidocaine anesthetic (see later).

In the *preferred* double-cuff system, two separate tourniquets are placed side by side on the extremity. One is termed the *proximal cuff* and the other the *distal cuff*. The proximal cuff is inflated at the beginning of the procedure, and anesthesia is obtained under the deflated distal cuff. When the patient begins to feel pain under the proximal cuff, the distal cuff is

Intravenous Regional Anesthesia

1

Place an IV catheter or butterfly needle as close to the pathologic site as possible. The site should be at least 10 cm distal to the tourniquet. A dorsal hand vein is ideal.

2

Exsanguinate the extremity by elevating and wrapping it in a distal-to-proximal fashion. Here, an Esmarch bandage is being used.

3

Apply the tourniquet to the patient's arm.

4

Inflate the tourniquet to 250 mm Hg or 100 mm Hg above systolic pressure. In the leg, inflate the cuff to 300 mm Hg or twice the systolic pressure measured in the arm.

5

Place the patient's arm by his side and remove the Esmarch bandage. The tourniquet remains inflated.

6

Slowly inject the 0.5% lidocaine solution into the infusion catheter at the calculated dose. See text for details and dosing information.

7

Remove the infusing needle/catheter, and tightly tape the puncture site to prevent extravasation of the anesthetic agent. Perform the procedure, including postreduction films and casting.

8

Once the procedure is complete, deflate the tourniquet in a cycling fashion (deflate for 5 seconds, reinflate for 1 to 2 minutes) 2 or 3 times. Then remove the tourniquet.

Figure 32.3 Intravenous regional anesthesia. A double cuff tourniquet is depicted in the figures. The procedure depicted demonstrates the use of a single tourniquet; refer to the text for details regarding the use of a double tourniquet.

BOX 32.1 IVRA: Step-by-Step Procedure

Begin an intravenous (IV) line in the uninvolved extremity (optional, but highly recommended to give fluids, sedatives, or other medications should any adverse reactions occur). Draw up and dilute 1% plain lidocaine (1.5- to 3-mg/kg total lidocaine dose) for a final concentration of 0.5% lidocaine.^a Place a padded tourniquet and inflate the upper cuff. Insert a small plastic IV cannula near the pathologic lesion and secure it. Deflate the tourniquet. Elevate and exsanguinate the extremity. Inflate the tourniquet (250 mm Hg), lower the extremity, and remove the exsanguination device. Inflate the proximal cuff only if a double-cuff system is used. Infuse the anesthetic solution. Remove the infusion needle and tape the site. Perform the procedure. If pain is produced by the tourniquet, *inflate the distal cuff first*, and then deflate the proximal cuff. After the procedure has been carried out, deflate the cuff for 5 seconds and then reinflate it for 1 to 2 minutes. Repeat this step three times. Do not deflate the cuff if total tourniquet time is less than 20 to 30 minutes. Observe 45 to 60 minutes for possible reactions.

^aCommercial preparations with or without preservatives are acceptable.

From Roberts JR: *Intravenous regional anesthesia*, JACEP 6:263, 1977. Reproduced with permission.

first inflated over an already anesthetized area, and the pain-producing proximal cuff is then deflated. One must be certain to inflate the distal cuff before the proximal cuff is released; otherwise, the anesthetic will rapidly diffuse into the general circulation.

After 45 to 60 minutes of observation, the patient may be discharged (Box 32.1). Observation time depends on the use of other medications, procedural difficulties, and overall assessment of the patient. There are no standard or specific post-procedure instructions, but precautions similar to those given for conscious sedation are reasonable. Driving is best prohibited for 6 to 8 hours, and the patient should leave with a responsible adult. Delayed complications from lidocaine have not been reported.

MECHANISM OF ACTION

Some of the anesthesia is undoubtedly related to the ischemia produced by the tourniquet, but most of the anesthesia is secondary to the anesthetic agent itself. Although the exact mechanism by which anesthesia is produced is unknown, the site of action of the anesthetic may be at sensory nerve endings, neuromuscular junctions, or major nerve trunks.¹³ Contrast-enhanced studies have demonstrated that the anesthetic agent does not diffuse throughout the entire arm, yet anesthesia of the entire limb is obtained. For example, when the anesthetic agent is injected into the elbow and kept in that region with both distal and proximal tourniquets, anesthesia of the entire arm develops.¹⁴ Evidence indicates that the local anesthetic does not simply diffuse from the venous system into tissue but

travels via vascular channels directly inside the nerve. Regardless of where the anesthetic is infused, the fingertips are the first area to experience anesthesia, thus suggesting that the core of the nerve is in contact with the anesthetic agent initially. After release of the tourniquet, a considerable amount of the drug still remains in the injected limb for at least 1 hour.¹⁵ This would suggest that at least a portion of the anesthetic leaves the vascular compartment and becomes fixed in tissue.

PROCEDURAL POINTS**Anesthetic Agent**

Use of 0.5% plain lidocaine at a dose of 1.5 to 3 mg/kg is preferred for the upper extremity. A similar dose may be used in the leg if a *calf* tourniquet is used. For procedures in the leg, using a thigh cuff, 150 mL of 0.25% lidocaine (375 mg) has been used. The greater volume can augment drug distribution in the larger lower extremity. Other agents have been used without demonstrable advantage and are not recommended.¹⁶ Bupivacaine (Marcaine, Sensorcaine) is *contraindicated* because of the potential for serious cardiovascular and neurologic complications.^{17,18}

Some authors have suggested the use of IV ketorolac (60 mg) or clonidine (0.15 mg if the IV preparation is available) in addition to the lidocaine.^{19,20} These additives are mixed with the lidocaine and injected into the operative arm. Both have been shown to be safe, and they decrease the need for postoperative analgesics and antiemetics. Tourniquet time is prolonged with these agents as pain under the tourniquet is the main reason for discontinuing the procedure. Opiates have not been found to be helpful when added to the lidocaine but may be given at a distant site (such as via the IV infusion in the opposite arm) for general pain control.

Dunbar and Mazze showed that patients with IVRA actually had significantly lower plasma lidocaine concentrations than did those with an axillary block or lumbar epidural anesthesia for similar procedures.⁸ Peak plasma concentrations are reached 2 to 3 minutes after deflation of the tourniquet, and side effects are minimal if the deflation is cycled after the surgical procedure. The plasma half-life of lidocaine is approximately 60 seconds (see the excellent detailed discussion of pharmacokinetics by Covino²¹), but the drug demonstrates a theoretical three-compartment model similar to a direct IV infusion once the tourniquet is released.²² Peak blood levels are related to the duration of vascular occlusion and to the concentration of the anesthetic.^{21,22}

Peak plasma lidocaine levels after release of the tourniquet decrease as the time of vascular occlusion (tourniquet time) increases. If the tourniquet is inflated for at least 30 minutes and the deflation-reinflation technique is used when the procedure is finished, the plasma concentration of lidocaine should be approximately 2 to 4 µg/mL, below the 5- to 10-µg/mL level at which dose-related lidocaine reactions occur.⁸ Tucker and Boas demonstrated a peak plasma lidocaine level of 10.3 µg/mL after a 10-minute period of vascular occlusion,²² as opposed to 2.3 µg/mL if the tourniquet was inflated for 45 minutes.

More dilute solutions of lidocaine are associated with lower peak lidocaine levels. When equal doses of lidocaine are used, peak arterial plasma levels are 40% lower if the 0.5% solution is used than if the 1% solution is used.²² For example, after 10

minutes of vascular occlusion, the peak plasma concentration of lidocaine has been demonstrated to reach 10.3 µg/mL with the 1% solution versus only 5.6 µg/mL when the drug was given under similar circumstances at a 0.5% concentration.²²

Exsanguination

Many clinicians consider exsanguination of the extremity before injection of the anesthetic agent to be essential for success. Others do not believe that it is a critical factor. Exsanguination by simple elevation of the extremity should be done in all cases, but in certain instances one should consider avoiding the painful wrapping of the extremity with an elastic or Esmarch bandage. (Note that applying an Esmarch wrap over a fracture site is usually quite painful.) A pneumatic splint, such as the type used for prehospital immobilization, is also a reasonable alternative to painful wrapping. The process of exsanguination is believed to allow better vascular diffusion of the anesthetic.

Site of Injection

Anesthesia is usually achieved no matter where the local anesthetic is injected, but some evidence indicates that the procedure is more successful when the anesthetic is injected distally. Sorbie and Chacha noted the following failure rates associated with specific sites of anesthetic injection²³: antecubital fossa, 23%; middle of the forearm or leg, 18%; and hand, wrist, or foot, 4%. In most cases a vein in the dorsum of the hand or foot is used. If local pathology precludes use of the hand, the midforearm or antecubital fossa of the elbow is an acceptable, albeit less desirable, alternative as long as the infusion catheter is well below the tourniquet to avoid systemic injection.

Although most of the literature stresses use of this technique on the upper extremity, it may also be used successfully on the leg. It cannot, however, be used for procedures above the knee. Tourniquet pain appears to be a limiting factor when the procedure is used on the leg. One must be certain to avoid damage to the peroneal nerve by using the tourniquet in the midcalf area only.

COMPLICATIONS

Although IVRA is both safe and simple, one should not be lulled into complacency because complications do occur and are usually related to equipment failure or mistakes in technique.

Anesthetic Agent

Serious complications seldom occur if proper attention is paid to technique. True lidocaine allergy is very rare. Other reactions to lidocaine are rare and are usually systemic reactions from high blood levels.^{8,18,24} High levels may result from miscalculation of dosages, from too rapid release of the tourniquet before the anesthetic has become fixed in tissue (“bolus effect”), or rarely, from advancement of the infusion catheter proximal to the tourniquet, thereby resulting in direct IV infusion.²⁵ To emphasize the safety of this procedure, note that the dose of lidocaine used in the minidose technique is similar to an IV bolus routinely given to patients with significant cardiovascular disease in the presence of ventricular dysrhythmias.

Generally, the central nervous system effects of lidocaine are minor and result in mild reactions such as dizziness, tinnitus, lethargy, headache, or blurred vision. This should not occur in more than 2% to 3% of patients and requires no treatment.⁸ Transient hypotension and bradycardia may develop but are generally self-limited. Convulsions may occur but are extremely rare.

The most common complication related to the anesthetic agent is rapid systemic vascular infusion, which occurs when a blood pressure cuff explodes or slowly leaks, with consequent loss of anesthesia and high blood levels.²⁶ Similar complications may occur if the cuff is deflated earlier than 20 to 30 minutes after the induction of anesthesia. Both complications are the result of a bolus effect of the anesthetic, similar to an IV injection.

Van Neikerk and Tonkin reported three seizures in a series of 1400 patients.²⁴ Auroy and colleagues reported 23 seizures in 11,229 cases,²⁷ with no cardiac arrest or fatalities, and deemed IVRA safer than general anesthesia or peripheral nerve blocks. Seizures are generally not recurrent and are treated with oxygen and anticonvulsant drugs. Transient cardiovascular reactions, such as bradycardia and hypotension, are possible with large doses of lidocaine. Vasovagal reactions do occur. If resuscitation equipment is available and a precautionary IV line is started in the opposite arm, there should not be any serious sequelae.

One case of cardiac arrest 15 seconds after the use of 200 mg lidocaine has been reported, but the actual clinical scenario may have been a vasovagal reaction rather than a true cardiac arrest.²⁸

Additional Complications

Thrombophlebitis can occur following the IV administration of anesthetics, and the formation of insignificant amounts of methemoglobin with the use of prilocaine hydrochloride (Citanest) has been reported.²⁹ Methemoglobinemia can also theoretically occur with lidocaine but has not been reported. Bupivacaine offers no benefit over lidocaine, has been associated with deaths, and should be avoided.³⁰

A particularly bothersome problem is infiltration or dislodgement of the infusion catheter during exsanguination and tissue extravasation of the anesthetic agent. In addition, some leakage of anesthetic can occur after the infusion needle has been removed. Both problems may result in poor anesthesia but may be minimized if a small, well-secured plastic infusion needle is used instead of a metal scalp vein (“butterfly”) needle and if the puncture site is tightly taped after withdrawal of the catheter.

This procedure cannot be used for manipulations or operations in which the pulse must be monitored as a guide to reduction (e.g., supracondylar fractures of the humerus) because the tourniquet occludes arterial flow. Use of the Bier block in patients with sickle cell disease is not well documented. It should be used with caution until the ischemic effect of the tourniquet on the red blood cells of such patients has been clarified. In all patients, tourniquet time should not exceed 90 minutes. Ischemia for less than this amount of time is not associated with serious sequelae.

An excellent summary of a very favorable experience with IVRA of both the arm and leg in 1900 outpatients is available.³¹

Systemic Analgesia and Sedation for Procedures

Kenneth Deitch

Procedural sedation and analgesia (PSA) refers to the use of analgesic, dissociative, and sedative agents to relieve the pain and anxiety associated with diagnostic and therapeutic procedures. PSA is an integral element of emergency medicine residency and pediatric emergency medicine fellowship training and curricula, and graduates of these programs are skilled in the practice of PSA. Moreover, by virtue of their training, emergency clinicians are proficient in resuscitation, vascular access, and advanced airway management, which permits them to effectively recognize and manage the potential complications associated with PSA.¹

In a study of all practitioners, the most common clinical errors associated with PSA were delayed recognition of respiratory depression and arrest, inadequate monitoring, and inadequate resuscitation,² mistakes that are unlikely to be made by emergency clinicians. The safety of PSA techniques by emergency clinicians has been well documented in numerous series in both children and adults.³⁻⁷ Safe and successful application of PSA requires careful patient selection, customization of therapy to the specific needs of the patient, and careful monitoring of patients for adverse events. Emergency clinicians must ensure that all patients receive pain relief and sedation commensurate with their individual needs during any procedure.

TERMINOLOGY

The progression from minimal sedation to general anesthesia is a nonlinear continuum that does not lend itself to division into arbitrary stages. Low doses of opioids or benzodiazepines induce mild analgesia or sedation, respectively, with little danger of adverse events. If, however, clinicians continue administering additional medication beyond this initial level, progressively altered consciousness ensues with a proportionately increased risk for respiratory and airway complications. If further medications are administered, the patient will advance along this continuum until protective airway reflexes are lost and general anesthesia is ultimately reached. This continuum of sedation is not drug specific in that varying states from mild sedation to general anesthesia can be achieved with virtually all nondissociative PSA agents (e.g., opioids, benzodiazepines, barbiturates, etomidate, propofol).

In 1985, the American Academy of Pediatrics (AAP) and the National Institutes of Health issued guidelines for the management and monitoring of children receiving sedation for diagnostic and therapeutic procedures in response to the growing use of opioids and sedative-hypnotic agents in the outpatient setting and a number of sedation-related deaths.^{8,9} In these documents, three levels of sedation were defined (conscious sedation, deep sedation, and general anesthesia) to

create a common language for describing drug-induced alterations in consciousness (Box 33.1).^{10,11} A key development in the field of PSA has been revision of the original terminology and adoption of clearer descriptions of varying types and degrees of sedation (see Box 33.1). Though historically popular, the widely misinterpreted and misused term “conscious sedation” has fallen into disfavor¹²; it has been labeled as “confusing,”¹³ “imprecise,”¹² and an “oxymoron”^{12,13} and has been replaced with the term “moderate sedation.”¹⁰

Despite improvements in PSA terminology, the system is imperfect and there is still no objective way to assess the depth of sedation. Levels of responsiveness remain at best crude surrogate markers of respiratory drive and retention of protective airway reflexes. This is especially true for all levels of sedation in young children (infants and toddlers) who do not understand or are unreliable in following verbal commands. Although respiratory depression and respiratory arrest can be detected quickly with standard interactive and mechanical monitoring, there is no safe and practical way to assess the status of protective airway reflexes. Data are currently insufficient to determine whether deep sedation is associated with impairment of protective reflexes or whether such danger is encountered only when “pushing” deep sedation to the point at which it approaches or reaches general anesthesia.

PSA GUIDELINES

Before the promulgation of PSA guidelines by specialty societies and governmental agencies, clinicians simply administered sedatives in varied clinical settings and used individual judgment to determine the need for specific monitoring devices and supporting personnel. Since 1985, at least 27 sets of PSA guidelines have been published,¹⁴ each crafted for the unique and differing settings in which PSA is practiced. Naturally, not all are in agreement.⁵ The intent of each of these guidelines is to better standardize the manner in which PSA is performed to enhance patient safety. Those most pertinent to emergency clinicians are from the American College of Emergency Physicians (ACEP),³ the AAP,¹⁵ and the American Society of Anesthesiologists (ASA).^{16,17}

In the early 1990s, the Joint Commission on Accreditation of Healthcare Organizations, an independent, not-for-profit organization that evaluates and accredits hospitals in the United States, took a special interest in PSA, with the central theme being that the standard of sedation care provided should be comparable throughout a given hospital. Thus, patients sedated in the emergency department (ED) should not receive a significantly different level of attention or monitoring than those sedated for a similar-level procedure in the operating room or in the endoscopy suite. To ensure this, the Joint Commission requires specific PSA protocols to be applied consistently throughout each institution. These hospital-wide sedation policies will vary from site to site based on the specific needs and expertise available within each institution. In 2001, the Joint Commission released new standards for pain management, sedation, and anesthesia care.¹⁰

At each hospital accreditation survey the Joint Commission determines whether practitioners practice PSA consistent with their hospital-wide sedation policy and whether they provide sufficient documentation of such compliance. Clinicians must be familiar with their hospital’s sedation policies and should work with their medical staff to ensure that such policies are

BOX 33.1 PSA: Terminology and Definitions**GENERAL**

- **Analgesia¹⁰**: Relief of pain without intentional production of an altered mental state such as sedation. An altered mental state may be a secondary effect of medications administered for this purpose.
- **Anxiolysis¹⁰**: A state of decreased apprehension concerning a particular situation in which there is no change in a patient's level of awareness.
- **PSA³**: A technique of administering sedatives, analgesics, dissociative agents, or any combination of such agents to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function. PSA is intended to result in a depressed level of consciousness but one that allows the patient to maintain airway control independently and continuously. Specifically, the drugs, doses, and techniques used are not likely to produce loss of protective airway reflexes.

CURRENT SEDATION STATE: TERMINOLOGY

- **Minimal sedation (anxiolysis)¹⁰**: A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular function is unaffected.
- **Moderate sedation (formerly conscious sedation)¹⁰**: A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either

alone or accompanied by light tactile stimulation. Reflex withdrawal from a painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

- **Dissociative sedation¹¹**: A trancelike cataleptic state induced by the dissociative agent ketamine and characterized by profound analgesia and amnesia with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.
- **Deep sedation¹⁰**: A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
- **General anesthesia¹⁰**: A drug-induced loss of consciousness during which patients cannot be aroused, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients frequently need assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

PSA, *Procedural sedation and analgesia*.

suitably detailed, yet reasonable and realistic. Unduly restrictive policies do a disservice to patients by discouraging appropriate levels of analgesia and sedation. Most hospitals pattern their sedation policies after the Joint Commission standards and definitions. It is important to note that the unique ketamine dissociative state does not fit into the existing Joint Commission definitions of sedation and anesthesia.¹¹ A ready solution is to assign a distinct definition for “dissociative sedation” (see Box 33.1).

The Joint Commission requires that PSA practitioners who are permitted to administer deep sedation be qualified to rescue patients from general anesthesia.¹⁰ Emergency clinicians typically perform all levels of sedation except general anesthesia. Moderate sedation suffices for the majority of procedures in adults and cooperative children, although it will not be adequate for extremely painful procedures (e.g., hip reduction, cardioversion). Deep sedation can facilitate such procedures, but with greater risk for cardiorespiratory depression than is the case with moderate sedation. Moderate sedation is frequently insufficient for effective anxiolysis and immobilization in younger, frightened children, and deep or dissociative sedation is an appropriate alternative.

The Centers for Medicare & Medicaid Services (CMS) has published similar requirements for hospital anesthesia services that also includes the provision of PSA throughout a given institution. Health care institutions wishing to bill Medicare must adhere to these guidelines and provide supporting documentation when requested. In 2011, CMS issued revised guidelines to help clarify various provisions of their anesthesia services requirements.¹⁸ The new CMS guidelines emphasize that hospital policies governing the provision of anesthesia

services (including PSA) must be based on nationally recognized guidelines; the source of these guidelines may include a number of specialty organizations, including ACEP.³ CMS also notes that “The ED is a unique environment where patients present on an unscheduled basis with often very complex problems that may require several emergent or urgent interventions to proceed simultaneously to prevent further morbidity or mortality,” and that, “...emergency medicine-trained physicians have very specific skill sets to manage airways and provide the ventilation necessary for patient rescue. Therefore these practitioners are uniquely qualified to provide all levels of analgesia/sedation and anesthesia (moderate to deep to general).”¹⁸

EVALUATION BEFORE PSA

The practice of PSA has three essential components performed in sequence: the initial presedation evaluation, sedation during the procedure, and postprocedure recovery and discharge from the ED. In all but the most emergency situations, perform a directed history and physical examination before PSA. If this evaluation suggests additional risk, reconsider the advisability of sedation. High-risk cases may be better managed in the more controlled environment of the operating room.

Presedation assessment is a Joint Commission requirement, and most hospitals have developed specific forms to facilitate consistent documentation of the required items. In general, however, all the appropriate parameters are already documented in the general ED record or are obvious by simply evaluating the patient's complaint. Except in emergency situations, discuss the risks, benefits, and limitations of any PSA with the patient

TABLE 33.1 ASA Physical Status Classification

ASA CLASS	DESCRIPTION	EXAMPLES	SUITABILITY FOR SEDATION
1	Normal healthy patient	Unremarkable past medical history	Excellent
2	Patient with mild systemic disease—no functional limitation	Mild asthma, controlled seizure disorder, anemia, controlled diabetes mellitus	Generally good
3	Patient with severe systemic disease—definite functional limitation	Moderate to severe asthma, poorly controlled seizure disorder, pneumonia, poorly controlled diabetes mellitus, moderate obesity	Intermediate to poor; consider benefits relative to risks
4	Patient with severe systemic disease that is a constant threat to life	Severe bronchopulmonary dysplasia; sepsis; advanced degrees of pulmonary, cardiac, hepatic, renal, or endocrine insufficiency	Poor; benefits rarely outweigh risks
5	Moribund patient not expected to survive without the operation	Septic shock, severe trauma	Extremely poor

or parent or guardian in advance and obtain verbal agreement. Formal written informed consent is not required as a standard of care (but may be an institutional requirement), although documentation, as discussed earlier, is essential.

General

Assess the type and severity of any underlying medical problems. This is usually best documented by the standard ED medical record, history, physical examination, and nursing notes. Another tool used for this purpose is the ASA physical status classification for preoperative risk stratification (Table 33.1). Verify current medications and allergies and inquire about previous adverse experiences with PSA or anesthesia.

Airway

Inspect the airway to determine whether any abnormalities (e.g., severe obesity, short neck, small mandible, large tongue, trismus) are present that might impair airway management. Consider assessments such as Mallampati scoring or the distance between the chin and hyoid bone (see Chapter 4; Fig. 4.3).

Cardiovascular

Perform cardiac auscultation to assess for disturbances in rhythm or other abnormalities. In patients with known cardiovascular disease, evaluate their degree of reserve because most PSA agents can cause vasodilatation and hypotension.

Respiratory

Perform lung auscultation to assess for active pulmonary disease, especially obstructive lung disease and upper respiratory infections that may predispose the patient to airway reactivity.

Gastrointestinal

Assess the time and nature of the last oral intake because pulmonary aspiration of gastric contents may occur if the patient

vomits when protective airway reflexes are impaired. Fig. 33.1 shows a four-step assessment tool to stratify the risk for aspiration before sedation and to identify prudent limits of targeted sedation,¹⁹ although this tool has not yet been validated.

More conservative guidelines from the ASA for elective surgery or procedures in healthy patients specify an age-stratified fasting requirement of 2 to 3 hours for clear liquids and 4 to 8 hours for solids and nonclear liquids.²⁰ Nonetheless, they acknowledge that, regarding PSA, “the literature provides insufficient data to test the hypothesis that preprocedure fasting results in a decreased incidence of adverse outcomes.”^{14,17} Since these guidelines were published, multiple ED studies comparing fasting times in both pediatric and adult patients undergoing PSA failed to demonstrate a significant difference in the rates of emesis or aspiration and no other serious adverse events resulting from emesis or aspiration were identified.^{21–25}

The concept of preprocedure fasting is logistically difficult or impossible for emergency clinicians, who have no control over patients’ oral intake before arrival at the ED. In actual practice, emergency clinicians routinely perform PSA safely on patients who are noncompliant with the ASA elective-procedure fasting guidelines.^{19,20,26} Procedures can sometimes be delayed for several hours; however, this must be balanced against prolongation of pain and anxiety in the patient, inconvenience for the patient and family, and expenditure of room space and other finite ED resources. In addition, many ED procedures require urgent if not immediate attention (e.g., débridement and repair of animal bite wounds, acute burn management, arthrocentesis for suspected septic arthritis, reduction of joint dislocations, lumbar puncture in an uncooperative septic patient, hernia reduction, eye irrigation for ocular trauma or chemical burns, cardioversion in a hemodynamically unstable patient). Though uncommon, there may be occasions in which nonfasting patients require urgent procedures with a substantial depth of sedation that may be more safely managed in the operating room with endotracheal intubation to protect the airway.

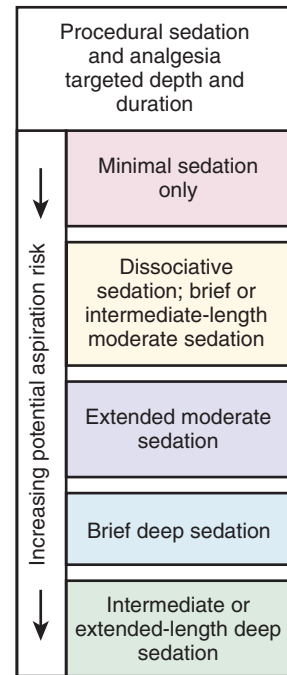

Selecting agents that are less likely to produce vomiting, such as fentanyl instead of morphine or meperidine, may decrease the potential for aspiration. Concomitant antiemetic

Standard-risk patient^a

 Intermediate: 10–20 minutes
 Extended: > 20 minutes

Figure 33.1 Prudent limits of targeted depth and length of emergency department procedural sedation and analgesia based on presedation assessment of aspiration risk.

A. Higher-risk patients are those with one or more of the following present to a degree individually or cumulatively judged clinically important by the treating clinician:

- Potential for difficult or prolonged assisted ventilation should an airway complication develop (e.g., short neck, small mandible/micrognathia, large tongue, tracheomalacia, laryngomalacia, history of difficult intubation, congenital anomalies of the airway and neck, sleep apnea)
- Conditions predisposing to esophageal reflux (e.g., elevated intracranial pressure, esophageal disease, hiatal hernia, peptic ulcer disease, gastritis, bowel obstruction, ileus, tracheoesophageal fistula)
- Extremes of age (e.g., > 70 years or < 6 months)
- Severe systemic disease with definite limitation in function (i.e., American Society of Anesthesiologists physical status ≥ 3)
- Other clinical findings leading the emergency physician to judge the patient to be at higher than standard risk (e.g., altered level of consciousness, frail appearance)

B. Procedural urgency:

- Emergency (e.g., cardioversion for life-threatening dysrhythmia, reduction of a markedly angulated fracture or dislocation with soft tissue or vascular compromise, intractable pain or suffering)
- Urgent (e.g., care of dirty wounds and lacerations, animal and human bites, incision and drainage of abscesses, fracture reduction, hip reduction, lumbar puncture for suspected meningitis, arthrocentesis, neuroimaging for trauma)
- Semiurgent (e.g., care of clean wounds and lacerations, shoulder reduction, neuroimaging for new-onset seizures, removal of foreign bodies, examination for sexual assault)
- Nonurgent or elective (e.g., nonvegetable foreign body in the external auditory canal, chronic embedded soft tissue foreign body, ingrown toenail) (From Green SM, Roback MG, Miner JR, et al: Fasting and emergency department procedural sedation and analgesia: a consensus-based clinical practice advisory, *Ann Emerg Med* 49:454,2007.)

administration is an unproven adjunct but a common consideration. In summary, common sense should apply and clinical judgment should prevail, but it is standard for PSA to be performed in the ED on patients in the nonfasting state.

Hepatic and Renal

The implications of delayed metabolism or excretion of PSA agents in infants younger than 6 months, in the elderly, and in patients with hepatic or renal abnormality should be considered.

PERSONNEL AND INTERACTIVE MONITORING

The most important element of PSA monitoring is close and continuous observation of the patient by an individual capable of recognizing complications of sedation (Fig. 33.2). This person must be able to continuously observe the patient's face, mouth, and chest wall motion. Equipment or sterile drapes must not interfere with such visualization. Such careful observation allows prompt detection of adverse events such as respiratory depression, apnea, partial airway obstruction, emesis, and hypersalivation.

PSA personnel should understand the pharmacology of analgesic and sedative agents and their respective reversal agents. They must be proficient in maintaining airway patency and assisting ventilation if needed. PSA requires a minimum of two experienced individuals, most frequently one clinician and one nurse or respiratory therapist. The clinician typically oversees drug administration and performs the procedure, whereas the nurse or respiratory therapist continuously monitors the patient for potential complications. The nurse or respiratory therapist should also document the medications administered and the response to sedation and measure vital signs periodically. The nurse or respiratory therapist may assist in minor, interruptible tasks but must remain focused on the patient's cardiopulmonary status, and this responsibility must not be impaired. An individual with advanced life support skills should also be immediately available, which is a requisite easy to fulfill in the ED setting.

During deep sedation, the individual dedicated to patient monitoring should have experience with this depth of sedation and no other responsibilities that would interfere with the advanced level of monitoring and documentation appropriate for this degree of sedation.¹⁶ Individual hospital-wide sedation policies may have additional requirements regarding how and when deep sedation is administered based on the patient's specific needs and the clinician's expertise.

It is not mandatory to have intravenous (IV) access in situations in which sedation is administered by the intramuscular (IM), oral, nasal, inhalational, or rectal routes, but it may be preferable based on the anticipated depth of sedation, comorbid conditions, or additional drug titration. When sedation is performed without IV access, an individual skilled in initiating such access should be immediately available.

EQUIPMENT AND MECHANICAL MONITORING

The routine use of mechanical monitoring has greatly enhanced the safety of PSA. With current technology, oxygenation (via pulse oximetry), ventilation (via capnography), and hemodynam-

ics (via blood pressure and electrocardiogram [ECG]) can all be monitored noninvasively in nonintubated, spontaneously breathing patients.

Pulse Oximetry

Mechanical monitoring for PSA should include continuous pulse oximetry with an audible signal. Pulse oximetry measures the percentage of hemoglobin that is bound to oxygen. If the patient is breathing room air (21% oxygen), pulse oximetry will detect a decrease in alveolar ventilation rather quickly. Most patients undergoing procedural sedation in the ED are given supplemental oxygen by nasal cannula. With preoxygenation or the continued use of supplemental oxygenation during a procedure, the pulse oximetry will take significantly longer to drop despite the complete absence of ventilation. With preoxygenation it may take 4 to 5 minutes of apnea before the pulse oximetry will drop significantly. Hence, pulse oximetry is not a substitute for monitoring ventilation because of the variable lag time between the onset of hypoventilation or apnea and a change in the oxygen saturation of hemoglobin molecules.

Capnography

Capnography is a very useful tool that provides a continuous, breath-by-breath measure of the respiratory rate and CO₂ exchange. Capnography readings are not affected by the presence or absence of additional oxygen. When sedated patients begin to hypoventilate, the end-tidal CO₂ will rise. When apnea occurs, the end-tidal CO₂ drops to zero. Importantly, capnography can detect the common adverse airway and respiratory events associated with PSA.^{27–39} Capnography detects the earliest airway or respiratory compromise and will show abnormally high or low end-tidal CO₂ pressure well before pulse oximetry detects falling oxyhemoglobin saturation, especially in patients receiving supplemental oxygen. Early detection of respiratory compromise is especially important in infants and toddlers, who have smaller functional residual capacity and greater oxygen consumption than older children and adults.^{40–42} Capnography provides a non-impedance-based respiratory rate directly from the airway (via an oral-nasal cannula). This is more accurate than impedance-based respiratory monitoring, especially in patients with obstructive apnea or laryngospasm, in whom impedance-based monitoring will interpret chest wall movement without ventilation as a valid breath.

Multiple studies of patients undergoing PSA in a variety of clinical settings have demonstrated that capnography identifies respiratory depression earlier^{28,43} and more frequently^{34,42,44–46} than standard monitoring techniques (e.g., pulse oximetry, observation). Moreover, several additional studies have demonstrated that the use of capnography reduces the incidence of hypoxic events in both children⁴⁷ and adults.^{48–51} However, there is no evidence that capnography reduces the incidence of serious adverse events such as neurologic injury (secondary to hypoxia), aspiration, or death.⁵² An additive role for capnography in cases of PSA in the ED has not been proven. As a result, capnography is not an agreed upon standard for procedural sedation in the ED. The American College of Emergency Physician's current clinical policy on PSA gives the use of capnography a level B recommendation (recommendations for patient care that may identify a particular strategy or range of strategies that reflect moderate clinical

Procedural Sedation and Analgesia

1 After a thorough pre-sedation assessment, attach the patient to the monitoring system. Routine use of pulse oximetry, capnography, ECG monitoring, and blood pressure monitoring greatly enhances the safety of PSA.

2 Apply supplemental oxygen, especially for patients undergoing deep sedation with agents such as propofol. In addition to pulse oximetry, observe the rise and fall of the chest, for the earliest indication of apnea. Ideally, capnography should be used in all situations in which high-flow oxygen is administered.

3 Ensure that all necessary age-appropriate resuscitation equipment is available, including oxygen, a bag-valve-mask device, suction, reversal agents, and a defibrillator (for patients with significant cardiovascular disease).

4 Administer the agent selected. The choice of appropriate medications is discussed in detail in the text. Here, propofol is being administered.

5 PSA requires a minimum of two experienced individuals: one to perform the procedure and one to continuously monitor the patient for potential complications. The person monitoring the patient must be focused on the patient's cardiopulmonary status.

6 Perform the procedure. Here, the patient is being cardioverted for new-onset atrial fibrillation. After the procedure, monitor the patient until there is no further risk for cardiorespiratory depression. Before discharge, be sure that the patient is alert and oriented with stable vital signs.

Figure 33.2 Procedural sedation and analgesia (PSA). ECG, electrocardiographic.

certainty [i.e., based on evidence from one or more Class of Evidence II studies or strong consensus of Class of Evidence III studies]), stating, “Capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED.”³³

ECG Monitoring

Although continuous ECG monitoring cannot be considered mandatory or standard of care in the absence of cardiovascular disease, such monitoring is simple, inexpensive, and readily available.

BIS Monitoring

The bispectral index (BIS) is a monitoring modality that uses a processed electroencephalogram signal to quantify the depth of anesthesia or sedation. A BIS value of 100 (unitless scale) is considered complete alertness, 0 represents no cortical activity at all, and the range of 40 to 60 is believed to be consistent with general anesthesia. Although this technology has been used widely to monitor the depth of sedation in the operating room, the ASA has judged that its clinical applicability for this purpose “has not been established.”⁵³ Furthermore, a 2011 study found that patients in whom a modified minimum alveolar concentration protocol (i.e., the inhalational anesthetic concentration needed for 50% of patients to not move with the application of a noxious stimulus) was used had fewer awareness events than did those in whom a BIS protocol was used.⁵⁴ Even though PSA research has demonstrated statistical associations between BIS and standard sedation scores, these studies have also noted unacceptably wide ranges of BIS values at various depths of sedation.^{55–58} Thus, although BIS is correlated with the depth of sedation in aggregate groups, it lacks sufficient capacity to reliably gauge such depth in individual patients and therefore cannot currently be recommended for ED PSA.

Resuscitation Equipment and Supplies

Gather all necessary age-appropriate equipment for airway management and resuscitation in the sedation area, including oxygen, a bag-valve-mask device, suction, and drug reversal agents. For subjects with significant cardiovascular disease, include a defibrillator as well.

Vital Signs

Measure vital signs periodically at individualized intervals, in most cases including measurements at baseline, after drug administration, on completion of the procedure, during early recovery, and at completion of recovery. During deep sedation it is reasonable to assess vital signs approximately every 5 minutes. Patients are at highest risk for complications 5 to 10 minutes after IV medications are administered and during the immediate postprocedure period when external stimuli are discontinued. Continuous monitoring of the ECG, blood pressure, pulse rate, and pulse oximetry via a standard monitor generally fulfills the monitoring requirements. Actual documentation in the medical record varies, and fewer entries on the record are necessary when continuous monitoring is used. There are no standards mandating the frequency of vital sign

documentation in the medical record. Thus, in the absence of institutional requirements, frequency is generally guided by the specific patient scenario, medications used, and depth of sedation, with common sense prevailing in most cases.

SUPPLEMENTAL OXYGEN

Substantial variation in practice exists with regard to the use of supplemental oxygen during PSA. The premise is a logical one: increasing systemic oxygen reserves should naturally delay, or perhaps avert, hypoxemia should an airway or respiratory adverse event occur. However, the price paid for this well-intentioned safeguard is the loss of pulse oximetry as an early warning device.^{12,15,27} Hyperoxygenated patients will desaturate only after the apnea is prolonged. Indeed, the time required for preoxygenated, apneic, healthy adults and adolescents to desaturate to 90% averages more than 6 minutes.^{59,60}

Deitch and colleagues have shown in a series of randomized controlled trials that high-flow supplemental oxygen decreases the incidence of hypoxia during propofol sedation (number needed to benefit of 4),⁴⁶ whereas lesser amounts of oxygen (3 L/min) do so only marginally with propofol and not at all with lighter levels of sedation.^{29,45} Thus, high-flow oxygen is strongly recommended with propofol or other deep sedation, assuming that interactive monitoring includes capnography to promptly identify respiratory depression.^{49,61} For lighter levels of sedation, supplemental oxygen has no established benefit and may impair detection of respiratory depression when using pulse oximetry without capnography.⁶¹

DISCHARGE CRITERIA

Monitor all patients receiving PSA until they are no longer at risk for cardiorespiratory depression (Table 33.2). Before

TABLE 33.2 Complications After Sedation

COMPLICATION	ETIOLOGY
Delayed awakening	Prolonged drug action Hypoxemia, hypercapnia, hypovolemia
Agitation	Pain, hypoxemia, hypercapnia, full bladder Paradoxical reactions Emergence reactions

discharge be sure that patients are alert and oriented (or have returned to an age-appropriate baseline) with stable vital signs. Many hospitals have chosen to use standardized recovery scoring systems similar to those used in their surgical postanesthesia recovery areas (Table 33.3). Although no generally accepted minimum durations for safe discharge have been established, one large ED study found that, in children with uneventful sedation, no serious adverse effects occurred more than 25 minutes after final medication administration.⁶² This suggests that in most cases, prolonged observation beyond an hour is unlikely to be necessary.

Make sure that all patients leave the hospital with a reliable adult who will observe them after discharge for postprocedural complications. Document the name of the individual in the hospital record. Give written instructions regarding appropriate diet, medications, and level of activity (Boxes 33.2 and 33.3). Even though patients may appear awake and able to comprehend instructions, they may not remember details once they leave the ED.

To be eligible for safe discharge, children are not required to walk unaided or demonstrate that they can tolerate an oral

BOX 33.2 Sample Adult Disposition Instructions After PSA

1. Do not drive or operate heavy machinery for 12 hours.
2. Eat a light diet for the next 12 hours.
3. Take only your prescribed medications as needed, including any pain medication you were discharged with. Avoid alcohol.
4. Do not make any important decisions or sign important documents for 12 hours. You may be forgetful because of the medications that were administered.
5. If you experience any difficulty breathing or persistent nausea and vomiting, return to the emergency department.
6. You should have a responsible person with you for the rest of the day and during the night.

PSA, *Procedural sedation and analgesia*.

BOX 33.3 Sample Pediatric Disposition Instructions After PSA

Your child has been given medicine for sedation and/or pain control. These medicines may cause your child to be sleepy and less aware of the surroundings, thus making it easier for accidents to happen while walking or crawling. Because of these side effects, your child should be watched closely for the next few hours. We suggest the following:

1. No eating or drinking for the next 2 hours. Infants may resume half-normal feedings when they are hungry.
2. No playing for 12 hours that requires normal coordination, such as bike riding or jungle gym activities.
3. No playing without an adult to watch and supervise for the next 12 hours.
4. No baths, showers, cooking, or use of potentially dangerous electrical appliances unless supervised by an adult for the next 12 hours.

If you notice anything unusual about your child, call us for advice or return to the emergency department for reevaluation.

PSA, *Procedural sedation and analgesia*.

challenge because most PSA agents are emetogenic. Forcing fluids after sedation can lead to emesis before or after discharge. The AAP guidelines require only that “the patient can talk (if age-appropriate)” and “the patient can sit up unaided (if age-appropriate).”¹⁶ When infants and young children are discharged after their evening bedtime, caution parents to position the child’s head in the car seat carefully. Significant forward flexion might cause airway obstruction if the child falls asleep on the way home.

GENERAL PRINCIPLES

Therapeutic mistakes that result in inadequate analgesia and sedation include using the wrong agent, the wrong dose, the wrong route or frequency of administration, and poor use of adjunctive agents. With proper training and technique, adequate PSA can be provided in almost any circumstance. Understanding titration principles is critical to providing safe and effective PSA. Clinicians must have a thorough knowledge of the pharmacokinetics, dosing, administration, and potential complications of the PSA agents that they use. Time of onset from injection to the initial observed effect must be appreciated, especially when using drugs in combination, to avoid stacking of drug doses and oversedation.

The correct agent (or combination of agents) and the route and timing of administration depend on the following factors: How long will the procedure last? Will it be seconds (e.g., simple relocation of a dislocated joint, incision and drainage of a small abscess, cardioversion), minutes (e.g., complex manipulation of a fracture for reduction, breaking up loculations in a large abscess and then packing it), or prolonged (e.g., complex facial laceration repair)? How likely is it that the procedure will need to be repeated (e.g., fracture reduction)? Can topical, local, or regional anesthesia be used as an adjunct? Does the patient require sedation only for a noninvasive diagnostic imaging study?

Before drug administration, every effort should be made to minimize a patient’s anxiety and distress, particularly in children. The emotional state of a patient on induction strongly correlates with the degree of distress on emergence and in the days immediately after the procedure.^{63–66} Avoid being pressured by consultants to cut corners or rush PSA. Incorporating into the pre-sedation preparation a discussion with the consultant about the sedation plan and the length of time required to safely prepare and sedate the patient can avoid the risks associated with hurried sedation.

For pediatric PSA, the clinician should appreciate the adult dose of the sedative being administered and consider this the maximum threshold. Understand that the initial dose of midazolam for PSA in a 100-kg patient on a milligram-per-kilogram basis is far less than the 0.1 mg/kg used in a child to avoid unexpected mishaps in drug dosing.

ROUTES OF ADMINISTRATION

For nondissociative agents, titrate IV medications to the patient’s response for the best method of achieving rapid and safe analgesia and sedation. Wait the appropriate time for the medications to produce the intended effect before adding more doses. When using opioids, administer doses in 2- to 3-minute increments and observe for side effects such as miosis, somnolence, decreased responsiveness to verbal stimuli, impaired speech, and diminished pain on questioning as appropriate initial end points. For sedative-hypnotics, use similar incremental dosing and end points such as ptosis (rather than miosis), somnolence, slurred speech, and alterations in gaze. Repeated doses may be given in a titrated fashion based on the patient’s response during the procedure.

The oral, transmucosal (i.e., nasal, rectal), and IM routes are more convenient means of administration when IV access is not necessary, but they are much less reliable for timely dose titration to a desired response. New drug delivery systems, however, are expanding the effectiveness and ease of use of these routes of administration. The refinement of intranasal drug delivery has significantly increased the efficacy of this route of administration.^{67,68} Before the development of metered-dose atomizers, the degree of absorption and effectiveness of intranasal drug administration were operator dependent. Furthermore, new drug formulations with concentrations appropriate for intranasal administration are becoming available for study.^{69,70}

The main advantage of these other routes is for pediatric patients in whom IV access may be problematic or for procedures that may require only minimal sedation in conjunction with the use of local anesthetics. These routes are also advantageous for simple sedation during diagnostic imaging.

With the exception of ketamine, agents administered intramuscularly have erratic absorption and a variable onset of action. Accordingly, prolonged preprocedural and postprocedural observation may be necessary. When required, the IM route offers little advantage over oral or transmucosal administration.

Another PSA route is via inhalation of nitrous oxide. This gas can either be delivered by a demand-flow system using a handheld mask or be delivered to young children using a nose mask in a continuous-flow system under close clinician supervision.

Because individual needs may vary widely, the application of arbitrary ceiling doses of analgesic and sedative regimens

is unwarranted. The true ceiling dose of an agent is the level that provides adequate pain relief or sedation without major cardiopulmonary side effects such as respiratory depression, apnea, bradycardia, hypotension, or allergic reactions.

There are two absolute contraindications to PSA: severe clinical instability requiring immediate attention and refusal by a competent patient. Relative contraindications include hemodynamic or respiratory compromise, altered sensorium, or an inability to monitor for adverse events (e.g., magnetic resonance imaging [MRI] without remote monitoring). However, even in many of these circumstances, appropriate agents can be given to provide analgesia and sedation while minimizing the chance for further deterioration. Although safely sedating patients at the extremes of age is challenging and requires additional care, as well as reductions in drug dosing (because of decreased drug metabolism and excretion), age is not a contraindication to PSA.

DRUG SELECTION STRATEGIES

The majority of nonpainful or minimally painful ED procedures in older children and adults can be performed without systemic sedation and analgesia. Skilled practitioners can frequently combine a calm, reassuring bedside manner with distraction techniques, careful local or regional anesthesia, or both.^{71–73} Many procedures, however, cannot be technically or humanely performed without PSA. These situations can be divided into three categories.

Insufficient Analgesia. Despite a cooperative patient, for some procedures it is impossible to achieve effective pain control with local or regional anesthesia. Examples of procedures requiring systemic PSA include fracture reductions, dislocation reductions, incision and drainage of large loculated abscesses, wounds that require scrubbing such as “road rash,” cardioversion, bone marrow aspiration/biopsy, and extensive burn débridement.

Insufficient Anxiolysis. Despite effective local or regional anesthesia, some patients will be so frightened that procedures cannot be technically or humanely performed without PSA. Young children requiring repair of lacerations are frequently terrified, and older children and adults may be highly anxious in anticipation of such repairs in sensitive or personal regions (e.g., face, genitalia, perineum).

Insufficient Immobilization. Despite effective local or regional anesthesia and anxiolysis, PSA may be indicated to prevent excessive motion during procedures that require substantial immobilization (e.g., repair of complex facial lacerations, diagnostic imaging studies). Immobilization is most commonly an issue with young children and the mentally challenged.

General Considerations. Clinicians must therefore base customization of their selection of drugs (e.g., anxiolysis, sedation, analgesia, immobilization) on the unique needs of the patient and their individual level of experience with specific agents (Table 33.4). A risk-benefit analysis should be performed before every sedation (Box 33.4). The benefits of reducing anxiety and controlling pain should be carefully weighed against the risk for respiratory depression and airway compromise.

BOX 33.4 Risk-Benefit Analysis for PSA

- Why is PSA needed in the first place? Is the procedure very painful, frightening, or requiring extreme cooperation?
- Are the risks of PSA appropriate for the procedure involved?
- If the patient is a child, do the parents or guardian consent to the use of PSA?
- How long will the procedure take? If it is a short procedure, is it worth the added risk and expense to the patient? If it is a longer procedure, is there an appropriate agent that can be titrated to allow adequate PSA throughout the entire length of the procedure?
- Are there significant side effects that limit a particular drug's usefulness?
- Are enough nurses and support personnel present to safely allow the use of PSA?
- What is the recovery period for a given agent? Are there enough treatment areas and staff in the ED to allow adequate observation during recovery?
- When did the patient last eat? Is a delay in waiting for a sufficient fasting time worth the time lost in performing the procedure?

ED, Emergency department; PSA, procedural sedation and analgesia. From Krauss B, Brustowicz R, editors: Pediatric procedural sedation and analgesia. Philadelphia, 1999, Lippincott Williams & Wilkins, p 294.

Factors influencing the extent of pharmacologic management are listed in Box 33.5. Some general drug selection strategies are discussed later and shown in Boxes 33.6, 33.7, and 33.8.

MINOR PROCEDURES IN COOPERATIVE ADULTS AND OLDER CHILDREN. Such procedures can usually be managed with topical, local, or regional anesthesia. Systemic PSA is typically unnecessary, although mild anxiolysis (e.g., nitrous oxide, oral midazolam) can make these patients more comfortable.

MORE COMPLEX PROCEDURES OF LONGER DURATION IN COOPERATIVE ADULTS AND OLDER CHILDREN. Supplementation of topical, local, or regional anesthesia with either nitrous oxide or IV midazolam and fentanyl permits customization of the depth of sedation and pain relief to the specific needs of each patient.

PROCEDURES IN UNCOOPERATIVE ADULTS OR THE MENTALLY CHALLENGED. Essentially all procedures in uncooperative adult-sized patients are difficult without systemic PSA. Depending on operator experience, IV midazolam, IV propofol, IV etomidate, or IM/IV ketamine or midazolam may be used in these situations. Given that the sedatives midazolam, propofol, and etomidate lack specific analgesic properties, many emergency physicians attempt to control pain with an opioid such as fentanyl before the procedure. Midazolam can be titrated intravenously to a relatively deep level of sedation, although as discussed previously, the risk for adverse effects increases with the depth of sedation. Ketamine (typically with coadministered midazolam when used in adults) can also provide the profound analgesia and immobilization necessary to perform painful procedures. However, in adults there is a risk for unpleasant hallucinatory recovery reactions. Ketamine should be used with extreme caution in older adults because its

TABLE 33.4 Indications for PSA and Sedation Strategies^a

CLINICAL SITUATION	INDICATION	PROCEDURAL REQUIREMENTS	SUGGESTED SEDATION STRATEGIES

^aThere is no universally accepted or clinically correct dose, medication, or combination. Many regimens are acceptable. This table is intended as a general overview. Sedation strategies should be individualized. Although the pharmacopoeia is large, clinicians should familiarize themselves with a few agents that are flexible enough to be used for the majority of procedures. In all cases it is assumed that practitioners are fully trained in the technique, appropriate personnel and monitoring are used as detailed in this chapter, and specific drug contraindications are absent.

CT, Computed tomography; IM, intramuscularly; IN, intranasally; IV, intravenously; MRI, magnetic resonance imaging; PO, orally; PR, per rectum; PSA, procedural sedation and analgesia.

sympathomimetic properties may aggravate underlying coronary artery disease or hypertension. Occasionally, procedures in extremely uncooperative adults or the mentally challenged are best managed in the operating room with general anesthesia.

MINOR PROCEDURES IN UNCOOPERATIVE OLDER CHILDREN AND IN YOUNG CHILDREN. Minor procedures (e.g., small lacerations, IV cannulation, venipuncture, removal of superficial foreign bodies) in uncooperative children can frequently be managed by skilled practitioners with a combination of

nonpharmacologic techniques (e.g., distraction, guided imagery, hypnosis, comforting, breathing techniques) in conjunction with topical anesthesia, careful local anesthesia, and when necessary, brief forcible immobilization (by personnel or a restraining device). In other cases, supplementing nonpharmacologic techniques with topical or local anesthesia and anxiolysis with oral midazolam may be sufficient to permit successful wound repair. Although oral administration is most popular and least invasive, the nasal or rectal routes can also be used depending on operator experience and preference.

BOX 33.5 Factors Influencing the Extent of Pediatric Pharmacologic Management**AGE**

Selected drugs and routes of administration have age limitations and are not recommended above or below a certain age (e.g., demand-flow nitrous oxide in children < 5 years, nasal and rectal routes of administration in children > 6 years).

TIME OF DAY

A toddler seen at naptime or at 9 PM who is tired and sleepy will usually require smaller dosing and possibly a lower level of PSA than required at 9 AM. Young children with facial lacerations at night, after their normal bedtime, may require only topical anesthesia and a quiet room for 20 to 30 minutes to achieve a painless laceration repair while the child sleeps.

FASTING STATUS

Young children can be extremely difficult and uncooperative when hungry, tired, or both. In anticipation of PSA, many children are kept without oral intake from the time that they are triaged in the ED. This can further increase hunger and irritability, especially if the child waits 1 to 2 hours to be seen by a clinician.

AVAILABILITY OF STAFFING AND EQUIPMENT

Staffing availability can affect the use and timing of sedation and is especially important in busy EDs with multiple sedations occurring concurrently and in smaller units that are set up for only one sedation at a time.

LOCATION OF THE INJURY

Injuries located in areas of cosmetic concern (especially on the face) or near sensory organs (e.g., ears, eyes, mouth, nose) will often require a high degree of agitation control and a concomitant level of PSA.

PREVIOUS MEDICATIONS

An accurate history of previous medication administration is important in situations in which a child is referred from another facility because this can affect the type and timing of PSA agents that can be given. In particular, a child may have received opioids or sedative-hypnotics before transfer and may still be sedated on arrival, thus necessitating an adjustment in the PSA regimen.

LEVEL OF ANXIETY

The level of anxiety of both the child and the accompanying adult or adults must be accurately assessed. Children manifest anxiety in many different ways, and emergency clinicians must be facile at recognizing the varying expressions of anxiety, especially in young children. A child with a facial laceration quietly sitting on the stretcher during the initial examination will not necessarily be a calm and cooperative patient during repair of the laceration

(infants and toddlers). The nursing assessment at triage of the state of the child and accompanying adult or adults can be very helpful in some cases in determining the need for PSA. A child who was frightened and uncooperative in triage may be calm and compliant during a procedure. Unfortunately, the reverse is also true. When confronted with an extremely anxious child, ED personnel should ascertain what the parents have told the child about the upcoming procedure. Many parents, in the hope of lessening their child's anxiety, will tell the child that she or he will get a "shot" or a "needle" and that the procedure will "only hurt for a minute." This type of parental preparation, especially in young children who do not have the cognitive ability to mediate their anxiety, often results in a significant increase in the child's anxiety and a decrease in the child's ability to cooperate, especially if the child has had a previous negative experience with a procedure in the ED. It is also important to assess the parents' level of anxiety because this will determine the degree to which they can assist during the procedure. An extremely anxious parent or a parent who must take care of other siblings during the procedure will find it difficult to assist in distracting the child or otherwise helping the child cope with the procedure.

PREVIOUS EXPERIENCE

Children's previous experience in hospitals can greatly affect their response to the current situation. Direct experience is not the only way to create anxious, frightened, and uncooperative patients, though. Images from television, stories from peers, or previous witness of a sibling being forcibly restrained for repair of a laceration can leave a powerful and lasting impression. This type of influence should be especially suspected in children whose anxiety seems out of proportion to the present situation. Eliciting from the parents a history of a previous difficult experience in the ED can be a decisive factor in determining the degree of sedation required. Children who have had a recent unpleasant laceration repair and who now have a new laceration may well require PSA as opposed to simple anxiolysis (either pharmacologic or nonpharmacologic) had there been no previous trauma.

CHILD'S BEHAVIOR AT ROUTINE PRIMARY CARE VISITS

Inquiring into how a child behaves during routine primary care visits can yield important information on how the child reacts to stressful situations, how cooperative the child will be with the anticipated procedure, and whether pharmacologic management is needed. Children who cry but hold still when vaccinated may be more compliant than children who are described by their parents as being "afraid of doctors" or "wild" during visits to the primary care physician.

ED, *Emergency department*; PSA, *procedural sedation and analgesia*.

MAJOR PROCEDURES IN UNCOOPERATIVE CHILDREN. Major painful procedures (e.g., fracture reduction, incision and drainage of large loculated abscesses, or arthrocentesis of a major joint) require systemic PSA. Options include IM/IV ketamine, IV propofol, IV etomidate, or IV midazolam. Given that the sedatives midazolam, propofol, and etomidate lack specific analgesic properties, many emergency physicians attempt to control pain with an opioid such as fentanyl before the procedure. Ketamine may be the best option in such children

because dissociative sedation can consistently provide immobilization and analgesia while maintaining protective airway reflexes and upper airway muscular tone.

PHARMACOPEIA

There is no universally correct or preferred medication or drug regimen. Many options are acceptable and successful.

BOX 33.6 Procedure for Moderate to Deep Sedation With Intravenous Midazolam and Fentanyl**CAVEATS**

- Do not consider this procedure if you lack experience with the drugs or do not have the time to perform procedural sedation and analgesia properly. Do not attempt this procedure if the pulse oximeter, suction, oxygen, or bag-mask device is not working, the intravenous line is not secured, or the room is too small or not set up for procedural sedation and analgesia.
- This is a two-person procedure, one to monitor the patient and one to perform the procedure.
- The individual response to the drugs is variable and dependent on the patient's underlying physiologic state and the presence of concomitant drugs and medications.
- The maximum drug effect occurs 2 to 3 minutes after administration. Proceed slowly and patiently and allow the medication to take full effect before giving the next dose.
- Have naloxone and flumazenil immediately available for oversedation or respiratory depression.
- If the patient seems overly sedated, begin the procedure. The pain of the procedure often stimulates respiration and lessens sedation.

CONTRAINDICATIONS—ABSOLUTE (RISKS ESSENTIALLY ALWAYS OUTWEIGH BENEFITS)

- Active hemodynamic instability
- Active respiratory distress or hypoxemia

CONTRAINDICATIONS—RELATIVE (RISKS MAY OUTWEIGH BENEFITS)

- Respiratory depression or altered level of consciousness
- Anticipated difficulty if ventilatory assistance should become necessary (e.g., facial deformity or trauma, small mandible, large tongue, trismus)

PROTOCOL

- Establish intravenous access.
- Preoxygenate the patient.

- Connect appropriate monitoring equipment to the patient. Administer supplemented oxygen if deep sedation is anticipated.
- The pulse, respiratory rate, blood pressure, and level of consciousness should all be recorded initially and periodically throughout the procedure, depending on the depth of sedation.
- Suction equipment, oxygen, a bag-valve-mask assembly, and reversal agents should be available immediately. An age-appropriate resuscitation cart with oral and nasal airways, endotracheal tubes, and a functioning laryngoscope must be nearby.
- The order of drugs is one of personal preference. The ratio of analgesia to sedation is determined by the nature of the procedure. Some procedures require primary analgesia and secondary anxiolysis or sedation (e.g., incision and drainage of an abscess, bone marrow aspiration, arthrocentesis, burn débridement, central catheter placement). In this case, administer fentanyl first. Others require primary anxiolysis or sedation with secondary analgesia (e.g., lumbar puncture, simple foreign body removal); administer midazolam first.
- Administer a local anesthetic if indicated after procedural sedation and analgesia are initiated (this often serves to help gauge the effectiveness of systemic analgesia).
- Perform the procedure. Additional doses of fentanyl or midazolam may be required if further pain or anxiety is noted based on the response and length of the procedure.
- If hypoxemia, oversedation, or slowed respirations are seen during or after the procedure, the patient should first be stimulated while oxygen is applied and the airway repositioned. If the patient's response is insufficient, assist ventilations with a bag-valve-mask device. Reversal agents should be considered if there is not a prompt response to assisted ventilation.
- Continue close observation until the patient is awake and alert, and release the patient with a friend, parent, or relative only after a sufficient discharge score has been attained.

The best choice is an agent whose pharmacologic properties are familiar to the operator, that is used frequently by the operator, is easily titratable, and has a short duration of action or is readily reversible. All drugs should be given in adequate doses because under-dosing of opioids or sedatives provides no useful purpose. Dosing recommendations for PSA drugs are provided in Table 33.5, and specialized protocols for midazolam or fentanyl, propofol, and ketamine are presented in Boxes 33.6, 33.7, and 33.8, respectively. Individual agents are discussed in the following sections.

Sedative-Hypnotic Agents

Chloral Hydrate

Pharmacology. Chloral hydrate is a pure sedative-hypnotic agent without analgesic properties. When administered orally, the average time to peak sedation is approximately 30 minutes, with a recovery time of an additional 1 to 2 hours.^{74,75} Residual motor imbalance and agitation may persist for several hours

beyond this period.⁷⁶ Rectal administration is erratically absorbed and therefore not recommended.

Adult Use. Use of chloral hydrate is limited to diagnostic imaging studies in children. It has no current use in adults.

Pediatric Use. Chloral hydrate is widely used as a sedative to facilitate nonpainful outpatient diagnostic procedures such as electroencephalography, computed tomography (CT) or MRI.^{75,77–81} IV pentobarbital appears to be more effective than chloral hydrate for the latter indication,⁸² although many centers prefer chloral hydrate in younger children (e.g., < 18 months) simply to avoid the need for IV access.^{76,79,82}

Adverse Effects. Despite a wide margin of safety, chloral hydrate can cause airway obstruction and respiratory depression, especially at higher doses (75 to 100 mg/kg).^{1,75,78,80,81} The incidence was 0.6% in one large series.⁷⁵ There is no known dosage threshold of chloral hydrate below which this potential

BOX 33.7 Procedure for Deep Sedation With Propofol**INDICATIONS**

- Brief, painful procedures for which deep sedation is indicated, including fracture and dislocation reduction, incision and drainage of abscesses, cardioversion, tube thoracostomy, bone marrow aspiration or biopsy, and central line placement.

CONTRAINDICATIONS**Absolute (Risks Essentially Outweigh Benefits)**

- Known or suspected allergy to soy or eggs.

Patients at Higher Relative Risk

- Patients older than 55 years, debilitated, or with significant underlying illness (i.e., ASA physical status score of 3 or 4) are at an increased risk for propofol-induced hypotension and other complications. When the benefits of using propofol outweigh the risks, administer lower doses more slowly. Patients should ideally have their volume status optimized before receiving propofol.
- Because there is no clear consensus on the optimal fasting time before sedation, decision making should balance the relatively low probability of aspiration with the patient's underlying risk factors, the timing and nature of recent oral intake, the urgency of the procedure, and the depth and length of sedation required.

PERSONNEL

- The minimum personnel present during deep sedation should be an emergency clinician and an ED nurse. When available, consider adding a separate emergency clinician who is solely dedicated to drug administration and patient monitoring.

PRESEDATION

- Physicians should perform a standard pre sedation assessment with special attention paid to the potential for airway management during deep sedation.
- Suction, airway, and resuscitation equipment should be available immediately.
- Preoxygenate the patient.
- Because propofol does not have analgesic properties, pretreatment with fentanyl (1 $\mu\text{g}/\text{kg}$) or coadministration with ketamine (0.5 mg/kg) should be considered for painful procedures.

- Assuming that capnography is in place to identify respiratory depression, high-flow oxygen is recommended because it has been shown to decrease the risk for hypoxia with propofol (number needed to benefit of 4).

PROPOFOL ADMINISTRATION: GENERAL

- Propofol induces sedation approximately 30 seconds after bolus injection, with typical resolution of clinical effects occurring within 6 minutes.
- The most common ED dosing is an initial bolus dose of 1 mg/kg followed by 0.5 mg/kg every 2 to 3 minutes as needed to achieve or maintain the desired level of sedation.
- Propofol is typically titrated to slurring of speech, lid ptosis, or both, depending on the depth of sedation and degree of relaxation needed for the procedure.

INTERACTIVE AND MECHANICAL MONITORING

- Patients should have their airway patency, oxygen saturation, electrocardiographic tracing, and level of consciousness monitored continuously.
- The addition of end-tidal CO_2 monitoring (capnography) can provide the earliest possible warning of impending airway and respiratory complications before clinical examination or pulse oximetry and is particularly important when supplemental oxygen negates pulse oximetry as a warning device.

POTENTIAL ADVERSE EFFECTS

- Respiratory depression or apnea leading to assisted ventilation (0% to 3.9%).
- Transient hypotension (2.2% to 6.5%).
- Emesis (0% to 0.5%).
- Pain with injection (2% to 20%).

RECOVERY AND DISCHARGE

- Patients receiving propofol should be monitored until they have returned to their baseline mental status.
- Qualified personnel should accompany patients who require transport before recovery.

ASA, American Society of Anesthesiologists; *ED*, emergency department.

complication can be consistently avoided,^{1,80} and accordingly, standard interactive and mechanical monitoring precautions apply to chloral hydrate as they do to other PSA agents.

Because it is a halogenated hydrocarbon, overdoses of chloral hydrate can be arrhythmogenic and produce ventricular dysrhythmias. β -Blockers may be most effective in terminating ventricular arrhythmias. Despite reports of potential carcinogenicity, the AAP has judged that the evidence is currently insufficient to avoid single doses of chloral hydrate for this reason alone.⁸³

Midazolam

Pharmacology. Benzodiazepines are a group of highly lipophilic agents that possess anxiolytic, amnestic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties. They

lack direct analgesic properties and thus are commonly coadministered with opioids. Caution must be exercised when using benzodiazepines and opioids together because the risk for hypoxia and apnea is significantly greater than when either is used alone.⁸⁴

Midazolam is by far the most common benzodiazepine used for PSA and is preferred over the longer-acting lorazepam and diazepam. The time to peak effect for midazolam is approximately 2 to 3 minutes when given intravenously. Unlike diazepam, midazolam and lorazepam are water soluble, thus making parenteral administration less painful and mucosal absorption faster. Midazolam is readily reversed with flumazenil, and individuals undergoing PSA with midazolam are good candidates for this antidote should reversal be required.

BOX 33.8 Procedure for Dissociative Sedation With Ketamine**DEFINITION OF DISSOCIATIVE SEDATION**

- A trancelike cataleptic state induced by the dissociative agent ketamine and characterized by profound analgesia and amnesia with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.

CHARACTERISTICS OF THE KETAMINE “DISSOCIATIVE STATE”

- **Dissociation:** After the administration of ketamine, the patient passes into a fugue state or trance. The eyes may remain open, but the patient does not respond.
- **Catalepsy:** Normal or slightly enhanced muscle tone is maintained. On occasion, the patient may move or be moved into a position that is self-maintaining. Occasional muscular clonus may be observed.
- **Analgesia:** Analgesia is typically substantial or complete.
- **Amnesia:** Total amnesia is typical.
- **Maintenance of airway reflexes:** Upper airway reflexes remain intact and may be slightly exaggerated. Intubation is unnecessary, but occasional repositioning of the head may be needed for optimal airway patency. Suctioning of hypersalivation may occasionally be necessary.
- **Cardiovascular stability:** Blood pressure and pulse rate are not decreased and are typically mildly increased.
- **Nystagmus:** Nystagmus is typical.

INDICATIONS

- Short, painful procedures, especially those requiring immobilization (e.g., facial laceration, burn débridement, fracture reduction, abscess incision and drainage, central line placement, tube thoracostomy).
- Examinations judged likely to produce excessive emotional disturbance (e.g., pediatric sexual assault examination).

CONTRAINDICATIONS: ABSOLUTE (RISKS ESSENTIALLY ALWAYS OUTWEIGH BENEFITS)

- Age younger than 3 months (higher risk for airway complications).
- Known or suspected schizophrenia, even if currently stable or controlled with medications (can exacerbate the condition).

CONTRAINDICATIONS: RELATIVE (RISKS MAY OUTWEIGH BENEFITS)

- Major procedures stimulating the posterior pharynx (e.g., endoscopy) increase the risk for laryngospasm, whereas typical minor ED oropharyngeal procedures do not.
- History of airway instability, tracheal surgery, or tracheal stenosis (presumed higher risk for airway complications).
- Active pulmonary infection or disease, including upper respiratory infection or asthma (higher risk for laryngospasm).
- Known or suspected cardiovascular disease, including angina, heart failure, or hypertension (exacerbation caused by the sympathomimetic properties of ketamine). Avoid ketamine in patients who are already hypertensive and in older adults with risk factors for coronary artery disease.
- Central nervous system masses, abnormalities, or hydrocephalus (increased intracranial pressure with ketamine).
- Glaucoma or acute globe injury (increased intraocular pressure with ketamine).

- Porphyria, thyroid disorder, or thyroid medication (enhanced sympathomimetic effect).

PERSONNEL

- Dissociative sedation requires two persons, one (a nurse) to monitor the patient and one (a physician) to perform the procedure. Both must know about ketamine's unique characteristics.

PRESEDATION

- Perform a standard pre sedation assessment.
- Educate accompanying family members about the unique characteristics of the dissociative state if they will be present during the procedure or recovery.
- Frame the dissociative encounter as a positive experience. Consider encouraging adults and older children to “plan” specific, pleasant dream topics in advance of sedation (believed to decrease unpleasant recovery reactions). Emphasize, especially to school-aged children and teenagers, that ketamine delivers sufficient analgesia, so there will be no pain.

KETAMINE ADMINISTRATION: GENERAL

- Ketamine is not administered until the physician is ready to begin the procedure because the onset of dissociation typically occurs rapidly.
- Ketamine is initially administered as a single IV loading dose or IM injection. There is no apparent benefit from attempts to titrate to effect.
- In settings in which IV access can be obtained with minimal upset, the IV route is preferable because recovery is faster and there is less emesis.
- The IM route is especially useful when IV access cannot be consistently obtained with minimal upset and in patients who are uncooperative or combative (e.g., the mentally disabled).
- IV access is unnecessary for children receiving IM ketamine. Because unpleasant recovery reactions are more common in adults, IV access is desirable in these patients to permit rapid treatment of these reactions should they occur.

KETAMINE ADMINISTRATION: IV ROUTE

- Administer an IV loading dose of 1.5 to 2.0 mg/kg in children or 1.0 mg/kg in adults, with this dose being administered during a 30- to 60-second period. More rapid administration produces high central nervous system levels and has been associated with respiratory depression or apnea.
- Additional incremental doses of ketamine may be administered (0.5 to 1.0 mg/kg) if initial sedation is inadequate or repeated doses are necessary to accomplish a longer procedure.

KETAMINE ADMINISTRATION: IM ROUTE

- Administer IM ketamine, 4 to 5 mg/kg in children; the IV route is preferred for adults.
- Repeat the IM ketamine dose (full or half dose) if sedation is inadequate after 5 to 10 minutes (unusual) or if additional doses are required.

BOX 33.8 Procedure for Dissociative Sedation With Ketamine—cont'd**COADMINISTERED MEDICATIONS**

- Prophylactic anticholinergics are no longer recommended.
- Prophylactic benzodiazepines are no longer recommended for children; however, they should be available to treat rare, unpleasant recovery reactions should they occur. Prophylactic IV midazolam, 0.03 mg/kg, may be considered for adults (number needed to benefit, 6).
- Prophylactic ondansetron can slightly reduce the rate of vomiting (number needed to benefit, 9 or higher).

	ROUTE OF ADMINISTRATION	
	IV	IM
Advantages	Ease of repeated dosing, less vomiting, slightly faster recovery	No IV access necessary
Peak concentrations and clinical onset, minutes	1	5
Typical duration of effective dissociation (min)	5–10	20–30
Typical time from dose to discharge (min)	50–110	60–140

PROCEDURE

- Adjunctive physical immobilization may occasionally be needed to control random motion.
- An adjunctive local anesthetic is usually unnecessary when a dissociative dose is used.
- Suction equipment, oxygen, a bag-valve-mask device, and age-appropriate equipment for advanced airway management should be immediately available. Supplemental oxygen is not mandatory but may be used when capnography is used to monitor ventilation.

INTERACTIVE MONITORING

- Close observation of the airway and respirations by an experienced health care professional is mandatory until recovery is well established.
- Drapes should be positioned so that airway and chest motion can be visualized at all times.
- Occasional repositioning of the head or suctioning of the anterior pharynx may be indicated for optimal airway patency.

MECHANICAL MONITORING

- Maintain continuous monitoring (e.g., pulse oximetry, cardiac monitoring, capnography) until recovery is well established.

- The pulse and respiratory rate should both be recorded periodically throughout the procedure. Blood pressure measurements after the initial value are generally unnecessary because ketamine stimulates catecholamine release and does not depress the cardiovascular system in healthy patients.

POTENTIAL ADVERSE EFFECTS

Percent estimates are for children; corresponding adult estimates are not yet reliable enough to report.

- Airway misalignment requiring repositioning of the head (occasional)
- Transient laryngospasm (0.3%)
- Transient apnea or respiratory depression (0.8%)
- Hypersalivation (rare)
- Emesis, usually well into recovery (8.4%)
- Recovery agitation (mild in 6.3%, clinically important in 1.4%)
- Muscular hypertonicity and random, purposeless movements (common)
- Clonus, hiccupping, or short-lived nonallergic rash on the face and neck

RECOVERY

- Maintain minimal physical contact or other sensory disturbance.
- Maintain a quiet area with dim lighting, if possible.
- Advise parents or caretakers not to stimulate the patient prematurely.

DISCHARGE CRITERIA

- Return to the pretreatment level of verbalization and awareness
- Return to the pretreatment level of purposeful neuromuscular activity
- A pre-discharge requirement of tolerating oral fluids or being able to ambulate independently not required or recommended after dissociative sedation

DISCHARGE INSTRUCTIONS

- Nothing by mouth for approximately 2 hours
- Careful family observation and no independent ambulation for approximately 2 hours

ASA, American Society of Anesthesiologists; ED, emergency department; IM, intramuscular; IV, intravenous.

Modified from Green SM, Roback MG, Kennedy RM, et al: *Clinical practice guideline for emergency department ketamine dissociative sedation: 2011 update*, Ann Emerg Med 57:449–461, 2011.

Adult Use. Midazolam can be used effectively for moderate and deep sedation through careful IV titration to effect, typically together with fentanyl (see Box 33.6).

Pediatric Use. Advantages of midazolam over other benzodiazepines for pediatric PSA are its short duration of action, reversibility, and availability in multiple routes of administration. Midazolam may be used for the same indications and in the same manner as in adults. Some children require larger doses than would be typical for adults on a milligram-per-kilogram

basis,⁸⁵ and paradoxical responses (e.g., hyperexcitability) are not uncommon.^{76,86,87} Midazolam does not reliably render a child motionless, and therefore methohexital or pentobarbital is generally preferred for neuroimaging.^{82,88,89}

To avoid the need for IV access in frightened children, midazolam has been alternatively administered via the IM,⁹⁰ oral,^{86,91–95} intranasal,^{91,96–99} and rectal routes.¹⁰⁰ However, the inability to effectively titrate with these routes dictates that a reliable depth of sedation cannot be predictably or regularly achieved. Consequently, these non-IV routes are primarily

TABLE 33.5 Drug Dosing Recommendations for PSA^a

DRUG	CLINICAL EFFECTS	INDICATIONS	ADULT DOSE ^b	PEDIATRIC DOSE	ONSET (min)	DURATION (min)	COMMENTS
Sedative-Hypnotics							
Choral Hydrate (Noctec, Apothecon Pharmaceuticals, District Vadodara, Gujarat, India)	Sedation, motion control, anxiolysis No analgesia Not reversible	Diagnostic imaging (age < 3 yr)	Not recommended	PO: 25–100 mg/kg, after 30 min may repeat 25–50 mg/kg Maximum total dose: 2 g or 100 mg/kg (whichever is less) Single use only in neonates	PO: 15–30	PO: 60–120	Effects unreliable if age > 3 yr Avoid in patients with significant cardiac, hepatic, or renal disease Rectal absorption is erratic May produce paradoxical excitement Because drugs cannot be titrated with the PO route, monitor closely for oversedation
Etomidate (Amidate, Pfizer Inc., New York, NY)	Sedation, motion control, anxiolysis No analgesia Not reversible	Procedures requiring sedation and/or anxiolysis	Sedation: 0.1 mg/kg IV; repeat if inadequate response	Not FDA approved in children	IV: < 1	IV: 5–15	Adverse effects include respiratory depression, myoclonus, nausea, and vomiting Adrenocortical suppression occurs but is of no clinical significance
Midazolam ^c (Versed, Sandoz Inc., East Hanover, NJ)	Sedation, motion control, anxiolysis No analgesia Reversible with flumazenil	Procedures requiring sedation and/or anxiolysis	IV: Initial dose 1 mg, then titrated to max of 5 mg IM: 5 mg or 0.07 mg/kg	IV (0.5–5 yr): Initial dose of 0.05–0.1 mg/kg, then titrated to max of 0.6 mg/kg IV (6–12 yr): Initial dose of 0.025–0.05 mg/kg, then titrated to max of 0.4 mg/kg IM: 0.1–0.15 mg/kg PO: 0.5–0.75 mg/kg IN: 0.2–0.5 mg/kg PR: 0.25–0.5 mg/kg	IV: 2–3 IM: 10–20 PO: 15–30 IN: 10–15 PR: 10–30	IV: 45–60 IM: 60–120 PO: 60–90 IN: 60 PR: 60–90	Reduce the dose when used in combination with opioids May produce paradoxical excitement Because drugs cannot be titrated with the PO/PR/IN routes, monitor closely for oversedation
Methohexital (Brevital, Par Pharmaceutical, Chestnut Ridge, NY)	Sedation, motion control, anxiolysis No analgesia Not reversible	Diagnostic imaging	Anesthesia induction IV: 1 mg/kg (less for sedation) <i>Caution:</i> limited research	PR: 25 mg/kg IV (<i>caution</i> , limited research): 0.5–1 mg/kg	PR: 10–15	PR: 60	Avoid in patients with temporal lobe epilepsy or porphyria Because drugs cannot be titrated with the PR route, monitor closely for oversedation

Pentobarbital (Nembutal, Akorn Inc., Lake Forest, IL)	Sedation, motion control, anxiolysis No analgesia Not reversible	Diagnostic imaging	Not recommended	IV: 1–6 mg/kg, titrated in increments of 1–2 mg/kg to desired effect IM: 2–6 mg/kg, max of 100 mg PO/PR (< 4 yr): 3–6 mg/kg, max of 100 mg PO/PR (> 4 yr): 1.5–3 mg/kg, max of 100 mg	IV: 3–5 IM: 10–15 PO/PR: 15–60	IV: 15–45 IM: 60–120 PO/PR: 60–240	May produce paradoxical excitement Avoid in patients with porphyria Because drugs cannot be titrated with the PO/PR routes, monitor closely for oversedation
Propofol (Diprivan, APP Pharmaceuticals, Inc., Schaumburg, IL)	Sedation, motion control, anxiolysis No analgesia Not reversible	Procedures requiring sedation and/or anxiolysis	Load 1 mg/kg IV; may administer additional 0.5-mg/kg doses as needed to enhance or prolong sedation	Load 1–2 mg/kg IV; may administer additional 0.5-mg/kg doses as needed to enhance or prolong sedation	IV: < 1	IV: 5–15	Frequent hypotension and respiratory depression Avoid with egg or soy allergies
Thiopental (Pentothal, Hospira Inc., Lake Forest, IL)	Sedation, motion control, anxiolysis No analgesia Not reversible	Diagnostic imaging	Not recommended	PR: 25 mg/kg	PR: 10–15	PR: 60–120	Avoid in patients with porphyria Because drugs cannot be titrated with the PR route, monitor closely for oversedation
Analgesic^d							
Fentanyl (Sublimaze, Akorn Inc., Lake Forest, IL)	Analgesia Reversible with naloxone	Procedures with moderate to severe pain	IV: 50 µg, may repeat q 3 min, titrate to effect	IV: 1 µg/kg per dose, may repeat q 3 min, titrate to effect	IV: 3–5	IV: 30–60	
Dissociative Agent							
Ketamine (Ketalar, JHP Pharmaceuticals, Rochester, MI)	Analgesia, dissociation, amnesia, motion control Not reversible	Procedures with moderate to severe pain or requiring immobilization	IV: 1–1.5 mg/kg slowly over 30–60 sec, may repeat ½ dose q 10 min prn	IV: 1.5 mg/kg slowly over 30–60 sec, may repeat ½ dose q 10 min prn IM: 4–5 mg/kg, may repeat after 10 min (½ dose)	IV: 1 IM: 3–5	IV: dissociation, 15; recovery, 60 IM: dissociation, 15–30; recovery, 90–150	Multiple contraindications ^e

Continued

TABLE 33.5 Drug Dosing Recommendations for PSA^a—cont'd

DRUG	CLINICAL EFFECTS	INDICATIONS	ADULT DOSE ^b	PEDIATRIC DOSE	ONSET (min)	DURATION (min)	COMMENTS
Inhalational Agent							
Nitrous oxide (Nitronox, Medical Gas Solutions Ltd., Flint, United Kingdom)	Anxiolysis, analgesia, sedation, amnesia (all mild)	Procedures requiring mild analgesia or sedation (age > 4 yr)	Preset mixture with a minimum of 40% O ₂ self-administered by a demand-valve mask (requires a cooperative patient)	Preset mixture for a cooperative child; continuous-flow nasal mask in an uncooperative child with close monitoring	< 5	< 5 following discontinuation	Requires specialized apparatus and gas scavenger capability Several contraindications ^f Synergistic effect with recent opioids or sedative-hypnotics—use with caution in this setting
Reversal Agents (Antagonists)							
Naloxone (Narcan, Adapt Pharma Inc., Radnor, PA)	Opioid reversal	Opioid toxicity	IV/IM: 0.4–2 mg	IV/IM: 0.1 mg/kg per dose up to max of 2 mg/dose, may repeat q 2 min prn	IV: 2	IV: 20–40 IM: 60–90	If shorter acting than the reversed drug, serial doses may be required
Flumazenil (Romazicon, Genentech USA Inc., San Francisco, CA)	Benzodiazepine reversal	Benzodiazepine toxicity	IV: 0.2 mg, may repeat q 1 min up to 1 mg	IV: 0.02 mg/kg per dose, may repeat q 1 min up to 1 mg	IV: 1–2	IV: 30–60	If shorter acting than the reversed drug, serial doses may be required Do not use in patients chronically taking benzodiazepines, cyclosporine, isoniazid, lithium, propoxyphene, theophylline, tricyclic antidepressants

^aAlterations in dosing may be indicated depending on the clinical situation and the practitioner's experience with these agents. Individual dosages may vary when used in combination with other agents, especially when benzodiazepines are combined with opioids.

^bUse lower doses in geriatric patients and those with significant cardiopulmonary disease.

^cMidazolam is preferred over other benzodiazepines (e.g., diazepam, lorazepam) for procedural sedation and analgesia because of its shorter duration of action and multiple routes of administration.

^dFentanyl is preferred over other opioids (e.g., morphine, meperidine) for procedural sedation and analgesia because of its faster onset, shorter recovery, and lack of histamine release.

^eGenerally accepted contraindications to ketamine include age younger than 3 months; history of airway instability, tracheal surgery, or tracheal stenosis; procedures involving stimulation of the posterior pharynx; active pulmonary infection or disease (including active upper respiratory infection); cardiovascular disease, including angina, heart failure, or hypertension; significant head injury, central nervous system masses, or hydrocephalus; glaucoma or acute globe injury; psychosis; porphyria; and thyroid disorder or thyroid medication.

^fGenerally accepted contraindications to nitrous oxide include pregnancy (patient or personnel), preexisting nausea or vomiting, trapped gas pockets (e.g., middle ear infection, pneumothorax, bowel obstruction).

ED, Emergency department; FDA, US Food and Drug Administration; IM, intramuscularly; IN, intranasally; IV, intravenously; PO, orally; PR, per rectum; prn, as needed; PSA, procedural sedation and analgesia.

Adapted from Krauss B, Green SM: Sedation and analgesia for procedures in children, *N Engl J Med* 342:938, 2000.

reserved for pure anxiolysis or mild sedation (or both) for minimally painful procedures. Respiratory depression can also occur via these routes.⁹⁵

Adverse Effects. When administered by skilled practitioners using standard precautions (see Box 33.6), the safety profile for midazolam is excellent.^{5,6,101} However, when administering benzodiazepines, one must maintain continuous vigilance for respiratory depression.^{1,7,6,84,101,102} Such respiratory depression is dose dependent and greatly enhanced in the presence of ethanol or other depressive drugs, especially opioids. These effects are exaggerated in the elderly. Deaths from undetected apnea have occurred,⁸⁴ thus underscoring the critical role of continuous interactive and mechanical monitoring.

Benzodiazepines induce minimal cardiovascular depression. Although hypotension can occur, it is rare when the agents are carefully titrated. One reason that midazolam is ideal for painful procedures is its significant amnesic effect. Even though patients appear to feel pain during the procedure, it is often not remembered.

Pentobarbital

Pharmacology. Pentobarbital is a barbiturate capable of profound sedation, hypnosis, amnesia, and anticonvulsant activity in a dose-dependent fashion. It has no inherent analgesic properties. When carefully titrated intravenously, sedation is evident within 5 minutes with a duration of approximately 30 to 40 minutes.⁸⁸

Adult Use. Pentobarbital has no advantage over midazolam for adult PSA and is rarely used for this purpose.

Pediatric Use. Pentobarbital is the IV sedative of choice in many centers for diagnostic imaging in children.^{79,82,88,103,104} It is regarded as superior to midazolam^{82,88,89} or chloral hydrate for this indication.⁸² Pentobarbital, like midazolam, is available in multiple routes of administration.

Adverse Effects. Like other barbiturates, pentobarbital can lead to respiratory depression and hypotension because it is a negative inotrope.^{79,82,88,89}

Ultrashort-Acting Sedative-Hypnotic Agents

Ultrashort-acting sedatives (i.e., propofol, etomidate, thiopental, methohexital) can rapidly produce potent sedation when administered intravenously, and all exhibit rapid awakening (< 5 minutes) after discontinuation of the drug. ED use of these agents (propofol in particular) for a variety of common short, painful procedures has expanded dramatically in recent years because their brief yet profound obtundation creates superlative conditions.

Substantial controversy surrounded the early administration of these agents for ED PSA.¹⁰⁵ Proponents have cited their extremely rapid onset and recovery as enormous advantages over other sedatives. Critics have cited the level of continuous vigilance required to achieve a desired effect while simultaneously avoiding significant cardiopulmonary depression because these agents can result in rapid swings in levels of consciousness. Research that includes thousands of ED patients for propofol and hundreds for etomidate has subsequently demonstrated that the safety profiles of these agents are the same or better than those of other agents in the PSA pharmacopoeia.²⁷

Figure 33.3 Propofol is emerging as an agent of choice for painful emergency department procedures. It is safe, effective, and very short acting. It can be cautiously combined with the short-acting narcotic fentanyl or with ketamine. All the safety caveats for procedural sedation and analgesia apply. The pain of a propofol injection can be minimized by choosing a large vein not on the dorsum of the hand and slowly injecting 2 to 3 mL of 2% lidocaine into the vein before injection of propofol.

Given the rapid onset and offset of propofol, consider (when available) an additional dedicated clinician (separate from the individual performing the procedure) to oversee administration of medication.¹⁰⁶

Propofol

Pharmacology. Propofol is becoming an agent of choice for PSA in the ED because of its efficacy and safety profile (Fig. 33.3). When administered by IV bolus, its onset of action is typically within 30 seconds. The half-life for blood-brain equilibration is approximately 1 to 3 minutes, and its clinical effects typically resolve within 5 to 7 minutes. Longer procedures can be facilitated by repeated dosing. Patients are typically awake and alert within 15 minutes after discontinuation. Propofol exhibits inherent antiemetic and perhaps euphoric properties, and patient satisfaction is typically high. Propofol should be avoided in patients with known or suspected allergy to eggs or soy products.^{28,106–113}

Adult and Pediatric Use. Deep sedation can be achieved reliably in both adults and children with a single IV loading dose of propofol. Repeated bolus dosing is preferred, but an IV drip can be administered as needed to enhance or prolong sedation.^{28,106–113}

Adverse Effects. Transient apnea and respiratory depression can occur with propofol but typically resolve spontaneously before intervention is necessary. Reported rates of assisted ventilation range from 0% to 4.6%.¹⁰⁶ Similarly, transient hypotension (via direct negative inotropy as well as arterial and venous dilation) is common but typically resolves spontaneously without treatment. Injection site pain is noted less frequently in the ED setting than in the operating room, where higher doses are generally administered.^{28,106–113} Propofol usually causes pain on injection in awake individuals. Injecting slowly through a large vein, not a dorsal hand vein, and administering

2 to 3 mL of 2% lidocaine slowly into the vein before propofol infusion will lessen the pain of injection.

Etomidate

Pharmacology. When administered by IV bolus, the onset of action of etomidate is typically within 30 seconds, and patients are usually awake and alert within 30 minutes after discontinuation.

Adult Use. Deep sedation can be achieved reliably with single loading doses.¹¹⁴⁻¹¹⁷ Dosing can be repeated as needed to enhance or prolong sedation. Etomidate may be somewhat less effective overall than propofol and, given its additional adverse effect of myoclonus, appears to be a less desirable choice than propofol for deep sedation.^{27,48}

Pediatric Use. The safety and efficacy profile of etomidate appears to be similar to that in adults.^{118,119} For short-duration painful ED procedures, etomidate 0.2 mg/kg intravenously administered after fentanyl was associated with effective sedation, successful procedural completion, and readily managed respiratory events in children (oxygen supplementation, stimulation, or airway repositioning).¹²⁰ Etomidate has also been compared to ketamine for orthopedic procedures in children, with equal rates of success and favorable safety profiles.¹²¹

Adverse Effects. The primary adverse effects of etomidate are respiratory depression, myoclonus, nausea, and vomiting.¹¹⁹⁻¹²² Respiratory depression has been reported to be less common with propofol PSA than with methohexital, fentanyl/midazolam, or etomidate.¹²³ Myoclonus is common yet generally benign, but it may be disconcerting and can interfere with the procedure. It consists of transient jerking or twitching movements that can be mistaken for seizure activity. Transient adrenal suppression occurs with etomidate in septic patients but appears to lack clinical significance for single doses when used for ED PSA.^{27,122,124}

Thiopental and Methohexital

Pharmacology. Because of their lipid solubility, barbiturates are rapidly absorbed rectally. When given by the IV route, both thiopental and methohexital produce sedation within 1 minute. Clinical recovery is rapid (\approx 15 minutes) as a result of rapid redistribution from the central nervous system to the periphery.

Adult Use. There is limited published experience using these IV barbiturates for ED PSA,¹²⁵ and propofol or etomidate would appear to be a better choice.

Pediatric Use. Rectal thiopental and methohexital can reliably produce sedation suitable for CT or MRI and obviates the need for IV access.¹²⁶⁻¹³¹ Respiratory depression is unusual when using typical doses (see Table 33.5) but can occur.^{126,127,129-131} There is limited published experience using these IV barbiturates for ED PSA,¹²⁵ and propofol would appear to be a better choice.

Adverse Effects. Barbiturates cause potent respiratory depression; in one ED report, apnea occurred in 10% of patients.¹³² Barbiturates also frequently cause hypotension at typical IV doses, so their use should be avoided whenever possible in patients with volume depletion or cardiovascular compromise.

Analgesic Agents

Fentanyl

Fentanyl is the most common opioid used for PSA because of its rapid onset, brief duration, rapid reversibility with naloxone, and lack of histamine release.⁷ It is often combined with other agents such as propofol, etomidate, and midazolam to provide additional effect and pain relief. The effects of fentanyl can be reversed immediately with naloxone should excessive sedation or respiratory depression occur. The longer-duration opioids morphine and meperidine are preferred for nonprocedural or preprocedural pain control and are frequently given initially for acute analgesia followed by fentanyl to facilitate the needed procedure. Although longer-acting opioids can be readily used for analgesia during PSA, they will be associated with longer recovery times and a higher incidence of histamine-related effects (e.g., nausea and vomiting, hypotension, pruritus). Fentanyl lacks these effects and is therefore preferred.

Pharmacology. Fentanyl is 100 times more potent than morphine and has no intrinsic anxiolytic or amnestic properties. A single IV dose has a rapid onset ($<$ 30 seconds) with a peak at 2 to 3 minutes and brief clinical duration (20 to 40 minutes). This increase in potency and onset of action is in part related to its greater lipid solubility, which facilitates passage of the drug across the blood-brain barrier. The effects of fentanyl can be rapidly and completely reversed with opioid antagonists (e.g., naloxone, nalmefene).

Adult Use. Because of its pharmacokinetics, IV fentanyl is an ideal agent when analgesia is required for painful procedures; it can be easily and rapidly titrated.⁷ Because anxiolysis and sedation do not occur at low doses (1 to 2 μ g/kg), concurrent administration of a pure sedative, most commonly midazolam, is advisable, especially in children (see Box 33.6).

Pediatric Use. The combination of fentanyl and midazolam remains a popular PSA sedation regimen in children, with a strong safety and efficacy profile when both drugs are carefully titrated to effect.^{6,101,133,134} Any necessary level of mild to deep sedation can be achieved with these agents.

Fentanyl is also available in an oral transmucosal preparation. Although this novel and noninvasive delivery route obviates the need for IV access, titration is difficult and its efficacy is variable.¹³⁵ Furthermore, the incidence of emesis is high (31% to 45%),¹³⁵⁻¹³⁷ and consequently this formulation has never become popular for PSA.

Adverse Effects. Like all opioids, fentanyl can cause respiratory depression.^{6,7,101,133,134} When used for PSA, standard interactive and mechanical monitoring is required. Because the opioid effect is most pronounced on the central nervous system respiratory centers, apnea precedes loss of consciousness. If apnea should occur, verbal or tactile stimulation should be attempted before the administration of opioid antagonists. As discussed earlier, caution must be exercised when using benzodiazepines and other PSA agents and opioids together because the risk for hypoxia and apnea is significantly greater than when either is used alone.^{5,84}

In the absence of significant ethanol intoxication, hypovolemia, or concomitant drug ingestion, hypotension is rare, even with very large doses of fentanyl (doses of 50 μ g/kg are

common in adult and pediatric cardiac surgery). Because of its safe hemodynamic profile, fentanyl is an ideal analgesic agent for use in critically ill or injured patients. In addition, nausea and vomiting are rare in comparison to analgesia with morphine or meperidine. A commonly observed reaction to fentanyl is nasal pruritus, and patients frequently attempt to scratch their nose during the procedure.⁷

A rare side effect of fentanyl with potential for respiratory compromise is chest wall rigidity. This complication has not been problematic in the ED and is related to higher doses (> 5 µg/kg as a bolus dose) than those used for PSA and has not been reported in any ED series.^{6,7,133,134} If it should occur, chest wall rigidity can usually be reversed with opioid antagonists, positive pressure ventilation, or both. Equipment for urgent pharmacologic paralysis should be available if reversal and positive pressure ventilation are unsuccessful.

Diamorphine

Diamorphine is a nasal opioid that is currently available in the United Kingdom, Australia, New Zealand, and Canada, but not in the United States.^{67,68,138} Diamorphine has an onset and duration of action similar to that of morphine; however, its higher water solubility permits potent doses to be delivered in the small (0.1 mL) volumes necessary for comfortable intranasal administration. In two studies of children and teenagers with fractures, intranasal diamorphine, 0.1 mg/kg, provided a similar level of analgesia with faster onset as IM morphine, 0.2 mg/kg. Intranasal spray administration was better tolerated than the injection, and there were no adverse events.^{67,68,138} Diamorphine may prove to be a useful initial analgesic for children and teenagers with acute pain, although in practice, an IV line would most likely be established to permit titration to full pain relief and PSA for any procedures needed (e.g., fracture reduction). The role of diamorphine in adults remains to be determined.

Other Short-Acting Opioids

Sufentanil, alfentanil, and remifentanil are other short-acting opioids that have a potential role in PSA. Currently, however, there is insufficient published experience to warrant their routine use. Although intranasal sufentanil, 0.75 µg/kg, appeared promising in one small pediatric trial,¹³⁹ in another, doses of 1.5 µg/kg resulted in oxygen desaturation in 8 of the 10 children studied.⁹⁷ This low toxic-to-therapeutic ratio and inability to titrate would appear to limit the utility of intranasal sufentanil by itself. However, a 2014 proof of concept trial using a lower dose of intranasal sufentanil (0.5 mcg/kg) with intranasal ketamine (0.5 mg/kg) showed promise with high patient acceptance and few adverse events.¹⁴⁰ In the one published report of IV remifentanil with midazolam for PSA, there was an unacceptably high incidence of hypoxemia.¹⁴¹ Currently, there does not appear to be a clinically important advantage with these drugs versus fentanyl.

Ketamine

Pharmacology. Ketamine produces a unique state of cortical dissociation that permits painful procedures to be performed more consistently and effectively than with other PSA agents (Video 33.1). This state of dissociative sedation is characterized by profound analgesia, sedation, amnesia, and immobilization (Fig. 33.4) and can be rapidly and reliably produced with IV

Figure 33.4 A, Child undergoing insect removal from the ear under ketamine sedation. No child or adult can cooperate for this painful procedure, and general anesthesia is often the other option to ketamine. The blank stare is common. B, Insect successfully and atraumatically removed.

or IM administration.¹¹ Ketamine is widely used worldwide and has demonstrated a remarkable safety profile in a variety of settings.^{4,6,142–145} Clinicians administering ketamine must be especially knowledgeable about the unique actions of this drug and the numerous contraindications to its use (see Table 33.5).

Ketamine differs from other PSA agents in several important ways. First, it uniquely preserves cardiopulmonary stability. Upper airway muscular tone and protective airway reflexes are maintained. Spontaneous respiration is preserved, although when administered intravenously, ketamine must be given slowly (over a period of 30 to 60 seconds) to prevent respiratory depression. Second, it differs from other agents in that it lacks the characteristic dose-response continuum to progressive titration. At lower doses ketamine produces analgesia and disorientation. However, once a dosage threshold (≈1 to 1.5 mg/kg intravenously or 3 to 4 mg/kg intramuscularly) is achieved, the characteristic dissociative state appears. This dissociation has no observable levels of depth, and thus the only value of ketamine “titration” is to maintain the presence of the state over time. Finally, the dissociative state is not consistent with formal definitions of moderate sedation, deep sedation, or general anesthesia (see Box 33.1) and must therefore be

Figure 33.5 Ketamine can occasionally induce excessive salivation, generally easily handled with minimal suctioning. Routine use of atropine or glycopyrrolate is not recommended; however they can be administered should excessive secretions be noted.

considered from a different perspective than agents that exhibit the classic sedation continuum.^{11,15}

Ketamine is most effective and reliable when given intravenously or intramuscularly. Ketamine has a rapid circulation time when given intravenously, with onset of dissociation noted within 1 minute and effective procedural conditions lasting for approximately 10 to 15 minutes. When given intramuscularly, the same effect is achieved within 5 minutes, with effective procedural conditions for approximately 15 to 30 minutes. The typical duration from dosing to dischargeable recovery is 50 to 110 minutes when given intravenously and 60 to 140 minutes when given intramuscularly.^{142,145}

Like the benzodiazepines, ketamine undergoes substantial first-pass hepatic metabolism. As a result, oral and rectal administration results in less predictable effectiveness and substantially higher doses are required. Clinical onset and recovery are considerably longer than when given parenterally, and thus these routes are rarely used in the ED.^{100,146}

Ketamine can occasionally induce excessive salivation, and to combat this, some have historically coadministered atropine or glycopyrrolate. However, there is no evidence that either of these anticholinergic agents diminishes the risk for airway or respiratory adverse events,¹⁴⁷⁻¹⁴⁹ and their routine prophylactic use is no longer recommended.¹⁴⁷ Instead, they can be reserved for treatment should excessive secretions occur (Fig. 33.5).

Adult Use. The safety and efficacy of ketamine are well established in ED adults despite less published experience than in children.^{147,150-156} Such experience is corroborated by the wide and successful use of ketamine in adults throughout the developing world for both minor and major surgery, particularly in areas lacking resources for inhalational anesthesia.^{142,143,154,155}

Ketamine presents potential risk to patients with coronary artery disease because it is sympathomimetic and produces mild to moderate increases in blood pressure, heart rate, and myocardial oxygen consumption. Accordingly, other sedatives are preferred in the setting of known or possible ischemic heart disease, congestive heart failure, or hypertension.^{147,155}

There is no accepted maximum age for ketamine; instead, emergency physicians must weigh the risks and benefits of ketamine in older adults who may have unrecognized coronary artery disease.

Hallucinatory so-called emergence reactions have been reported in up to 30% of adults receiving ketamine (though rare in children) and can be fascinating and pleasurable or, alternatively, unpleasant and nightmarish.¹⁴² In adults, co-administered IV midazolam (0.03 mg/kg) can modestly reduce their incidence (number needed to benefit of 6),¹⁵³ although not all such reactions are clinically important and this therapy should be considered optional.¹⁵⁷

Pediatric Use. Ketamine is an ideal agent to facilitate short, painful procedures in children because of its superbly documented ED safety and efficacy.^{4,6,142,145,147,148,158} The IM route is simple and effective, with venous access being unnecessary. IV administration is attractive because a lower cumulative dose can be used and recovery is faster than with the IM route. The primary caution with this route is that the initial bolus of ketamine must be administered slowly (over a 30- to 60-second period) or respiratory depression and transient apnea can occur.¹⁴⁵

Unpleasant recovery reactions are uncommon in children and teenagers and are typically mild when they do occur.^{159,160} Benzodiazepine co-administration does not measurably reduce the incidence of such reactions in children (unlike adults),^{147,148,158-160} and these agents should be reserved for treating preprocedural anxiety or unpleasant reactions if they occur.¹⁴⁷

Adverse Effects. In a meta-analysis of ketamine administration in 8282 pediatric patients, the overall incidence of airway and respiratory adverse events was 3.9%—primarily airway malalignment but also including transient laryngospasm (0.3%) and transient apnea (0.8%). None of these patients were intubated or had adverse sequelae.¹⁴⁷ The frequency of such events was slightly higher when unusually high doses of ketamine were administered; otherwise, there was no clinically important association with age, doses within the typically recommended range, or other clinical factors.

Vomiting was noted in 8.4% overall in this same meta-analysis, with early adolescence representing the greatest risk and a lower incidence of emesis occurring in younger and older children.¹⁵⁸ It occurs more frequently with the IM route than with the IV route, and there is no evidence to support any dose relationship within the usual range of clinically administered doses.¹⁵⁸ When emesis occurs, it is typically late during the recovery phase when the patient is alert and can clear the airway without assistance.¹⁴⁷ Vomiting does occur in some patients after discharge, including some who do not vomit in the ED.¹⁴⁷ Although ondansetron prophylaxis (0.15 mg/kg up to a maximum of 4 mg intravenously) does reduce vomiting with ketamine, the magnitude of this effect is modest (number needed to benefit of 13), and thus it cannot be considered mandatory.¹⁶¹

In 40 years of regular use there have been no documented reports of clinically significant ketamine-associated aspiration in patients without established contraindications.¹⁴⁷ Because of its unique preservation of protective airway reflexes, ketamine may be preferred over other agents for urgent or emergency procedures when fasting is not ensured.^{4,5,142}

Mild agitation (whimpering or crying) during recovery was noted in 7.6% of children in the large meta-analysis, with

more pronounced agitation occurring in 1.4%. Such recovery reactions are not related to age, dose, or other factors to any clinically important degree, except for a higher incidence with dissociative (< 3 mg/kg intramuscularly) dosing.¹⁵⁸ In contrast to traditional thinking, adolescents are not at substantially higher risk.¹⁵⁸

Despite the modest impact of prophylactic midazolam in reducing adult recovery agitation, in children, two controlled trials and a large meta-analysis failed to note even a trend toward a measurable benefit.^{158–160} Children have far fewer recovery reactions than adults do, and their reactions are milder when they do occur. Midazolam is therefore not recommended for routine prophylaxis but is optimally reserved to treat unpleasant ketamine-associated recovery reactions when they do rarely occur.¹⁴⁷

Ketamine is relatively contraindicated in patients with central nervous system masses, abnormalities, or hydrocephalus; however, there is no compelling evidence that it needs to be avoided in the setting of acute head trauma.^{147,162,163} Repeated reports that ketamine can increase intracranial pressure have prompted traditional caution against use of this drug in the setting of real or potential neurologic compromise,^{1,5,142,147,164–166} and there are case reports of deterioration in patients with hydrocephalus.^{167,168} However, newer suggestive evidence indicates that in most patients the resulting increases in pressure are minimal, assuming normal ventilation,^{162,163,167,169} and that the corresponding cerebral vasodilatory effect of ketamine may actually improve overall cerebral perfusion.^{162,163}

Dissociative sedation may represent a risk in patients with acute globe injury or glaucoma given the inconclusive and conflicting evidence of increased intraocular pressure with ketamine.^{170–174}

Ketamine-Propofol Combination (Ketofol) for PSA in the ED

The PSA combination of ketamine and propofol, referred to by the portmanteau “ketofol,” is both popular and controversial.¹⁷⁵ There is no doubt that ketofol is safe and effective in both adults and children^{176–183}; instead, the dispute is whether the combination exhibits any clinically important advantage over use of either drug alone.¹⁷⁵ Although this question has not been definitively answered, a recent meta-analysis evaluating 6 trials using ketofol suggests that the adverse event profile of ketofol may be superior to propofol alone.¹⁸⁴

An important allure to ketofol proponents is how these two completely different sedatives balance each other’s deficits. Propofol is a superb sedative but lacks the analgesia that ketamine can amply provide. Ketamine mitigates propofol-induced hypotension, and propofol mitigates ketamine-induced vomiting and recovery agitation. The drugs exhibit synergistic and perhaps smoother sedation,¹⁷⁷ and the combination has the theoretical benefits of minimizing the propofol dose and obviating the need for co-administered opioids.¹⁷⁵

Critics note that the existing ketofol literature fails to demonstrate superior procedural conditions or less respiratory depression than occurs with each drug alone¹⁷⁶ and question the added complexity of administering two drugs when one is sufficient. They argue that the purported advantages related to hemodynamics and the total propofol dose are not clinically important. Ketofol uses a dissociative dose of ketamine, and thus ketamine may just be replacing fentanyl as an analgesic rather than as a sedative.¹⁷⁵

Ketofol dosing is based on weight for both adults and children. One regimen uses an initial IV loading dose of ketamine of 0.5 mg/kg, followed by a 0.5 to 1.0 mg/kg IV propofol bolus, with subsequent titration of propofol alone.^{177–179,181} A second strategy mixes propofol and ketamine together 1:1 in the same syringe (both at 10-mg/mL concentrations) and then titrates in increments of 0.25 mg/kg of each drug to a usual effective dose of approximately 0.75 mg/kg.^{175,180,182,183}

Careful observation for respiratory depression is required, and the precautions listed for both agents should be stringently observed.

Nitrous Oxide

Pharmacology. Inhaled nitrous oxide provides anxiolysis and mild analgesia. It is commonly dispensed at concentrations between 30% and 50%, with oxygen composing the remainder of the mixture. Nitrous oxide quickly diffuses across biologic membranes and, accordingly, has a rapid onset of action (30 to 60 seconds). Its maximum effect occurs after approximately 5 minutes, and the clinical effect wears off quickly on discontinuation. At typical PSA concentrations, there is preservation of hemodynamic status, spontaneous respirations, and protective airway reflexes.^{185–188} Nitrous oxide is widely used in dentistry at higher concentrations.¹⁸⁹

Nitrous oxide has an excellent safety profile; however, as a sole agent, it cannot reliably produce adequate procedural conditions.^{185–188} Given its relatively weak analgesic properties, in many cases nitrous oxide needs to be supplemented with an IV opioid or local or regional anesthesia (or both).

Adult and Cooperative Child Use. The safest method of administering nitrous oxide is via a self-administered demand-valve mask (Fig. 33.6).^{186–188} Patients must generate a negative pressure of 3 to 5 cm H₂O within the handheld mask or mouthpiece to activate the flow of gas. They can thus self-titrate the dose by inhaling at will through the mask. Naturally, this will be effective only when the patient is cooperative. This technique provides a built-in fail-safe measure in that if patients become somnolent, the mask will fall from their face and gas delivery will cease.

Nitrous oxide can be used as an adjunctive anxiolytic during mildly painful procedures or during the administration of local or regional anesthesia for other procedures. It may also be administered during difficult or high-anxiety procedures such as pelvic examination or during difficult IV attempts.

A double-tank system is commonly used to deliver the nitrous oxide and oxygen mixture. The system relies on a mixing valve preset to deliver a fixed ratio and will deliver gas only when oxygen is flowing. The double-tank system contains a fail-safe device that automatically stops the flow of nitrous oxide when the oxygen supply is depleted.

Uncooperative Child Use. The primary limitation of self-administration is that it is ineffective in uncooperative patients, including most frightened young children. Continuous-flow nitrous oxide via a mask strapped over the nose or over the nose and mouth has been used in this population (Fig. 33.7).^{190–193} Nitrous oxide can effectively produce moderate or deep sedation when administered in this manner; however, this technique necessitates an additional clinician dedicated to continuous

Figure 33.6 A, Demand-flow nitrous oxide/oxygen system. B, Example of a free mask for a nitrous oxide system. The patient must hold the mask in contact with the face. (A, Courtesy Nitronox delivery system by Matrx Medical, division of Henry Schein.)

gas titration to avoid oversedation. In addition, it appears that the continuous-flow technique is associated with a higher rate of emesis (10%) than self-administration is (0% to 4%),^{185–188,190–193} which may be a potential hazard if a mask is strapped tightly over the child's mouth.¹⁹¹

Adverse Effects and Precautions. A number of generally minor adverse effects may be seen, including nausea, dizziness, changes in voice, euphoria, and laughter.^{185–188} Nitrous oxide should be avoided in patients with closed-space disease such as bowel obstruction, middle ear disease, pneumothorax, or pneumocephalus. Because of its property of high diffusibility,

Figure 33.7 Nitrous oxide/oxygen continuous-flow system.

it has the potential to increase the size of the closed space. This should be unlikely for short-term use in typical PSA concentrations.

Make sure that a scavenging system is in place to collect exhaled nitrous oxide, and take care to ensure compliance with occupational safety regulations. Avoid exposure of pregnant ED staff members to nitrous oxide because it is a known teratogen and mutagen.

Although the potential for abuse by ED staff exists, such abuse is rare if simple steps are taken. As with other agents, maintain a strict protocol of accountability. Add a simple locking device to the cylinders of gas. In addition, lock the delivery valve or mouthpiece in the same location as controlled substances.

Antagonists

Do not routinely administer reversal agents after the administration of opioids or benzodiazepines for PSA, but rather reserve them for the rare situations of oversedation or significant respiratory depression. The downside of reversal agents is that one must wait for the antagonist to dissipate before analyzing any residual effect of the PSA agent, with the caveat that long-acting PSA agents may last longer than the administered antagonist. Serious resedation after antagonism is not usually an issue with fentanyl or midazolam, but caution is advised, especially when large doses of PSA agents and large doses of antagonists have been used. Obviously, the length of observation varies with the amount of antagonist that has been administered.

Naloxone

Naloxone is an antagonist that competitively displaces opioids from opiate receptors. It rapidly reverses the analgesic and respiratory depressant effects of opioids. It may be administered intravenously, intramuscularly, subcutaneously, or even sublingually if needed,¹⁷⁶ and dosing has been standardized for infants and children.¹⁹⁴ Naloxone will not induce systemic opioid withdrawal symptoms in a patient without preexisting physiologic dependence. However, some patients will experience nausea with opioid reversal, and patients with persistent pain after their procedure will be quite uncomfortable. Rapid reversal may also lead to return of anxiety and stimulation of the sympathetic nervous system. If the situation permits, careful titration of small amounts of naloxone (0.1-mg aliquots

intravenously) may permit partial rather than complete reversal. The only absolute contraindication to the use of naloxone is administration to a neonate born to an opioid-dependent mother because of the risk of precipitating life-threatening opioid withdrawal. The length of observation is dose related, but usually no more than 60 to 90 minutes after reversal will be sufficient if no more than 1 mg of naloxone has been administered intravenously.

Nalmefene

Nalmefene is a long-acting opioid antagonist with a duration of action significantly longer than that of naloxone.^{195,196} Nalmefene may be given intravenously, intramuscularly, or subcutaneously, although intravenously is the preferred route.^{196,197} Intravenously, it can be titrated in incremental doses of 0.25 µg/kg every 2 to 5 minutes until the desired effect is attained. Although either naloxone or nalmefene will reverse the analgesia of opioids, naloxone is the preferred agent. For ED PSA, short-acting opioids such as fentanyl are commonly used, and administration of a reversal agent with a duration of action as prolonged as that of nalmefene does not confer any additional benefit. Furthermore, nalmefene would interfere with postprocedure control of pain with opioids.

Flumazenil

Flumazenil is a benzodiazepine antagonist that can promptly reverse benzodiazepine-induced sedation and respiratory depression.^{1,15,198,199} In the setting of PSA, flumazenil is a safe and effective method of reversing oversedation caused by benzodiazepines. It is not routinely used to reverse PSA because of the potential for re sedation, and many clinicians prefer to allow patients to recover on their own. Flumazenil has not

been shown to substantially decrease the time of observation in the ED required for a patient undergoing PSA. Flumazenil lowers the seizure threshold and may rarely lead to life-threatening seizures. It should be avoided in patients with known benzodiazepine dependence, seizure disorder, cyclic antidepressant overdose, and elevated intracranial pressure.¹⁷⁸ It should also be given cautiously to patients who are taking medications known to lower the seizure threshold (cyclosporine, tricyclic antidepressants, propoxyphene, theophylline, isoniazid, lithium).²⁰⁰ These issues, however, are not usually involved in PSA in the ED. It has not been shown that simply taking therapeutic doses of these medications contraindicates the use of flumazenil, but flumazenil-induced seizures are generally associated only with drug overdose. Rapid reversal may also lead to return of anxiety and sympathetic stimulation. If the situation permits, careful titration of small amounts of flumazenil (0.1- to 0.2-mg aliquots intravenously) will reduce the risk for adverse effects and may permit partial rather than complete reversal. Observation times vary. For example, 1 hour after reversal will allow accurate assessment of residual sedation if less than 1 mg of flumazenil has been used to reverse conscious sedation with midazolam.

Soft Tissue Procedures

CHAPTER 34

Principles of Wound Management

Richard L. Lammers and Kim N. Aldy

Management of acute traumatic wounds is one of the most common procedures in emergency medicine. Although many aspects of traumatic wound management remain controversial, the clinician can follow some basic principles to maximize the chance for successful healing. The purpose of this chapter is to give the clinician a general approach to wound care and to describe appropriate indications and techniques for wound management.

Wound care involves much more than closure of divided skin. The primary goal of wound care is not technical repair of the wound, but to provide optimal conditions so that the natural reparative processes of the wound may proceed. The cornerstones of wound care are cleaning, débridement, closure (when appropriate), and protection. The primary objectives in wound care are to:

1. Preserve viable tissue and remove nonviable tissue
2. Restore tissue continuity and function
3. Optimize conditions for the development of wound strength
4. Prevent excessive or prolonged inflammation
5. Avoid infection and other impediments to healing
6. Minimize scar formation
7. Provide suitable anesthesia during wound management

Patients who seek care in the emergency department (ED) because of acute wounds report that their top priorities include prevention of infection, return to normal function, a good cosmetic outcome, and minimal pain during repair.^{1,2} This chapter reviews the current strategies for attaining these goals.

BACKGROUND: WOUND HEALING

For centuries victims of wounds have commonly experienced inflammation, infection, and extreme scarring; in fact, these processes were considered part of normal wound repair. Emergency clinicians should have a basic understanding of the process of wound healing. Highlights of this complex phenomenon as they relate to clinical decision-making are presented here.

Wounds extending beneath the epithelium heal by forming scar tissue. Among the various proposed overlapping phases from injury to repair, inflammation, epithelialization, fibroplasia, contraction, and scar remodeling/maturation constitute the main phases of this natural repair process.³⁻⁶

Inflammation is a beneficial response orchestrated by polymorphonuclear and mononuclear leukocytes that concentrate at the site of injury and phagocytose dead and dying tissue, foreign material, and bacteria in the wound, essentially performing a biologic débridement.⁵ As white blood cells die, their intracellular contents are released into the wound. In excessive amounts, the contents form the purulence that is characteristic of infected wounds. Some exudate is expected even in the absence of bacterial invasion, but infection with accumulation of pus interferes with epithelialization and fibroplasia, and impairs wound healing. Wounds contaminated with significant numbers of bacteria or foreign material may undergo a prolonged or persistent inflammatory response and not heal. Granuloma formation surrounding retained sutures is an example of chronic inflammation.⁷

Although white blood cells remove debris within the wound, keratinocytes at the surface of the wound begin to migrate across the tissue defect during *epithelialization*. In most sutured wounds, the surface of the wound develops an epithelial covering impermeable to water within 24 to 48 hours. Surface debris, dead tissue, and eschar formation can impair this process. The epithelium thickens and grows downward into the wound along the course of skin sutures. Although there is some “adhesiveness” at the wound edges during the first few days, this is eventually lost because of fibrinolysis.

By the fourth or fifth day, newly transformed fibroblasts in the wound begin synthesizing collagen and protein polysaccharides, thereby initiating the stage of scar formation known as *fibroplasia*. Collagen is the predominant component of scar tissue.⁵ Wound strength is a balance between the lysis of old collagen and the synthesis of new collagen that “welds” the edges of the wound together. The amount of scar tissue that forms is influenced by physical forces (e.g., the stresses imposed by movement) acting across the wound. When the wound edges are approximated, either naturally or by mechanical closure within the first 24 hours, the wound can heal by “first intention”. In contrast, a wound with extensive tissue loss and not closed by sutures or other means heals by “secondary intention,” a combination of processes that include contraction, collagen formation, and epithelialization (Fig. 34.1).⁶ *Contraction* consists of movement of the skin edges toward the center of the defect, primarily in the direction of underlying muscle.

Significant gains in tensile strength do not begin until approximately the fifth day after the injury. Strength increases rapidly for 6 to 17 days, more slowly for an additional 10 to

Figure 34.1 Steps in wound healing by first intention (*left*) and second intention (*right*). Note the large amounts of granulation tissue and wound contraction in healing by secondary intention.

Figure 34.2 Graphic representation of the various phases of wound healing. Note that the tensile strength of scar tissue never reaches that of unwounded skin. The values of tensile strength displayed are approximate and demonstrate the general concept of wound healing.

14 days, and almost imperceptibly for as long as 2 years (Fig. 34.2). The strength of scar tissue never quite reaches that of unwounded skin, approaching a maximum of 80%.^{3,6} Although the process of collagen formation is essentially completed within 21 to 28 days, the scar widens for another month, and collagen continues to *remodel* and strengthen the wound for up to 1 year.^{3,5,7} The normal desirable outcome of this complex process

is a wound that is either fully re-epithelialized or filled with an avascular scar.⁶

Decisions regarding the optimal time for suture removal and the need for continued support of the wound with tape are influenced by the following: (1) the tensile strength of the wound, (2) the period of scar widening, and (3) the cosmetically unacceptable effect of epithelialization along the suture track. Scars are quite red and noticeable at 3 to 8 weeks after closure. The appearance of a scar should not be judged before the scar is well into its remodeling phase. The cosmetic appearance of wounds 6 to 9 months after injury cannot be predicted at the time of suture removal.⁸ Therefore scar revision, if necessary, should be postponed until 6 to 12 months after injury.

One of the most important factors in predicting the cosmetic result of a wound is its location.⁹ In general, wounds on concave surfaces heal with better cosmetic results than do wounds on convex surfaces. Other factors that affect cosmesis include wound size, wound depth, and skin color.¹⁰ Small, superficial wounds in lax, light-colored skin, especially areas where the skin is thin, result in less noticeable scars. Wounds on convex surfaces look better after primary closure than after secondary healing. Static and dynamic forces, along with the propensity toward keloid formation, may influence the long-term cosmetic appearance of wounds more than the surgical skills of the clinician who repaired the wound.⁸ Repigmentation occurs over a period of 3 to 5 years, even in large wounds that heal by secondary intention.¹⁰ Patients should be advised to wear

sunscreen over the scar, especially during the first few years after injury, because unprotected exposure to the sun can alter the pigmentation as the wound heals and may result in noticeable darker pigmentation than the surrounding skin.^{11,12}

INITIAL EVALUATION

The approach to management of a particular wound and the decision to close a wound immediately or after a period of observation is based primarily on factors that affect the risk for infection, and secondarily on cosmesis and long-term functionality. The history and physical examination should be directed toward identifying these factors. Some wounds may appear benign but conceal extensive and devastating underlying tissue damage. The following findings should alert the provider of a more complicated injury including an extremity wound caused by a roller or wringer device, a high-pressure injection gun, high-voltage electricity, heavy and prolonged compressive force, or the bite of a human or a potentially rabid animal. These findings radically alter the overall management of the patient. The American College of Emergency Physicians' *Clinical Policy for the Initial Approach to Patients Presenting with Penetrating Extremity Trauma* provides a useful approach to the evaluation of all wounds.¹³

History

In the initial evaluation of a wound, identify all the extrinsic and intrinsic factors that jeopardize healing and promote infection, including: (1) the mechanism of injury, (2) the time of injury, (3) the environment in which the wound occurred, and (4) the patient's immune status.

Wound Age

In general, the likelihood of a wound infection increases with time, from the injury to definitive wound care.¹⁴ Definitive wound care does not always mean closing a wound. Some wounds should never be closed, such as small, contaminated lacerations on the bottom of the foot, whereas others can be closed many hours after the injury without increasing infection rates. A delay in wound cleaning is one of the most important factors in wound infection because it may allow bacteria contaminating the wound to proliferate. A delay of only a few hours in the treatment of a heavily contaminated wound can increase the risk for infection. Although no scientific data exist to fully answer the question, and there is no definitively accepted standard, it appears reasonable that most wounds that are not grossly contaminated can probably be closed safely 6 to 8 hours after injury, if the wound can be adequately cleaned. In contrast, some evidence suggests that wounds in highly vascular regions, such as the face and scalp, can be closed without increased risk for as long as 24 hours after injury. The "golden period"—the maximum time after injury that a wound may be closed safely without significant risk for infection—is an outdated term and not a fixed number of hours.¹⁵

Many factors affect risk for infection, and closure decisions should not be based solely on time considerations. All data accumulated in the initial evaluation, both historical and physical, must be considered when making the decision to close a wound in a particular patient.¹⁴ Delayed primary closure is a reasonable alternative when there is clinical concern regarding closure at initial assessment. However, the techniques

of wound care may extend the period; with skillful cleaning and débridement, a clinician may be able to convert a contaminated wound to a clean wound that can be safely closed in the ED. In most instances the clinician cannot totally eliminate infection risks but can favorably affect the probability and severity of infection with adequate wound care. Simply prescribing antibiotics in the hope that infection will somehow be averted is an unrealistic expectation, and can lead to antibiotic-resistant microorganisms.

In summary, any time frames offered are suggestions. Clinical judgment regarding potential for wound infection should be incorporated into the final decision-making process.

Other Historical Factors

Other factors that affect wound healing or the risk for infection include the patient's age and state of health. Patient age appears to be an important factor in host resistance to infection, and individuals who are at the extremes of age, such as young children and the elderly, have the greatest risk for infection.^{14,16} Infection rates are reported to be higher in patients with concurrent medical conditions such as diabetes mellitus, immunologic deficiencies, malnutrition, anemia, uremia, congestive heart failure, cirrhosis, malignancy, alcoholism, arteriosclerosis, arteritis, collagen vascular disease, chronic granulomatous disease, smoking, chronic hypoxia, renal failure, and liver failure. Morbid obesity, in addition to other conditions in which patients are taking steroids or immunosuppressive drugs, or undergoing radiation therapy, are also at higher risk for infection. Shock, remote trauma, distant infection, bacteremia, retained foreign bodies, denervation, and peripheral vascular disease also increase wound infection rates and can slow the healing process.^{6,14,16,17}

Additional information pertinent to decision making in wound management includes the following:

- *Associated symptoms* (severe pain, paresthesia, or anesthesia)¹¹
- *Current medications* (specifically, anticoagulants, steroids, and immunosuppressive drugs)
- *Allergies* (especially to local anesthetics, antiseptics, analgesics, antibiotics, and tape)
- *Tetanus immunization status*
- *Potential exposure to rabies* (in bite wounds and mucosal exposures)
- *Potential foreign bodies* (embedded in the wound, especially when the mechanism of injury is unknown or the injury was associated with breaking glass or vegetative matter)¹⁸
- *Previous injuries and deformities* (especially with extremity and facial injuries)
- *Associated injuries* (underlying fracture, joint penetration, crush injury, deep penetrating injury, animal or human bite)
- *Other factors* (availability for follow-up, patient understanding of wound care, compliance)

Physical Examination

All wounds should be examined for the amount of tissue destruction, degree of contamination, potential foreign bodies, and damage to underlying structures. The examiner should wear clean or sterile powder-free, latex-free gloves and avoid droplet contamination from the mouth. Examine the wound under good lighting and after the bleeding is controlled. Create a bloodless field, if necessary, with a tourniquet or sphygmomanometer (see Video 34.1 for equipment).¹⁹ Assess distal perfusion, motor and sensory function (prior to the

use of anesthetics), nearby tendon function, and document findings.

Mechanism of Injury and Classification of Wounds

The magnitude and direction of the injuring force and the volume of tissue on which the force is distributed determine the type of wound that is sustained. Three types of mechanical forces—shear, tension, and compression—produce soft tissue injury. The resulting disruption or loss of tissue determines the configuration of the wound. Wounds may be classified into six categories:

1. *Abrasions.* Wounds caused by forces applied in opposite directions result in the loss of epidermis and possibly dermis (e.g., grinding of skin against a road surface).
2. *Lacerations.* Wounds caused by shear forces produce a tear in tissues. Little energy is required to produce a wound by shear forces (e.g., a knife cut). Consequently, little tissue damage occurs at the wound edge, the margins are sharp, and the wound appears “tidy.” Tensile and compressive forces also cause separation of the tissues. The energy required to disrupt tissue by tensile or compressive forces (e.g., forehead hitting a dashboard) is considerably greater than that required for tissue disruption by shear forces because the energy is distributed over a larger volume. These lacerations often have jagged, contused, “untidy” edges, which have a higher risk for infection.¹⁶
3. *Crush wounds.* Wounds caused by the impact of an object against tissue, particularly over a bony surface, compress the tissue. These wounds may contain contused or partially devitalized tissue and have higher rates of infection if not appropriately débrided.¹⁴
4. *Puncture wounds.* Wounds with a small opening, whose depth cannot be entirely visualized, are caused by a combination of forces. They are particularly prone to infection because they are difficult to thoroughly clean and may retain foreign bodies.⁴
5. *Avulsions.* Avulsions are wounds in which a portion of tissue is completely separated from its base, which is lost, or left with a narrow base of attachment (a flap). Shear and tensile forces cause avulsions.¹⁹ Skin tear avulsions often result from low-force friction or shearing forces that separate the layers of the skin (epidermis and dermis) from the underlying tissue. These wounds often occur in older adults as a result of the combination of minimal impact and vulnerable thin skin.
6. *Combination wounds.* Wounds can also have a combination of configurations. For example, a stellate laceration caused by compression of soft tissue against underlying bone can create wounds with elements of both crush injury and tissue separation. Missile wounds involve a combination of shear, tensile, and compressive forces that puncture, crush, and sometimes avulse tissue.¹⁸

Contaminants (Bacteria and Foreign Material)

Infection rates in studies of traumatic wounds range from 1% to 38%. Numerous factors affect the risk for wound infection, but the primary determinants of infection are the amount of bacteria and dead tissue remaining in the wound, the patient’s immune response, and local tissue perfusion.

Essentially all traumatic wounds are contaminated with bacteria to some extent. The number of bacteria remaining

in the wound at the time of closure is directly related to the risk for infection. A critical number of bacteria must be present in a wound before a soft tissue infection develops. In experimental wounds, fewer bacteria are required to infect wounds caused by a compressive force ($\geq 10^4$ bacteria/g of tissue) than by a shear force ($\geq 10^6$).²⁰

The nature and amount of foreign material contaminating the wound often determines the type and quantity of bacteria implanted. In general, visible contamination of a wound increases the risk for infection.¹⁶ The presence of undetected, reactive foreign bodies in sutured wounds almost guarantees an infection. Although bullet or glass fragments by themselves rarely produce wound infection, these foreign bodies may carry particles of clothing, gun wadding, or soil into the wound. Minute amounts of organic or vegetative matter, feces, or saliva carry highly infective doses of bacteria. The bacterial inoculum from human bites often contains 1 billion or more organisms per milliliter of saliva.²¹ Inorganic particulate matter, such as sand or road surface grease, usually introduces few bacteria into a wound and has little chemical reactivity. These contaminants are relatively innocuous. Soil that contains a large proportion of clay particles or a high organic content (such as that found in swamps, bogs, and marshes), however, has a high risk for infection.²²

In industrialized countries most wounds encountered in the practice of emergency medicine have low initial bacterial counts. If wound cleaning and removal of devitalized tissue are instituted before bacteria within the wound enter their accelerated growth phase (3 to 12 hours after the injury), bacterial counts will generally remain below the threshold needed to initiate infection.^{12,13,23}

Devitalized Tissue

Devitalized and necrotic tissue in a traumatic wound should be identified and removed. If left in place, it will allow bacteria to proliferate, inhibit leukocyte phagocytosis, and create an anaerobic environment suitable for certain bacterial species.¹⁸

Wound Location

The anatomic location of the wound has considerable importance in the risk for infection. Bacterial densities on the surface of the skin range from a few thousand to millions per square centimeter.²² Distal extremity wounds are more at risk for the development of wound infections than are injuries on most other parts of the body.¹⁴ Levels of endogenous bacteria on hairy parts of the scalp, the mouth, axilla, nails, foreskin, perineum, and vagina may be high enough to serve as a potential source of infection in wounds in these locations.¹⁸ The high vascularity in areas such as the scalp, face, or perineum appears to offset the risk posed by the large numbers of endogenous microflora, whereas wounds in ischemic tissue are notoriously susceptible to infection.²⁴

Underlying Structures

If injury to underlying structures such as nerves, vessels, tendons, joints, bones, or ducts is found, the clinician may choose to forego wound closure and consult a surgical specialist (Fig. 34.3). Procedures such as joint space irrigation, reduction and débridement of compound fractures, neuroorrhaphy, vascular anastomosis, and hand flexor tendon repair are best accomplished in the controlled aseptic setting of the operating room,

Figure 34.3 This patient had weak, hesitant, but full flexion of the finger, thus suggesting at least a partial tendon laceration. The tendon was nearly 90% lacerated (*arrow*) and would have ruptured with any stress. Close examination of this wound, with careful blunt dissection down to the tendon itself *and the finger in the position of injury*, revealed significant trauma to the delicate flexor tendon that required consultation with a specialist. Use of a proximal tourniquet for a bloodless field and instruments to explore finger wounds is mandatory to increase sensitivity for finding injury to deep structures. This wound can be repaired within a few days by a hand specialist, but if discovered weeks later, problems are likely.

where optimal lighting, proper instruments, and assistance are available.

CLEANING

Clean the wound as soon as possible after evaluation. Although most wounds are initially contaminated with less than an infective dose of bacteria, given time and the appropriate wound environment, bacterial counts may quickly rise to infective levels. The goals of wound cleaning and débridement are as follows: (1) to remove bacteria and reduce their numbers below the level associated with infection, and (2) to remove particulate matter and tissue debris that would lengthen the inflammatory stage of healing or allow the growth of bacteria beyond the critical threshold.

There are two general wound-cleansing techniques: scrubbing and irrigation. Irrigation, which is recommended for most wounds, involves a steady flow of solution across the surface of the wound. This important step in wound management provides hydration to the wound, removes deeper debris, aids in visual examination, and also reduces the risk for infection. Normal saline or tap water is often used as an adequate irrigation fluid.

Soaking a wound in a saline or antiseptic solution before the clinician arrives is a common outdated practice that is of no proven value and may actually increase bacterial count; hence, it is not recommended.²⁵

Patient Preparation

Before examining, cleaning, exploring, or repairing a wound, allay the patient's fears and encourage cooperation by explaining

Figure 34.4 The ideal setup for evaluation and repair of a laceration is a supine patient, a seated clinician at the correct height for the procedure, and a bloodless field with good lighting.

the procedure and assuring the patient that everything possible will be done to minimize pain. In general, all wound care should be performed with the patient in a supine position because fainting is a common occurrence during wound preparation and repair (Fig. 34.4). Relatives and friends can be allowed to stay with the patient, but they should be cautioned to report any dizziness or nausea, and they should remain seated throughout the procedure.

Anyone cleaning, irrigating, or suturing wounds should wear protective eyewear and gloves because virtually any patient may be seropositive for human immunodeficiency virus (HIV). Although mucosal exposure to blood or tissue products that are contaminated by HIV is considered a relatively low risk for subsequent infection, universal precautions are currently recommended, and a mask should be considered. Minimal aseptic technique requires the use of gloves during the cleaning procedure.

Thorough cleansing of bacteria, soil, and other contaminants from a wound cannot be accomplished without the patient's cooperation. Scrubbing most open wounds is painful, and the patient's natural response is to withdraw the injured area away from the provider. Local or regional anesthesia should precede examination and cleansing of a wound (Video 34.2). Despite adequate anesthesia, the patient may be too apprehensive to cooperate. If reassurance does not alleviate the fears of young children, consider both sedation and physical restraining devices.

Mechanical Scrubbing

Scrubbing the internal surface of a wound is controversial. Although scrubbing a wound with an antiseptic-soaked sponge decreases the risk of infection by removing foreign particulates, bacteria, and tissue debris,²⁶ an abrasive sponge may inflict more damage on the tissue.¹⁸ As the amount of damage caused by scrubbing correlates with the porosity of the sponge, a fine-pore sponge (e.g., 90 pores/inch) should be used to minimize tissue abrasion. Mechanical scrubbing should be reserved for wounds contaminated with significant amounts of bacteria or foreign material (Fig. 34.5A and B), or should be considered if irrigation alone is ineffective in removing visible contaminants from a wound.

Wound Cleansing: Mechanical Scrubbing and Irrigation

A Grossly contaminated wounds such as this need to be thoroughly cleansed prior to repair, by mechanical scrubbing and/or irrigation.

B Reserve mechanical scrubbing for wounds contaminated with significant amounts of bacteria or foreign material. Use a fine-pore sponge (e.g., 90 pores/inch) to minimize tissue abrasion.

C *Top*, ZeroWet splash shield attached to the end of a syringe. The shield is held near or against the skin and protects the user from splashes from the high-pressure laminar flow nozzle. *Bottom*, a makeshift splash protector can be made from a medication cup.

D Use of the ZeroWet device. Note that the clinician is holding the laceration open with forceps to allow irrigation of the deep structures.

E Tap water and nonsterile gloves are commonly used to copiously irrigate wounds of the extremities by taking advantage of the volume and force parameters from the faucet. Anesthetize lacerations before cleaning. Be mindful of the potential for the patient to faint.

F For foot wounds, the patient is placed on a stretcher and wheeled to the sink.

Figure 34.5 Wound cleansing: mechanical scrubbing and irrigation. Wound irrigation with tap water is acceptable.

Initially scrub a wide area of skin surface surrounding the wound with an antiseptic solution to remove contaminants that might be transferred into the wound by instruments, suture material, dressings, or the clinician's gloved hand during wound management. It is important to remove all nonabsorbable particulate matter; any such material left in the dermis may be retained in the healed tissue and result in a disfiguring "tattoo" effect.⁷ Detergents have an advantage over saline in that they minimize friction between the sponge and tissue, thereby limiting damage to tissue during scrubbing. Detergents also dissolve particles and thus help dislodge them from the surface of the wound. Unfortunately, many of the detergents available are toxic to tissues.^{11,27} Use caution when considering detergents.

Antiseptics During Cleaning

For many years, antiseptic solutions have been used for their antimicrobial properties in and around wounds (Table 34.1). Studies on the use of antiseptics in wounds demonstrate that there is a delicate balance between killing bacteria and injuring tissue.^{27,28} Intact skin can withstand strong microbicidal agents, whereas leukocytes and the exposed cells of skin and soft tissue can be damaged by these agents.

Povidone-iodine (Betadine [Purdue Products L.P., Stamford, CT]) is widely available as a 10% stock solution. Although the undiluted solution may be used to prepare the skin surrounding a wound, it may be harmful to some tissue; therefore it should not be placed within the interior of the wound. Diluted povidone-iodine solution in concentrations of less than 1% appears to be safe and effective for cleaning contaminated traumatic wounds,²⁶ but the precise concentration that provides

the most benefit is unclear. Even dilute povidone-iodine may be particularly irritating when used for scrubbing contaminated wounds. In contrast, povidone-iodine surgical scrub (Betadine scrub, 7.5% iodine) and hexachlorophene (pHisoHex [sanofi-aventis U.S. LLC, Bridgewater, NJ]) both contain anionic detergents that are harmful to tissues. In vitro studies have demonstrated that chlorhexidine gluconate-alcohol (Hibiclens [Mölnlycke Health Care US, LLC, Norcross, GA]) is toxic to both fibroblasts and keratinocytes.²⁷ When diluted to decrease its cytotoxic effect on these cells, it is no longer able to sufficiently kill *Staphylococcus aureus*.²⁸ Its effect on the actual wound infection rate is unknown. Hydrogen peroxide is hemolytic, and there is little reason to use it except to clean surrounding skin encrusted with blood and coagulum, or to soak off adherent blood-saturated dressings. Peroxide should not be used on granulation tissue because oxygen bubbles lift newly formed epithelium off the wound surface.²⁹

Nonantiseptic, nonionic surfactants are attractive alternatives to these toxic cleansing agents. In contrast to antiseptic solutions, these preparations cause no tissue or cellular damage, leukocyte inhibition, or impairment of wound healing. The solutions cause no corneal injury, have low risk of conjunctival irritation, and do not cause pain on contact with the wound.³⁰ Poloxamer 188 (Shur-Clens [ConvaTec, Greensboro, NC] or Pluronic F-68 [Thermo Fisher Scientific, Grand Island, NY]), a group of pluronic polyols, is nontoxic but has no antibacterial activity. Scrubbing experimental wounds with Shur-Clens reduced infection rates (though not statistically better than normal saline or povidone-iodine), thus proving it has the ability to cleanse a wound effectively and atraumatically.^{26,27} Pluronic polyols may be a good choice if the wound is near mucous membranes. The use of antiseptic preparations in

TABLE 34.1 Summary of Agents Used for Wound Care

AGENT	BIOLOGIC ACTIVITY	TISSUE TOXICITY ^a	SYSTEMIC TOXICITY ^a	POTENTIAL USES	COMMENTS
Povidone-iodine surgical scrub (Betadine 7.5%)	Virucidal; strongly bactericidal	Detergent component toxic to wound tissue	Painful in open wounds	Hand cleanser	Iodine allergy possible
Povidone-iodine solution (Betadine 10%)	Virucidal; bactericidal	Potentially toxic at full strength; 1% solution has no significant tissue toxicity	Extremely rare	Wound periphery cleanser; dilute to <1% for wound irrigation	Dilute 10:1 (saline to Betadine) if used to irrigate wounds
Chlorhexidine gluconate (Hibiclens)	Bactericidal	Toxic to tissues, including eyes	Extremely rare	Hand cleanser	Avoid in open wounds, eyes, or ears
Poloxamer 188 (Shur-Clens); Pluronic F-68	No antibacterial or antiviral activity	None known; does not inhibit wound healing	None known	Wound cleanser	Nontoxic in wounds and eyes
Hexachlorophene (pHisoHex)	Bacteriostatic against gram-positive bacteria	Potentially toxic to wound tissue	Possibly teratogenic with repeated use	Alternative hand cleanser	Systemic absorption causes neurotoxicity
Hydrogen peroxide	Very weak antibacterial agent	Toxic to tissue and red cells	Extremely rare	Wound periphery cleanser	Foaming activity removes surface debris and coagulated blood

^aBased largely on in vitro studies and animal data.

wounds can be considered in high risk, contaminated wounds where the benefits outweigh the risks.

Irrigation

It is important to distinguish between skin antiseptics and irrigating solutions. As a general rule, commercially available antiseptics should be used only to clean intact skin and not exposed wound surfaces. Most open wounds can be irrigated effectively with copious amounts of saline or tap water.^{26,31} Concerns about introducing infection by the use of common tap water are unfounded.

▶ Properly performed irrigation (Video 34.3) is effective in removing particulate matter, bacteria, and devitalized tissue that is loosely adherent to the edges of the wound and trapped within its depths. The effectiveness of irrigation is primarily determined by the hydraulic pressure at which the irrigation fluid is delivered.^{31,32} Low-pressure irrigation is defined as 1 to 2 psi, whereas high-pressure irrigation is greater than 8 psi. Port devices spiked into plastic intravenous bags that are squeezed by hand to deliver a stream of fluid, bulb syringes, or gravity flow irrigation devices all deliver fluid at very low pressures.³²⁻³⁴ Although irrigation at either low or high pressures will reduce levels of *Staphylococcus aureus*, higher pressures should be more effective at ridding wounds of small particulate matter.³⁴ There appears to be no significant differences between tap water and saline delivered at high pressures.³¹ Although irrigation may not be required for low-risk, highly vascular, uncontaminated facial and scalp wounds,³⁵ randomized, prospective trials are needed to answer this question.

Wound irrigation is best achieved with a large-volume syringe, 35 mL or 65 mL, and an 18- or 19-gauge catheter or needle to deliver irrigation volumes of at least 250 mL. The pressure that can be delivered with a syringe varies with the force exerted on the plunger and the internal diameter of the attached needle. A simple irrigation assembly consisting of a 19-gauge plastic catheter or needle attached to a 35-mL syringe produces 25 to 40 psi when the barrel of the syringe is pushed with both hands.³² High-pressure irrigation can also be achieved through IV tubing by placing a pressure cuff around a saline bag and inflating it to 400 mm Hg.¹² A standard running faucet can also generate approximately 45 psi. Irrigating extremity lacerations by holding them under a faucet of tap water is a common and accepted practice for wound preparations, and fears of introducing infection with a nonsterile irrigant are unfounded. (Note: One must anticipate potential fainting if a patient stands near a sink for faucet water irrigation.) These high-pressure irrigation systems remove significant numbers of bacteria and a substantial amount of particulate matter from the wound surface. Care must be taken to ensure that any method of irrigation is not exerting too much pressure because tissue damage can occur at pressures of 70 psi.³¹ Irrigation should continue until all visible, loose particulate matter has been removed. Warmed irrigating solutions are more comfortable for patients, even after the wound is anesthetized.³⁶

A potential complication of wound irrigation is that infectious material can be splashed into the face of the clinician, even when the tip of the irrigation device is held below the surface of the wound. Several commercial devices are available to contain the splatter, including devices that fit on the end of a syringe (see Fig. 34.5C and D) and devices that fit on the screw top of saline bottles (for this particular device the company reported variable pressure from 4 to 15 psi). An alternative

strategy is to pierce the base of a small medicine cup with a shorter, large-bore needle. The cup can be placed upside down to cover the area to be irrigated and the syringe with the 19-gauge needle can be inserted through the base of the cup (see Fig. 34.5C). The wound should be positioned to allow continuous drainage of fluid during irrigation by any method.

Antibiotic Solutions for Irrigation

A variety of antibiotic solutions have been instilled directly into wounds or used as irrigation solutions, including ampicillin, a neomycin-bacitracin-polymyxin combination, tetracycline, penicillin, kanamycin, and cephalothin. Although there have been no reports of topical sensitization or toxic tissue levels of the antibiotic, studies have found inconsistent effectiveness in reducing infection rates.³⁷ The indications for using antibiotic solutions to clean wounds have not been defined, and this practice is not considered standard.

Recommendations for Cleaning the Wound

The prerequisites for any wound-cleaning technique are a calm or sedated patient, satisfactory anesthesia, and thorough cleaning of the skin surface adjacent to the wound. The primary goal of wound cleaning is to rid the wound of major contaminants and lower the infective dose of bacteria (Video 34.4). Two strategies are recommended. A contaminated or “dirty” wound can be irrigated, or both scrubbed and irrigated, with a 0.9% saline solution. As an alternative, the wound can be scrubbed with pluronic polyols and irrigated with a normal saline solution. Only pluronic polyols or saline should be used near the eyes. Perform scrubbing with a soft, fine-pore sponge, and use high-pressure techniques for irrigation. Avoid using hydrogen peroxide on open wounds. Either gentle scrubbing with pluronic polyols and normal saline high-pressure irrigation or irrigation alone appears to be a satisfactory method for cleaning minimally contaminated wounds.²⁶

A sterile bottle of saline solution can be used to irrigate a wound, but once the bottle is opened, bacterial contamination occurs quite rapidly³⁸ and it should be discarded after use. Patients frequently irrigate their wounds with tap water before going to the ED. Many clinicians routinely irrigate wounds, especially extremity wounds, with tap water instead of sterile saline, and infection rates have been found to be comparable to that of saline irrigation^{31,39-41} (see Fig. 34.5E and F). The advantage of using tap water from a faucet is that large volumes of irrigant can be quickly applied to an open wound at the high pressures required to remove debris and bacteria. The disadvantages of this technique are that irrigation pressures are difficult to control, and the patient may faint if allowed to stand at a sink. If tap water is used to irrigate wounds, it may also be safely delivered through a syringe at the bedside.

Preparation for Wound Closure

Before débridement or wound closure, prepare and drape the wound. Avoid shaving body hair because preoperative wounds that were shaved demonstrated higher infection rates.^{17,18,42} For wounds in hair-bearing areas, hair can be removed by clipping if it interferes with the procedure. Stubborn hairs that repeatedly invade the wound during suturing can be coated with petrolatum jelly or a water-soluble ointment to keep them out of the field. Do not shave eyebrows because critical landmarks for exact approximation of the wound edges would

be lost. Although shaved eyebrows will grow back eventually, shaving also produces an undesirable cosmetic effect. Clip hair rather than shaving it.

Disinfect the skin surface adjacent to the wound (not the wound itself) with a standard 10% povidone-iodine or chlorhexidine gluconate (Hibiclens) solution. Paint the solution widely on the skin surrounding the wound, but do not allow it to seep into the interior of the wound itself (Fig. 34.6A).

After hand washing, the clinician and any assistants involved in the procedure must wear sterile or nonsterile but clean gloves.⁴³ Sterile gloves are not required, and their use does not decrease infection rates. However, sterile gloves fit better on hands and result in better control of instruments and sutures.¹² Wear face masks, especially if you have an upper respiratory bacterial infection. Because droplets of saliva may leak even from around the edges of a face mask, avoid talking

Wound Preparation and Exploration

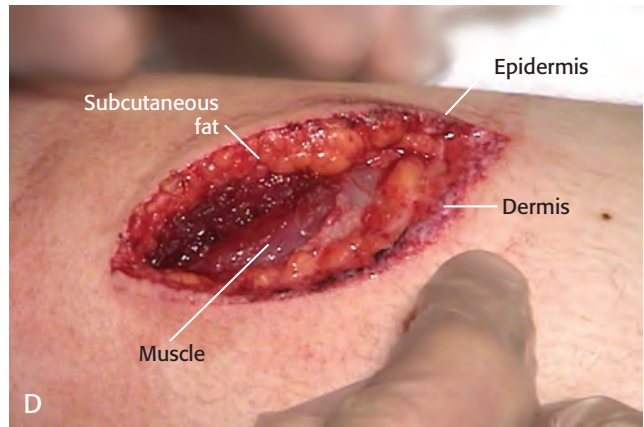

A Disinfect the skin surface adjacent to the wound with 10% povidone-iodine or chlorhexidine gluconate, but do not allow it to seep into the wound.

B A nonsterile clean glove on the hand with the finger cut out and a finger tourniquet to provide a bloodless field make examination and suturing of a wound easier.

C Explore the depths of the wound and examine for injured structures, foreign bodies, and the extent of injury.

D Anatomy of a deep laceration.

1, This patient punched out a window, a setup for retained glass. **2**, Do *not* explore this laceration with a finger. **3**, Instead, use radiographs and instruments to search for foreign bodies (the arrow defines a large piece of glass that could cut the examining finger). Many patients are unaware of the presence of large foreign bodies in a deep wound, although they should be questioned about the possibility or sensation of retained material.

Figure 34.6 Wound preparation and exploration.

in proximity to the wound.⁴⁴ Use a single fenestrated drape or multiple folded drapes around the wound site. Place a sterile glove on a patient who has a hand wound to provide a sterile field in lieu of a fenestrated drape. The area to be sutured can then be exposed by cutting the glove, and the extremity can be placed on a sterile towel (see Fig. 34.6B). This technique provides a clean field without the need to continually adjust the drape or to operate through a small opening.

Explore the entire depth and the full extent of every wound to locate hidden foreign bodies, particulate matter, bone fragments, or any injuries to underlying structures that may require repair (see Fig. 34.6C and D). Avoid the common temptation to initially explore wounds and assess their characteristics with a finger in search of a foreign body (see Fig. 34.6E) because embedded glass, metal fragments, or sharp pieces of bone may cut the clinician and cause exposure to blood-borne infections. Visualize directly with good lighting in a bloodless field, explore the wound with a metal probe, and use radiographs as safer approaches to wound exploration. Despite these measures, lacerations through thick subcutaneous adipose tissue are treacherous because large amounts of particulate matter can be completely obscured in deep folds of soft tissue. Unless a careful search is undertaken, contaminants may be inadvertently left in the depths of a sutured wound, resulting in infection. Some clinicians are reluctant to extend lacerations to properly clean or explore them; however, opening the wound to permit adequate visualization is often necessary for successful wound exploration.

Débridement

Débridement of foreign material and devitalized tissue is of undisputed importance in the management of a contaminated wound. Use this technique to remove tissue embedded with foreign matter or bacteria. Devitalized tissue impairs the ability of the wound to resist infection and also prolongs the period of inflammation. Débridement also creates a tidy, sharp wound edge that is easier to repair and results in a more cosmetically acceptable scar.

If the wound is already clean and the edges are viable, sharp débridement may not improve the outcome. Irregular wounds have greater surface areas than linear lacerations. Because skin tension is distributed over a greater length, the width of the scar is usually less with jagged wounds than if the wound is converted to an elliptical defect with tidy edges. If the edges are devitalized or contaminated though, the wound edges must be débrided (Fig. 34.7A and B). To avoid a wide scar in this situation, undermine the wound, and consider judicious removal of soft tissue within the wound to decrease the tension between the wound edges.

Excision

Excision is the most effective type of débridement because it converts a contaminated traumatic wound into a clean wound. If significant contamination occurs in areas in which there is laxity of tissues, and if no important structures such as tendons or nerves lie within the wound, the entire wound may be excised (see Fig. 34.7C). Complete excision of grossly contaminated wounds such as animal bites allows the primary closure of such wounds with no greater risk of infection than occurs with relatively uncontaminated lacerations.¹⁸

When a puncture wound is excised, make the axis of the excision parallel to a wrinkle, a skin line, or a line of dependency. Make the long axis of this lenticular excision three to four

times as great as the short axis (see Fig. 34.7D). Premark the skin with a surgical marking pen or by making a superficial “scoring” mark (cutting only down to the epidermis) around the wound with a No. 15 scalpel blade. Place tension on the surrounding skin with a finger or a skin hook. While steadying your hand on the table or on the patient, use the No. 15 blade and cut through the skin at right angles or at slightly oblique angles to the surface of the skin. If complete excision of the entire depth of the wound is not necessary, use tissue scissors to cut the edge of the wound by following the path premarked in the epidermis with the scalpel blade. If complete excision is desired, incise each wound edge past the deepest part of the wound. Excise and remove the wedge of tissue carefully without contaminating the fresh wound surface.

Plan the excision carefully because excessive removal of tissue can create a defect that is too large to close. Wounds on the trunk, the gluteal region, or the thigh are amenable to excision. In contrast, simple excision of a wound on the palm or the dorsum of the nose will make approximation of the resulting surgical wound edges difficult. In hair-bearing areas of the face, particularly through the eyebrows, angle the incision parallel to the angle of the hair follicles to avoid linear alopecia (see Fig. 34.7E).

Selective Débridement

Complete excision is impossible for most wounds because of insufficient skin elasticity and area, so selective débridement must be used. Stellate wounds and wounds with an irregular, meandering course have greater surface area and less skin tension per unit length than do linear lacerations. In some cases, excision of an entire wound would result in the loss of too much tissue (i.e., produce a gaping defect and excessive tension on the edges of the wound when closed). Avoid this problem by selective débridement and approximation of the irregular wound edges. This technique involves sharp débridement of devitalized or heavily contaminated tissue in the wound piece-by-piece and eventual matching of one edge of the wound to the other. Selective débridement is time-consuming but preserves more of the surrounding viable tissue.

Identifying devitalized tissue in a wound remains a challenging problem. Tissue with a narrow pedicle or base, especially distally based narrow flaps on extremities, is unlikely to survive and should be excised. Approximately 24 hours after the wound occurs, a sharp line of demarcation often occurs and can help distinguish devitalized skin and viable skin,¹⁸ but in most fresh wounds, usually only a subtle bluish or blanched discoloration is present. Try to predict tissue viability by comparing the capillary refill of injured tissue with that of the adjacent skin. If circulation is adequate, viable tissue also becomes hyperemic soon after the release of a proximal tourniquet.

In heavily contaminated wounds, especially those with abundant adipose tissue, remove all exposed fat and all fat impregnated with particulate matter. The subcutaneous adipose tissue attached to large flaps or to avulsed viable skin should be débrided before reapproximation of the wound; removal of this fatty layer allows better perfusion of the flap or the graft. Contaminated bone fragments, nerves, and tendons are almost never removed. Every effort should be made to clean these structures and return them to their place of origin because they may be functional later. Fascia and tendons perform important functions despite potential loss of viability. If they can be cleaned adequately, these tissues should not be débrided.

Wound Débridement

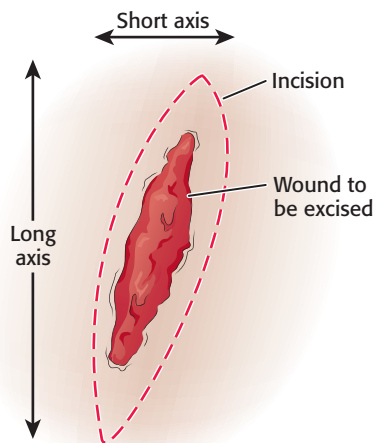

A Sharp débridement is the best way to remove devitalized tissue and create a more cosmetic result. Here, the wound edges are trimmed with iris scissors.

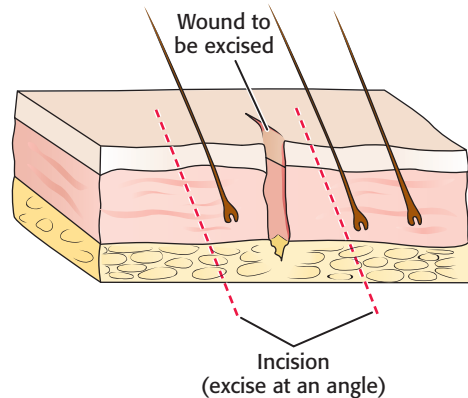

B A scalpel can also be used. Alternatively, the skin is first sharply incised with a scalpel for a clean edge, and then the rest of the subcutaneous tissue is removed with scissors.

C Excision is the most effective type of débridement because it converts a contaminated wound into a clean one. The entire wound may be excised if no important structures (such as tendons or nerves) are present. Grossly contaminated wounds may be excised and sutured primarily.

D The long axis of an excision around a wound should be three to four times as great as the short axis.

E Excision through an eyebrow. Use an angled incision to remove tissue in the eyebrow, thus avoiding further injury to hair follicles.

Figure 34.7 Wound débridement.

They may be left in wounds as free grafts and be covered by viable flaps of tissue.¹⁸

Instruments generally required for débridement include two fine single- or double-pronged skin hooks, a scalpel with a No. 15 blade, tissue scissors, hemostats, and a small tissue forceps. Using gentle tissue pressure, stabilize the jagged wound edges with skin hooks or forceps, and use the scalpel or scissors to cut away devitalized tissue from one end of the wound to

the other. After débridement or excision, irrigate the wound again to remove any remaining tissue debris.

Control of Hemorrhage

Hemostasis is essential at any stage of wound care. Persistent bleeding obscures the wound and hampers exploration and closure of the wound. If bleeding is not a problem before wound débridement, it may become a complication during

cleaning or after the edges of the wound are excised. If it is significant, hematoma formation in a sutured wound can separate the wound edges, impair healing, and cause dehiscence or infection.

Several practical methods of achieving hemostasis are available. Provide direct pressure with gloved fingers, gauze sponges, or packing material, and elevate the wound. This technique is usually effective in immediately controlling a single bleeding site or a small number of sites until the cut ends of vessels constrict and coagulation occurs. In a patient with multiple injuries and several urgent problems, control hemorrhage temporarily with a compression dressing. Apply several absorptive sponges directly over the bleeding site and secure them in place with an elastic bandage (e.g., Ace wrap) or elastic adhesive tape (Elastoplast). Then apply pressure with the elasticity of the bandage and elevate the bleeding part. Wound care can then be deferred while the clinician attends to more pressing matters.

Although simply crushing and twisting the end of a small vessel with a hemostat avoids dissection further into the wound, this method provides unreliable hemostasis. Ligation of the vessel with fine absorbable suture material is preferred. Clamp the bleeding ends of vessels with fine-point hemostats to provide immediate hemostasis. Because nerves often course with these vessels, clamp them only under direct visualization. The tip of the hemostat should project beyond the vessel to hold a loop of a ligature in place (Fig. 34.8A). With an assistant lifting the handle of the hemostat, pass a synthetic 5-0 or 6-0 *absorbable suture* around the hemostat from one hand to the other. Tie the first knot beyond the tip of the hemostat. Once the suture is securely anchored on the vessel, release the hemostat.⁴⁵ Three knots are sufficient to hold the ligature in place. Cut the ends of the suture close to the knot to minimize the amount of suture material left in the wound.

Ligate vessels with diameters greater than 2 mm. Vessels smaller than 2 mm that bleed despite direct pressure can be controlled by pinpoint, bipolar electrocautery. A dry field is required for an effective electrical current to pass through the tissues. If sponging does not dry the field, use a suction-tipped catheter. Minimize trauma by using fine-tipped electrodes to touch the vessel, or touch the active electrode of the electrocautery unit to a small hemostat or fine-tipped forceps while gripping the vessel. Keep the power of the unit to the minimum level required for thrombosis of the vessel. Self-contained, sterilizable, battery-powered coagulation units are alternatives to electrocautery. These devices cauterize vessels by the direct application of a heated wire filament. Although these units may damage more surrounding tissue than electrocautery units do, they are compact, simple, and well suited for use in the ED (see Fig. 34.8B).

A cut vessel that retracts into the wall of the wound may frustrate attempts at clamping, ligation, or cauterization. First, control bleeding by downward compression on the tissue. Pass a suture through the tissue twice via a figure-of-eight or horizontal mattress stitch, and then tie it. This stitch will constrict the tissue containing the cut vessel (see Fig. 34.8C).

Large superficial varicosities may bleed spontaneously or from minor trauma. They may bleed profusely, especially when the patient stands up and increases venous pressure. Use a simple figure-of-eight suture to halt the bleeding (see Fig. 34.8D).

Epinephrine is an excellent vasoconstrictor. Place topical epinephrine (1:100,000) on a moistened sponge and apply it

to a wound to reduce the bleeding from small vessels. When combined with local anesthetics, such as lidocaine with epinephrine, concentrations of 1:100,000 and 1:200,000 prolong the effect of the anesthetic and provide some hemostasis in highly vascular areas. Use vasoconstrictors only in situations in which widespread small-vessel and capillary hemorrhage in a wound cannot be controlled by direct pressure or cauterization. Hemostasis of a specific vessel may be achieved by directly injecting the soft tissues around the base of the bleeder with a small amount of lidocaine with epinephrine solution, even though the wound has previously been anesthetized. The combination of pressure and vasoconstriction may halt the bleeding long enough for the vessel to be ligated or cauterized, or to allow the wound to be closed and a compression dressing applied.

Fibrin foam, gelatin foam, and microcrystalline collagen may be used as hemostatic agents. Their utility is limited in that vigorous bleeding will wash the agent away from the bleeding site. Their greatest value may be in packing small cavities from which there is constant oozing of blood. Another novel hemostasis technique uses 2-octyl-cyanoacrylate (Dermabond [Ethicon, Cincinnati, OH]) to achieve hemostasis of skin avulsions on the fingertips, which are known to bleed aggressively. A tourniquet should first be used to minimize bleeding, and moisture should be dabbed away from the wound. Then the Dermabond can be layered on at least twice. This method is an off-label, anecdotal use of this product, and the consequence of exposing dermal skin layers directly to it have not been evaluated to date.⁴⁶

Do not spend excessive time attempting to tie off several small bleeding vessels while the patient slowly exsanguinates (Fig. 34.9). In highly vascular areas such as the scalp, it is sometimes best to suture the laceration after exploration and irrigation of the wound despite active bleeding; the pressure exerted by the closure will usually stop the bleeding. If bleeding is too brisk to permit adequate wound evaluation and irrigation, control hemorrhage by clamping and everting the galea or dermis of each wound edge with hemostats (Fig. 34.10A and B). Raney clamps or a large hemostat is an excellent way to stop scalp bleeding; they are used during neurosurgical procedures (see Fig. 34.10C). If the edge of the entire scalp is compressed the bleeding will generally stop. In the majority of simple wounds with persistent but minor capillary bleeding apposition of the wound edges with sutures, followed by a compression dressing, provides adequate hemostasis.

Tourniquets

If bleeding from an extremity wound is refractory to direct pressure, electrocauterization, or ligation, or if the patient has exsanguinating hemorrhage from the wound, place a tourniquet proximal to the wound to control the bleeding temporarily. Tourniquets are also helpful in examining extremity lacerations by providing a bloodless field. However, tourniquets can cause injury in three ways:

1. They can produce ischemia in an extremity.
2. They can compress and damage underlying blood vessels and nerves.
3. They can jeopardize the survival of marginally viable tissue. Although problems rarely develop from the use of tourniquets in routine wound care, potential problems can be minimized if (1) a limit is placed on the total amount of time that a tourniquet is applied, and (2) excessive tourniquet pressure is avoided. It is also imperative that all tourniquets be removed

Hemorrhage Control

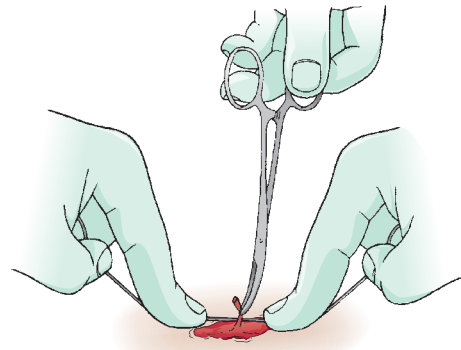

1

A

When tying off a bleeding vessel, the tip of the hemostat should project beyond the clamped vessel. An assistant raises the handles of the hemostat as a ligature is passed under them.

2

Stretch the ligature thread between the index fingertips and carry it under the projecting tips of the hemostat.

B

Battery-powered cautery can be used to coagulate minor subcutaneous bleeders.

1

2

C

Ligation of a retracted, bleeding vessel. 1, Horizontal mattress technique. 2, Figure-of-eight technique.

D

This elderly patient experienced massive spontaneous bleeding from a ruptured varicose vein. Blood loss was substantial and recurrent when she walked.

2

After cautery, a figure-of-eight suture was placed. Simple cautery without suturing is not always effective. A pressure dressing is applied after hemostasis is verified by walking.

Figure 34.8 Hemorrhage control.

Figure 34.9 Scalp lacerations can bleed profusely. This patient's pressure dressing fell off while he was on a stretcher in the back hall, and he experienced significant blood loss from a large scalp laceration. His intoxication prevented him from supplying his history of hemophilia.

before releasing the patient. A small tourniquet may be overlooked if it is covered by a bulky dressing.

A single-cuff tourniquet (sphygmomanometer cuff) placed around an arm or a leg stops most distal venous or arterial bleeding without crushing any underlying structures. The length of time that a tourniquet may remain in place is limited by the development of pain underneath and distal to the tourniquet. This occurs within 15 to 30 minutes in a conscious patient, which is well within the limits of safety.¹⁶

Before application of the tourniquet, elevate the injured extremity and manually exsanguinate it to prevent persistent venous oozing (Fig. 34.11A). Wrap an elastic bandage (e.g., Ace wrap or Esmarch) circumferentially around the extremity, starting distally and moving in a proximal direction. Place a cuff that is 20% wider than the diameter of the limb around the arm proximal to the wound, inflate it to 250 to 300 mmHg or 70 mm Hg higher than the patient's systolic blood pressure, and then clamp the tubing. Remove the bandage and lower the extremity. Because tourniquets impair the circulation and may produce neurapraxia, limit their use in the ED to a maximum of 2 hours.^{12,18}

Tourniquets on digits have a greater potential for complications. The maximum tourniquet time that is safe for a finger is 30 to 45 minutes,¹² thus it may easily be exceeded. In addition, finger tourniquets can exert excessive pressure over a small surface area at the base of the finger and injure digital nerves or cause pressure necrosis of digital vessels. For this reason, standard rubber bands should not be used as tourniquets. Instead, place a 0.5-inch Penrose drain around the base of the finger and stretch it to no more than two thirds of its circumference (see Fig. 34.11B). This will provide safe and effective hemostasis. The pressure under a Penrose drain ranges between 100 and 650 mm Hg, but it can easily be controlled.⁴⁷ A few millimeters of difference in total stretch makes a large difference

in the pressure applied by this type of tourniquet.⁴⁸ In digits, tourniquet pressures of only 150 mm Hg are needed for hemostasis.

A surgical glove placed over a patient's cleaned hand can also serve as a finger tourniquet (see Fig. 34.11C). Remove the tip of the glove covering the injured digit, and then roll it proximally along the patient's finger to form a constricting band at the base. Another advantage of this technique is that contamination of the wound during closure is less likely. Rolled surgical gloves produce pressures ranging from 113 to 363 mmHg, depending on the thickness, the amount of glove finger removed, the number of rolls, and the size of the glove in relation to the size of the patient's hand.⁴⁸ Ring-shaped exsanguinating digit tourniquets are available commercially (Tourni-Cot [Mar-Med Company, Grand Rapids, MI]) (see Fig. 34.11D). There is a real danger of forgetting to remove such a small tourniquet and accidentally incorporating it into the dressing.

These techniques provide bloodless fields in which to examine, clean, and close extremity wounds. Débridement of questionably devitalized tissue in a wound is best accomplished without a tourniquet or pharmacologic vasoconstriction because bleeding from tissues is often an indication of their viability.

CLOSURE

The various techniques for wound closure are presented in Chapter 35. The remainder of this chapter addresses issues related to wound management (e.g., secondary closure, wound dressings, use of antibiotics, aftercare instructions, and suture removal).

Open Versus Closed Wound Management

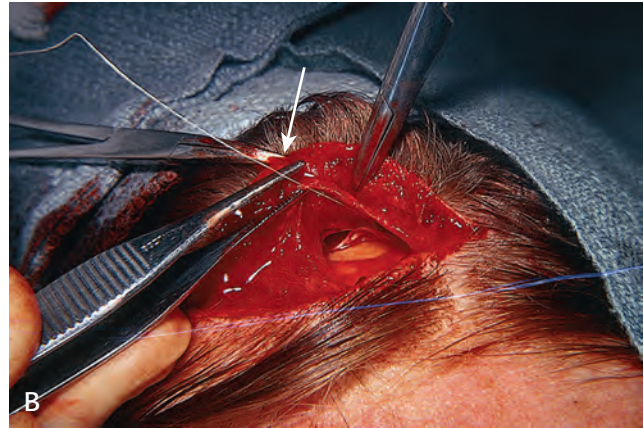

Wounds that heal spontaneously (i.e., by secondary intention) undergo much more inflammation, fibroplasia, and contraction than do those whose edges are reapproximated by wound closure techniques.⁷ During wound healing contraction covers the defect, but it may result in a deformity (contracture) or loss of function. Left to itself, the healing process may be unable to close a defect completely in areas in which the surrounding skin is immobile, such as on the scalp or in the pretibial area (Fig. 34.12). Exposed tendons, bone, nerves, or vessels may desiccate in an open wound. If the patient is careless with an otherwise adequate dressing that covers an open wound, the wound may be further contaminated. Surgical closure of wounds minimizes inflammation, fibroplasia, contracture, scar width, and contamination.

However, surgical closure of wounds can cause complications. Closure of contaminated wounds increases the probability of wound infection, with possible complications of impaired healing, dehiscence, and sepsis. For instance, raised pretibial flap lacerations in elderly patients often necrose when sutured, but survive and heal well by secondary intention if placed back into position with tape or tissue glue. Sutures in themselves are potentially detrimental to healing and can increase the risk for infection. Each suture inflicts a small intradermal incision that damages the surface epithelium, dermis, subcutaneous fat, blood vessels, small nerves, lymphatics, and epithelial appendages such as hair follicles, sweat glands, and ducts. Once divided and separated by a stitch, these appendages usually undergo inflammation and resorption.⁴⁹ Each suture is another piece

Hemorrhage Control of Scalp Lacerations

Scalp lacerations may bleed profusely, and arterial vessels may not retract if they are in tough fibrous tissue. This forceps was used to crush a small pumping artery. Placing large (3-0 nylon) sutures that incorporate all scalp layers, defined as all tissue between the thumb and index finger (arrows), is preferred to attempting to cauterize or ligate small bleeders.

A hemostat placed on the scalp edge can similarly be used on a single bleeder.

Note that the suture will incorporate all layers of the scalp. Both the galea and the periosteum are identified along with exposed skull (x). The periosteum is not sutured.

1 Load the Raney clip onto the applicator.

2 Lock the handles of the applicator to open the clip.

3 Slide the clip onto the wound edge.

4 Release the clip by unlocking the applicator.

Figure 34.10 Hemorrhage control of scalp lacerations. Note that the periosteum is often misidentified as the galea. The galea is adherent to the subcutaneous tissues, not covering the bone. (C, From Custalow CB: *Color Atlas of Emergency Department Procedures*, Philadelphia, 2005, Saunders, pp 136–137.)

Hemorrhage Control: Tourniquets

The cuff is not inflated until the extremity is exsanguinated

A

Before inflating a tourniquet such as a blood pressure cuff, wrap an elastic bandage (e.g., Ace wrap or Esmarch) around the extremity in a distal-to-proximal fashion. Inflate the cuff to 250 to 300 mm Hg or 70 mm Hg higher than systolic pressure. (The above photo is only a demonstration; gloves should obviously be worn in the case of a bleeding patient.)

Use of a sterile glove to provide a clean field and serve as a finger tourniquet. The distal end of the glove is clipped, and the glove finger is rolled proximally over the digit. A Penrose drain is also incorporated into this tourniquet.

Use of a Penrose drain placed over padding for a finger tourniquet. Do not stretch the drain to more than two thirds of its circumference. This will provide safe and effective hemostasis.

Commercial tourniquet for finger lacerations (Tournicot Mar Med Company). Various sizes are available. The accompanying warning tag has been left exposed to remind the operator of the tourniquet device. Note how the tendon injury can be seen once a bloodless field is obtained.

Figure 34.11 Hemorrhage control: use of tourniquets.

of foreign material that can provoke inflammation.⁷ When a suture is removed, bacteria that have settled on the exposed portion of the suture are pulled into the suture track and deposited there.⁴⁹

Therefore the clinician must estimate the risk for infection prior to closure. If the wound is judged to be clean or is rendered clean by scrubbing, irrigation, and débridement, it may be closed. If the wound remains contaminated despite the best of efforts, it must be left open to heal by secondary intention. If the status of the wound is uncertain, delayed primary closure is an option that should be considered.

Delayed Primary or Secondary Closure

There is a common misconception that all wounds must be either sutured within a few hours or left open and relegated

to slow healing and an unsightly scar. If there is a substantial risk that closure of a particular wound might result in infection, the decision to close or to leave the wound open can be postponed. After cleaning, wounds left unsutured appear to have higher resistance to infection than do closed wounds. The condition of the wound after 3 to 5 days will then determine the best strategy (Fig. 34.13).

Although cleaning and débridement should be accomplished as rapidly as possible, there is no urgency in closing a wound. Edlich and associates¹⁸ pointed out that “the rationale for delayed primary closure is that the healing open wound will gain resistance to infection and permit an uncomplicated closure.” Despite its effectiveness, delayed primary closure is a technique that remains largely unappreciated and probably underused by many clinicians (Fig. 34.14). It is a highly effective means of managing wounds that have a sufficient risk for

Figure 34.12 In areas in which the skin is immobile, as in the scalp, wounds left open may not heal.

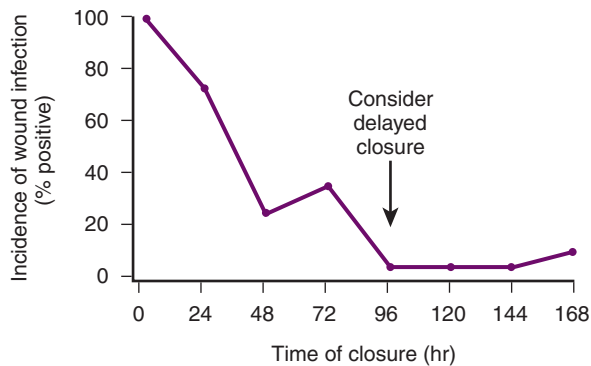

Figure 34.13 Incidence of wound infection over time when delayed closure is performed. Delayed closure is best accomplished on the fourth or fifth day to minimize the risk for infection. (From Edlich RF, Thacker JG, Rodeheaver GT, et al: *A Manual for Wound Closure*, St. Paul, MN, 1979, 3M Medical Surgical Products. Reproduced by permission. © 1979 by Minnesota Mining and Manufacturing Company.)

infection. After 4 to 5 days, a well-irrigated and cleaned wound may be closed primarily with very good results, and can even have better fascial strength than occurs after primary closure.¹⁸

Open wound management is usually an outpatient procedure. The technique consists of careful cleaning and débridement, followed by packing of the wound with sterile, saline-moistened, fine-mesh gauze. The packed wound is covered with a thick, absorbent, sterile dressing. Depending on the specifics of the wound and the ability of the patient to perform his or her own wound care, the packing may be changed daily at home or in the ED, or may be left undisturbed for several days. Sterile, saline-soaked packing is standard, and there is no need to impregnate wounds with antiseptics. Prophylactic antibiotics are occasionally prescribed, but their use is neither mandatory nor of proven benefit. On the fourth or fifth postoperative day, the wound is reevaluated for closure. If no evidence of infection is present, the wound margins can be approximated (*delayed primary closure*), or the wound can be excised and then sutured (*secondary closure*) with minimal risk for infection.

Because the wound is closed before the proliferative phase of healing, there is no delay in final healing, and the results are indistinguishable from those of primary healing.

Certain wounds should almost always be managed open or by delayed closure (Fig. 34.15). Such wounds include those that are already infected and those heavily contaminated by soil, organic matter, or feces. Wounds associated with extensive tissue damage, such as high-velocity missile injuries, explosion injuries involving the hand, complex crush injuries, and most bite wounds are also included in this category. Deep or contaminated lacerations on the bottom of the foot, such as those occurring when the patient steps on an unknown object while wading in a stream or running through a field, or wounds that are deep punctures, are ideal candidates for delayed closure. Some are never sutured but left open for primary healing. Human bite wounds (extending past the dermis) should never be closed primarily, even if they appear clean, and are often opened or extended further for cleaning. Clinicians disagree about which animal bite wounds may be closed initially. Most would suture cosmetically deforming injuries, including facial bites and bite wounds that can be excised completely.⁵⁰ Others would primarily suture dog bites not involving an extremity.⁵¹ In severe soft tissue injuries, delayed closure allows time for nonviable tissue to become demarcated from uninjured tissue. Débridement can then be accomplished with maximal preservation of tissue.

PROTECTION

Dressings

At the conclusion of wound repair, wipe away dried blood on the surface of the skin with moistened gauze to minimize subsequent itching, and cover the wound with a nonadherent dressing. Depending on the specifics of the wound and the type of repair, a dressing can consist of a simple dry gauze pad, a complex multilayer dressing, or an occlusive dressing. Some wounds, such as sutured scalp lacerations, do not routinely require any dressing. Although they are infrequently used on acute, traumatic lacerations managed in the ED, occlusive dressings have been shown to accelerate healing in a variety of wounds.⁵² Various specialized (and expensive) synthetic dressings are available, including vapor-permeable adhesive films, hydrogels, hydrocolloids, alginates, synthetic foam dressings, silicone meshes, tissue adhesives, barrier films, and collagen-containing dressings.⁵³

Function of Dressings

Dressings serve various functions. They protect the wound from contamination and trauma, absorb excess exudate from the wound, immobilize the wound and surrounding area, exert downward pressure on the wound, and improve the patient's comfort. Occlusive dressings on burns or abrasions maintain a moist environment and prevent painful exposure of the wound to air and dehydration of the wound's surface.^{52,54} Sutured wounds are particularly susceptible to infection from surface contamination during the first 2 days after wound repair. Dressings protect the wound from contamination during this vulnerable period.

One of the primary functions of gauze dressing is to absorb the serosanguineous drainage that exudes from all wounds. Absorbent dressings also reduce the development of stitch

Delayed Primary Closure

1 This dirty and contused extremity wound, now 18 hours old, is an ideal candidate for delayed primary closure.

2 At arrival in the emergency department, the wound is anesthetized, scrubbed, irrigated, and sharply débrided.

3 The wound is packed with sterile gauze and covered with a dry dressing. No antibiotics were prescribed and the wound was left undisturbed.

4 4 days later
Four days later the packing is removed and the wound is minimally débrided.

5 Interrupted sutures are placed as though this is a fresh, clean wound. At suture removal 10 days later, only a linear scar was evident.

Figure 34.14 Delayed primary closure. Not all wounds have to be repaired on the initial visit, but may be left open to slowly heal. A delayed primary closure in 3 to 4 days is often the best choice for dirty or old lacerations.

abscesses to some extent. Surface sutures produce small indentations at their points of entrance; tiny blood clots and debris overlie these indentations and allow bacterial growth at the site. Small “stitch abscesses” can develop; they are initially undetectable but are nevertheless destructive to epithelium.

Stitch abscesses rarely infect the entire wound but can slightly increase the width of the scar and produce noticeable, punctate suture marks.

The most common type of dressing is constructed in three layers: a nonadherent contact layer, an absorbent layer, and

Figure 34.15 **A**, Human bites are never closed primarily because of risk for infection. They are often opened and extended to facilitate cleaning and a search for other injuries or foreign bodies (FBs) such as fragments of teeth. **B**, Dog bites in a cosmetic area may be closed primarily. Large cosmetic defects are best closed in the operating room by a surgeon with adequate time to correctly prepare the wound. **C**, This wound on the bottom of the foot, sustained by stepping on an unknown object while running in a stream, should not be closed but rather left open to heal primarily. Always check for foreign bodies in these wounds. Ask an assistant to hold the wound open while you perform pressure irrigation. This was initially a much smaller puncture wound that was extended to search for a suspected FB and also to clean and initially pack the wound open. Sutures were never required and the wound healed in 7 days.

an outer wrap (Fig. 34.16A). Ideally this dressing provides nonadherence without maceration. The optimal appearance of an abrasion or an open wound under a dressing is a moist red surface with capillary and epithelial growth.

Contact Layer: Dry, Semiocclusive, and Occlusive Dressings

Wounds covered with permeable dressings such as plain gauze tend to dry out. Although this is acceptable for dressing sutured wounds, drying of the wound surface damages a shallow layer of exposed dermis, which impedes epidermal resurfacing of abrasions, burns, and incisions.^{52,53,55} Wound desiccation results in further epidermal necrosis, crust formation, and increased inflammation. Coarse weaves of gauze, usually available in the form of multilayered pads, absorb blood and exudate, but the dressing will adhere if the interstices of the fabric are relatively large. Capillaries, fibrin, and granulation tissue will penetrate and become enmeshed in the material. If the proteinaceous exudate from the wound dries by evaporation, the scab usually clings to the dressing. Some clinicians use this effect to “debride” the wound when the gauze is removed. However, it may also destroy healing tissue, particularly the new epithelium. Even though débridement of the wound with wet-to-dry dressings is quick, careful débridement with surgical instruments is more controlled and less traumatic.

Adherence to the wound can be prevented if the dressing is nonabsorbent, occlusive, or finely woven. If the wound is kept moist by covering it with an occlusive film or nonadherent covering soon after wound management, and if the film is left in place for at least 48 hours, the epidermis will migrate over the surface of the dermis faster than when a dry scab is allowed to form.^{53,56,57} Protection of wounds that are healing by secondary intention with occlusive or semiocclusive dressings has several advantages¹⁰ including more rapid healing, less pain from exposure to air, better cosmetic result, fewer dressing changes, and protection from bacteria. Occlusive dressings

BOX 34.1 Advantages of Occlusive Dressings

- More rapid healing
- Less pain from exposure to air
- Better cosmetic results
- Fewer dressing changes
- Better protection from bacteria

Data from Eaglstein WH: Effect of occlusive dressings on wound healing, Clin Dermatol 2:107, 1984.

make good temporary coverings for wounds requiring delayed closure several days after wounding.⁵²

Petrolatum gauze (e.g., Adaptic [Acelyty, San Antonio, TX], Xeroform [Medtronic, Minneapolis, MN], Betadine [Purdue Pharma, Stamford, CT], Kendall [Medtronic, Minneapolis, MN]) is commonly applied next to the surface of the wound to prevent the wound from sticking to the dry gauze in the absorbent layer and to protect the regenerating epithelium (Box 34.1). Always use nonadherent material to cover skin grafts. Some clinicians use fine-mesh gauze (41 to 47 warp threads/inch²) rather than petrolatum gauze on abrasions, especially on wounds that are heavily contaminated, because removal of this type of dressing débrides only the small tufts of granulation tissue that become fixed in the mesh pores and leaves a clean, even surface. Once a healthy, granulating surface is present and reepithelialization is proceeding, nonporous dressings can be used. Fine-mesh gauze is also used next to exposed tissue in wounds being considered for delayed primary closure. Though petroleum gauze is beneficial for nonadherence of subsequent dressings to wounds, studies have shown that the petroleum may decrease the tensile strength of the knots in a stitch.⁵⁸

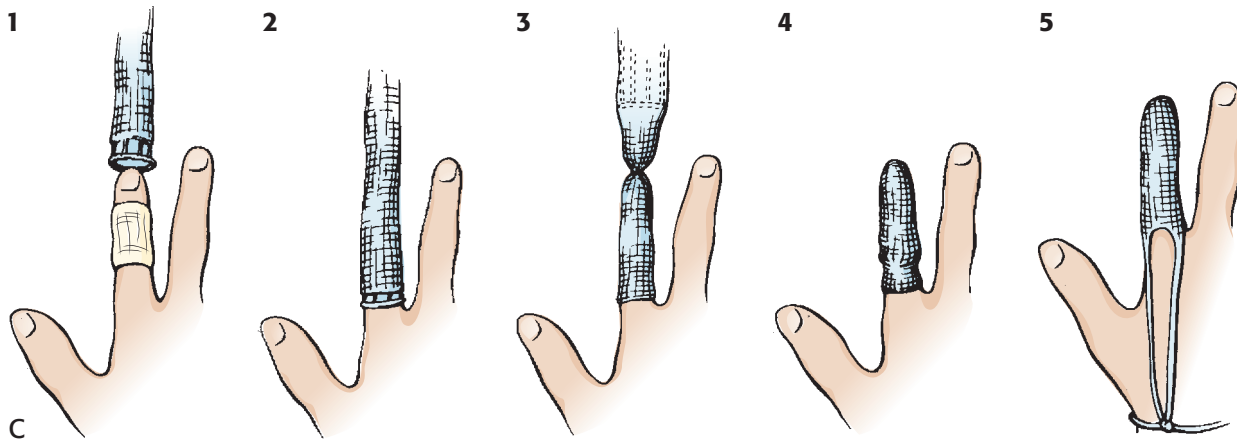

Wound Dressing

A common three-layer dressing consisting of antibiotic ointment, Adaptic, and gauze.

Snugness of the bandage is increased by 180° rotation of the bandage roll after each circular turn to create a reverse spiral.

Tube gauze finger dressing applied loosely. Throbbing pain under this dressing mandates removal. 1, The inner layer is nonadherent gauze. The middle layer is 2- × 2-inch gauze sponges wrapped circumferentially and held in place with tape. 2, Begin with No. 2 tube gauze at the base of the finger. Hold this end with one finger while the tube gauze applicator is pulled toward the fingertip. A twisting motion firms the wrap about the digit; about 90° is necessary. Excessive stretch or twisting can compromise the circulation. 3, When the fingertip is reached, make a 360° twist, but avoid placing a constricting twist around the finger itself. 4, Pass the applicator toward the base of the finger with an additional 90° twist. Repeat once more; thus, three layers are in place. 5, Cut enough gauze to reach the base of the finger, and tape it there. As an alternative, pull the final layer beyond the tip while leaving it long enough to reach to and around the wrist (about three times the finger length). Split this gauze into two strands; bring them dorsally to the wrist, knot, and loosely wrap around the wrist.

For a distal finger dressing, covering the gauze with a finger cut from a clean glove provides protection from dirt and wetness.

Figure 34.16 Wound dressings.

There are over a thousand types of occlusive dressings available today.⁵² Occlusive dressings are ideal for covering abrasions⁵⁴ and burns, but they are also used on lacerations and chronic wounds. Some experts report that they should be avoided if a wound is highly exudative, infected, or at high risk for infection.

There are four main types of occlusive dressings designed for the surfaces of wounds: films, hydrocolloids, foams, and hydrogels⁵² (Table 34.2). *Films* are transparent polyurethane-derived membranes that provide an occlusive effect; they include Omniderm (Omikron Scientific, Ltd., Alpharetta, GA), OpSite (Smith & Nephew, Ltd., Andover, MA), Tegaderm (3M, St. Paul, MN), and Bioclusive (Systagenix, Airebank Mills, Skipton, United Kingdom). They are best for wounds with minimal drainage and those that require frequent monitoring. *Hydrocolloids* are semiocclusive, waterproof dressings with soluble cellulose or gelatin backing, such as DuoDERM (ConvaTec) and Tegisorb (3M). They can be used in wounds with a moderate amount of exudate. *Hydrogels* are products with starch polymers and water, such as Curagel (Kendall) and Telfa

(Covidien, Minneapolis, MN). Because they provide moisture to wounds they are suitable for dry or painful wounds. *Foams* are moderately absorbent polyurethane or silicone products that are semiocclusive and provide a cushion-effect.^{52,53} *Silicon* dressings such as Mepitel (Mölnlycke Health Care) can be used for the treatment of fragile wounds, like skin tears.⁵⁹

One fear of using occlusive dressings is that microorganisms will proliferate in the moist environment beneath the occlusive film and increase wound infection rates. However, occlusive dressings such as DuoDERM actually serve more as a barrier to external pathogenic bacteria.^{53,60} Although skin bacteria under occlusive dressings can multiply,⁶¹ even chronic wounds contaminated with large numbers of bacteria are routinely treated with occlusive dressings successfully.⁵²

Adhesive-backed dressings (e.g., DuoDERM and OpSite) may adhere to an open wound and remove new epidermis; however, the adhesive usually only adheres to dry intact skin, which is located around the wound.⁵² These film dressings have low absorptive capabilities and do not allow exudate to drain out the edges of the dressing. Exudate pooling overlying

TABLE 34.2 Summary of Dressings Used for Acute Wound Care

AGENT AND TYPE	PROPERTIES	ADVANTAGES	DISADVANTAGES	CLINICAL APPLICATIONS	EXAMPLES
Gauze	Cotton or synthetic; woven; Plain or petrolatum-impregnated gauze	Cost effective	Poor absorbance; dehydrates the wound; impedes wound re-epithelialization; adherence causes pain with dressing changes	Primary dressing; must be changed every 12 to 24 hours	Curity (Covidien) Xeroform (Medtronic, Minneapolis, MN)
Film	Transparent; Self-adhesive; water-proof, but gas and water vapor permeable; flexible	Transparency allows for frequent wound inspection; adhesive does not stick to wound and thus low pain with dressing changes	Not absorbent; trapped excess exudate can cause wound maceration	Primary or secondary dressing; best for wounds with low exudate; ideal for flexible areas such as hands and joints; can be changed every 7 days	Tegaderm (3M) Transeal (DeRoyal) Bioclusive (Systagenix) Omniderm (Omidron Scientific)
Foam	Polyurethane or silicone center and semi-occlusive outer layer; adherent or non-adherent	Moderate absorption; cushions wounds	As wound exudate decreases, can dehydrate the wound; non-adherent foam may require a film covering	Good for wounds with high exudate; Ideal over bony areas; can be changed from daily to weekly	Optifoam (Medline) Mepilex (Mölnlycke)
Hydrogel	Water-based gel; sheet or amorphous form	Donates moisture; reduces wound pain	Non-adherent and requires a secondary dressing	Good for dry wounds or with low exudate; changed every 1 to 3 days	Curagel (Covidien) Tegagel (3M)
Hydrocolloid	Adhesive semi-occlusive water-proof	Moderate absorption; conforms to wound	Discharge can be malodorous and appears purulence-like	Changed every week	DuoDERM (ConvaTec) NuDerm (Systagenix)
Silicon	Porous soft silicon; nonadherent	Reduces wound pain	Expensive	Good for fragile wounds, like skin tears; changed every week	Mepitel (Mölnlycke)

the wound will macerate skin. Between dressing changes, coat the wound with petrolatum or an antibiotic ointment before applying these products.¹⁰ Wounds covered with certain occlusive dressings or with silver sulfadiazine (Silvadene, Marion Laboratories, Kansas City, MO) appear to be blanketed with pus; this exudate actually represents the beneficial proliferation of macrophages and polymorphonuclear leukocytes.⁶²

Absorbent Layer

When dressing wounds with considerable drainage, use sufficient gauze to cover the wound and absorb all the drainage. Change the dressing whenever it becomes soiled, wet, or saturated with exudate. Once a dressing becomes moist, pathogens can pass through the mesh-like structure to the underlying wound. Consequently, a dressing that is used to absorb exudate or débride the wound must be changed more frequently than one designed solely to occlude. Absorbent dressings on draining wounds can be changed daily to avoid bacterial overgrowth beneath the dressing.^{7,52} Aspirate fluid accumulating under an occlusive dressing and change the dressing every 1 to 2 days during the first week, or until the exudate no longer accumulates.

Outer Layer

Bleeding may persist despite attempts to provide good hemostasis. Compressive dressings help prevent hematoma formation and eliminate dead space within a wound. They are particularly useful for wounds that have been undermined extensively, and for facial wounds in which subcutaneous capillary bleeding and swelling can exert tension on fine skin sutures and jeopardize skin closure. Pressure dressings should be used to immobilize skin grafts. Surgical tape can serve as a pressure dressing in areas on which bandages cannot be applied easily, such as fingertips.

Apply pressure dressings to all ear lacerations to prevent hematoma formation and subsequent deformation and destruction of cartilage. Envelop the ear in the dressing to distribute pressure from the outer bandage evenly across the irregular surface of the pinna. Pack moistened cotton into the concavities of the pinna until the cotton is level with the most lateral aspect of the helical rim. Cut square pieces of gauze to fit the curvature of the ear and place them behind (medial to) the pinna. Place several more gauze squares on the lateral surface of the ear. Secure the packing in place with a circumferential head bandage, but do not encompass the opposite ear because it would just as easily cause pressure necrosis of that ear if left unprotected.

Bandage traumatic wounds to compress, immobilize, secure, and protect the wound and underlying dressing. Most bandaging is performed on extremities, where dressings are difficult to secure with tape alone. Rolls of cotton (Kerlix [Covidien], Kling [Johnson & Johnson] stretch gauze) are well suited for this purpose. Wind the bandage around the extremity and advance it proximally with circular, overlapping turns. Take care to avoid making wrinkles in the bandage, which may create pressure points, and also be careful not to make loose turns, which shorten the effective life of the dressing. When joint surfaces are crossed, anchor the cotton distally with several turns, then unroll it obliquely across the joint several times in a figure-of-eight pattern, and anchor it again proximally with two complete turns. Repeat this process until the bandage is securely in place. Fasten the ends of the bandage to the skin with strips of adhesive tape.

Bandages over the forearm and the lower extremities are particularly prone to slippage because of the constant motion of these parts and the marked changes in diameter of the extremity over a short distance. To help prevent this problem, rotate the roll of bandage 180 degrees after each circular turn to produce a reverse spiral and reduce the bandage's mobility (see Fig. 34.16B). A simple dressing for a single digit is to use tube gauze or cover it with a finger cut from a surgical glove (see Fig. 34.16C and D). When bandaging digits, be cautious not to create a band-like dressing that can slip down the finger and cause constriction and ischemia.⁶³ This can be especially problematic in children.⁶⁴ Always include the hand and wrist in the dressing to create an anchor point and reduce circumferential bunching.

Certain chemically treated wide-mesh weaves have the properties of cling and stretch, which hold it snugly in place but expand if edema develops. An elastic cotton roll (Kerlix) allows the bandage to conform to body contours, provides some mobility to bandaged joints, and permits the wound to swell without the circumferential bandage constricting the extremity. An inelastic Kling bandage better immobilizes the part. Use rigid immobilization with plaster splints or braces to protect wounds in mobile areas, such as around large joints.

Scalp wounds do well when left uncovered; bulky occlusive dressings of the scalp are discouraged. Encourage the patient to shower daily to remove debris from a sutured scalp laceration. If a dressing is thought necessary, hold it in place with a bandage. Change the outer layer of the dressing when it becomes externally contaminated, it is saturated with exudate, or when inspection and wound cleaning are required.

Dressings vary in their absorbency, adhesiveness, occlusiveness, opacity, and insulating properties. Further research may identify types of dressings that are best suited for different phases of the healing wound. Currently a two- or three-layer dressing is used for most traumatic wounds. Base the choice of material for the contact layer on the characteristics of the individual wound (see Table 34.2).

Splinting and Elevation

Wounds and sutured lacerations may be immobilized to enhance healing and to provide patient comfort (Fig. 34.17). Immobilization of an injured extremity promotes healing by protecting the closure and by limiting the spread of contamination and infection along lymphatic channels. Wounds overlying joints are subjected to repeated stretching and movement, which delays healing, widens the scar, and potentially disrupts the sutures. Short-term splints are almost always beneficial for lacerations that overlie joints and are frequently necessary for the protection of wounds involving the fingers, hands, wrists, volar aspect of the forearms, extensor surface of the elbows, posterior aspect of the legs, plantar surface of the feet, and the extremities when skin grafts have been applied. A plaster or aluminum splint may be incorporated into a bandage to reduce the mobility of the injured part.

Elevate injured extremities in all but the most trivial injuries. Elevation limits edema formation, allows more rapid healing, and reduces throbbing pain. Patients given this information are often more motivated to elevate the extremity as instructed. Use slings to elevate wounds involving the forearm or the hand. The patient can also wrap a pillow around an injured hand to promote elevation at home (see Fig. 34.17A). Another technique to suggest is to lie down on a sofa with the injured

Figure 34.17 **A**, A pillow wrapped around a bandaged hand promotes elevation at home. Note that this sutured hand laceration also has a plaster splint for comfort. In general, immobilization promotes healing. **B**, Elevation of a severe hand injury in the emergency department with a stockinette, splint, and intravenous pole while awaiting the surgeon.

extremity resting on the back of the sofa. With severe injuries, begin elevation in the ED (see [Fig. 34.17B](#)).

Ointments

The safety and efficacy of topical antibiotic preparations used on wound surfaces are largely unproven, and no universal standard exists. Many clinicians routinely suggest the use of antibiotic ointments over sutured wounds, whereas others opt for a simple dry dressing. Use of a triple-antibiotic preparation containing neomycin, bacitracin, and polymyxin (Neosporin, Johnson & Johnson) provides a broad spectrum of protection against infection in abrasions without systemic absorption, toxicity, or the emergence of resistant strains of bacteria. There is some evidence that Neosporin ointment, Silvadene cream, and mupirocin (Bactroban, GlaxoSmithKline, London, UK), in addition to their inert bases and vehicles, either improve wound healing or slightly reduce infection rates.⁶⁵ In comparing mupirocin and nitrofurazone ointment, mupirocin has higher

Figure 34.18 This patient used a neomycin-containing ointment on a minor wound, and redness, swelling, pruritus, and skin changes developed. The patient thought that it was an infection, but it was contact dermatitis from the neomycin. Plain bacitracin ointment will not cause this relatively common reaction. Bacitracin and Silvadene are alternative topicals, but any topical preparation is probably of minimal value.

antibacterial capabilities against *Streptococcus* and *Staphylococcus* species in crush wounds, but topical nitrofurazone can increase the proliferation of granulation tissue.⁶⁶ Although there is a risk for allergic sensitization or contact dermatitis with preparations containing neomycin, allergic reactions are uncommon (roughly 1%)⁶⁷ unless the ointment is used repeatedly ([Fig. 34.18](#)).

One obvious benefit of using topical antibiotics is that ointments prevent adherence of the wound surface to the dressing. Use ointments to reduce the formation of a crust that covers and separates the edges of the wound. Lacerations surrounded by abraded skin are especially predisposed to coagulum formation. In such cases, instruct the patient to cleanse the wound frequently and to follow the cleansing with an application of ointment during the first few days.

Strong topical corticosteroids have detrimental effects on healing. Application of 0.1% triamcinolone acetonide in an ointment retards healing in wounds by as much as 60%, whereas hydrocortisone probably does not interfere with epithelialization.⁶⁸ Some clinicians believe that single and low doses of oral corticosteroids probably have no effect on wound healing but that repeated, large doses of steroids (≤ 40 mg of prednisone per day) inhibit healing, particularly if used before the injury or during the first 3 days of the healing phase.⁶⁹ There is some evidence that topical vitamin A may reverse some of the antiinflammatory and immunosuppressive effects of corticosteroids.⁷⁰

The exact value of ointments in the treatment of lacerations has yet to be determined. However, routine use of ointments after wound cleaning does encourage inspection of the wound by patients. Ointments without antibiotics that are used solely for moisture to the wound have a higher rate of infection and should not be used.⁷¹ Antibiotic ointments can be placed over abrasions or sutured lacerations. Do not use ointments on wounds closed with tissue adhesive because the ointment will dissolve the adhesive.

Wound Cultures

Tissue taken for culture at the time of wound preparation and closure in the ED serves no useful purpose and is not

recommended. The results of such cultures cannot logically guide future antibiotic selection. It is not necessary to routinely culture all minimally infected wounds after closure. Cultures should be considered if there is a subsequent infection that is extensive, unusual, or otherwise concerning, if the patient is immunocompromised, or if there is suspicion of methicillin-resistant *Staphylococcus aureus*. All wounds that are grossly infected at the time of follow-up should also be assessed for the presence of a foreign body.

It is not uncommon to encounter a minor infection or inflammation of the suture tracks at the time of suture removal, as evidenced by a small drop of pus when the suture is removed. Such minor infections, so-called stitch abscesses, usually do well with warm soaks or topical antibiotic ointments and do not require wound cultures or systemic antibiotics.

Systemic Antibiotics

Most traumatic soft tissue injuries sustain a low level of bacterial contamination. Uncomplicated wound infection rates in ED patients range from 2% to 5%, *regardless of clinician intervention*. In a number of clinical studies of relatively uncontaminated and uncomplicated traumatic nonbite wounds (which represent the majority of wounds managed in the ED), prophylactic antibiotics administered in various routes and regimens did not reduce the incidence of infection.⁷²⁻⁷⁴ Studies of antibiotic prophylaxis for animal bite wounds have produced variable results, and no large study providing stratification of the many prognostic factors has been conducted.⁷⁵

As multiple studies on the use of prophylactic antibiotic regimens for wounds treated in the ED have failed to demonstrate a benefit, there is no clear practice standard.⁷⁶ In most soft tissue wounds in which the level of bacterial contamination after cleaning and débridement is low, antibiotics are not recommended. Heavily contaminated wounds (such as wounds in contact with saliva, pus, or feces) often become infected despite antibiotic treatment. Nevertheless, antibiotics may have marginal benefit when the level of contamination is overwhelming, or if the amount of questionably viable tissue left in the wound is considerable (e.g., with crush wounds). Antibiotics may be considered for extremity bite wounds, puncture-type bite wounds in any location, intraoral lacerations that are sutured, orocutaneous lip wounds, wounds that cannot be cleaned or débrided satisfactorily, and highly contaminated wounds (e.g., those contaminated with soil, organic matter, purulence, feces, saliva, or vaginal secretions). They may also be considered for wounds involving tendons, bones, or joints; for wounds requiring extensive débridement in the operating room; for wounds in lymphedematous tissue; for distal extremity wounds when treatment is delayed for 12 to 24 hours; for patients with orthopedic prostheses; and for patients at risk for the development of infective endocarditis.^{12,77}

Although some consider prescribing prophylactic antibiotics for immunocompromised patients (diabetics and others), a true benefit has not consistently been demonstrated in any subset. Many resistant strains of bacteria now encountered in clinical practice (patients and in the community) have been linked to the excessive use of needless antibiotics. Other disadvantages of routine antibiotic use include unnecessary expense and potential side effects (e.g., rash, anaphylaxis, diarrhea, vomiting). It seems most prudent to avoid routine antibiotic prophylaxis and opt for meticulous wound care, close follow-up, and the selective use of antibiotics for proven infection. If antibiotics

are being considered in a specific case, give them as soon as possible after wounding and continue them for only 2 to 3 days in the absence of development of an infection. If the risk for infection is high enough to warrant antibiotics, delayed primary closure may also be considered.

Many patients have difficulty determining whether their wounds are infected and mistake the normal healing process for infection; therefore in high-risk patients (a clinical judgment), mandatory follow-up is usually necessary.^{78,79}

The choice of antibiotic, particularly for bite wound prophylaxis, is as controversial as the indications for use.⁸⁰ Many species of bacteria cause animal bite wound infections, thus making complete coverage impossible.^{77,81} Antibiotic regimens vary with the species of the biter and with evolving bacterial resistance. The duration of antibiotic prophylaxis is also in question. It is common practice to provide antibiotics for 72 hours. (See additional comments on animal bites at the end of this chapter.)

Tetanus Immunoprophylaxis

Although tetanus is rare, it still occurs in the United States and is a preventable disease. Therefore any wound should be assessed for its potential to cause tetanus, and prophylaxis should be considered in the ED. Approximately 70% of Americans older than 6 years have protective levels of tetanus antibodies, but levels decline as age increases, with elderly women having the lowest levels of protection. New immigrants are most likely to have inadequate immunity. Hence, efforts at preventing tetanus should especially be addressed in immigrants and the elderly. The recommendations of the Centers for Disease Control and Prevention for tetanus prophylaxis are listed in [Fig. 34.19](#) and [Table 34.3](#).^{82,83}

When questioning patients about their tetanus immunization status, determine if they ever completed the primary immunization series, and if not, how many doses were given. Patients who have not completed a full primary series of injections (three or four doses) may require both tetanus toxoid and passive immunization with tetanus immune globulin. Tetanus immune globulin will decrease, but not totally eliminate, the subsequent development of clinical tetanus. Tetanus and diphtheria immunizations are often given together (as DT or DTaP for pediatrics, and Td or Tdap for adults). The preferred active tetanus immunization in patients 7 years of age and older is Tdap or Td. For passive immunity, prepare 500 units of tetanus immune globulin. Give most of this dose intramuscularly, and infiltrate the remainder around the wound.⁸³

TABLE 34.3 Summary of Tetanus Vaccine Recommendations

VACCINE HISTORY	Clean, Minor Wounds		All Other Wounds	
	TDAP OR TD	TIG	TDAP OR TD	TIG
Unknown or fewer than 3 doses	Yes	No	Yes	Yes
3 or more doses	No	No	No	No

From Hamborsky J, Kroger A, Wolfe S: *Centers for Disease Control and Prevention. Epidemiology and Prevention of Vaccine-Preventable Diseases*, ed 13, Washington D.C., 2015, Public Health Foundation, p 341.

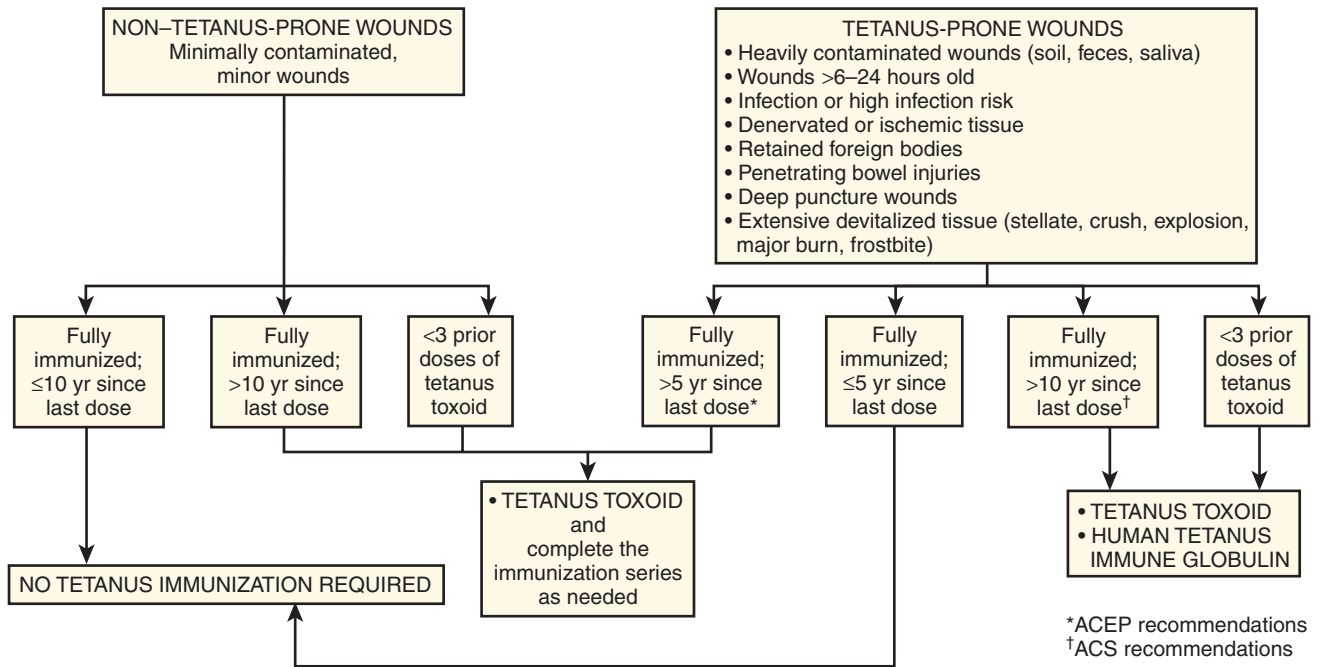

Figure 34.19 Tetanus immunization guidelines. ACEP, American College of Emergency Physicians; ACS, American College of Surgeons.

Mild local reactions consisting of erythema and induration are common ($\approx 20\%$) after tetanus toxoid injections; occasionally, they are accompanied by fever and mild systemic symptoms. Reactions are approximately twice as common if diphtheria immunization is coupled with tetanus immunization. This is a hypersensitivity reaction, not an infection, and does not represent an absolute contraindication to further immunizations. A minor febrile illness, such as an upper respiratory infection, is not a reason to delay immunization. Although serious reactions are rare, a hypersensitivity reaction consisting of tenderness, erythema, and swelling or serum sickness develops in some patients with high antibody levels. Generalized urticarial reactions and anaphylaxis are the severe reactions associated with the tetanus vaccine. Although peripheral neuropathy and Guillain-Barré syndrome have also been reported, there is inadequate evidence to accept or reject a causal relationship.⁸³ The only absolute contraindication to tetanus toxoid is a history of anaphylaxis or a neurologic event. In such cases, tetanus immune globulin can be given safely. Pregnancy is not a contraindication to either toxoid or immune globulin, although some suggest that the toxoid be used “with caution” during the first trimester. Given the excellent amnestic response to the toxoid, it is likely that the primary immunization series, coupled with intermittent boosters every 5 to 10 years, depending on the cleanliness of the wound, conveys immunity for most of one’s life. However, a significant percentage of elderly patients fail to develop protective antitoxin antibody titers after 14 days when given tetanus toxoid boosters.

Treatment decisions are based on the differentiation between clean and contaminated wounds. Even though any break in the skin can harbor *Clostridium tetani*, traditional definitions of tetanus-prone wounds include the following: injuries more than 6 hours old; wounds contaminated by feces, saliva, purulent exudate, or soil; wounds with retained foreign bodies or containing devitalized or avascular tissue; established wound infections;

penetrating abdominal wounds involving bowel; deep puncture wounds; and wounds caused by crush, burns, or frostbite.

Tetanus can develop despite prior immunization, and it can result from chronic skin lesions in apparently minor or clean wounds. In 10% to 20% of cases, no previous wound can be identified. Patients’ recall of past immunizations is imperfect, and immunity may be, on rare occasions, inadequate after a complete series of tetanus toxoid.⁸³ Tetanus boosters given more frequently than advised increase the incidence of adverse reactions to subsequent injections. However, the benefits of overtreatment seem to outweigh the risks.

PATIENT INSTRUCTIONS

Successful wound healing is partly dependent on the care given to the wound once the patient leaves the ED. Patient satisfaction depends not only on the cosmetic result but also on the expectation of that result.⁹ Both are reasons why patients should receive thorough and clear instructions.

Inform the patient that no matter how skillful the repair, any wound of significance produces a scar. Most scars deepen in color and become more prominent before they mature and fade. The final appearance of the scar cannot be judged until 6 to 12 months after the repair.⁸ Some wounds heal with wide, unattractive scars despite ideal management and closure. Wounds more likely to have significant scars are those that cross perpendicular to joints, wrinkle lines or lines of minimum tension (Kraissl lines), and those that retract more than 5 mm. Wounds that are likely to scar are those that are located over convexities or in certain anatomic locations (e.g., anterior upper part of the chest, back, shoulders) where hypertrophic scars are common. A wound crossing a concave surface may result in a bowstring deformity; one crossing a convexity may leave a scar depression. To avoid these complications, a Z-plasty

procedure can be performed at the time of initial wound management, or the scar can be revised later. Tell the patient to expect suboptimal outcomes in these situations.²²

Patients may experience dysesthesia in or around a scar, particularly about the midface. Gentle rubbing or pressing on the skin may relieve the symptoms. If wounds extending to subcutaneous levels lacerate cutaneous nerves, patients may be bothered by hypoesthesia distal to the wound. The dysesthesia and anesthesia usually resolve in 6 months to 1 year.¹⁰

After 48 hours, the patient may remove the dressing on uncomplicated wounds and check for evidence of infection as follows: redness, warmth, increasing pain, swelling, purulent drainage, or the “red streaks” of lymphangitis. Not all patients are able to identify these signs, and often overlook an early infection or overcall an infection in the presence of normal healing. Patients with complicated or infection-prone wounds should be examined in 2 to 3 days by a clinician or nurse.⁷⁹ Inform patients that a painful wound is often a sign of infection or suture reaction, and pain should prompt inspection of the wound. If no sign of infection is present after 48 to 72 hours, the patient can care for the wound until it is time for removal of the sutures.

Because the edges of a wound are sealed by coagulum and bridged by epithelial cells within 48 hours, the wound is essentially impermeable to bacteria after 2 days.^{6,84} Instruct the patient to protect the wound and keep the dressing clean and dry for 24 to 48 hours. In this initial period change the dressing only if it becomes externally soiled or soaked by exudate from the wound. If possible, keep the injured part elevated.

Daily gentle washing with mild soap and water to remove dried blood and exudate is probably beneficial, especially in areas such as the face or the scalp,⁷⁹ but vigorous scrubbing of wounds should be discouraged. Patients may bathe with sutures in place but should not immerse the wound for a prolonged time. Although diluted hydrogen peroxide can be used to remove blood from the skin surface, it should not be repeatedly used as a cleaning agent on the healing wound itself.²⁹ Generally, a wound should be protected with a dressing during the first week and the dressing changed daily. Sutured scalp lacerations are usually left open, and showering is encouraged.

If an injured extremity or finger is protected by a splint, it should be left undisturbed until the sutures are removed. Patients with intraoral lacerations can be instructed to use warm salt water mouth rinses at least three times a day.

Patients may ask about the efficacy of various creams and lotions (e.g., vitamin E, aloe vera, cocoa butter) in limiting scar formation. At this time there are no data to evaluate the use of these substances. Their use is acceptable and may prompt some patients to participate in wound inspection and cleaning more regularly.

SECONDARY WOUND CARE

Reexamination

Patients with simple closed wounds may be released with appropriate instructions for home care and be told to return for removal of the sutures at an appropriate time. Examine high-risk wounds, such as bite wounds and other infection-prone wounds, in 2 to 3 days for signs of infection. Inspect the wound if the patient experiences increasing discomfort, develops a

Figure 34.20 Scalp wounds rarely become infected. This patient was seen twice with a scalp wound infection and given two courses of antibiotics with initial improvement, all before the blade of a utility knife (*arrow*) was discovered in the wound. He was intoxicated during a bar fight and resisted wound closure in the emergency department, so it was done hastily and not thoroughly explored.

fever, or believes that the wound is infected. Evaluate wounds being considered for delayed primary closure in 3 to 5 days.¹¹

Wounds in which extensive dissection of subcutaneous tissue has been performed may develop an intense inflammation similar in appearance to low-grade, localized cellulitis. It is rarely necessary to open these wounds. Remove one or two stitches to relieve some of the tension caused by mild swelling, if necessary. Cleanse daily with water and a mild soap and apply warm compresses, and this type of wound reaction should subside within 24 to 48 hours.

If a wound becomes infected, evaluate for the presence of a retained foreign body as the nidus of the infection (*Fig. 34.20*). In most sutured wounds that become infected, remove the sutures to allow drainage. If a wound exhibits a minor infection, remove a few sutures or all of them. Pack grossly infected wounds open to allow further drainage. Treat infected wounds with daily cleansing, warm compresses, and antibiotics. Leave wounds that have been opened to heal by secondary intention, which involves wound contraction, granulation tissue formation, and epithelialization.

Most wound infections can be treated in the outpatient setting with oral antibiotics and follow-up. Lymphangitis does not mandate intravenous antibiotics or hospitalization.

Suture Removal

The optimal time for suture removal varies with the location of the wound, the rate of wound healing, and the amount of tension on the wound. Certain areas of the body such as the back of the hand heal slowly, whereas facial or scalp wounds heal rapidly. The speed of wound healing is affected by systemic factors such as malnutrition, neoplasia, and immunosuppression. Therefore only general guidelines can be given for the timing of suture removal. At the time that suture removal is being considered, one or two sutures may be cut to determine whether

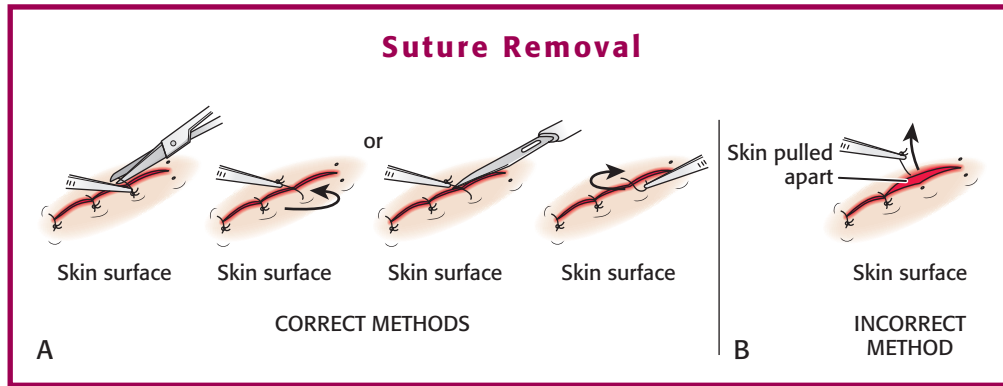

Figure 34.21 Technique for removal of sutures. **A**, Pull toward the wound line rather than **B**, away from it, which causes the wound to tear apart. After suture removal, supporting the wound with surgical tape (Steri-Strips) may be advisable if tension or minor dehiscence is present.

the edges of the skin are sufficiently adherent to allow removal of all the sutures. Removing sutures too early invites wound dehiscence and widening of the scar, whereas leaving sutures in longer than necessary may result in epithelial tracks, infection, and unsightly scarring.⁸⁵

Percutaneous sutures stimulate an inflammatory reaction along the suture track. Infection around a suture can lead to the formation of a stitch mark.⁸⁶ Other factors that determine the severity of stitch marks include the length of time that sutures are left in place, skin tension, the relationship of the suture to the edge of the wound, the region of the body, and the patient's tendency for keloid formation.^{86,87} The skin of the eyelids, palms, and soles and the mucous membranes seldom show stitch marks. In contrast, oily skin, and the skin of the back, the sternal area, the upper part of the arms, the lower extremities, the dorsum of the nose, and the forehead are likely to exhibit the permanent imprints of suture material on the skin surface.⁸⁶

If sutures are removed within 7 days, generally no discernible needle puncture or stitch marks will persist.⁸⁷ However, at 6 days the wound is held together by a small amount of fibrin and cells, and has minimal strength.⁴⁹ The tensile strength of most wounds at this time is adequate to hold the wound edges together, but only if there is no appreciable dynamic or static skin force pulling the wound apart.⁸⁸ Minimal trauma to an unsupported wound at this point could cause dehiscence. The clinician should decide on the proper time to remove the sutures after weighing these various factors. If early suture removal is necessary (such as on the face), wound repair can be maintained with strips of surgical skin tape. The key to wound tensile strength after suture removal is an adequate deep tissue layered closure.

Some general guidelines exist for suture removal. Remove sutures on the face on the fifth day after the injury, or remove alternate sutures on the third day and the remainder on the fifth day. On the extremities and the anterior aspect of the trunk, leave sutures in place for approximately 7 days to prevent disruption of the wound. Leave sutures on the scalp, back, feet, hands, and joints in place for 10 to 14 days, even though permanent stitch marks may result.⁸⁶ Some clinicians recommend removal of the sutures used to repair eyelid lacerations as early as 72 hours to avoid epithelialization along the suture track along with subsequent cyst formation.⁸⁹

Removing sutures is usually relatively simple. Cleanse the wound and any remaining crust overlying the surface of the wound or surrounding the sutures. Wipe the skin with an alcohol swab. Cut each stitch with scissors or the tip of a No. 11 scalpel blade at a point close to the surface of the skin on one side. Grasp the suture knot on the opposite side with forceps and pull it across the wound (Fig. 34.21). The amount of exposed suture dragged through the suture track is thereby minimized. It is difficult to remove sutures with very short ends. At the time of suture placement, cut the length of the suture ends so they generally equal the distance between sutures. This makes it easier to grasp the suture during subsequent removal while avoiding entanglement during the knotting of adjacent sutures.

Once the skin sutures are removed, the width of the scar increases gradually over the next 3 to 5 weeks unless it is supported. Support is provided by previously placed subcutaneous stitches that bring the edges of the skin into apposition or by the application of skin tape at the time of removal. A nonabsorbable, subcuticular suture can be left in place for 2 to 3 weeks to provide continued support for the wound. Although complications such as closed epithelial sinuses, cysts, or internal tracts can occur from prolonged use of this stitch,^{90,88,90} they are unusual and can be avoided by placement of a buried subcuticular stitch with an absorbable suture.

Small stitch abscesses may occur in wounds when sutures remain in place for more than 7 to 10 days. Localized stitch abscesses generally resolve after removal of the sutures and application of warm compresses, and without antibiotics in simple cases.

If time and effort have been invested in cosmetic closure of the face, protect the repair with skin tape after the skin sutures have been removed. Wound contraction and scar widening continue for 42 days after the injury.⁴⁹ Because the desired result is a scar of minimal width, the tape can be used for as long as 5 weeks after removal of the sutures. With exposure to sunlight, scars in their first 4 months redden to a greater extent than the surrounding skin does. In exposed cosmetic areas and when prolonged exposure to the sun is anticipated, appropriate sun protection and avoidance strategies should be used (e.g., a hat and sunscreen). Sunscreen may have a role in protecting scars from the sun, but more studies are needed to better understand its impact.

COMPLICATIONS

There are several reasons why wounds fail to heal; some are related to decisions made at the time of wound closure, and others are consequences of later events. Some of the impediments to healing include ischemia or necrosis of tissue, hematoma formation, prolonged inflammation caused by foreign material, excessive tension on the edges of the skin, and immunocompromising systemic factors. A primary cause of delayed healing is wound infection. Wound cleaning and débridement, atraumatic and aseptic handling of tissue, and the use of protective dressings minimize this complication. Inversion of the edges of a wound during closure produces a more noticeable scar, whereas skillful technique can convert a jagged, contaminated wound into a fine, inapparent scar. The patient's actions also affect wound healing. Delay in seeking treatment of an injury may significantly affect the ultimate outcome of the wound. Furthermore, in the first few days after an injury, the patient must take responsibility for protecting the wound from contamination, further trauma, and swelling.

Infection is probably the most common cause of dehiscence. If the patient is careless or unlucky, reinjury can reopen a wound despite the protection of a thick dressing. If the size of the suture is too small, the stitch may break. A stitch that is too fine or tied too tightly may cut through friable tissue and pull out. Knots that have not been tied carefully may unravel. The suture material may be extruded or absorbed too rapidly. Finally, if a stitch is removed too early (i.e., before tissues regain adequate tensile strength), the wound loses necessary support and can open. If the wound edges show signs of separating at the time of suture removal, alternate stitches can be left in place and the entire length of the wound supported by strips of adhesive tape.

The final appearance of a scar is determined by several factors. Infection, tissue necrosis, and keloid formation widen a scar. Wounds located in sebaceous skin or oriented 90 degrees to dynamic or static skin tension lines result in wide scars. Dynamic tension is primarily a result of nearby joint movement. Wounds located in areas of high static skin tension will gape initially and often heal with wide scars despite adequate closure, whereas wounds in areas of loose or lax skin often heal with fine, narrow scars.¹⁸

Miscellaneous Aspects of Wound Care

Traumatic wounds are created by a wide variety of mechanisms, and clinicians must sometimes adjust wound management techniques to match special circumstances.

The ED Approach to Puncture Wounds

Puncture wounds are common, yet there are no prospective studies to identify the most effective way to manage puncture wounds in the ED. Aside from evaluating tetanus immunization status and considering the possibility of a foreign body, the clinician has few proven options to prevent infection in a puncture wound. Scrubbing the surface of the puncture, evaluating the opening for retained foreign matter, and trimming jagged skin and tissue edges may be helpful. The value or appropriateness of coring, probing, or irrigating the puncture track has not been established. Deep irrigation is usually ineffective unless the puncture site is converted into a larger laceration to make the full depth of the puncture

accessible, but routine enlargement of a puncture track is not recommended. For through-and-through punctures, the track can often be débrided by pulling gauze through the wound (Fig. 34.22).

It is impossible to accurately predict the final outcome of a puncture wound, though it may be determined at the time of the injury. Gross contamination or deep foreign bodies may not be appreciated for days. No prospective randomized trials have evaluated the role of prophylactic antibiotic administration to prevent infection in puncture wounds. Hence there are no standards on the use, type, or duration of prophylactic antibiotic therapy, even in high-risk patients. Most clinicians forego routine antibiotics and opt for simple cleaning and appropriate follow-up. Puncture wounds of the bottom of the foot may be an exception and are discussed in more detail in Chapter 51.

Gunshot Wounds

A subset of gunshot wounds may be definitively handled in the ED with outpatient follow-up. Studies by Ordog and colleagues^{91,92} documented a very low infection rate in gunshot wounds treated with standard wound care on an outpatient basis, even when the missile was left in place and minor fractures were present. Because most gunshot wounds are puncture wounds, only minimal deep wound cleaning is possible. Superficial soft tissue wounds with entrance and exit wounds in proximity may be débrided by passing sterile gauze back and forth through the wound track (Fig. 34.23). Though prescribed frequently, no data support the routine use of antibiotics following gunshot wounds.

Animal Bites

Many aspects of the treatment of animal bites are controversial, and no universal standards exist. Most bites are caused by dogs or cats that are family pets. Numerous organisms can be cultured from an infected bite wound caused by a dog or cat, and cultures may guide antibiotic therapy in infected wounds.⁸¹ However, cultures that are performed during the initial treatment of an animal bite are not predictive of subsequent infection or infecting organisms. The predominant pathogens in animal bites are the oral flora of the biting animal and human skin flora. Approximately 85% of bites harbor potential pathogens, and the average wound yields five types of bacterial isolates; almost 60% have mixed aerobic and anaerobic bacteria.⁹³ Skin flora such as staphylococci and streptococci are isolated in approximately 40% of bites. The gram-negative rod *Pasteurella canis* (*multocida*), *S. aureus*, and *Streptococcus viridans* are common culprits in bite wound infections. *Pasteurella* species are isolated from 50% of dog bite wounds and 75% of cat bite wounds.⁹³ Cat bites are usually puncture wounds that cannot be completely cleaned because of the sharp, pointed shape of their teeth. When compared with dog bites, cat bites may become infected rather quickly after the bite (within 24 hours), thus suggesting *Pasteurella* infection (Fig. 34.24). Cat bite wounds tend to penetrate deeply, with a higher risk for osteomyelitis, tenosynovitis, and septic arthritis than with dog bites, which are associated with crush injury and wound trauma. *Capnocytophaga canimorsus*, a fastidious gram-negative rod, can cause bacteremia and fatal sepsis after animal bites, especially in asplenic patients or those with underlying hepatic disease. Anaerobes isolated from dog and cat bite wounds include *Bacteroides*, fusobacteria, *Porphyromonas*, *Prevotella*, propionibacteria, and peptostreptococci. Puncture wounds from a dog can be problematic because

Figure 34.22 Puncture wounds cannot be cleaned meticulously and they may contain debris. The ultimate course of a puncture wound is likely set at the time of injury and they often do well. If an infection is seen at follow-up, a foreign body (FB) is highly likely. **A–C**, This nail gun puncture of the distal finger joint was able to be débrided by **D**, passing a small hemostat through the puncture wound and pulling gauze through the wound. **E**, A small piece of metal, used to attach the nails together (arrows), was removed with this maneuver. **F**, Note that nails from a nail gun clip are held together with a piece of metal or glue that may hamper removal or be left in the wound. A splint and 3 days of cephalexin prophylaxis (because of the discovered foreign body) were provided, and this wound healed well.

they are difficult to clean unless they are through-and-through wounds (Fig. 34.25). Some clinicians have advocated primary closure of large dog bite lacerations that are centrally located on the body; however, markedly contused lacerations are good candidates for delayed primary closure (see Fig. 34.15B).

Infected animal bites should be treated with antibiotics, but the use of prophylactic antibiotics for animal bites is controversial. Depending on location, dog bites may have an infection rate of 3% to 5%, whereas cat bites may become infected 50% of the time.⁷⁷ Antibiotics for either prophylaxis or infection should have in vitro activity against *P. canis*. Prophylactic

amoxicillin-clavulanate (875/125 mg twice daily) given for 3 to 5 days may reduce infection rates after cat or dog bites, especially for a puncture wound, when the patient is seen more than 8 hours after the bite, or when wound cleaning has been inadequate.^{77,93} Some clinicians administer prophylactic antibiotics for all cat bites, for a dog bite that has been sutured, for hand wounds, for wounds close to a bone or joint, or for bites associated with deep tissue or crush injury. Although this is a reasonable and common approach, there are no data strongly supporting this practice. Alternative antibiotic combinations include clindamycin (300 mg four times daily) plus doxycycline

Figure 34.23 Patients with minor gunshot wounds may be treated as outpatients, even when bullet fragments remain and minor fractures are present. **A** and **B**, This through-and-through injury traversed the hypothenar eminence. No bullet remained and no bones were involved. **C**, Usually, it is impossible to irrigate a puncture wound, but in this case, note the saline at the exit site. **D**, After the entrance wound is débrided of the powder burn, pass an instrument through the wound. Grasp the gauze packing with the instrument and pull it into the wound. Pull the gauze *back and forth* to débride the wound track. Similarly, place clean packing. **E**, For a similarly cleansed gunshot wound of the leg, leave the gauze packing in the track for 48 hours. No antibiotics were given, the pack was removed at wound check in 48 hours, and the patient did well.

Figure 34.24 Cat bites are puncture wounds that become infected rather quickly. See text for discussion of antibiotics.

(100 mg twice daily), or trimethoprim-sulfamethoxazole (1 double-strength tablet twice daily). Antibiotics that do not have adequate activity against *P. canis* include first-generation cephalosporins (such as cephalexin), penicillinase-resistant penicillins (such as dicloxacillin), macrolides (such as erythromycin), and clindamycin alone.

The best way to approach bite wounds is simply to adhere to the basic principles of wound care. Search for underlying fractures or tooth fragments with deep animal bites. When a wound results from the bite or scratch of either a wild or a domestic animal, give rabies prophylaxis if indicated (Tables 34.4 and 34.5).⁹⁴

Human Bites

Human bite wounds are problematic for several reasons: these wounds are contaminated with human saliva; they may hide foreign material; deep structural damage may complicate the injury; and wound care may be delayed. Pathogens include aerobic bacteria (such as streptococci and *S. aureus*) and anaerobic bacteria (such as *Eikenella*, *Fusobacterium*, *Peptostreptococcus*, *Prevotella*, and *Porphyromonas* species). When cultured, most infected human bites harbor three to four pathogens, including both aerobes and anaerobes. Limited case reports suggest that viral pathogens including hepatitis, HIV, and herpes simplex virus, may be transmissible by human bites; however, data are lacking to guide the clinician on the best approach

Figure 34.25 Dog bite puncture wounds are difficult to clean if not through and through. See text for discussion of the appropriate use of antibiotics.

in the ED for these potential infections. Generally, prophylaxis is not suggested if the wound does not penetrate the dermis, is not over a joint, and does not involve the hands, feet, or cartilaginous structures.⁹⁵

Clenched fist injuries caused by contact with another person's teeth during a fight, or "fight bites," are among the most serious human bite wounds. Lacerations typically occur over the third and fourth metacarpophalangeal or proximal interphalangeal joints of the dominant hand. Even small lacerations or punctures are highly prone to infection. Joint penetration is relatively common. Relaxation of the fist may disseminate organisms into the deep compartments and the deep tendon spaces of the hand, predisposing the patient to deep soft tissue infection, septic arthritis, and osteomyelitis. Many patients ignore these wounds until the onset of pain, swelling, or purulent discharge; as a result, these injuries are often complicated by established infection at the initial ED visit. In addition, some patients are not always forthcoming about the origin of the wound, especially if interpersonal violence is involved, thereby leading to incorrect ED treatment of a seemingly minor injury (Fig. 34.26).

Irrigate bite wounds copiously with tap water or sterile saline, and remove grossly visible debris. Many clinicians will extend a small laceration to allow visualization of the underlying structures and better cleaning. Look for tooth chips, tendon injury, and joint penetration. Wounds involving tendons or joint spaces are more serious and require close follow-up.

In general, leave all human bite wounds open (unsutured), even when treated soon after the injury and with seemingly

Figure 34.26 Human bite. This patient was seen on a Monday morning with a small puncture wound on the dorsal surface of his hand (arrow), and he claimed that it was an injury sustained at work. Hence, minimal wound care was given. In reality, it was a human bite from a bar fight the night before. In 3 days, a serious infection was obvious and hospitalization was required. Note that the wrist is flexed, a patient held position that is common and increases hand edema.

benign wound conditions. Pack them with gauze until follow-up. Do not use deep sutures. On reevaluation within a few days, perform delayed primary closure if desired. Facial bite wounds are an exception; primary closure may be considered for these wounds. Consider splinting the hand in a position of function with a short-arm volar splint for a few days to minimize joint movement. Advise the patient to elevate the injured area.

Most clinicians administer *prophylactic* antibiotics for 3 to 5 days for human bites, although there are no studies that

TABLE 34.4 Rabies Postexposure Prophylaxis Guide

The following recommendations are only a guide. In applying them, take into account the animal species involved, the circumstances of the bite or other exposure, the vaccination status of the animal, and the presence of rabies in the region. Local or state public health officials should be consulted if questions arise about the need for rabies prophylaxis.

ANIMAL SPECIES	CONDITION OF ANIMAL AT TIME OF ATTACK	TREATMENT OF EXPOSED PERSON ^a
Domestic		
Dog and cat	Healthy and available for 10 days of observation	None unless rabies develops in the animal ^b Local wound healing should be included in the treatment of the exposed person for each category RIG ^c and HDCV Consult public health officials. If treatment is indicated, give RIG ^c and HDCV
	Rabid or suspected rabid	
	Unknown (escaped)	
Wild		
Skunk, bat, fox, coyote, raccoon, bobcat, and other carnivores	Regard as rabid unless proved negative by laboratory tests ^d	RIG ^c and HDCV
Other		
Livestock, rodents, and lagomorphs (rabbits and hares)	Consider individually. Local and state public health officials should be consulted on questions about the need for rabies prophylaxis. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other rodents, rabbits, and hares almost never call for antirabies prophylaxis.	

^aAll bites and wounds should be immediately cleansed thoroughly with soap and water. If antirabies treatment is indicated, both rabies immune globulin (RIG) and human diploid cell rabies vaccine (HDCV) should be given as soon as possible, regardless of the interval after exposure. Local reactions to vaccines are common and do not contraindicate continuing treatment. Discontinue vaccine if fluorescent antibody tests of the animal are negative.

^bDuring the usual holding period of 10 days, begin treatment with RIG and HDCV at the first sign of rabies in a dog or cat that has bitten someone. The symptomatic animal should be killed immediately and tested.

^cIf RIG is not available, use antirabies serum, equine. Do not use more than the recommended dosage.

^dThe animal should be killed and tested as soon as possible. Holding for observation is not recommended. Vaccination may be discontinued if immunofluorescence tests of the animal are negative.

From Human rabies prevention—United States, 1999: Recommendations of the Advisory Committee on Immunization Practices (ACIP), *MMWR Recomm Rep* 48(RR-1):1, 1999. <http://www.cdc.gov/mmwr/preview/mmwrhtml/00056176.htm>.

TABLE 34.5 Rabies Postexposure Prophylaxis Schedule, United States

VACCINATION STATUS	TREATMENT	REGIMEN ^a
Not previously vaccinated	Local wound cleansing RIG	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water 20 IU/kg of body weight; if anatomically feasible, up to half the dose should be infiltrated around the wounds and the rest administered IM in the gluteal area. Note: RIG should not be administered in the same syringe or into the same anatomic site as the vaccine because RIG may partially suppress active production of antibody. No more than the recommended dose should be given. HDCV or RVA, 1 mL IM (deltoid area ^b), one each on days 0, 3, 7, 14, and 28
	Vaccine	
Previously vaccinated ^c	Local wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water. RIG should not be administered. HDCV or RVA, 1 mL IM (deltoid area ^b), one each on days 0 and 3
	RIG	
	Vaccine	

^aThese regimens are applicable for all age groups, including children.

^bThe deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. The vaccine should never be administered in the gluteal area.

^cAny person with a history of preexposure vaccination with HDCV or RVA, previous postexposure prophylaxis with HDCV or RVA, or prior vaccination with any other type of rabies vaccine and a documented history of antibody response to the previous vaccination.

HDCV, Human diploid cell rabies vaccine; IM, intramuscularly; IU, international units; RIG, rabies immune globulin; RVA, rabies vaccine, adsorbed. Four formulations of three inactivated rabies vaccines are currently licensed for preexposure and postexposure prophylaxis in the United States.

From Human rabies prevention—United States, 1999: Recommendations of the Immunization Practices Advisory Committee, *MMWR Recomm Rep* 40(RR-3):1, 1999.

demonstrate the effectiveness of this practice, or to identify the best antibiotic. Most infections are polymicrobial, but use of antibiotics with activity against *S. aureus*, *Eikenella corrodens*, *Haemophilus influenzae*, and β -lactamase-producing oral anaerobic bacteria, is advised. Amoxicillin-clavulanate (875/125 mg twice daily) for 3 to 5 days is a common recommendation for monotherapy. Alternative empirical combination regimens include clindamycin (450 mg three times daily) plus trimethoprim-sulfamethoxazole (1 double-strength tablet twice daily), or ciprofloxacin (500 to 750 mg twice daily), or moxifloxacin (400 mg once daily) for 3 to 5 days.

Grossly infected wounds should be treated with intravenous antibiotics, but the need for hospitalization is based on the patient's profile and the clinician's assessment of the severity of the infection in addition to the need for close monitoring.

Serious Wound Infections

Most wound infections are easily recognized and can be treated in the outpatient setting with oral antibiotics, suture removal, evaluation for a retained foreign body, and a follow-up examination within a few days. Consider inpatient treatment for a patient with systemic complaints (fever, malaise, nausea), worsening infection at follow-up, an unreliable patient, or an immunocompromised patient. Some infections, such as a subgaleal infection in a scalp laceration, can be serious and will require prompt, aggressive treatment (Fig. 34.27).

Figure 34.27 Scalp lacerations rarely become infected because of the excellent blood supply to the area. **A**, This patient had a painful swollen area under a sutured scalp laceration (*long arrow*) and impressive forehead and facial swelling (*short arrow*) from a laceration on top of the head. It was originally thought to be a hematoma. **B**, Removal of sutures revealed frank pus and an extensive subgaleal abscess that required drainage and intravenous antibiotics. This infection can drain into the brain, face, neck, or mediastinum.

Digital Nerves

Numbness in the area of digital innervation, concomitant injury to a digital artery (flash, pulsating bleeding), or an electric shock sensation when exploring a laceration should alert the clinician to a possible digital nerve injury. If there is uncertainty about nerve injury, the diagnosis can be established at the time of a follow-up visit. However, lacerations of digital arteries that impair the distal circulation must be identified early during the initial evaluation.

Débridement of hand and finger lacerations should be minimal, and wound cleaning should be gentle yet thorough. Digital nerves that are transected distal to the metacarpophalangeal joint may be candidates for surgical repair. It is unclear at which point along the course of a digital nerve a transection can be repaired successfully, so referral to a hand specialist is essential. Frequently injuries proximal to the distal interphalangeal joint are not repaired, but many other factors will influence operative decisions. Repair of a digital nerve will often result in return of good sensory function, but it takes months, and repair can prevent painful neuromas from developing. Most hand surgeons will not repair digital nerves at the initial visit. Instead, they advise wound cleaning, skin closure, splinting, and outpatient follow-up in 24 to 36 hours, followed by delayed nerve repair.

Accidental Soft Tissue Injection With an EpiPen

An EpiPen provides self-injected subcutaneous epinephrine (0.3 or 0.15 mg) for emergency treatment of anaphylaxis (Fig. 34.28).

Occasionally the device is inadvertently discharged, usually into a finger, producing intense distal vasospasm (Fig. 34.29). The patient has a blanched finger and minor sensory disturbances. The natural history of untreated vasospasm is unknown; although ischemia may last for an hour or two, it may be self-limited. Digit amputation from this event has not been reported. Nonetheless, clinicians faced with an obviously ischemic finger may consider an intervention. Local heat and nitroglycerin ointment are of no proven benefit. Placing a

Figure 34.28 The EpiPen and EpiPen, Jr. Each injector issues only one dose of epinephrine, and each delivers a total volume of 0.3 mL. The adult version injects 0.3 mg of epinephrine (it contains epinephrine in a 1:1000 concentration, so there is 1 mg of epinephrine in 1 mL of volume). The EpiPen, Jr. injects a similar 0.3-mL volume but uses a 1:2000 dilution of epinephrine, so only 0.15 mg of epinephrine is delivered with the injection.

Figure 34.29 Accidental discharge of an EpiPen into a finger will usually cause intense distal vasoconstriction. **A**, This patient sustained such an injection into the volar tuft of the index finger (*arrow*) 2 hours before evaluation in the emergency department. **B**, Blanching of the distal end of the finger (*arrow*) caused by the vasoconstriction. **C**, A pulse oximetry probe was applied to the finger, and normal saturation (96%) (*arrow*) was found. She was simply observed for another hour, the blanching resolved, and she was discharged without intervention. **D**, This patient suffered from a similar injection on the volar surface of the middle finger. Blanching is obvious (*arrow*). **E**, Phentolamine and lidocaine were injected along the volar surface of the finger. **F**, Five minutes later the finger was hyperemic (*arrow*). No further intervention was required.

pulse oximeter on the fingertip can indicate the degree of resultant hypoxia, an indirect quantification of ischemia, and can also be used to assess reversal therapy.

Injecting the digit with the α -adrenergic antagonist phentolamine (Regitine) can be safely performed in the ED to immediately and permanently reverse the ischemia (see Fig. 34.29D-F). Phentolamine is reconstituted and diluted in 2% plain lidocaine at a ratio of 1.5:1, or diluted with saline at a ratio of 1:1.⁹⁶ Inject a small aliquot of the mixture with a

25- to 27-gauge needle. Both a digital block and direct injection of the reversal agent into the site of epinephrine injection have been described. Injecting the actual site of penetration is intuitively the best option, but few case studies have been reported.⁹⁷ Within 5 to 10 minutes, the ischemia is reversed, and no further action is required.^{96,98}

Methods of Wound Closure

Richard L. Lammers and Lovita E. Scrimshaw

WOUND TAPE

Surgical tape strips are now routinely used to close simple wounds. Tape strips can be applied by health care personnel in many settings, including emergency departments (EDs), operating rooms, clinics, and first aid stations. Advantages include ease of application, reduced need for local anesthesia, evenly distributed wound tension, no need for suture removal, no residual suture marks, minimal skin reaction, superiority for some grafts and flaps, and suitability for use under plaster casts. One main advantage of wound tape over standard sutures and wound staples is its greater resistance to wound infection.¹⁻⁵ Wound closure strips are the most cost-effective means for closure of low-tension lacerations and provide results comparable to tissue adhesive.⁶⁻⁹

Background and Tape Comparisons

Currently, several brands of tape with different porosity, flexibility, strength, and configuration are available. Steri-Strips (3M Corporation, St. Paul, MN) are nonwoven microporous tapes with ribbed backing (Fig. 35.1 and Video 35.1). They are porous to air and water, and the ribbed backing provides extra strength. Shur-Strip (Deknatel, Inc., Floral Park, NY) is another nonwoven microporous tape. Cover-Strips (Beiersdorf, South Norwalk, CT) are woven in texture and have a high degree of porosity. They allow not only air and water but also wound exudates to pass through the tape. Clearon (Ethicon, Inc., Somerville, NJ) is a synthetic plastic tape whose backing contains longitudinal parallel serrations to permit gas and fluid permeability. An iodoform-impregnated Steri-Strip (3M Corporation) is intended to further retard infection without sensitization to iodine.³ Other tape products include Curi-Strip (Kendall, Boston), Nichi-Strip (Nichiban Co., Ltd., Tokyo), Cicagraf (Smith & Nephew, London), and Suture Strip (Genetic Laboratories, St. Paul, MN). Steri-Strip S (formerly marketed as ClozeX) is a novel method of tape application which has shown benefit in surgical wounds.¹⁰⁻¹⁴

Scientific studies of wound closure tapes provide some comparisons of products. Koehn¹⁵ showed that Steri-Strip tape maintains adhesiveness approximately 50% longer than Clearon tape does. Rodeheaver and coworkers¹⁶ compared Shur-Strip, Steri-Strip, and Clearon tape in terms of breaking strength, elongation, shear adhesion, and air porosity. The tapes were tested in both dry and wet conditions. Steri-Strip tape had approximately twice the breaking strength of the other two tapes in both conditions; there was minimal loss of strength in all tapes when wetted. Shur-Strip tape showed approximately two to three times the elongation of the other tapes at the breaking point, whether dry or wet. Shear adhesion (amount of force required to dislodge the tape when a load is applied

at the place of contact) was slightly better for the Shur-Strip tape than for the Steri-Strip tape and approximately 50% better than for the Clearon tape. Of these three wound tapes, the investigators considered Shur-Strips to be superior for wound closure.

One comprehensive study of wound tapes compared Curi-Strip, Steri-Strip, Nichi-Strip, Cicagraf, Suture Strip, and Suture Strip Plus.¹⁷ All tapes were 12 mm wide except for Nichi-Strip, which was 15 mm. Each tape was compared for breaking strength, elongation under stress, air porosity, and adhesiveness. Curi-Strip, Cicagraf, and Steri-Strip exhibited equivalent dry breaking strength. However, when wet (a condition that can occur in the clinical setting), Cicagraf outperformed all tapes. All the tapes tested had similar elongation-under-stress profiles with the exception of Suture Strip Plus. This tape did not resist elongation under low or high force. Excessive elongation may allow wound dehiscence. Nichi-Strip was the most porous to air, and Cicagraf was almost vapor impermeable. Nichi-Strip and Curi-Strip had the best adherence to untreated skin. When the skin was treated with tincture of benzoin, however, Steri-Strip dramatically outperformed all other products. When all study parameters were considered, Nichi-Strip, Curi-Strip, and Steri-Strip achieved the highest overall performance rankings.

Indications

The primary indication for tape closure is a superficial straight laceration under little tension. If necessary, tension can be reduced by placing deep closures. Areas particularly suited for tape closure are the forehead, chin, malar eminence, thorax, and non-joint-related areas of the extremities. Tape may also be preferred for wounds in anxious children when suture placement is not essential. In young children who are likely to remove the tape, tape closure must be protected with an overlying gauze bandage.

In experimental wounds inoculated with *Staphylococcus aureus*, tape-closed wounds resisted infection better than wounds closed with nylon sutures.² Tape closure works well under plaster casts when superficial suture removal would be delayed. Wound tape effectively holds flaps and grafts in place, particularly over the fingers, the flat areas of the extremities, and the trunk (Fig. 35.2).^{3,4} Tape closure can also be applied to wounds after early suture removal, particularly on the face, to maintain approximation of the wound edges while reducing the chance of permanent suture mark scarring. Finally, because of the minimal skin tension created by tape, it can be used on skin that has been compromised by vascular insufficiency, altered by prolonged use of steroids, and in the fragile skin of the aged. For example, wounds on the pretibial area are difficult to close, especially so in the elderly because of tissue atrophy. Wound tape provides an alternative or adjunct to suture closure in this situation.

Contraindications

Tape closure has disadvantages as well. Tape does not work well on wounds under significant tension or on wounds that are irregular, on concave surfaces, or in areas of marked tissue laxity. In many cases, tape does not provide satisfactory apposition of the wound edges without concurrent underlying deep closure. Naturally moist areas, such as the axilla, the palms of the hands, the soles of the feet, and the perineum prevent tape from sticking well. Tape also has difficulty adhering to wounds

that will have secretions, copious exudates, or persistent bleeding. It is of little value on lax and intertriginous skin, on the scalp, and on other areas with a high concentration of hair follicles. Tape strips are also at risk for premature removal by young children.

Do not place tape tightly and circumferentially around digits because it has insufficient ability to stretch or lengthen (Fig. 35.3). If placed circumferentially, the natural wound edema of an injured digit can make the tape act like a constricting band,

which can lead to ischemia and possible necrosis of the digit. Use semicircular or spiral placement techniques if digits are to be taped.

Equipment

For simple tape closure, the equipment required includes forceps and tape of the proper size (see Fig. 35.1). Most taping can

Figure 35.1 Equipment required for the application of wound tape. Wound tape (3M Steri-Strip brand depicted here) comes in a variety of widths. The use of benzoin helps Steri-Strips stay in place longer.

Figure 35.3 After suturing this proximally based flap, Steri-Strips (3M) are applied under a tourniquet to compress the flap, arrest motion of the flap, and lessen buildup of fluid. Tissue movement and fluid buildup are some reasons why flaps and avulsed skin fail to heal. Tape should be placed in a semicircular or spiral pattern on digits to avoid constriction.

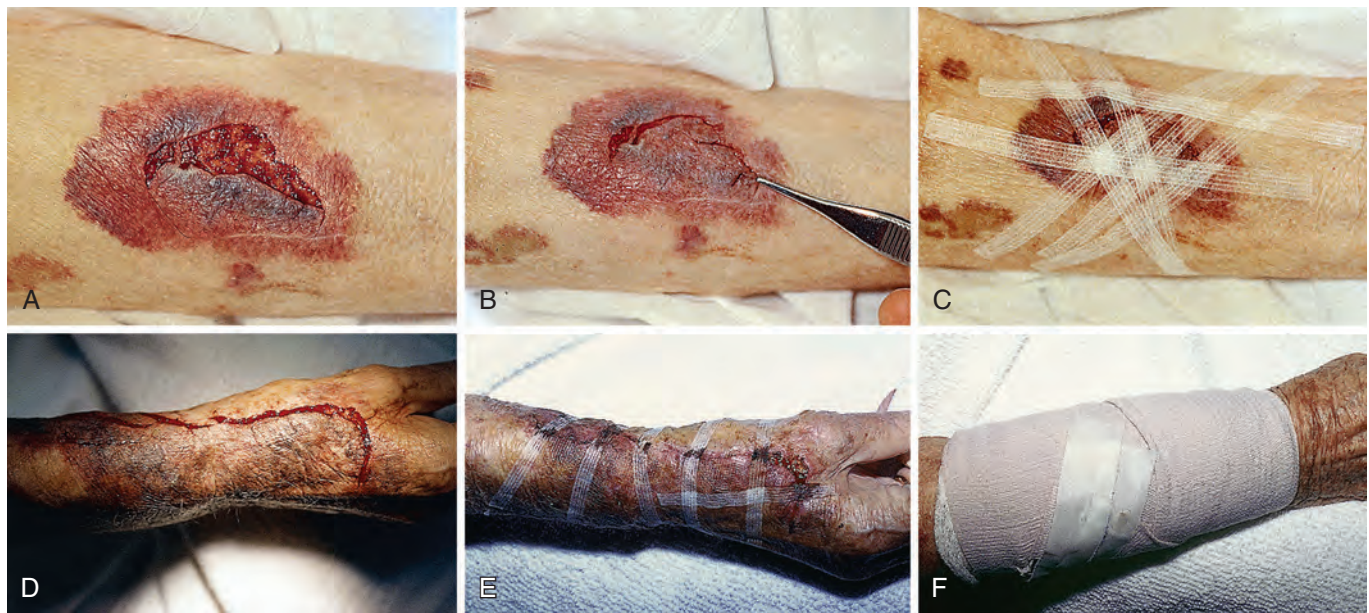

Figure 35.2 Wound tape in the care of avulsion injuries is preferred over sutures (see Fig. 35.5). A skin avulsion in the elderly following minor trauma is an ideal wound to repair with closure tape because such injuries cannot be closed with sutures. The goal is to provide approximation of the avulsed skin and apply pressure to avoid movement of the skin flap or accumulation of fluid under the avulsion. Tissue glue can augment this procedure. **A**, An elderly woman who was taking steroids had extremely thin skin and suffered a skin avulsion that could not be repaired with sutures. **B**, The skin edges are uncurled, stretched, and anatomically replaced. **C**, The wound should heal while closure tape keeps the skin in place. Tissue glue (Dermabond, Ethicon Inc.) was also dabbed on various parts of the edges to allow egress of fluid. **D**, Another elderly patient with a large avulsion injury on the forearm. **E**, Repair with Steri-Strips (3M) and skin glue. **F**, A compression dressing, such as an elastic bandage or a Dome paste (Unna boot) dressing, can be applied to minimize movement of the flap and decrease buildup of fluid under the flap.

be done in the ED with 1/4-inch × 3-inch strips. For wounds larger than 4 cm, however, 1/2-inch-wide strips provide greater strength. Most companies manufacture strips up to 1 inch wide and 4 inches long.

Procedure

Proper wound preparation, irrigation, débridement, and hemostasis must precede tape closure. Fine hair may be cut short. Dry the area of tape application thoroughly to ensure proper adhesion. Do not attempt to apply tape to a wet area or over a wound that is slowly oozing blood because it will usually result in failure of the tape to stick to the skin. On fingers, tape can be applied to a wound that is kept dry by temporarily placing a tourniquet at the base of the finger (see Fig. 35.3).

The technique of applying tape is shown in Fig. 35.4. After the wound has been dried, apply a liquid adhesive such as tincture of benzoin or Mastisol (Eloquest Healthcare Inc, Ferndale, MI) to the skin adjacent to the wound to increase adhesion of the tape.² All tape comes in presterilized packages. Open them directly onto the operating field. Handle tape with gloved hands. With the backing still attached, cut the tape to the desired length or long enough to allow approximately 2 to 3 cm of overlap on each side of the wound. After the end tab is removed, gently peel off the tape from its backing using forceps by pulling straight back. Do not pull to the side because the tape will curl and be difficult to apply to the wound. Place half of the tape securely on one side at the midportion of the wound. Gently but firmly appose the opposite wound edge to its counterpart. Apply the second half of the tape next. Hold the wound edges as close together as possible and at equal height to prevent the development of a linear, pitted scar. Apply additional tape by bisecting the remainder of the wound. Place a sufficient number of tape strips so that the wound is completely apposed without totally covering the entire length of the wound. An arrangement of tape strips parallel to each other and perpendicular to the wound provides good tape adherence over time.¹⁸ Finally, if using a woven tape, place additional cross strips to add support and prevent blistering caused by unsupported tape ends.¹ Cross strips are unnecessary when using nonwoven tape, such as Steri-Strip or Shur-Strip, because nonwoven tapes have sufficient ability to elongate, which also prevents blister formation.^{18,19} The use of cross strips with nonwoven tape actually decreases the longevity of tape adherence.¹⁸

Do not cover taped wounds with occlusive dressings. Adhesive bandages (e.g., Band-Aids) and other impermeable dressings promote excessive moisture, which can lead to premature separation of tape strips from the wound. An adhesive bandage may also adhere to the tapes and pull them off the skin during dressing changes. Keep the tape in place for approximately 2 weeks or longer, if necessary. Instruct the patient to clean the taped laceration gently with a slightly moist, soft cloth after 24 to 48 hours. However, emphasize that if excessive wetting or mechanical force is used, premature tape separation may result. Instruct patients to gently trim the curled edges of the closure tape with fine scissors to avoid premature loss of the tape.

Pretibial lacerations, particularly in the aged and in those with thin skin, may be challenging to manage. Some studies of pretibial lacerations suggest using wound tape alone.^{20,21} However, wounds in this location are under great tension, and

wound tape alone may be inadequate. Several studies have shown good results with a combination of tape and sutures.^{22–25} The approach by Silk²² showed improved healing time and decreased need for skin grafting (Fig. 35.5).²⁶ Steri-Strips are placed parallel to and 1 cm from the wound edges, and then 2–0 silk sutures are used to approximate the wound margins. For flap-type lacerations, an immobilizing suture placed in the middle of the flap would act much like a button, lessening the tension along the wound margins. Bain and coworkers advocate using tissue glue rather than tissue tape to support suture placement.²⁷

Complications

Complications are uncommon with tape closure. The wound infection rate in clean wounds closed with tape compares favorably with rates for other standard closures.¹ The cosmetic result of closure with wound tape is comparable to other closure methods.^{5,7–9} Premature tape separation occurs in approximately 3% of cases.¹⁶ Other complications include: (1) skin blistering, which occurs if the tape is stretched too tightly across the wound, and (2) wound hematoma, which can result if hemostasis is inadequate. Tape may loosen prematurely over shaved areas as hair grows back.

When tincture of benzoin is used, apply it carefully to the surrounding, uninjured skin. If spillage into the wound occurs, there is a higher risk for infection.²⁸ Benzoin vapor can cause pain when applied near an open wound that has not been anesthetized. Benzoin can also injure the conjunctival and corneal membranes of the eye.

Summary

Modern tape products and techniques serve a valuable role in the management of minor wounds in the ED. In selected wounds, tape closure is as successful as suture closure.^{1,29} Closure tape should be considered for superficial wounds in cosmetically unimportant areas and for wounds on relatively flat surfaces that are too wide for simple dressings but do not require sutures.

TISSUE ADHESIVE (TISSUE GLUE)

Tissue adhesive (also called *tissue glue*) provides a simple, rapid method of wound closure that is likely underused. Tissue adhesive has been approved for use in the United States since 1998. Two types of tissue adhesive are available: 2-octylcyanoacrylate (Dermabond, Ethicon, Inc.; derma+flex QS, Chemence Medical Products, Alpharetta, GA; SurgiSeal, Adhezion Biomedical, Hudson, NC) and *N*-butyl-2-cyanoacrylate (Indermil, Connexicon Medical Ltd., Dublin, Ireland; Histoacryl, TissueSeal LLC, Ann Arbor, MI). LiquiBand (Advanced Medical Solutions, Winsford, United Kingdom) is a blend of an octylcyanoacrylate and butylcyanoacrylate. Animal studies have shown octylcyanoacrylate-based adhesive to have significantly greater strength and flexibility than butylcyanoacrylate-based adhesive, and Dermabond Advanced has better viscosity, as well as strength and flexibility, among the products in this category.³⁰ Dermabond, like other tissue adhesives, is packaged in sterile, single-use ampules (Fig. 35.6 and Video 35.2). These bonding agents can be used on superficial wounds, even in hair-bearing areas. Tissue adhesives polymerize on contact with water. These

Wound Tape Application

1. After wound preparation (and placement of deep closures, if needed), dry the skin thoroughly at least 2 inches around the wound. Failure to dry the skin and failure to obtain perfect hemostasis are common causes of failure of tape to stick to the skin.

2. Apply a thin coating of tincture of benzoin around the wound to enhance tape adhesiveness. Benzoin should not enter the wound because it increases the risk of infection. Do not allow benzoin to enter the eye.

3. Cut the tape to the desired length before removing the backing.

4. The tape is attached to a card with perforated tabs on both ends. Gently peel the end tab from the tape.

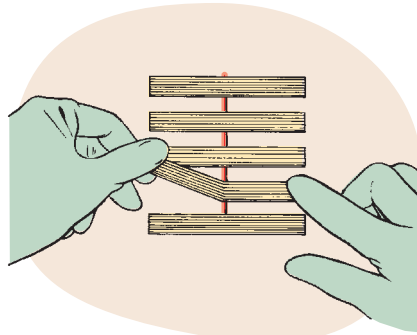

5. Use forceps to peel the tape off the card backing. Pull directly backward, not to the side.

6. Place half of the first tape at the midportion of the wound; secure firmly in place.

7. Gently but firmly appose the opposite side of the wound with the free hand or forceps. If an assistant is not available, the operator can approximate the wound edges. The tape should be applied by bisecting the wound until the wound is closed satisfactorily.

8. Wound margins are completely apposed without totally occluding the wound.

9. Only if using woven tape strips, additional supporting strips of tape are placed approximately 2.5 cm from the wound and parallel to the direction of the wound. Taping in this manner prevents the skin blistering that may occur at the ends of the tape.

Figure 35.4 Proper technique for the application of wound tape.

Figure 35.5 **A**, Strips of wound tape are placed parallel to the wound on both sides, approximately 1 cm from the wound margin. A strip of tape is also placed in the center of the thin flap. These strips will support the stitches and prevent them from tearing through the fragile tissue. **B**, A stitch is placed through the center strip of tape, tacking the flap to the base of the wound and reducing the tension along the wound margins. **C**, The needle is passed through the two strips that are parallel to the wound, and the knot is tied with minimal tension. **D**, Additional strips of tape are placed around the other two sides of the flap, which is sutured in place. (Modified from Silk J: A new approach to the management of pretibial lacerations, *Injury* 32:375, 2001.)

Figure 35.6 Tissue adhesive, 2-octylcyanoacrylate, comes in a variety of commercially available dispensers.

substances are biodegradable but remain in the wound until well after healing.^{31,32} Tissue adhesive has also been shown to be useful in closure of scalp lacerations using hair apposition techniques (see later section on [Scalp Lacerations](#)) and in both

repairing nail bed lacerations and securing the nail plate to the nail bed (see later section on [Nail Bed Lacerations](#)).

Procedure

Tissue adhesive can be used to approximate wounds that do not require deep-layer closure and do not have significant tension on the edges of the wound ([Fig. 35.7](#)). In preparation for closure, clean and anesthetize the wound. Débride the wound if necessary. It is especially important to control bleeding from the wound.

Hold the wound edges together with forceps, gauze pads, or fingers. Squeeze the small, cylindrical plastic container to expel droplets of tissue adhesive through the cotton-tipped applicator at the end of the container. Apply the adhesive in at least three to four thin layers along the length of the wound's surface, and extend it approximately 5 to 10 mm from each side of the wound. The purple color of the solution facilitates placement of the droplets. Support and hold the edges of the wound together for at least 1 minute while the adhesive dries. Low-viscosity tissue adhesives may seep into the wound or trickle off rounded surfaces during application. This tendency toward migration or “runoff” can be minimized by using high-viscosity adhesives³³ (e.g., Dermabond HV Topical Skin

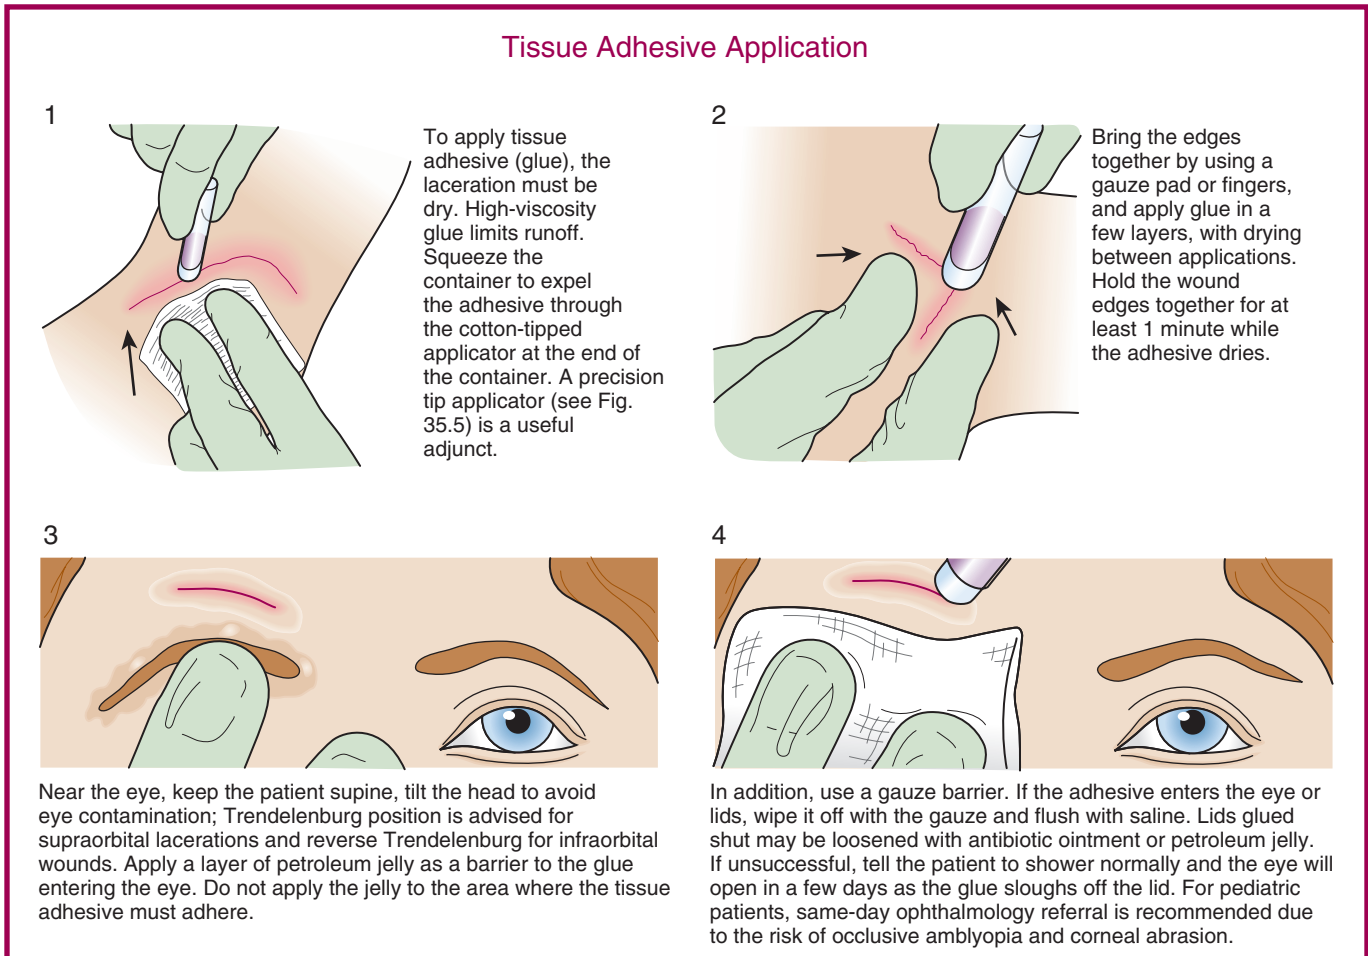

Figure 35.7 Application of tissue adhesive. Note: glue that touches a latex glove, gauze, or a plastic instrument (but not vinyl gloves or metal instruments) will cause them to stick to the patient.

Adhesive, Ethicon, Inc.), positioning the wound horizontally, or applying the adhesive slowly. Contain runoff with wet gauze or by creating a barrier of petrolatum.

Wound closures with tissue adhesive can be reinforced by pulling the edges of the wound into apposition with a few strips of porous surgical tape before application of the adhesive. Tissue adhesive can be placed on top of surgical tape, but tape should not be placed on top of dried tissue adhesive. Once the adhesive has dried completely, further protect the closure with a nonocclusive bandage.

Tissue adhesives can also be used to treat superficial skin tears that do not extend past the dermis. After the wound and skin flap are cleaned, lay the flap over the base of the wound and approximate the edges of the wound. Express any remaining blood and serum from under the flap, and ensure the entire area is dry. Apply a thin layer of adhesive over the wound margins and 1 to 2 cm beyond the margin. After the first layer dries, apply a second layer of adhesive. A dressing is not required unless there is a reason to protect the wound from repeated injury.^{34,35}

The primary advantage of tissue adhesive is the speed of closure. Wounds can be closed in as little as one-sixth the time required for repair with sutures. Application is rapid and painless. Use of tissue adhesive avoids suture marks adjacent to the wound and reduces the risk for needlestick injuries to

health care personnel. Wounds closed with tissue adhesive have less tensile strength in the first 4 days than do sutured wounds,^{36,37} but 1 week after closure, the tensile strength and overall degree of inflammation in wounds closed with tissue adhesive are equivalent to those closed with sutures.^{32,38,39} Cosmetic results are similar to those obtained with suture repair.^{37,40–46} Tissue adhesive serves as its own wound dressing and has an antimicrobial effect against gram-positive organisms.^{47,48} The material sloughs off in 5 to 10 days, thereby saving the patient from another visit to a clinician. Do not apply ointments or occlusive bandages on wounds closed with tissue adhesive.

Complications

Although tissue adhesive is classified as nontoxic, some authors warn against placing it within the wound cavity.^{37,38} However, various investigators have applied specially formulated octyl-2-octylcyanoacrylate (*liquid adhesive bandage*) directly to open minor lacerations, abrasions, and partial-thickness wounds. Though rare, exudates, pain, tenderness, swelling, and foreign body reactions have been reported after tissue adhesive has entered the wound.^{49,50} When compared with adhesive bandages, wounds covered with tissue adhesive had equivalent rates of healing and complications.^{51,52}

If hemostasis is inadequate or an excessive amount of adhesive is applied too quickly, the patient can experience a burning sensation or sustain a local burn from the heat of polymerization. After polymerizing, tissue adhesive can fracture with excessive or repetitive movement. Although gentle rinsing is permitted, if the adhesive is washed or soaked, it will peel off in a few days, before the wound is healed.^{37,53}

If the clinician's gloved fingers, gauze, or plastic instruments contact the tissue adhesive during application, the glove may adhere to the patient's skin. Tissue adhesive can be removed with antibiotic ointment or petrolatum jelly or more rapidly with acetone.⁴⁶ Indermil (Connexicon Medical) must be stored under refrigeration.

One risk involving the use of tissue adhesive is its ease of use; clinicians may fail to adequately clean wounds before closure with tissue adhesive.⁵⁴ It should not be used to close infected wounds. There is a slightly higher risk for wound dehiscence in closures with tissue glue than with sutures.^{55,56}

If the edges of the wound cannot be held together without considerable tension, tissue adhesive should not be used.⁴⁶ Percutaneous sutures provide a more secure immediate closure than tissue adhesive.³² It should also not be used over or near joints, on moist or mucosal surfaces, or on wounds under significant static or dynamic skin tension. See Fig. 35.7 for information on managing eyelids that are accidentally glued shut.

WOUND STAPLES

Background

Automatic stapling devices have become commonplace for closure of surgical incisions and traumatic wounds (Fig. 35.8). Clinical studies of patients with stapled surgical incisions have found no significant difference between stapling and suturing when infection rates, healing outcome, and patient acceptance are compared.^{57–61} Wound stapling (Video 35.3) and nylon suture closure of skin compared favorably in wound tensile strength, complication rates, patient tolerance, efficiency of closure, scar width, color, general appearance, suture or staple

marks, infection rates, and cost. In animal models, staples caused less wound inflammation and offered more resistance to infection with contaminated wounds.^{62–65}

The most significant advantage of wound stapling over suturing is speed of closure. The most significant downside is loss of the cosmetic effect that can be achieved with meticulous suture closure. On average, stapling is three to four times faster than suturing traumatic wounds.^{66–68} When clinician time and cost of instruments are considered, the difference in cost between stapling and suturing is either minimal⁶⁷ or favors stapling.^{66,69}

Indications and Contraindications

The indications for stapling are limited to relatively linear lacerations with straight, sharp edges located on an extremity, the trunk, or the scalp. Staples may be especially useful for superficial scalp lacerations in an agitated or intoxicated patient. Because of their superficial placement in the adult scalp (usually above the galea), staples are not recommended for deep scalp lacerations. Staples may not provide the same hemostasis that is possible with deep sutures. They should not be placed in scalp wounds if computed tomography head scans are to be performed because staples produce scan artifacts. Similarly, staples should not be used if the patient is expected to undergo magnetic resonance imaging because the powerful magnetic fields may avulse the staples from the surface of the skin. Staples should not be used on the face, neck, hands, or feet.

Equipment

Standard wound care should precede wound closure. In many cases, when débridement and dermal (deep) closure are unnecessary, only tissue forceps are needed to assist in everting wounds.

Many stapling devices are commercially available. The most versatile and least expensive is the Precise stapler (3M Corporation). Different units that hold between 5 and 25 staples can be purchased. The 10-staple unit will suffice for most lacerations. Other devices include the Proximate 11 (Ethicon, Inc.), Appose (Covidien, New Haven, CT), and Reflex One (ConMed, Utica, NY).

A novel device, the Insoorb (Incisive Surgical, Inc., Plymouth, MN) absorbable stapler, uses absorbable staples (made of polylactic and polyglycolic acids) placed intradermally. The device has shown both time and cost savings in repair of abdominal and breast surgical wounds comparable to intradermal sutures.^{70,71} The device is not widely available in the emergency setting.

Procedure

Before stapling, sometimes it is necessary to place deep, absorbable sutures to close deep fascia and reduce tension in the superficial fascia and dermal layers. To facilitate the stapling process, the edges of the wound should be everted, preferably by a second operator (Fig. 35.9, step 1). The assistant precedes the operator along the wound and everts the edges of the wound with forceps or pinches the skin with the thumb and forefinger. Stapling flattened wound edges may place the staple precisely but results in inversion of the wound. Once the edges are held in eversion, the staple points are gently placed across the wound. The center of the staple device should be placed over the center of the wound to ensure the best closure and

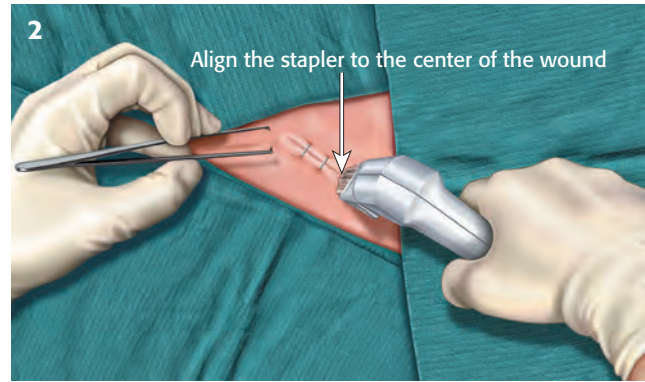

Figure 35.8 Skin stapling device. Skin staples may be used for relatively linear lacerations with straight, sharp edges on the extremity, trunk, or scalp. Their main advantage is speed of closure. Their main disadvantage is loss of the better cosmetic effect afforded by meticulous suture closure.

Wound Staples

1 Approximate and evert the skin edges by hand or with forceps before they are secured with staples. If possible, have an assistant perform this duty. Failure to evert the wound edges is a common error that may cause an unacceptable result.

2 Align the center of the stapler over the center of the wound. Squeeze the stapler handle to advance one staple into the wound margins. Do not press too hard on the skin to prevent placing the staple too deeply.

3 As the handle is squeezed, an anvil automatically bends the staple to the proper configuration.

4 Allow a small space to remain between the skin and the crossbar of the staple. Excessive pressure created by placing the staple too deep causes wound edge ischemia, as well as pain on removal. Note that the staple bar is 2 to 3 mm above the skin line.

5 Supply the patient with a staple remover when being referred to an office for removal or for self-removal. To remove the staple, place the lower jaw of the remover under the crossbar of the staple.

6 Squeeze the handle gently, and the upper jaw will compress the staple and allow it to exit the skin.

Figure 35.9 Wound staples. Failure to align the center of the staple device directly over the center of the laceration is a common cause of a less than ideal staple closure. (Steps 1 and 2, From Custalow C: *Color atlas of emergency department procedures*, Philadelphia, 2005, Elsevier; steps 3–6, from Edlich RF: *A manual for wound closure*, St. Paul, MN, 1979, 3M Medical-Surgical Products. Reproduced by permission.)

to avoid overriding or misaligned edges (which can be difficult in an uncooperative patient). When the stapler handle or trigger is squeezed, the staple is advanced automatically into the wound and bent to the proper configuration (see Fig. 35.9, steps 2 and 3). The operator should not press too hard on the skin surface to prevent placing the staple too deeply and causing ischemia within the staple loop. When placed properly, the crossbar of the staple is elevated a few millimeters above the surface of the skin (see Fig. 35.9, step 4). A sufficient number of staples should be placed to provide proper apposition of the edges of the wound along its entire length. (One suggested method is to place a staple in the midpoint of the length of the wound and then bisect either side of the wound with additional staples. Continue the process until the edges of the wound are well opposed.) After the wound is stapled, an antibiotic ointment may be applied. Stapled wounds may be left uncovered, or a sterile dressing may be applied. The patient can remove the dressing and gently clean the wound in 24 to 48 hours. Scalp lacerations can be cleaned by showering within a few hours.

Removal of staples requires a special instrument made available by each manufacturer of stapling devices. The lower jaw of the staple remover is placed under the crossbar, and the handle is squeezed (see Fig. 35.9, steps 5 and 6). This action compresses the crossbar and bends the staple outward, thereby releasing the points of the staple from the skin. Many primary

care physicians do not routinely stock the instrument. If referred to a primary care physician's office for removal of staples, the patient can be given a disposable staple removal device to bring with them. If well-instructed, patients can remove their own staples with the removal device. The interval between staple application and removal is the same as that for standard suture placement and removal. Staples can cause significant scarring if left in place too long (Fig. 35.10).

Complications

Patient acceptance, comfort, and rates of wound infection and dehiscence are similar with staple-closed wounds and sutured wounds. However, removal of staples can be somewhat more uncomfortable than removal of sutures.

A common error during insertion of staples is failure to evert the edges of the skin before stapling (see Fig. 35.10). Eversion avoids the natural tendency of the device to invert the closure. Eversion may be accomplished with forceps or by pinching the skin with the thumb and index finger, a procedure that requires some practice. Another common error is to fail to align the middle of the staple exactly in the midline of the wound.

Staples will cause marks in the skin that are similar to sutures. However, in patients who tend to scar more easily, the scar

Figure 35.10 **A**, A very poor result occurred when staples (some marked with *arrows*) were used to close this deep scalp laceration. The edges of the wound were not everted, staples were not in the midline, sections of the skin overlapped significantly, poor hemostasis was obtained, and the galea could not be closed by the superficial staples. The patient did not wash his hair as instructed. **B**, Three days later during inspection of the wound, the staples were removed and **C**, the laceration was closed with 3-0 interrupted nylon sutures. The clinician should attempt to obtain a cosmetic closure on all scalp lacerations because as patients lose their hair, a previously hidden, unsightly scar emerges. In general, staples should not be used to close full-thickness scalp lacerations, especially wounds that are actively bleeding. **D**, Sloppy stapling on an extremity with inversion rather than eversion of the edges of the wound. Some staples are totally misaligned and barely include the opposite skin edge. **E**, The staples were left in too long, which caused a poor cosmetic result.

resulting from staples may be more pronounced than that produced by sutures, especially if the staples are left in place for prolonged periods.

Wound stapling achieves results that are generally comparable to those of sutures for the closure of traumatic, linear lacerations in noncosmetic areas, such as the scalp, trunk, and extremities. Stapling is much faster than suturing. Wound stapling does not differ significantly from suturing in terms of cost, infection rates, wound healing, and patient acceptance, but cosmesis may suffer, especially if the staples are left in too long (see Fig. 35.10D and E).

SUTURES

In the United States, most traumatic wounds are closed by suturing.

Equipment

Instruments

In addition to the instruments used for débridement, a needle holder and suture scissors are required for suturing (Fig. 35.11). The mechanical performance of disposable needle holders distributed by different surgical instrument companies varies considerably.⁷² The size of the needle holder should match the size of the needle selected for suturing; the needle holder should be large enough to hold the needle securely as it is passed through tissue, yet not so large that the needle is crushed or bent by the instrument.

Instruments used to debride a grossly contaminated wound should be discarded and replaced with fresh instruments for closure. Instruments covered with coagulated blood can be cleansed with hydrogen peroxide, rinsed with sterile saline or water, and then used for suturing.

In addition, 2.5 loupe magnification may improve inspection of wounds and facilitate the repair of facial and hand wounds.⁷³

Suture Material

A wide variety of suture material is available to satisfy clinician preferences (Fig. 35.12). There are no definitive standards on which to base the use of suture material for a particular wound or site. For most wounds that require closure of more than

one layer of tissue, the clinician must choose sutures from two general categories: an absorbable suture for the deeper, subcutaneous (SQ) layer and a nonabsorbable suture for surface (percutaneous) closure.

Sutures can be described in terms of four characteristics:

1. Composition (i.e., chemical and physical properties).
2. Handling characteristics and mechanical performance.
3. Absorption and reactivity.
4. Size and retention of tensile strength.

Composition

Sutures are made from natural fibers (cotton, silk), from sheep submucosa or beef serosa (plain gut, chromic gut), or from synthetic material such as nylon (Dermalon [Medtronic, Minneapolis, MN], Ethilon [Ethicon Inc.], Nurolon [Ethicon Inc.], Surgilon [Medtronic]), Dacron (Ethiflex, Mersilene [both Ethicon Inc.]), polyester (Ti-Cron [Medtronic]), polyethylene (Ethibond [Ethicon Inc.]), polypropylene (Prolene [Ethicon Inc.], Surgipro [Medtronic]), polyglycolic acid (Dexon [Medtronic]), and polyglactin (Vicryl, coated Vicryl, Vicryl Rapide [all Ethicon Inc.]). Stainless steel sutures are rarely, if ever useful in wound closure in the ED setting because of handling difficulty and fragmentation. Some sutures are made of a single filament (monofilament); others consist of multiple fibers braided together (Table 35.1).⁷⁴

Handling and Performance

Desirable handling characteristics in a suture include smooth passage through tissue, ease in knot tying, and stability of the knot once tied (Table 35.2). Smooth sutures pull through tissue easily, but knots slip more readily. Conversely, sutures with a high coefficient of friction have better knot-holding capacity but are difficult to slide through tissue. Smooth sutures will loosen after the first throw of a knot is made, and thus a second throw is needed to secure the first in place. Rougher, multifilament types of suture make it more difficult to tighten a knot further after the first throw is made.

Multifilament sutures have the best handling characteristics of all sutures, whereas steel sutures have the worst. In terms of performance and handling, significant improvements have been made in the newer absorbable sutures. Gut sutures have

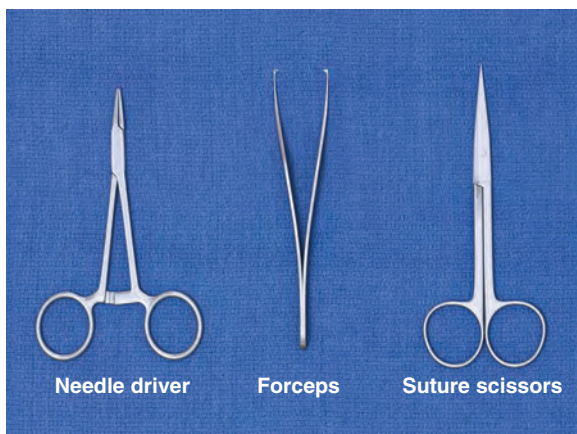

Figure 35.11 Basic suturing equipment includes a needle driver, forceps, and suture scissors.

Figure 35.12 A wide variety of both absorbable and nonabsorbable suture material is available. Other variables include suture size (e.g., 4-0, 5-0, 6-0), and type (e.g., PS-2, reverse cutting, conventional cutting). These variables are discussed in detail in the text.

TABLE 35.1 Commonly Available Suture Material

ABSORBABLE SUTURE		NONABSORBABLE SUTURE

many shortcomings, including relatively low and variable strength, a tendency to fray when handled, and stiffness despite being packaged in a softening fluid.^{75,76} Multifilament synthetic absorbable sutures are soft and easy to tie and have few problems with knot slippage. Polyglactin 910 (coated Vicryl, Ethicon Inc.) sutures have an absorbable lubricant coating. The frictional drag of these coated sutures as they are pulled through tissue is less than that of uncoated multifilament materials, and resetting of knots after the initial throw is much easier. This characteristic allows retightening of a ligature without knotting or breakage and with smooth, even adjustment of suture line tension in running subcuticular stitches.⁷⁷ Synthetic monofilament sutures have the troublesome property of “memory”: a tendency of the filament to spring back to its original shape, which causes the knot to slip and unravel. Some nonabsorbable monofilament sutures are coated with polytetrafluoroethylene (Teflon) or silicone to reduce their friction. This coating improves the handling characteristics of these monofilaments but results in poorer knot security.⁶⁶

Three square knots will secure a stitch made with silk or other braided, nonabsorbable material, and four knots are sufficient for synthetic, absorbable, and nonabsorbable monofilament sutures.⁷⁸ Five knots are needed for the Teflon-coated synthetic Tevdek (Teleflex, Morrisville, NC).⁷⁹ When coated synthetic suture material is used, attention to basic principles of knot tying is even more important. An excessive number of throws in a knot weakens the suture at the knot. If the

clinician uses square knots (or a surgeon's knot on the initial throw, followed by square knots) that lie down flat and are tied securely, knots will rarely unravel.⁸⁰

Absorption and Reactivity

Sutures that are rapidly degraded in tissue are termed absorbable; those that maintain their tensile strength for longer than 60 days are considered nonabsorbable (see Table 35.1). Plain gut may be digested by white blood cell lysozymes in 10 to 40 days; chromic gut will last 15 to 60 days. Remnants of both types of suture, however, have been seen in wounds more than 2 years after placement.^{75,78,81} Ethicon catgut is rapidly absorbed within 10 to 14 days and is associated with less inflammation than chromic catgut.⁸² Polydioxanone (PDS; Ethicon) and Vicryl produce less tissue reaction and erythema than polypropylene.⁸³ Vicryl is absorbed from the wound site within 60 to 90 days^{75,78} and Dexon (Medtronic), within 120 to 210 days.^{84,85} When placed in the oral cavity, plain gut disappears after 3 to 5 days, chromic gut after 7 to 10 days, and Dexon after 16 to 20 days.⁸⁶ When used on the skin surface, fast absorbing catgut disappears in 9 to 13 days.⁸⁷ In contrast, SQ silk may not be completely absorbed for as long as 2 years.⁷⁸ The rate of absorption of synthetic absorbable sutures is independent of suture size.⁸⁴

Sutures may lose strength and function before they are completely absorbed in tissues. Braided synthetic absorbable sutures lose nearly all their strength after approximately 21 days. In contrast, monofilament absorbable sutures (modified polyglycolic acid [Maxon, Davis & Geck] and PDS) retain 60% of their strength after 28 days.^{88,89} Gut sutures treated with chromium salts (chromic gut) have prolonged tensile strength; however, all gut sutures retain tensile strength erratically.^{75,78} Of the absorbable types of suture, a wet and knotted polyglycolic acid suture is stronger than a plain or chromic gut suture subjected to the same conditions.^{76,90}

Polypropylene remains unchanged in tissue for longer than 2 years after implantation.⁹¹ In comparison testing, sutures made of natural fibers such as silk, cotton, and gut were the weakest; sutures made of Dacron, nylon, polyethylene, and polypropylene were intermediate in tensile strength; and metallic sutures were the strongest.⁷⁶ Comparison of suture strength versus wound strength is a measure of the usefulness of a suture. Catgut is stronger than the soft tissue of a wound for no more than 7 days; chromic catgut, Dexon, and Vicryl are stronger for 10 to 21 days; and nylon, wire, and silk are stronger for 20 to 30 days.⁹²

All sutures placed within tissue will damage host defenses and provoke inflammation. Even the least reactive suture impairs the ability of the wound to resist infection.⁹¹ The magnitude of the reaction provoked by a suture is related to the quantity of suture material (diameter \times total length) placed in the tissue and to the chemical composition of the suture. Among absorbable sutures, polyglycolic acid and polyglactin sutures are the least reactive, followed by chromic gut. Nonabsorbable polypropylene is less reactive than nylon or Dacron.^{76,93,94} Significant tissue reaction is associated with catgut, silk, and cotton sutures. Absorbable polyglycolic acid sutures are less reactive than those made of nonabsorbable silk.⁹⁵ Highly reactive material should be avoided in contaminated wounds.

The chemical composition of sutures is a factor in early infection. The infection rate in experimentally contaminated wounds closed with polyglycolic acid sutures is lower than the rate when gut sutures are used.⁹¹ However, other authors have

compared plain gut and nonabsorbable nylon sutures for skin closure in children and found comparable cosmetic results and infection rates.⁹⁶

Lubricant coatings on sutures do not alter suture reactivity, absorption characteristics, breaking strength, or the risk for infection.^{77,91} Multifilament sutures provoke more inflammation and are more likely than monofilament sutures to produce infection if left in place for prolonged periods.^{97,98} Monofilament sutures elicit less tissue reaction than do multifilament sutures, and multifilament materials tend to wick up fluid by capillary action. Bacteria that adhere to and colonize sutures can envelop themselves in a glycocalyx that protects them from host defenses,⁹⁹ or they can "hide" in the interstices of a multifilament suture and, as a result, be inaccessible to leukocytes.⁹⁷ PDS provides the advantages of a monofilament suture in an absorbable form, thus making it a good choice as a subcuticular stitch. Vicryl Plus and Monocryl (Ethicon Inc.) have been found to have less bacterial adherence when compared to Vicryl, making these two materials reasonable choices for subcuticular closure in contaminated wounds.¹⁰⁰ Polypropylene sutures have a low coefficient of friction and subcuticular stitches with this material are easy to pull out.¹⁰¹

Size and Strength

The size of suture material (thread diameter) is related to the tensile strength of the suture; threads with greater diameter are stronger. The strength of the suture is proportional to the square of the diameter of the thread. Therefore a 4-0 suture of any type is larger and stronger than a 6-0 suture. The correct suture size for approximation of a layer of tissue depends on the tensile strength of that tissue. The tensile strength of the suture material should be only slightly greater than that of the tissue because the magnitude of damage to local tissue defenses is proportional to the amount of suture material placed in the wound.^{78,102}

Synthetic absorbable sutures have made the older, natural suture material unnecessary for most wound closures. Polyglycolic acid (Dexon) and polyglactin 910 (coated Vicryl) have improved handling characteristics, knot security, and tensile strength. Their absorption rates are predictable, and tissue reactivity is minimal.^{103,104} The distinct advantages of synthetic nonabsorbable sutures over silk sutures are their greater tensile strength, low coefficient of friction, and minimal tissue reactivity.^{91,103} They are extensible and elongate without breaking as the edges of the wound swell in the early postoperative period.^{102,103} In contrast to silk sutures, synthetics can easily and painlessly be removed once the wound has healed. The monofilament synthetic suture Novafil (Medtronic) has elasticity that allows a stitch to enlarge with wound edema and to return to its original length once the edema subsides. Stiffer materials lacerate the encircled tissue as the wound swells.¹⁰⁵

The suture material most useful to emergency clinicians for wound closure is coated Vicryl for SQ layers and synthetic nonabsorbable suture (e.g., nylon or polypropylene) for skin closure.¹⁰⁶ Fascia can be sutured with either absorbable or nonabsorbable material. In most situations, 3-0 or 4-0 suture is used for the repair of fascia, 4-0 or 5-0 absorbable suture for SQ closure, and 4-0 or 5-0 nonabsorbable suture for skin closure. The lips, eyelids, and skin layer of facial wounds are repaired with 6-0 suture, whereas 3-0 or 4-0 suture is used when the edges of the skin are subjected to considerable dynamic stress (e.g., wounds overlying joint surfaces) or static stress (e.g., scalp).

Absorbable sutures have been used as an alternative to nonabsorbable sutures for simple skin closure with similar cosmetic results and infection rates in both adult and pediatric lacerations.^{96,107-111} Sutures that were evaluated include fast-absorbing gut, Vicryl Rapide, and Monocryl. Absorbable suture used for skin closure obviates the need for suture removal, and thus may be particularly advantageous in children. Still, some authors advise usual patient follow-up for skin closed with nonabsorbable sutures to remove any remaining suture material and to evaluate for complications.^{107,108}

Needles

The eyeless, or “swaged,” needle is used for wound closure in most emergency centers (Fig. 35.13). Selection of the appropriate needle size and curvature is based on the dimensions of the wound and the characteristics of the tissue to be sutured. The needle should be large enough to pass through tissue to the desired depth and then to exit the tissue or skin surface far enough that the needle holder can be repositioned on the distal end of the needle at a safe distance from the tip of the needle (Fig. 35.14). Although it is tempting to use the fingers to grasp the tip of the needle to pull it through the skin, this practice risks a needlestick. The clinician should either reposition the needle holder or use forceps to disengage the needle from the laceration.

In wound repair, needles must penetrate tough, fibrous tissue (skin, SQ tissue, and fascia) yet should slice through this tissue with minimal resistance or trauma and without bending. The type of needle best suited for closure of SQ tissue is a conventional cutting needle in a three-eighths or one-half circle

Figure 35.13 The eyeless, or “swaged,” needle. (From *Suture use manual: use and handling of sutures and needles*, Somerville, NJ, 1977, Ethicon, Inc., p 29. Reproduced by permission.)

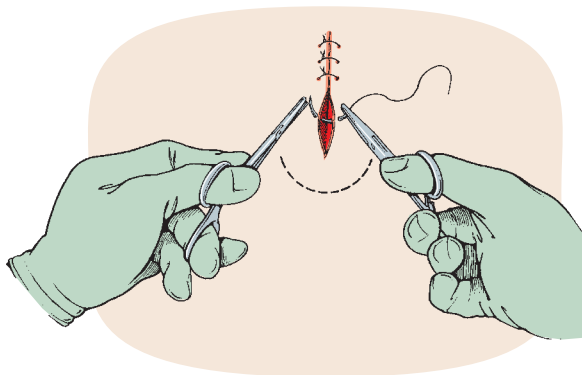

Figure 35.14 The needle should be large enough to pass through tissue and should exit far enough to enable the needle holder to be repositioned on the end of the needle at a safe distance from the point.

(Fig. 35.15). Double-curvature needles (coated Vicryl with PS-4-C cutting needles, Ethicon) may be easier to maneuver in narrow, deep wounds. For surface closure, a conventional cutting-edge needle permits more precise needle placement and requires less penetration force (Fig. 35.16).^{112,113}

Suturing Techniques (Figs. 35.17 and 35.18)

Skin Preparation

Before suturing, the clinician should ensure adequate exposure and illumination of the wound, and placement of the patient at the appropriate height. The clinician should assume a comfortable standing or sitting position at one end of the long axis of the wound.

The skin surrounding the wound is prepared with a povidone-iodine solution and covered with sterile drapes. A clear plastic drape (Steri-Drape, 3M Corporation) can be used to provide a sterile field and a limited view of the area surrounding the wound. Some surgeons do not drape the face but prefer to leave the facial structures and landmarks adjacent to the wound uncovered and within view. If no drapes are used on the face, the skin surrounding the wound should be widely cleansed and prepared. Wrapping the hair in a sheet or placing the patient's hair in an oversized scrub hat prevents stray hair from falling into the operating field. For a finger laceration, a sterile glove can be placed on the patient's hand to avoid using a drape.

Closure Principles

There is a tendency to overuse sutures for minor lacerations that will heal nicely with no intervention. Therefore, before suturing, one must assess the need for the procedure (Fig. 35.19).

Figure 35.15 One-half and three-eighths circle needles, used for most traumatic wound closures.

Figure 35.16 Types of needles. **A**, The conventional cutting needle has two opposing cutting edges and a third edge on the inside curvature of the needle. The conventional cutting needle changes in cross section from a triangular cutting tip to a flattened body. **B**, The reverse cutting needle is used to cut through tough, difficult-to-penetrate tissue such as fascia and skin. It has two opposing cutting edges and a third cutting edge on the outer curvature of the needle. The reverse cutting needle is made with a triangular shape extending from the point to the swage area, with only the edges near the tip being sharpened. (From *Suture use manual. use and handling of sutures and needles*, Somerville, NJ, 1977, Ethicon, Inc., p 31. Reproduced by permission.)

General Suturing Technique

1 Cleanse the skin surrounding the wound with an antiseptic such as chlorhexidine or povidone-iodine. Avoid introducing antiseptic into the wound because it may be toxic to tissue.

2 Anesthetize the wound prior to exploration and irrigation. Introduce the needle through the wound (as opposed to through the epidermis).

3 Explore the wound to exclude the presence of foreign bodies, gross contamination, or injuries to deep structures. Débride grossly contaminated or devitalized tissue.

4 Irrigate the wound thoroughly until it is visibly clean. Use of a large syringe with a splash guard is ideal. Retract the wound edges with an instrument to facilitate thorough irrigation.

5 Apply a sterile drape, gather the instruments, and ensure that the field is appropriately lit.

6 Place the first suture at the center of the wound so that it bisects the laceration into two equal segments.

7 Tie the knot. The first throw should be a double throw (i.e., surgeon's knot) to prevent it from loosening. Place an additional three (single) throws and then cut the sutures while leaving 1- to 2-cm tails.

8 Continue to place additional sutures by further bisecting each segment of the laceration. After the last stitch has been placed, cleanse the area and apply an appropriate dressing.

Figure 35.17 General suturing technique.

Instrument Tie

1 Place the needle driver parallel to the wound and wrap the suture end twice over the needle driver. This forms the surgeon's knot, which prevents the first throw from loosening.

2 Rotate the needle driver 90 degrees and grasp the short suture end on the opposite side of the laceration.

3 Gently pull the suture ends to the side of the laceration opposite their origin. Tighten only enough to approximate the skin edges; avoid overtightening, which may lead to tissue strangulation.

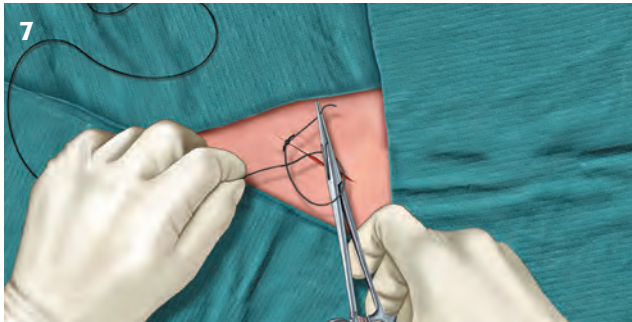

4 To begin the second throw, again place the needle driver parallel to the laceration. Wrap the long suture end over and around the needle driver once. (Only one wrap is used on throws 2 to 4.)

5 Rotate the needle driver 90 degrees and grasp the short suture end on the opposite side of the laceration.

6 Pull the suture ends to the side of the laceration opposite their origin. On the second and subsequent throws, you can tighten the knot down snugly.

7 Place an additional two throws (for a total of four), as depicted in steps 4 through 6. Remember to place the needle driver parallel to the wound and pull the long suture end *over* the driver; this will ensure that all knots tied are square knots.

8 After the last throw, cut the ends of the suture while leaving 1- to 2-cm tails. Avoid cutting the ends too short, which may lead to knot unraveling or difficulty during suture removal.

Figure 35.18 Instrument tie. (From Custalow C: *Color atlas of emergency department procedures*, Philadelphia, 2005, Elsevier.)

Figure 35.19 Not all wounds require suturing. **A**, This child sustained a superficial forehead laceration just through the epidermis. The swelling accentuated the defect. Treatment was simply keeping the laceration clean. **B**, Four months after the injury, an excellent result was achieved. As the laceration was healing, it became red and more noticeable (as do all scars), but eventually faded.

Three principles apply to suturing lacerations in any location: (1) minimize trauma to tissues, (2) relieve tension exerted on the edges of the wound by undermining and layered wound closure, and (3) accurately realign landmarks and skin edges by layered closure and precise suture placement.

Minimizing Tissue Trauma

The importance of carefully handling tissue has been emphasized since the early days of surgery. Skin and SQ tissue that has been stretched, twisted, or crushed by an instrument or strangled by a suture that is tied too tightly may undergo necrosis, and increased scarring and infection may result. When the edges of a wound must be manipulated, the SQ tissues should be lifted gently with toothed forceps or a skin hook while avoiding the surface of the skin.

When choosing suture size, the clinician should select the smallest size that will hold the tissues in place. Skin stitches should incorporate no more tissue than is needed to coapt the wound edges with little or no tension. Knots should be tied securely enough to approximate the edges of the wound without blanching or indenting the skin surface.¹¹⁴

Relieving Tension

Many forces can produce tension on the suture line of a reapproximated wound. Static skin forces that stretch the skin over

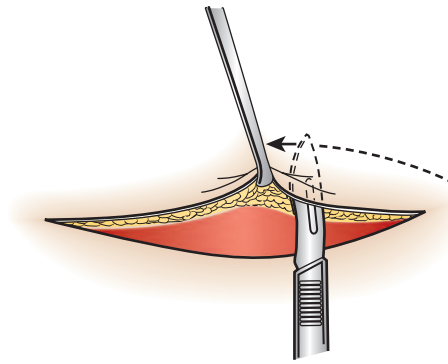

Figure 35.20 The technique of undermining can markedly improve cosmetic results by relieving wound tension. The scalpel is used to find an appropriate site; a natural plane often exists at the junction of the epidermis and dermis.

bones cause the edges of a new wound to gape, and they also continuously pull on the edges of the wound once it has been closed. Traumatic loss of tissue or wide excision of a wound may have the same effect. The best cosmetic result occurs when the long axis of a wound happens to be parallel to the direction of maximal skin tension; such alignment brings the edges of the wound together.¹⁰⁵

Muscles pulling at right angles to the axis of the wound impose dynamic stress. Swelling after an injury creates additional tension within the circle of each suture.¹¹⁴ Skin suture marks result not only from tying sutures too tightly but also from failing to eliminate any underlying forces distorting the wound. Tension can be reduced during wound closure in two ways: undermining of the wound edges and layered closure.

Undermining. The force required to reapproximate the edges of a wound correlates with the subsequent width of the scar.¹¹⁵ Wounds subject to significant static tension require the undermining of at least one tissue plane on both sides of the wound to achieve a tension-free closure. To undermine a wound, the clinician frees a flap of tissue from its base at a distance from the edge of the wound approximately equal to the width of the gap that the laceration presents at its widest point (Fig. 35.20).

The depth of the incision can be modified, depending on the orientation of the laceration to skin tension lines and the laxity of skin in the area. A No. 15 scalpel blade held parallel to the surface of the skin is used to incise the adipose layer or the dermal layer of the wound. The clinician can also accomplish this technique by spreading scissors in the appropriate tissue plane. Undermining allows the edges of the skin to be lifted and brought together with gentle traction.¹¹⁶ Potential complications of this procedure include injury to cutaneous nerves and creation of a hematoma under the flap. Because undermining may harm the underlying blood supply, this technique should be reserved for relatively uncontaminated wounds when no other methods adequately relieve wound tension.¹¹²

Layered Closure. The structure of skin and soft tissue varies with the location on the body (Fig. 35.21). Most wounds handled in an ED require approximation of no more than three basic layers: fascia (and associated muscle), SQ tissue, and skin surface (papillary layer of the dermis and epidermis).¹¹⁷ Any “dead space” (or unapposed edges) within a wound may

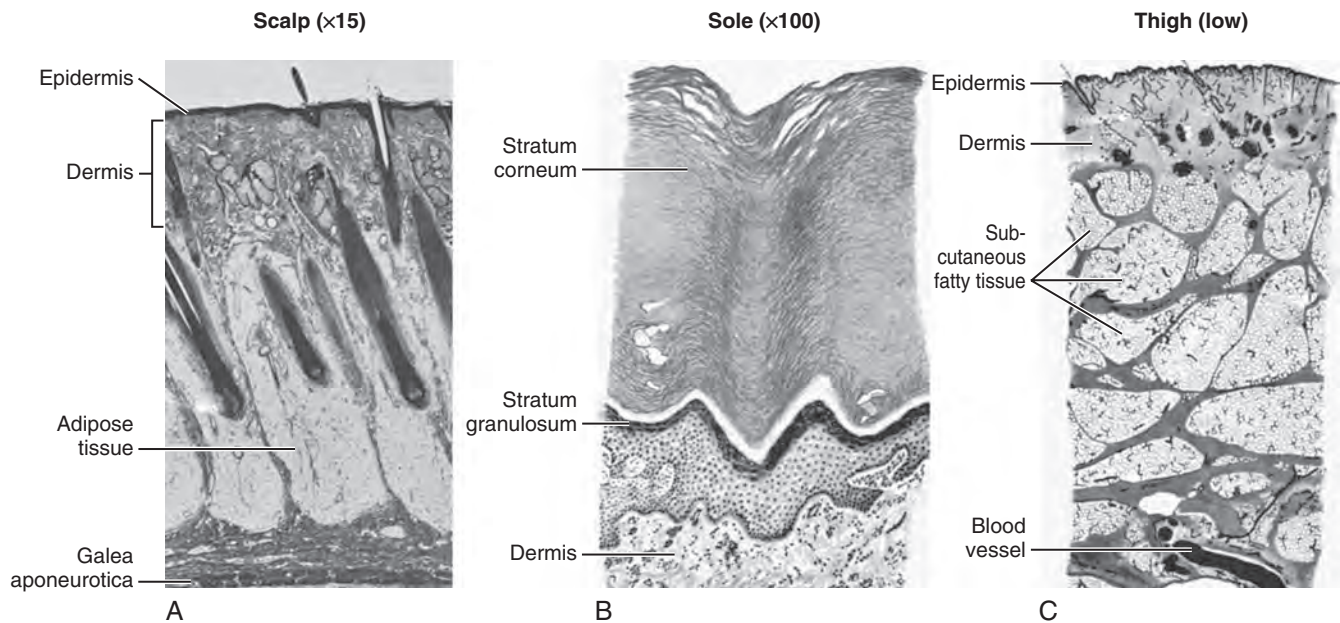

Figure 35.21 Variation in the structure of skin. **A**, Section of the skin of the scalp, $\times 15$. **B**, Section of human sole perpendicular to the free surface, $\times 100$ (after Maximow AA.) **C**, Section through human thigh perpendicular to the surface of the skin (after Maximow AA.) Blood vessels are injected and appear black (low magnification). (**A**, Courtesy H. Mizoguchi; **B** and **C**, From Bloom W, Fawcett DW: *A textbook of histology*, ed 10, Philadelphia, 1975, Saunders. Reproduced by permission.)

Figure 35.22 Note how a subcutaneous suture almost closes the wound with minimal tension on the edges of the skin while obliterating any subcutaneous space. Tie and bury the knot by pulling the sutures in the long axis of the wound as shown.

fill with blood or exudate and enhance the development of infection. Closure of individual layers obliterates this dead space (Fig. 35.22).

Approximation of a lacerated muscle hastens healing and return of function to the muscle. However, the fascia, not muscle, should be sutured. Muscle tissue itself is too friable to hold a suture. Layered closure is particularly important in the management of facial wounds; this technique prevents scarring of muscle to the SQ tissue and consequent deformation of the surface of the wound with contraction of the muscle.

If a deep, gaping wound is closed without approximation of underlying SQ tissue, a disfiguring depression may develop at the site of the wound. Finally, layered closure provides support to the wound and considerably reduces tension at the skin surface.

Several exceptions exist to the general rule of multilayered closure. The adipose layer of soft tissue should not be closed separately. A “fat stitch” is not necessary because little support is provided by closure of the adipose layer and additional suture material may increase the possibility of infection.^{2,118}

Scalp wounds are generally closed in a single layer. For lacerations penetrating the dermis in the fingers, hands, toes, and feet and the sebaceous skin of the nasal tip, the amount of SQ tissue is too small to warrant layered closure; in fact, SQ stitches may leave tender nodules in these sensitive locations. Layered closure is not recommended for wounds without tension, those with poor vascularity, and those with a moderate or high risk for infection. With single-layer closure, the surface stitch should be placed more deeply.⁹²

Suture Placement

SQ Layer Closure

Once the wound has been assessed and appropriately managed for fascial reapproximation, the SQ layer should be addressed (Video 35.4). Although histologically the fatty and fibrous SQ tissue (hypodermis) is an extension of (and continuous with) the reticular layer of the dermis,¹¹⁹ suturing these layers is traditionally referred to as an *SQ closure*. One approach is to close the length of this layer in segments by placing the first stitch in the middle of the wound and bisecting each subsequent segment until closure of the layer has been completed.⁷⁴ This technique is useful for the closure of wounds that are long or sinuous, and it is particularly effective for wounds with one elliptical and one linear side. The needle is grasped with the

tip of the needle holder perpendicular to the needle. This angle provides the most stable grip on the needle. In some cases, however, SQ sutures may be easier to place if the needle is loaded at a 135-degree angle between the long axis of the needle and the needle driver (Fig. 35.23).¹²⁰

Figure 35.23 A simple modification to the angle of the needle may make subcutaneous suturing easier. **A**, In most situations, the needle should be loaded perpendicular to the needle driver. **B**, If the wound is narrow, the needle can be grasped at a slightly obtuse, 135-degree angle to the needle driver. (Modified from Ahmed AM, Orengo I: Surgical Pearl: alternate method of loading needle to facilitate subcuticular suturing, *J Am Acad Dermatol* 56:S105, 2007.)

Some clinicians can suture more rapidly if the fingers are placed on the midshaft of the needle holder rather than in the rings of the instrument (Fig. 35.24). The suture enters the SQ layer at the bottom of the wound (Fig. 35.25A) or, if the wound has been undermined, at the base of the flap (see Fig. 35.25B) and exits in the dermis. Once the suture has been placed on one side of the wound, it can be pulled across the wound to the opposite side (or the edges of the wound pushed together) to determine the matching point on the opposite side. The needle is then advanced into this point. The needle should enter the dermis at the same depth as it exited from the opposite side, pass through the tissue, and exit at the bottom of the wound (or the base of the flap). The edges of the wound can be closely apposed by pulling the two tails of the suture in the same direction along the axis of the wound (see Fig. 35.25C). Some clinicians place their SQ stitch obliquely rather than vertically to facilitate knot tying. When the knot in this SQ stitch is tied, it will remain inverted, or “buried,” at the bottom of the wound. Burying the knot of the SQ stitch avoids a painful, palpable nodule beneath the epidermis and keeps the bulk of this foreign material away from the surface of the skin. Most emergency clinicians construct knots with the instrument tie technique (see Fig. 35.18). Hand and instrument knot-tying techniques are described and illustrated in wound care texts.^{121,122}

Once the knot has been secured, pull the tails of the suture taut for cutting. Hold the scissors with the index finger on the junction of the two blades. Slide the blade of the scissors down the tail of the suture until the knot is reached. With the cutting edge of the blade tilted away from the knot, cut the tails. This technique prevents the scissors from cutting the knot itself and leaves a 3-mm tail, which protects the knot from unraveling.¹²³ Suture the entire SQ layer in this manner.

After the SQ layer has been closed, the distance between the skin edges determines the approximate width of the scar in its final form. If this width is acceptable, insert surface sutures.¹²⁴ Despite undermining and placement of a sufficient number of SQ sutures, on occasion a large gap between the edges of the wound may persist. In such cases, use a horizontal dermal stitch to bridge this gap (see Fig. 35.31).

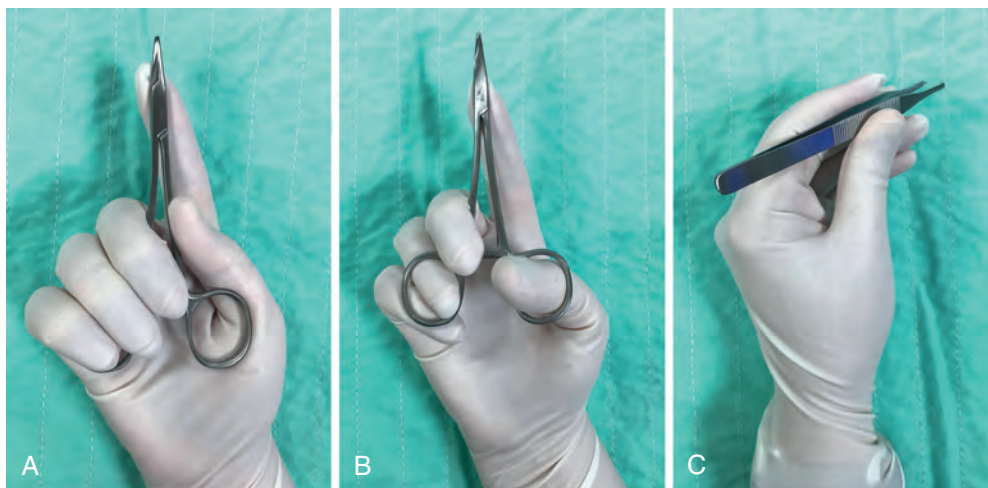

Figure 35.24 **A**, Thenar grip technique of handling the needle holder. The index finger is placed on the side of the needle holder, where it guides placement of the needle. Neither the index nor the middle finger is placed in the ringlet hole. This method allows more rapid suturing. **B**, An alternative method is the thumb-ring finger grip. **C**, Hold the forceps in your nondominant hand as you would hold a pencil or a dart.

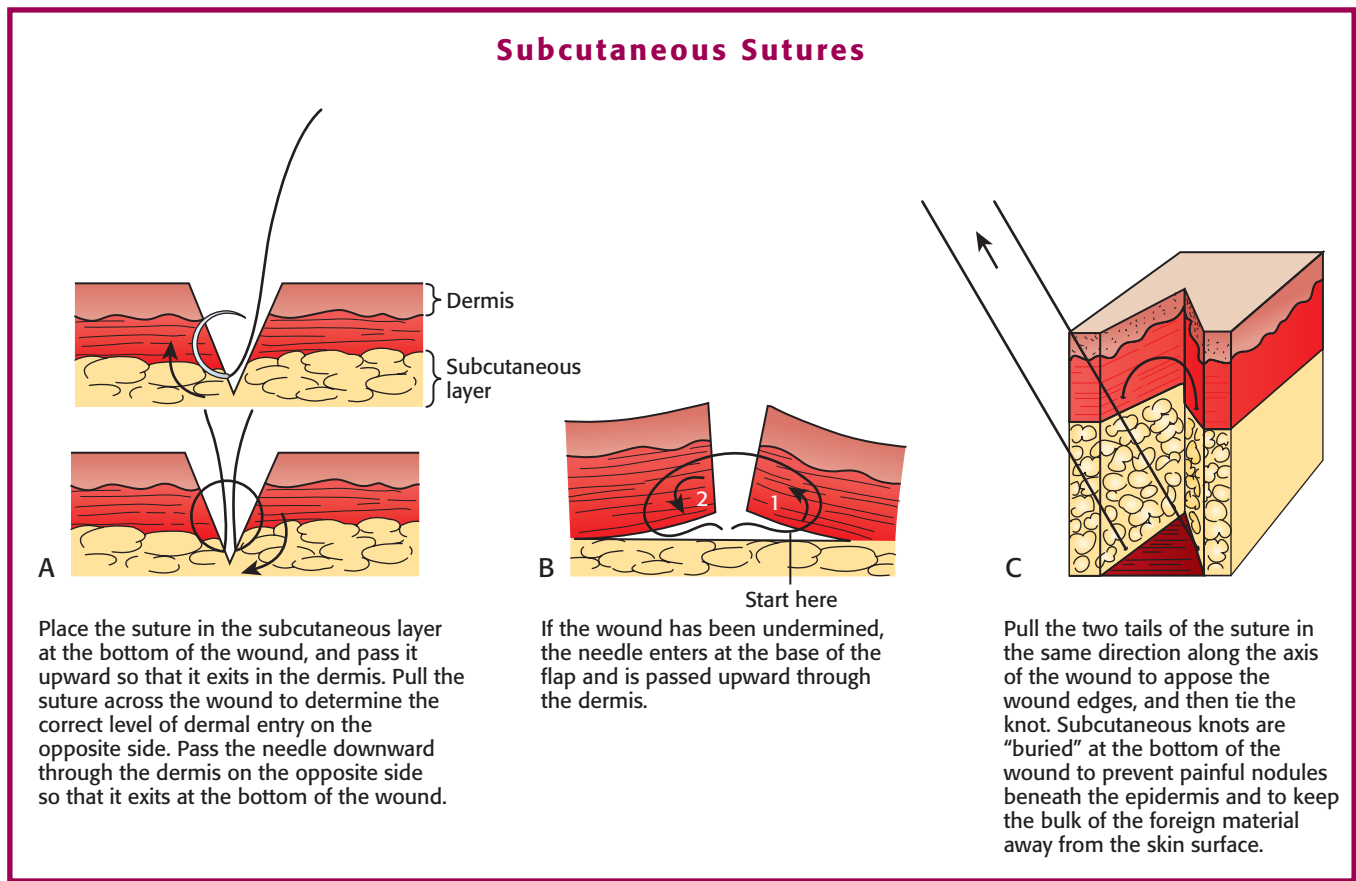

Figure 35.25 Subcutaneous sutures.

Surface Closure

The epidermis and the superficial layer of dermis are sutured in a single layer with nonabsorbable synthetic suture. The choice of suture size, the number of sutures used, and the depth of suture placement depend on the amount of skin tension remaining after SQ closure.

If the edges of the wound are apposed after closure of the deeper layers, small 5-0 or 6-0 sutures can be used simply to match the epithelium on each side. Wounds with greater tension and separation should have skin stitches placed closer to each other and closer to the edge of the wound with consideration for an interrupted vertical mattress suture; layered closure is important in such wounds. If the edges of the wound remain separated, or if SQ stitches were not used, a larger-size suture placed deeply may be required.

The number of sutures used in closing any wound will vary with the wound's location, the amount of tension on the wound, and the degree of accuracy required by the clinician and patient. For example, sutures on the face are often placed between 1 and 3 mm apart.⁹⁷ Unless the edges of the wound are uneven, sutures should be placed in a mirror-image fashion such that the depth and width are the same on both sides of the wound.⁷⁸ In general, the distance between each suture should be approximately equal to the distance from the exit of the stitch to the edge of the wound.^{74,121}

Skin closure may be accomplished by placing the appropriate number of sutures in segments (Fig. 35.26). When suturing the skin, right-handed operators should pass the needle from the right side of the wound to the left. The needle should be

driven through tissue by flexing the wrist and supinating the forearm; the course taken by the needle should result in a curve identical to the curvature of the needle itself (see Fig. 35.26, steps 1 and 2, and Fig. 35.27). The angle of exit for the needle should be the same as its angle of entrance so that an identical volume of tissue is contained within the stitch on each side of the wound (see Fig. 35.26, steps 3 and 4).

Once the needle exits the skin on the opposite side of the wound, regrasp it with the needle holder and advance it through the tissue; care should be taken to avoid crushing the point of the needle with the instrument. Forceps are designed for handling tissue and thus should not be used to grasp the needle tightly. Forceps can stabilize the needle by holding it within the tissue through which the needle has just passed. An assistant can keep excess thread clear of the area being sutured, or the excess can be looped around the clinician's fingers. If the point of the needle becomes dull before all the attached thread has been used, the suture should be discarded.

Complications

Sutures act as foreign bodies in a wound, and any stitch may damage a blood vessel or strangulate tissue. Therefore, the clinician should use the smallest size and the least number of sutures that will adequately close the wound.⁹¹ However, if spaced too widely, surface stitches will leave a “crosshatch” pattern of marks.

Encompassing too much tissue with a small needle is a common error. Forcefully pushing or twisting the needle in an effort to bring the point out of the tissue may bend or break

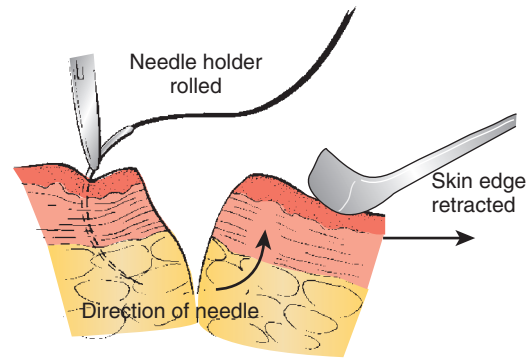

Simple Interrupted Sutures

1

Hold the needle pointing downward by excessively pronating the wrist so that the needle tip initially moves farther from the laceration as the needle penetrates deeper into the skin. Drive the needle tip downward and away from the cut edge into the subcutaneous layer.

2

Advance the needle into the laceration. The needle tip is directed toward the opposite side at the same level by rolling the needle holder. The arc of the needle pathway is controlled by retracting the stitch in the deeper layers of the wound than at the surface. As an alternative, if a small needle is used in thick skin or the distance across the wound is great, the needle can be removed from the first side, remounted on the needle holder, and advanced to the opposite side.

3

Advance the needle upward toward the surface so that it exits at the same distance from the wound edge as on the contralateral side of the wound. Grasp the needle behind the tip and roll it out in the arc of the needle.

4

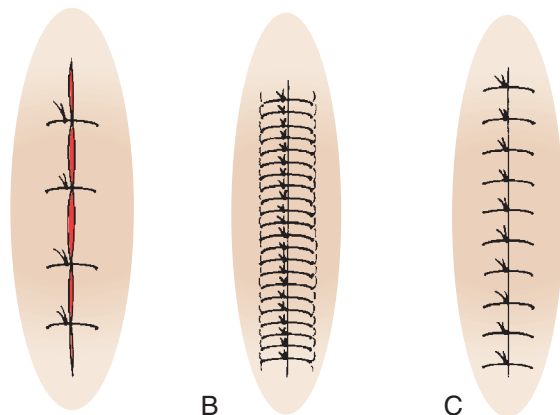

The final position, with more tissue in the depth than in the surface. The distance from each exit of the suture to the laceration is half the depth of the dermis.

5

Close the surface of the wound in segments rather than from one end. Place the first suture in the center of the wound for a straight suture line.

6

A, Too few stitches used. Note the gapping between the sutures. **B**, Too many stitches used. **C**, Correct number of stitches used for a wound under an average amount of tension.

Figure 35.26 Simple interrupted sutures. See also [Figs. 35.17](#) and [35.18](#). (Steps 1–4, From Kaplan EN, Hentz VR: *Emergency management of skin and soft tissue wounds: an illustrated guide*, Boston, 1984, Little, Brown, p 86. Reproduced by permission.)

Figure 35.27 Motion of the needle holder mimics the curve of the needle. Rotate the wrist (pronate) so that the needle enters the skin perpendicularly, not at an angle, as the wrist supinates. This helps evert the edge of the wound. (From Anderson CB. *Basic surgical techniques*. In Klippel AP, Anderson CB, editors: *Manual of outpatient and emergency surgical techniques*. Boston, 1979, Little, Brown. Reproduced by permission.)

the body of the needle. Using a needle of improper size will defeat the best suturing technique.

If sutures are tied too tightly around the edges of the wound or if individual stitches are under excessive tension, blood supply to the wound may be compromised, thereby increasing the chance of infection. Suture marks may form even after 24 hours.^{78,125}

If the techniques described are applied to most wounds, the edges will be matched precisely in all three dimensions, with the least number of sutures required to appose the edges and relieve tension, while avoiding excessive scarring.

Eversion Techniques

If the edges of a wound invert or if one edge rolls under the opposite side, a poorly formed, deep, noticeable scar will result. Excessive eversion that exposes the dermis on both sides will also result in a larger scar than if the edges of the skin are perfectly apposed, but inversion produces a more visible scar than eversion does. Because most scars undergo some flattening with contraction, optimal results are achieved when the epidermis is slightly everted without excessive suture tension (Fig. 35.28). Wounds over mobile surfaces, such as the extensor surfaces of joints, should be everted. In time, the scar will be flattened by the dynamic forces acting in the area.

Numerous techniques can be used to avoid inversion of the edges of the wound. If the clinician angles the needle obliquely away from the laceration, a surface stitch can be placed so that it is deeper than it is wide¹¹⁶ and the stitch encircles more tissue in the SQ layer than at the surface. In other words, the stitch is wider at its deepest part and narrower at the surface. If this “bottle-shaped stitch” is intended to produce some eversion of the wound edges, the stitch must include a sufficient amount of SQ tissue (see Fig. 35.26, step 4).

To accomplish eversion, lift and turn the edge of the wound outward with a skin hook or fine-toothed forceps before inserting the needle on each side (Fig. 35.29, plate 1). Eversion can also be achieved simply by pressing on the skin adjacent to the wound with closed forceps (see Fig. 35.29, plate 2).

Figure 35.28 Skin edges that are slightly everted will gradually flatten to produce a level wound surface when the sutures are removed. An inverted wound catches the light in a shadow and is more visible. In addition, eversion allows subcutaneous tissue to heal. The black oval beneath the surface stitch represents a subcutaneous stitch. (From Grabb WC: *Basic technique of plastic surgery*. In Grabb WC, Smith JW, editors: *Plastic surgery: a concise guide to clinical practice*, Boston, 1979, Little, Brown. Reproduced by permission.)

Vertical mattress sutures are particularly effective in everting the edges of the wound, and they can be used exclusively or alternated with simple interrupted sutures (see Fig. 35.29, plate 3).¹²⁶ In wounds that have been undermined, an SQ stitch placed at the base of the flap on each side can by itself evert the wound (see Fig. 35.29, plate 4).

Interrupted Stitch

The simple interrupted stitch (Video 35.5) is the most frequently used technique for closure of skin. It consists of separate loops of suture tied individually. Although tying plus cutting each stitch is time-consuming, the advantage of this method is that if one stitch in the closure fails, the remaining stitches continue to hold the wound together (see Fig. 35.26).

Continuous Stitch

A continuous stitch is an effective method for closing relatively clean, low-risk wounds that are under little or no tension and are on flat, immobile skin surfaces. In a continuous, or “running,” stitch, the loops are the exposed portions of a helical coil tied at each end of the wound. A continuous suture line can be placed more rapidly than a series of interrupted stitches. A continuous stitch has the additional advantages of strength (with tension being evenly distributed along its entire length), fewer knots (which are the weak points of stitches), and more effective hemostasis. This stitch will accommodate mild wound swelling. The continuous technique is useful as an epithelial or surface stitch in cosmetic closures; however, if the underlying SQ layer is not stabilized in a separate closure, a continuous surface stitch tends to invert the edges of the wound.

The continuous suture technique has some disadvantages. This technique should not be used to close wounds overlying joints. If a loop breaks at one point, the entire stitch may unravel. Likewise, if infection develops and the incision must be opened at one point, cutting a single loop may allow the entire wound to fall open. A simple continuous stitch has a tendency to produce suture marks if used for the closure of large wounds and if left in place for more than 5 days.¹¹⁴ However, if all tension on the wound can be removed with SQ sutures, stitch marks are seldom a problem.

Among the variations of the continuous technique, the simple continuous stitch is the most useful to emergency clinicians (Fig. 35.30A). Place an interrupted stitch at one end of the wound and cut only the free tail of the suture. Next, encircle the tissue

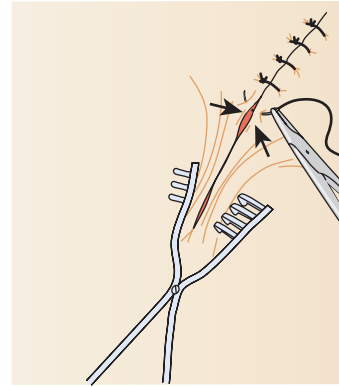

Eversion Techniques

1

Use of forceps or a skin hook to evert the wound edge. This technique allows the operator to see the needle path, thereby ensuring that the proper depth has been reached, and promotes eversion of the skin edges.

2

Eversion of the wound edge by forceps. Great care must be taken to avoid a needlestick.

3

A vertical mattress suture is the best technique for producing skin edge eversion. **A**, The usual type of mattress suture for approximating and everting wound edges. **B**, "Tacking" type of vertical mattress suture extending into the deep fascia to obliterate dead space under the wound. Note that only a small bite of skin is included on the inner suture.

4

Deep dermis suturing technique. The suture enters the base of the flap, is brought up into the dermis, and exits just proximal to the wound edge along the base of the flap to be tied and cut.

Figure 35.29 Eversion techniques. (Steps 2 and 3, From Converse JM: Introduction to plastic surgery. In Converse JM, editor: *Reconstructive plastic surgery: principles and procedures in correction, reconstruction, and transplantation*, Vol 1, ed 2. Philadelphia, 1977, Saunders. Reproduced by permission; step 4, from Stuzin J, Engrav LH, Buehler PK: Emergency treatment of facial lacerations, *Postgrad Med* 71:81, 1982. Reproduced by permission.)

in a spiral pattern. After each passage of the needle, tighten the loop slightly, and hold the thread taut in your nondominant hand. The needle should then travel perpendicularly across the wound on each pass. Place the last loop just beyond the end of the wound and tie the suture, using the last loop as a tail to tie the knot. One can also use a locking loop with continuous suturing to prevent slippage of the loops during suturing (see Fig. 35.30B). The interlocking technique allows use of the continuous stitch along an irregular laceration.¹¹⁶

Continuous Subcuticular Stitch

Nonabsorbable sutures used for surface closure outlast their usefulness and must be removed. On occasion, wounds require an extended period of support, longer than that provided by surface stitches. Some patients with wounds that require skin closure are unlikely or unwilling to return for removal of the

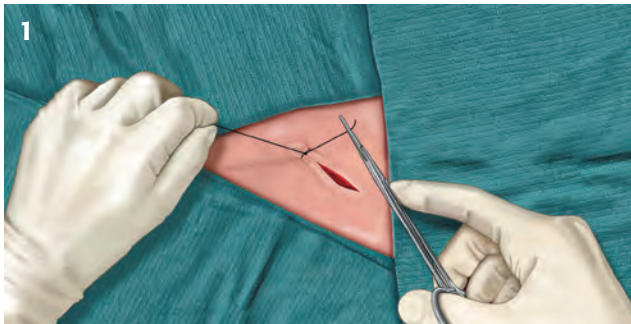

sutures. Some sutured wounds are covered by plaster casts. On occasion, the patient (child or adult) is likely to be as frightened by and uncooperative with suture removal as they were for suture placement. Surface sutures are more likely to produce stitch marks in children because the wounds are under greater tension than those in adults. The continuous subcuticular (or dermal) suture technique is ideal for these situations; the wound can be closed with an absorbable subcuticular stitch, thereby obviating the need for later suture removal. In patients prone to keloid formation, the subcuticular technique can be used in lieu of surface stitches to avoid disfiguring stitch marks. Buried, absorbable subcuticular stitches do not appear to provoke more inflammation than percutaneous running stitches with monofilament nylon.¹¹³ Because stitch marks are not a problem, a nonabsorbable subcuticular suture can be left in place for a longer period than a surface suture can.¹²⁶

Although this technique is commonly used for cosmetic closures, closure of the subcuticular layer alone may not alter the width of the scar.¹²⁷ This technique does not allow perfect approximation of the vertical height of the two edges of a wound,¹²⁸ and in cosmetic closures it is often followed by a surface stitch. The subcuticular stitch requires a 4-0 or 5-0 suture made of either absorbable material or nonabsorbable synthetic monofilament. An absorbable suture can be buried within the wound, whereas a nonabsorbable suture is used for a “pullout” stitch. The absorbable synthetic monofilament suture PDS (Ethicon) is designed for subcuticular closure. It

passes through tissues as easily as nonabsorbable monofilament sutures do and is absorbed if left in the wound.

Before beginning the subcuticular stitch, approximate the SQ layer with interrupted sutures to minimize tension on the wound. Start the pullout subcuticular stitch at the skin surface approximately 1 to 2 cm away from one end of the wound. Insert the needle and exit the dermis at the apices of the wound (see Fig. 35.30C, plate 1). Take bites through tissue in a horizontal direction, with the needle penetrating the dermis 1 to 2 mm from the skin surface. Make the intradermal bites small, of equal size, and at the same level on each side of the

Continuous Sutures

1 Place a suture at one end of the laceration in an analogous fashion to a simple interrupted stitch. However, cut only the distal end of the suture while leaving the needle end attached.

2 Cross over the wound at a 45-degree angle, and reenter the wound parallel to the first pass. Do not tie the suture or cut the ends.

3 Advance the needle back to the original side and exit the skin at an equal distance from the previous suture pass.

4 Continue in this fashion until the wound edges are closed and the end of the wound is approached.

5 On the last pass, leave a loop of suture. Use this loop as a free end to tie.

6 Tie the loop to the needle end of the suture with an instrument tie, and then cut the knot.

Figure 35.30 A, Continuous sutures.

Continued

Continuous Locked Sutures

1 Begin the repair as you would a regular continuous stitch (Fig. 35.30A, steps 1 and 2). As the needle exits the near side, “lock” the suture by passing through the circle of the previous suture loop.

2 As the suture is pulled through the circle (arrow), it will become locked.

3 Keep tension evenly distributed across the suture as it is pulled down to the skin. The lock should be parallel to the wound edge (arrow).

4 Continue in this fashion by locking each throw along the way. On the last pass, leave a loop of suture and use it to tie to the needle end of the suture.

B

Figure 35.30, cont'd B, Continuous locked sutures.

wound.^{104,126} Place each successive bite 1 to 2 mm behind the exit point on the opposite side of the wound so that when the wound is closed, the entrance and exit points on either side are not directly apposed. Take small bites to avoid puckering of the skin surface, and do not accidentally interlock the stitch. Some clinicians prefer to place a fine (6-0) running skin suture on the surface, in addition to the subcuticular suture, for meticulous skin approximation. Remove the skin suture in 3 to 4 days to avoid suture marks.

If a subcuticular stitch is used on lengthy lacerations, it is difficult to remove. One option is to place “reliefs,” which are periodic loops, through the skin every 4 to 5 cm along the length of the stitch, to facilitate removal later (see Fig. 35.30C, plate 2). Cross the suture to the opposite side, and pass the needle from SQ tissue to the surface of the skin. Carry the suture over the surface for approximately 2 cm before reentering the skin and SQ tissue. Continue the subcuticular stitch at approximately the same point at which the next bite would have been placed had the relief not been used.

At the completion of the stitch, place the needle through the apex and exit the skin 1 to 2 cm away from the end of the wound. Tighten the stitch by pulling each end taut. If reliefs have been used, pull on them to take up any slack in the stitch. Secure the two ends of the stitch by taping them to the skin surface with wound closure tape, by placing a cluster of knots on each tail close to the skin surface, or by tying the two ends

of the suture to each other over a dressing. The subcuticular stitch will become lax as tissue swelling subsides 48 hours after wound closure. Tighten the stitch at this time.

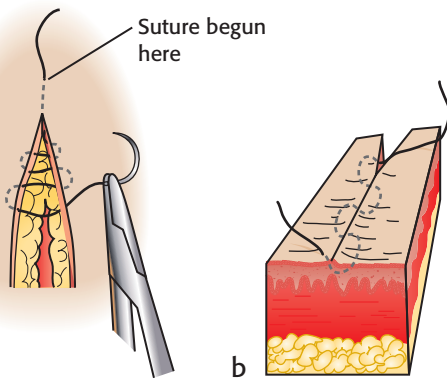

Subcuticular closure can be accomplished with absorbable sutures that do not penetrate the skin. Begin closure with a dermal or SQ suture placed at one end of the wound and secure it with a knot. After placement of the continuous subcuticular stitch from apex to apex, pull the suture taut, and tie a knot with a tail and a loop of suture (see Fig. 35.30C, plate 3). Bury the final knot by inserting the needle into deeper tissue and exit with the needle several millimeters from the edge of the wound. Pull on the end of the needle so the knot disappears into the wound.¹⁰³ The advantage of this technique is that there are no suture marks on the skin.

Nonabsorbable subcuticular sutures can be left in place for 2 to 3 weeks, thus providing a longer period of support than with surface sutures and without the problem of stitch marks.¹¹⁴ If skin sutures are used in conjunction with a subcuticular stitch, remove the surface stitches in 3 to 4 days. A subcuticular closure in itself is stronger than a tape closure. If the subcuticular technique is used exclusively to approximate the skin surface, apply skin tape to correct surface unevenness and to provide more accurate apposition of the epidermis.

The primary disadvantage of the subcuticular stitch is that it is time-consuming, especially when supporting surface stitches are used. Another, faster method that avoids penetrating

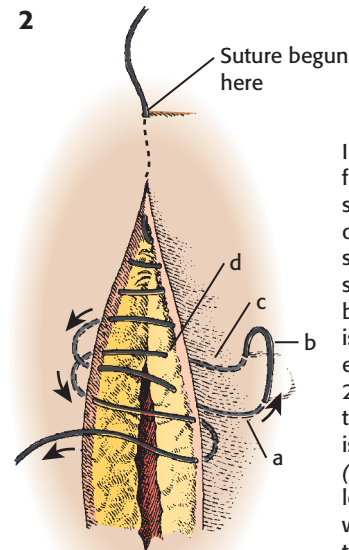

Continuous Subcuticular Sutures

1

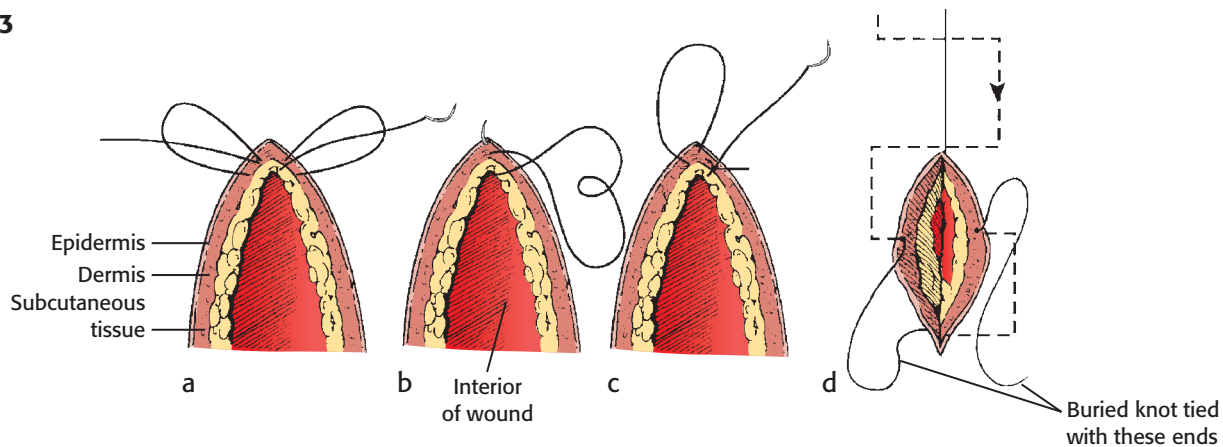

a Pullout subcuticular stitch. For deep wounds, first place interrupted sutures to relieve tension on the skin edge. The suture is introduced into the skin in line with the incision, approximately 1 to 2 cm away.

2

In constructing the relief to facilitate suture removal, the suture is crossed to the opposite side by going into the subcuticular area beneath the skin for approximately 2 cm before exiting (a). The suture is then carried over the epidermis for approximately 2 cm (b) and then back under the dermis again (c). Reentry is made into the wound area (d) at approximately the same location where the next "bite" would have been placed had the relief not been used.

3

a The initial knot is secured in dermal or subcutaneous tissue. **b** The short strand is cut, and the needle is inserted into the dermis at the apex of the wound. **c** The needle in the dermis close to the corner of the wound and exiting the wound at the same horizontal level. **d** After the subcuticular stitch has been completed, a knot is tied with the tail and the loop of the suture.

C

Figure 35.30, cont'd C, Continuous subcuticular sutures. (A and B, From Custalow C: *Color atlas of emergency department procedures*. Philadelphia, 2005, Elsevier; C, 1–2, from Grimes DW, Garner RW: "Reliefs" in intracuticular sutures, *Surg Rounds* 1:47, 1978. Reproduced by permission; 3, modified from Stillman RM: Wound closure: choosing optimal materials and methods, *ER Reports* 2:43, 1981.)

the skin is the interrupted subcuticular stitch (Fig. 35.31). Wounds with strong static skin tension may benefit from a few interrupted dermal stitches placed horizontal to the skin surface instead of a continuous subcuticular stitch.

Mattress Stitch

The various types of mattress stitches of use to the emergency clinician are interrupted stitches. The *vertical mattress stitch* (Video 35.6) is an effective method of everting skin edges (Fig. 35.32A; see also Fig. 35.29, plate 3). A vertical mattress stitch

may be used to take a deep bite of skin, thereby eliminating the need for layered closure in areas where excessive tension does not result. If the superficial loop is placed first, the tails can be pulled upward while the deep loop is placed; this technique ensures eversion of the wound in less time than needed with the traditional technique.¹²⁹

The *horizontal mattress stitch* (Videos 35.7 and 35.8) is an SQ stitch that is oriented 90 degrees to the interrupted SQ stitch, described previously (see Fig. 35.32B). The horizontal mattress stitch apposes the skin edges closely while providing

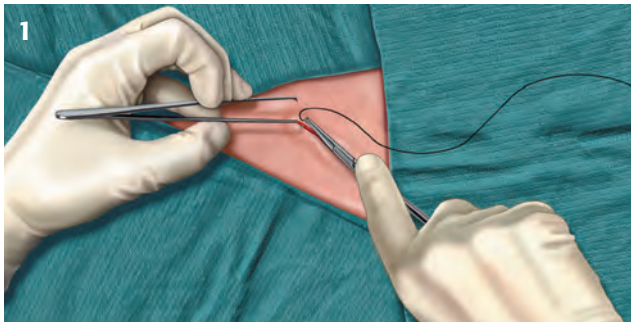

Figure 35.31 Interrupted subcuticular stitch (also called a horizontal dermal stitch). Absorbable sutures are used. (A vertical suture also closes the deep tissue.)

some degree of eversion.¹¹⁴ A horizontal mattress suture may be ideal for areas where eversion is desirable but there is little SQ tissue.

The *half-buried horizontal mattress suture* is particularly useful in suturing the easily damaged apex of a V-shaped flap (see Fig. 35.32B). In performing the “corner stitch” (Video 35.9), penetrate the skin at a point beyond the apex of the wound with the suture needle and exit through the dermis. Elevate the corner of the flap, and pass the suture through the dermis of the flap. Then, place the needle in the dermis at the base of the wound and return it to the surface of the skin. Place all dermal bites at the same level. Tie the suture with sufficient tension to pull the flap snugly into the corner without blanching the flap.^{114,130} The tip of a large flap with questionable

Vertical Mattress Suture

1 Pass the needle through both sides of the wound in the same manner as the first pass in a simple interrupted suture. This “inner” pass should be very close to the wound edge.

2 Reinsert the needle vertical to the previous exit site at a greater distance from the wound edge.

3 Pass the needle deeper than the previous pass, and exit about 0.5 cm vertical to the previous entrance site. Pull the suture through so that 2 cm of the short end remains outside the skin.

4 Tie the ends of the suture with an instrument tie, while everting the edges of the wound. Place subsequent sutures until the wound edges are apposed.

Steps in the vertical mattress stitch. The key to close apposition and exact alignment of edges is to place the inner sutures very close to the suture line (wound edge). Note: in steps 1–4 at the top of this figure the inner pass was placed first, whereas in steps a–e at the bottom the outer pass was placed first. Either method is acceptable.

A

Figure 35.32 A, Vertical mattress sutures.

Horizontal Mattress Suture

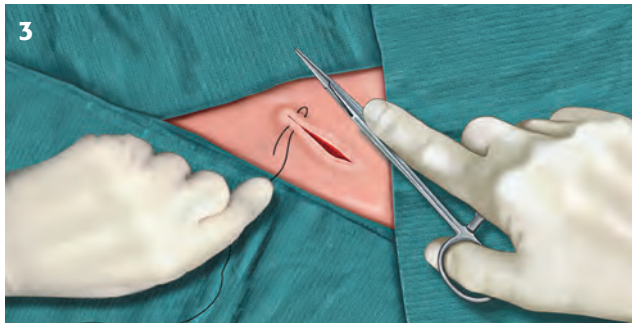

Standard Horizontal Mattress

1 Pass the needle through both sides of the wound in the same manner as the first pass in a simple interrupted suture.

2 Reinsert the needle approximately 5 mm from and horizontal to the previous exit site. Exit the wound on the opposite side, parallel to the first pass and at the same distance from the wound edge.

3 Pull the suture through so that approximately 2 cm of the short end of the suture remains outside the skin.

4 Tie the ends of the suture with an instrument tie, while everting the edges of the wound. Place subsequent sutures until the wound edges are apposed.

Half-Buried Horizontal Mattress

a and b, Corner stitch: Approximation of a flap with a half-buried horizontal mattress stitch, followed by interrupted sutures for the rest of the wound.

B

Figure 35.32, cont'd B, Horizontal mattress sutures. (A and B, From Custalow C: *Color atlas of emergency department procedures*. Philadelphia, 2005, Elsevier.)

viability may be further jeopardized by postoperative swelling, so a cotton stent can be placed underneath the knot of the corner stitch. The cotton absorbs the tension produced by swelling.

The only disadvantage of the horizontal and vertical mattress stitches is that they cause more ischemia and necrosis inside their loops than do either simple or continuous stitches.¹³¹ With mattress sutures, alternating the side of the wound margin

on which the knot is tied has been found to reduce wound tension and may reduce the risk of edge necrosis.¹³²

The *inverting horizontal mattress stitch* is a variation of the horizontal mattress stitch (Fig. 35.33). This stitch produces wound inversion and should only be used when wound inversion is desired, such as when re-creating the alar crease of the nose or the rolled helical rim of the ear.^{133,134} In most other wounds, inversion will create a depressed and more noticeable scar.

Figure 35.33 Inverting horizontal mattress sutures. **A**, Traditional everting horizontal mattress stitch and inverting horizontal mattress stitch. **B**, Application of the inverting horizontal mattress suture to the helix of the ear and final cosmetic result with re-creation of the helical rim. **C**, 1, Skin defect of the nasal ala. 2, Inverting horizontal mattress suture at 1 week follow-up. 3, Re-creation of the alar crease seen 2 weeks after initial repair. (A and B, from Wentzell J, Lund J: The inverting horizontal mattress suture: applications in dermatologic surgery, *Dermatol Surg* 38:1536, 2012. C, from Malone C, Wagner R: Recreation of the alar crease using the inverted horizontal mattress suture, *J Am Acad Dermatol* 73:e112, 2015.)

Figure-of-Eight Sutures

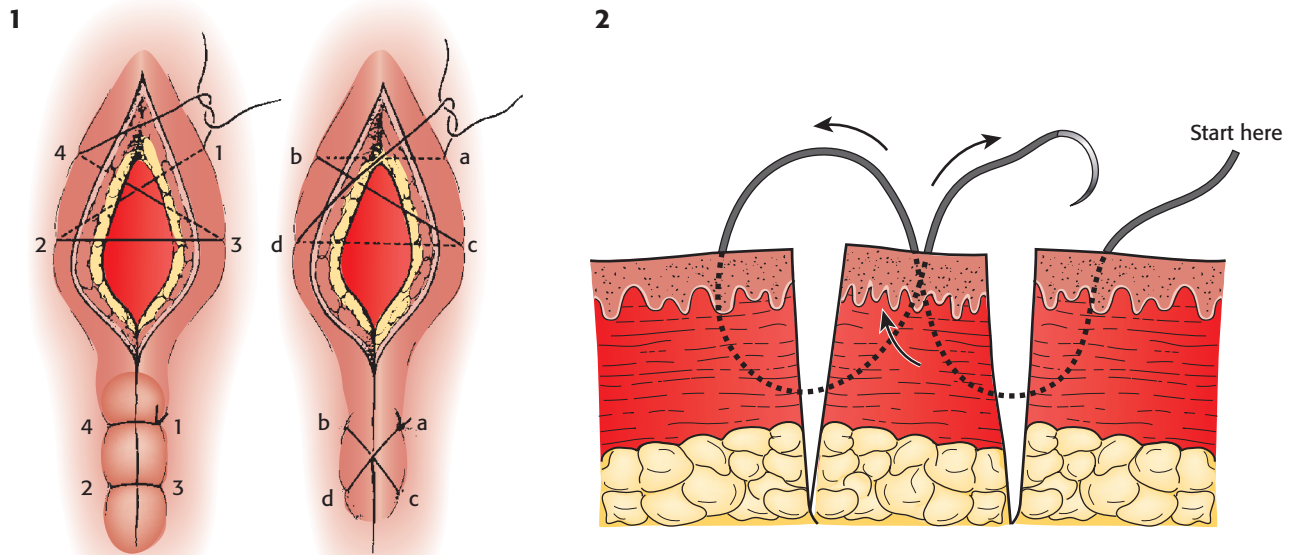

Figure-of-eight stitch, two methods. These stitches are useful in wounds with friable tissue or in areas where buried sutures are undesirable. This stitch reduces the amount of tension placed on the tissue by the suture.

Vertical figure-of-eight suture technique. It can be used to close parallel lacerations.

Figure 35.34 Figure-of-eight sutures. (Plate 1, Modified from Dushoff IM: About face, *Emerg Med* 6:11, 1974. Reproduced by permission; Plate 2, from Mitchell GC: Repair of parallel lacerations [letter], *Ann Emerg Med* 16:924, 1987.)

Figure-of-Eight Stitch

A figure-of-eight stitch is useful for wounds with friable tissue, on the eyelids where the skin is too thin for buried sutures, or in areas in which buried sutures are undesirable (Fig. 35.34, plate 1).¹³⁵ This stitch reduces the amount of tension placed on the tissue by the suture, which allows the stitch to stay in place when a simple stitch would tear through the tissue. The disadvantage of this technique is that more suture material is left in the wound. A vertical variation of the figure-of-eight stitch is sometimes used to approximate close, parallel lacerations (see Fig. 35.34, plate 2).¹³⁶ Another technique involves a vertical mattress stitch (Fig. 35.35).

Correction of Dog-Ears

When the edges of a wound are not precisely aligned horizontally, there will be excess tissue on one or both ends. This small flap of excess skin that bunches up at the end of a sutured wound is commonly called a *dog-ear*. This effect also occurs when one side of the wound is more elliptical than the opposite side or when excision of a wound is not sufficiently elliptical because it is either too straight or too nearly circular.^{74,126}

If a dog-ear is present, it can be eliminated on one side of the wound in the following manner. Elevate the flap of excess skin with forceps or a skin hook. Make an incision at an oblique angle from the apex of the wound toward the side with the excess skin. Undermine the flap and lay it flat. Trim the resulting triangle of skin, and complete the closure (Fig. 35.36, plate

Figure 35.35 Technique for closure of parallel lacerations in which the central tissue island has an intact base. (Redrawn from Samo DG: A technique for parallel lacerations, *Ann Emerg Med* 17:297, 1988.)

1).^{124,130} An alternative method consists of carrying the incision directly from the apex in line with the wound. Pull the flap of excess tissue over the incision while using skin hooks to retract the extended apex of the wound. Excise excess tissue, and suture the remainder of the wound.¹²⁶ If dog-ears are present on both sides of one end of the wound, excise the bulge of excess tissue in an elliptical fashion and close the wound (see Fig. 35.36, plate 2).¹³⁰

Stellate Lacerations

Repair of a stellate laceration is a challenging problem. Usually a result of compression and shear forces, these injuries contain large amounts of partially devitalized tissue. The surrounding

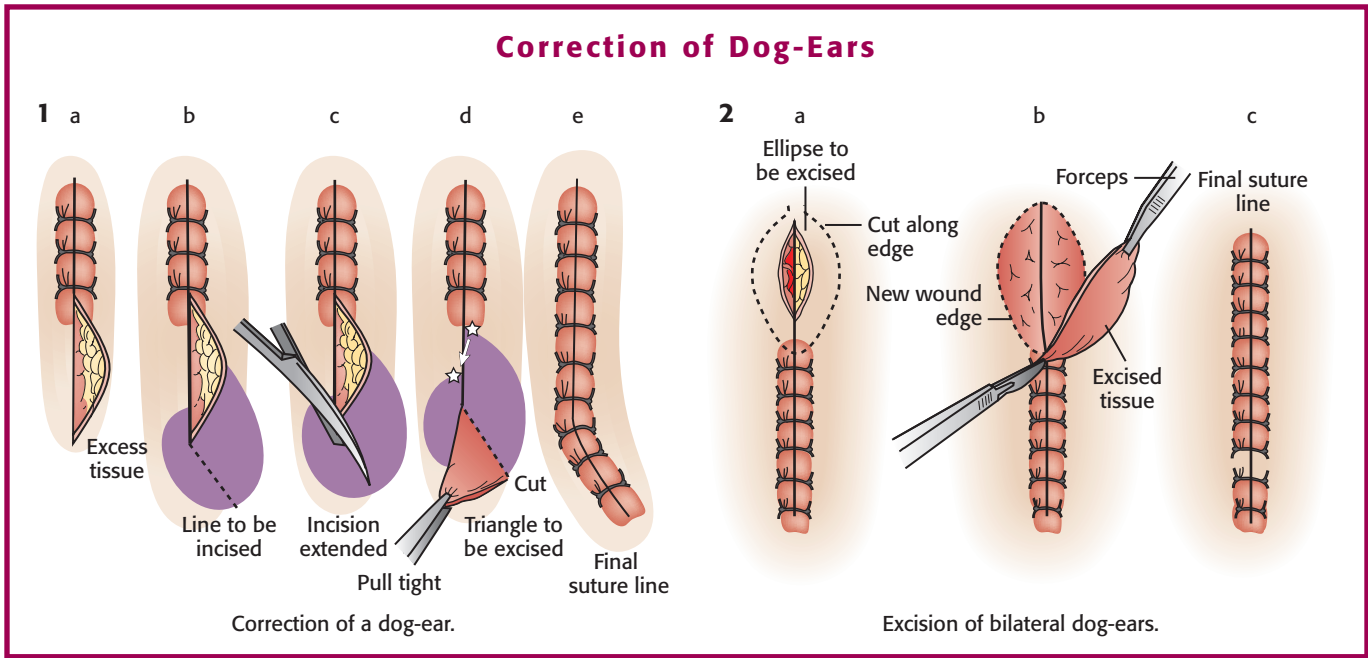

Figure 35.36 Correction of a dog-ear. The critical maneuver is shown, where the skin is pulled tight to align the starred areas and identify the triangular piece of excess tissue to be excised (1d). Note that a straight laceration becomes somewhat curved with this technique. (From Dushoff IM: A stitch in time, *Emerg Med* 5:1, 1973. Reproduced by permission.)

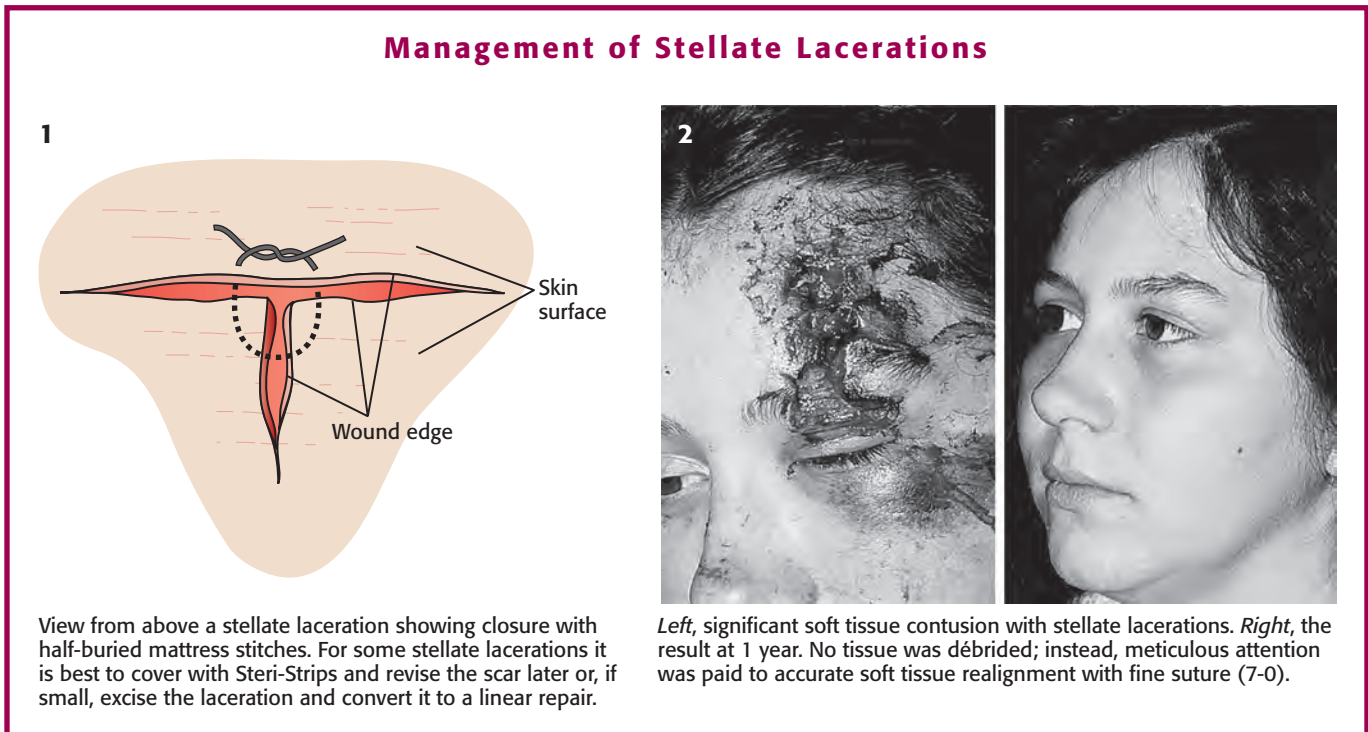

Figure 35.37 Management of stellate lacerations.

soft tissue is often swollen and contused. Much of this contused tissue cannot be débrided without creating a large tissue defect. Sometimes tissue is lost, yet the amount is not apparent until key sutures are placed. In repairing what often resembles a jigsaw puzzle, the clinician can remove small flaps of necrotic tissue with iris scissors; large, viable flaps can be repositioned

in their beds and carefully secured with half-buried mattress stitches. If interrupted stitches are used to approximate a thin flap, take small bites in the flap and larger, deeper bites in the base of the wound. A modification of the corner stitch can be used to approximate multiple flaps to a base (Fig. 35.37). Thin flaps of tissue in a stellate laceration with beveled edges

may be more easily repositioned and stabilized with a firm dressing.¹¹⁴

Closure of stellate lacerations cannot always be accomplished immediately, especially if considerable soft tissue swelling is present. It may be best in some instances to consider delayed closure or revision of the scar at a later date. In complicated lacerations, inexact tissue approximation may be all that is possible initially. For small stellate lacerations, it may be possible to excise the lesion totally and turn it into a linear repair.

Repair of Special Structures

Facial Wounds (General Features)

The ideal result in the repair of a facial laceration is an extremely narrow, flat, and inapparent scar. Facial and forehead lacerations that follow natural skin creases or lines will heal with a less noticeable scar than those that are oblique or perpendicular to the natural wrinkles of the skin (Fig. 35.38). In addition to basic wound management, a few additional techniques can be used to achieve satisfactory cosmetic results.

Although necrosis of partially devitalized wound edges contributes to wide scars, facial skin with apparently marginal circulation may survive because of excellent vascularity. SQ fat, which in other locations may be debrided thoroughly, should be preserved if possible in facial wounds to prevent eventual sinking of the scar and to preserve normal facial contours. Therefore débridement of most facial wounds should be conservative¹¹⁷ (Fig. 35.39). Carefully avoid underlying structures when débriding facial wounds. For example, the cheek contains both the seventh cranial nerve and the parotid gland. Clear drainage from a cheek laceration indicates parotid gland or Stensen's duct involvement and warrants consultation.¹³⁷

A layered closure has long been considered essential in the cosmetic repair of many facial wounds. However, the importance of layered closure in facial wounds was called into question by Singer and associates.¹³⁸ These investigators found similar cosmetic outcomes and scar widths in small facial wounds less than 3 cm in length and 10 mm in width that were repaired

Figure 35.38 Lacerations following natural skin lines (shown here) heal with a less noticeable scar than those that are oblique or perpendicular to natural lines (or wrinkles).

with and without deep dermal sutures. Further confirmation of these results is needed.

If a layered closure is undertaken, approximate the dermis with an SQ stitch or with a combination of SQ and subcuticular stitches to bring the edges of the wound together or to within 1 to 2 mm of apposition. This may be close enough that the use of additional sutures seems almost unnecessary.¹²⁴ If an SQ stitch is the only stitch used to close the deeper layers, pass the needle through the dermal-epidermal junction, or within 1 to 2 mm of the surface of the skin, without causing a dimpling effect. Tie the stitch snugly by pulling the two ends of the suture in the same direction (see Fig. 35.25C).

In cosmetic areas, a surface stitch should not be used to relieve a wound of significant tension. A surface stitch on the face is most appropriately used to match the epidermal surfaces precisely along the length of the wound. If the edges of the wound are separated more than approximately 2 to 4 mm after closure of the SQ layer, use a 5-0 or 6-0 subcuticular suture to eliminate the tension produced by this separation and to provide prolonged stability. Alternatively, use a few *guide stitches* to hold sections of the wound together before definitive closure with surface stitches. Guide stitches allow the surface stitches to be placed with little tension on each individual stitch; they match irregular edges; and they protect the SQ stitches from disruption. Place the first guide stitch at the midpoint of the wound, and subsequent guide stitches to bisect the intervening spaces. Once the definitive surface stitches have been placed, the guide stitches, if slack, can be removed. Because a needle damages tissue with each passage through the skin, use guide stitches only when necessary.

In a straight laceration, achieve better apposition during surface closure by stretching it lengthwise with finger traction or with skin hooks. When the needle is placed on one side of the wound, and that side is higher than the opposite side, take a shallow bite. Use the needle to depress the edges of the wound to the proper height, and allow the needle to “follow through” to the other side and pin the two sides together. If the first side entered is lower, elevate the needle when entering the second side to match the epithelial edges.

If the skin edges are apposed closely by the SQ stitch or a subcuticular stitch, a small, shallow *epithelial stitch* can be used in lieu of the standard, deeper, surface stitch to correct discrepancies in vertical alignment (Fig. 35.40).¹¹⁶ Achieve precise alignment of wound edges by inserting the needle as close to the edge as possible without tearing through the tissue. A 6-0 synthetic nonabsorbable suture is an excellent material for this stitch. A continuous stitch is preferable because it can be placed quickly, but interrupted stitches are acceptable. Space epithelial stitches no more than 2 to 3 mm apart and encompass no more than 2 to 4 mm of tissue.¹¹⁶ Once skin closure is complete, make final adjustments in the tension on a continuous suture line before tying the end of the stitch. If any discrepancies in level persist, use interrupted sutures or tape to flatten these few irregularities. The disadvantages of epithelial stitches are that they are time-consuming and add more suture material to the wound. Discrepancies in level can often be corrected with surgical tape.

Surgical tape is useful as a secondary support to protect the surface stitch from the stress produced by normal skin movement (Fig. 35.41). Facial wounds have a tendency to swell and place excessive stretch on a surface stitch. Minimize this by applying a pressure dressing and cold compresses to the wound after closure. Surgical tape can serve to a limited extent as a

Figure 35.39 **A**, This woman was punched in the face, suffered a laceration of her cheek, and went to the emergency department 35 hours later. The wound was not infected, but it had contracted and was beginning to heal by granulation. Under local anesthesia, the wound was opened, irrigated, and minimally débrided, and the skin edges were trimmed. **B**, Using a No. 15 blade, a 1-mm-deep incision was made in the skin along the edges of the wound border. **C**, The incised edges were then cut away with tissue scissors. **D**, The wound was undermined to relieve tension on the skin. **E**, The wound is clean, undermined, and ready to close. **F**, The wound was closed with 6-0 interrupted sutures, which were removed in 5 days. No antibiotics were used, and only a small linear scar resulted.

small pressure dressing. In simple, low-tension facial wounds, wound closure with surgical tape provides results that are equivalent to closure with tissue adhesive.¹³⁹

Forehead

Although the forehead is actually a part of the scalp, lacerations in this region are treated as facial wounds. Vertical lacerations across the forehead are oriented 90 degrees to skin tension lines, and the resulting scars are more noticeable than those from horizontal lacerations. Midline vertical forehead lacerations may result in cosmetically acceptable scars with standard closure techniques; uncentered lacerations may benefit from S-plasty or Z-plasty techniques during the initial repair or during later revision of the scar.

Superficial lacerations may be closed with skin stitches alone, but deep forehead lacerations must be closed in layers. First, approximate significant periosteal defects before closing more superficial layers (Fig. 35.42). If skin is directly exposed to

bone, adhesions might develop that in time may limit the movement of skin during facial expressions. Close the frontalis muscle fascia and adjacent fibrous tissue as a distinct layer; if left unsutured, the retracted ends of this muscle may bulge beneath the skin. If the gap in a muscle belly is later filled with scar tissue, movement of the muscle may pull on the entire scar and make it more apparent.¹¹⁷

A U-shaped flap laceration with a superiorly oriented base poses a difficult problem. Immediate vascular congestion and later scar contraction within the flap produce the “trapdoor” effect, with the flap becoming prominently elevated (Fig. 35.43, plates 1 and 2). To minimize this effect, approximate the bulk of the SQ tissue of the flap to a deeper level on the base side of the wound. This way the skin surfaces of the two sides are apposed at the same level (see Fig. 35.43, plate 3). Apply a firm compression dressing to eliminate dead space and hematoma formation within the wound. Despite these efforts, secondary revision is sometimes necessary.¹¹⁴ Frequently, swelling of the

Figure 35.40 Epithelial stitches. If the skin edges are well apposed by a subcutaneous or subcuticular stitch, epithelial stitches can be used to correct discrepancies in vertical alignment. Achieve precise alignment by inserting the needle as close to the edge as possible without tearing the tissue, no more than 2 to 3 mm apart and encompassing no more than 2 to 4 mm of tissue. This wound should be carefully evaluated for an occult globe injury.

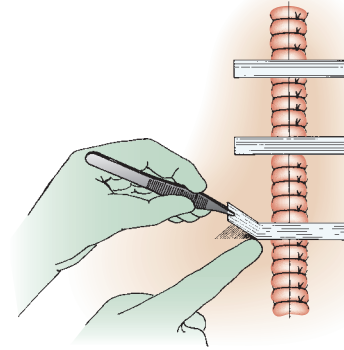

Figure 35.41 Wound closure tape can be used to provide additional support while sutures are in place and after they are removed. This may be especially useful in cosmetic areas such as the face.

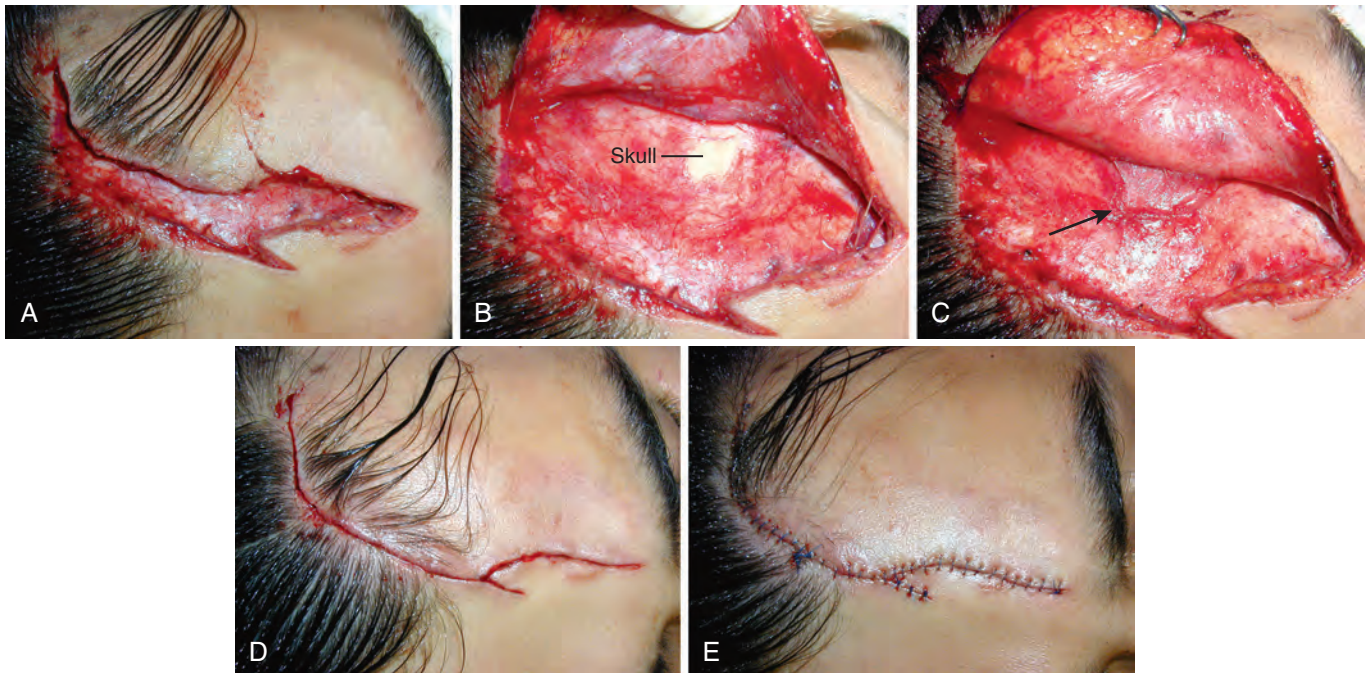

Figure 35.42 **A**, This patient suffered a full-thickness flap (partial avulsion) type of forehead laceration. **B**, The surface of the skull is visible in the upper portion of the wound. Injuries such as these must be closed in layers. **C**, The galea aponeurosis is repaired with absorbable suture. **D**, Additional subcuticular and subcutaneous stitches were placed meticulously, which resulted in excellent apposition of the wound edges. **E**, The surface is repaired with a combination of simple interrupted and continuous epithelial sutures.

flap resolves over a 6- to 12-month period. Because flap elevation can be quite disconcerting, forewarn the patient and family about a possible trapdoor effect.

When a forehead laceration borders the scalp and the thick scalp tissue must be sutured to thinner forehead skin, use a horizontal or vertical mattress stitch with an intradermal component (see Fig. 35.43, plates 3E and 3F).¹²⁶

Note that even a minor forehead contusion or laceration may bleed subcutaneously and, in a few days, produce blackness around the eyes (Fig. 35.44). Forewarn patients about this.

Repair of "Trapdoor" Injuries

Elevation of a forehead flap. The trapdoor effect is a natural healing process of elliptical or round lacerations. Patients should be advised of this phenomenon.

This flap-type laceration of the forehead will heal with a puffed-up center (trapdoor), even under the best of circumstances.

Repair of a U-shaped flap laceration with a superiorly oriented base to minimize the trapdoor effect. **A**, Excision of edges. **B**, Undermining. **C**, Approximation of subcutaneous tissue on the flap to subcutaneous tissue at a deeper level on the base. **B** and **C**, When a laceration in the thin skin of the forehead borders the thicker skin of the scalp, a horizontal mattress suture with an intradermal component can enhance healing by bringing tissues to the same plane. These figures show eversion of thinner skin to obtain adequate approximation with thicker scalp tissue. **D-F**, Skin closure.

Figure 35.43 Repair of trapdoor injuries. (Plate 1, from Grabb WC, Kleinert HE: *Techniques in Surgery: Facial and Hand Injuries*. Somerville, NJ, 1980, Ethicon, Inc. Reproduced by permission; Plate 3, from Converse JM: *Introduction to plastic surgery*. In Converse JM, editor: *Reconstructive plastic surgery: principles and procedures in correction, reconstruction, and transplantation*, Vol 1, ed 2. Philadelphia, 1977, Saunders. Reproduced by permission.)

Figure 35.44 **A**, Patients should be informed that minor forehead or nasal bridge trauma can produce benign blackness around the eyes in a few days. **B**, "Raccoon eyes" are most often benign; however, this phenomenon can be impressive. **C**, Under bilateral supraorbital nerve blocks, multiple small lacerations from this windshield injury are explored with a metal instrument and good lighting to remove tiny pieces of glass. Most superficial cuts can be left alone and others sutured with 6-0 nylon suture.

So-called raccoon eyes were once thought to represent a fracture, and although often associated with fractures, this is usually a common, benign finding, although occasionally a striking one.

Windshield injuries involving the forehead can be challenging to manage (see Fig. 35.44C) because multiple superficial cuts can harbor small glass particles and the injuries do not readily lend themselves to closure with suture. Supraorbital blocks can be used to anesthetize the forehead while the clinician meticulously looks for glass in each skin defect, often feeling pieces only with forceps or a small hemostat. Some pieces of glass are best felt; others are appreciated as shining objects under a good light source.

Eyebrow and Eyelid Lacerations

Manage jagged lacerations through eyebrows with little, if any, débridement of untidy but viable edges. The hair shafts of the eyebrow grow at an oblique angle and vertical excision may produce a linear alopecia in the eyebrow, whereas with simple closure, the scar remains hidden within the hair.

If partial excision is unavoidable, angle the scalpel blade in a direction parallel to the axis of the hair shaft to minimize damage to the hair follicles.

Align points on each side of the lacerated eyebrow precisely. Precede SQ closure with a single percutaneous stitch on each margin of the eyebrow. Use the edges of the eyebrow as landmarks for reapproximation; therefore do not shave the eyebrow because these landmarks will be lost. Shaved eyebrows grow back slowly and sometimes incompletely, and shaving them often results in more deformity than caused by the injury itself. Take care not to invert hair-bearing skin into the wound.¹²⁸

The thin, flexible skin of the upper eyelid is relatively easy to suture. A soft 6-0 suture (or smaller) is recommended for closure of simple lacerations. Traumatized eyelids are susceptible to massive swelling; compression dressings and cool compresses can be used to minimize this problem.

The emergency clinician must recognize that eyelid lacerations, especially complicated ones, require the expertise of an ophthalmologist with experience in ocular plastic surgery. Lacerations that traverse the lid margin require exact realignment to avoid entropion or ectropion. Injuries penetrating the tarsal plate frequently cause damage to the globe (Fig. 35.45A). A deep horizontal laceration through the upper lid that divides the thin levator palpebrae muscle or cuts its tendinous attachment to the tarsal plate can result in ptosis. In most cases an ophthalmologist should repair the injury primarily. A laceration through the portion of the upper or lower lid medial to the punctum frequently damages the lacrimal duct or the medial canthal ligament and requires specialized techniques for repair (see Fig. 35.45B). Adipose tissue seen within any periorbital laceration may be retrobulbar fat herniating through the wound, and further evaluation is required (see Fig. 35.45C). Leave the repair of lid avulsions, extensive lid lacerations with loss of tissue, and complex types of lid lacerations to ophthalmologists.

Ear Lacerations

The primary goals in the management of lacerations of the pinna are expedient coverage of exposed cartilage and prevention of wound hematoma (Fig. 35.46). Cartilage is an avascular tissue, and when ear cartilage is denuded of its protective, nutrient-providing skin, progressive erosive chondritis ensues. The first step in the repair of an ear injury is to trim away

jagged or devitalized cartilage and skin. If the skin cannot be stretched to cover the defect, remove additional cartilage along the wound margin. Depending on the location, as much as 5 mm of cartilage can be removed without significant deformity. Approximate the cartilage with 4-0 or 5-0 absorbable sutures placed at folds or ridges in the pinna, representing major landmarks. Sutures tear through cartilage; therefore include the anterior and posterior perichondrium in the stitch. Do not apply more tension than is needed to touch the edges together.

Next, in through-and-through ear lacerations, approximate the posterior skin surface with 5-0 nonabsorbable synthetic suture. Once closure of the posterior surface is completed, approximate the convoluted anterior surface of the ear with 5-0 or 6-0 nonabsorbable synthetic suture, joining landmarks point by point (see Fig. 35.46C and D). In repair of the helical fold, use the inverting horizontal mattress stitch (see prior section in this chapter on mattress suture). On the free rim, evert the skin to avoid notching later. Take care to cover all exposed cartilage. In heavily contaminated wounds of the ear (e.g., bite wounds) that already show evidence of inflammation, débride the necrotic tissue, cover the cartilage with a loose approximation of skin, and give the patient antibiotics.^{114,140} Once the lacerated ear has been sutured, enclose it in a compression dressing (see Chapter 63). Complex or complicated ear lacerations generally require consultation and close follow up.

Nose Lacerations

Lacerations involving the margin of the nostril are complicated and should be repaired accurately to ensure that unsightly notching does not occur (Fig. 35.47). In the medial portion of the nostril and superior columella, the lower lateral cartilages are quite close to the margin and relatively superficial. If the extent of the laceration is not recognized or repaired, wound healing may cause superior retraction of the margin of the nostril. Carefully palpate nasal wounds for underlying bone injury. If bony deformity is noted, consider consulting a plastic surgeon, because the fragments may require surgical wiring.¹⁴¹ Secondary repair of complications is difficult.

In repairing superficial lacerations of the nose, reapproximation of the edges of the wound is difficult because the skin is inflexible. Even deeply placed stitches will slice through the epidermis and pull out. When the edges of the wound cannot be coapted easily before skin closure, place 6-0 absorbable sutures in the fibrofatty junction with an SQ stitch. Because it is difficult to approximate gaping wounds in this location, keep débridement to a minimum. Fortunately, the nose has a rich supply of blood and often will heal without débridement. Nasal cartilage is frequently involved in wounds of the nose, but it is seldom necessary to suture the cartilage itself.

Align the free rim of the nostril precisely to avoid unsightly notching. The inverting horizontal mattress stitch may be useful in the alar crease of the nostril to help with inversion (see prior section in this chapter on mattress suture). Many clinicians recommend early removal of stitches to avoid stitch marks, yet the oily nature of skin in this area makes it difficult to keep the wound closed with tape. A running subcuticular stitch may be preferable when repairing nasal lacerations, but simple interrupted stitches are also acceptable.¹⁴¹ If the wound is gaping before closure, a subcuticular stitch is recommended to provide support for a prolonged period.¹⁴² If there is significant tissue injury, consultation with a facial plastic surgeon may be warranted.

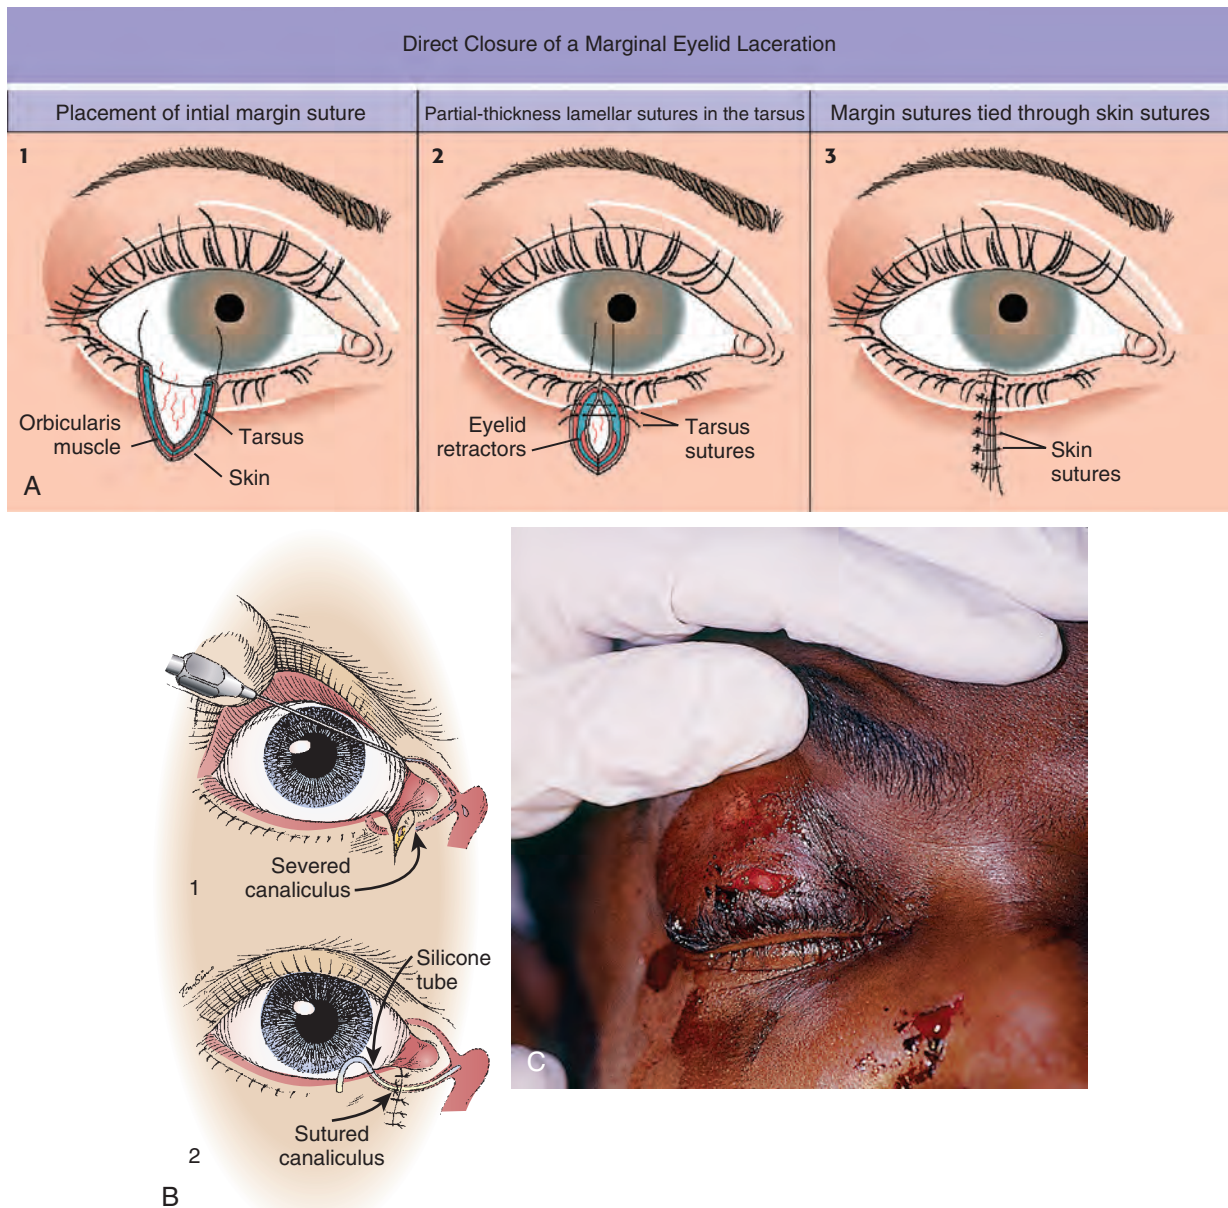

Figure 35.45 **A**, A laceration of the eyelid margin is a complicated repair usually performed by an ophthalmologist or plastic surgeon. The principles of repair are demonstrated here. *1*, The suture is placed precisely in the plane of the meibomian glands at the eyelid margin, approximately 2 mm from the edges of the wound and 2 mm deep. This placement should provide adequate eversion of the margins. *2*, Partial-thickness lamellar sutures are placed across the tarsus and tied anteriorly. *3*, The anterior skin and muscle lamella are closed with fine sutures, and these are tied over the long marginal sutures to prevent them from touching the cornea. **B**, A method of identifying and repairing the canaliculus. This repair is best left to the ophthalmologist, but the emergency clinician must recognize the potential for a canaliculus injury. **C**, Deep laceration of the left upper lid with herniation of orbital fat. For fat to prolapse, the orbital septum (and potentially the globe itself) must have been perforated. This is a wound requiring operating room exploration and repair.

Lip and Intraoral Lacerations

Lip lacerations are cosmetically deforming injuries, but if the clinician follows a few guidelines, these lacerations usually heal satisfactorily.

The contamination of all intraoral and lip wounds is considerable, and they must be thoroughly irrigated. Regional nerve blocks are preferred over local anesthetic injection because the latter method distends tissue, distorts the anatomy of the lip, and obscures the vermilion border. Loss of less than 25%

of the lip permits primary closure with little deformity. The following types of wounds require initial surgical consultation or later reconstructive surgery: loss of more than 25% of the lip, extensive lacerations directly through the commissure of the mouth,¹⁴⁰ and deep scars in the vermilion of the upper lip (which can later result in a redundancy of tissue).¹⁴⁰

Small puncture-type lacerations heal well only if the skin is closed and the small intraoral laceration is left open (Fig. 35.48A). Such injuries commonly occur when the victim's tooth

Figure 35.46 **A**, Lacerations of the ear require a special repair aimed at covering cartilage and preventing hematoma formation. With this through-and-through laceration of the margin of the pinna, the cartilage is trimmed just enough to allow the skin to be approximated to cover all exposed cartilage. Sutures are not used in the cartilage itself for this laceration, but the edges are approximated by skin sutures that incorporate the perichondrium. **B**, The repair is easiest if the posterior pinna is sutured first. **C** and **D**, Lacerations of the helical rim that traverse the two skin surfaces and the cartilage require a three-layer repair with accurate reapproximation of the auricular cartilage, as is done for the nose, to avoid notching. The cartilage is repaired by placing 5-0 or 6-0 clear absorbable suture through the perichondrium and cartilage. The skin is repaired with 6-0 or 7-0 nonabsorbable suture. **E**, An ear compression dressing should be used to prevent hematoma (see [Chapter 63](#) for discussion of anesthesia and dressing for this injury).

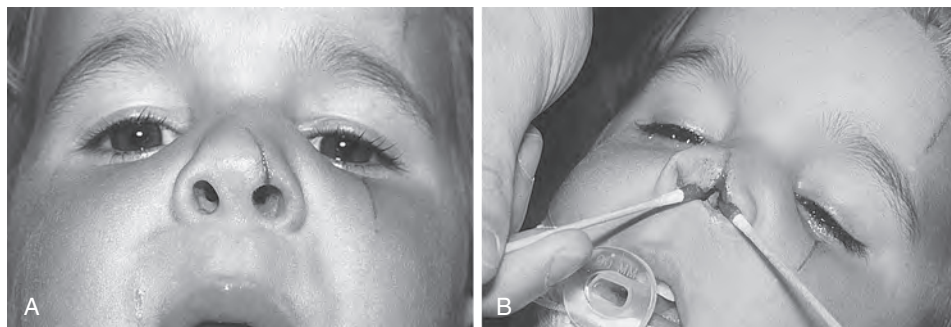

Figure 35.47 **A**, Initially benign-appearing laceration of the left nostril of a 2-year-old patient. **B**, However, further investigation shows a full-thickness injury with a laceration of the lower lateral cartilage. A three-layer closure with reapproximation of the cartilage was performed.

Figure 35.48 Check all lip lacerations for tooth fragments embedded in the wound. **A**, This superficial mucosal laceration produced by the teeth can be cleaned, minimally trimmed, and left open to heal. Note the broken upper teeth (*arrow*); fragments may be embedded in the laceration. Healing produces a whitish tissue that can be mistaken for infection. **B**, This extensive laceration of the mucosa requires a layered suture closure. **C**, Small through-and-through lacerations made by the teeth can be irrigated and closed with skin and mucosal sutures in two layers. Small defects in the mucosa may be left open. Large through-and-through injuries and lacerations of the tongue margins require sutures to achieve anatomic healing. The muscle layer should be closed separately (with absorbable sutures) to prevent hematoma formation. In general, buried sutures are better tolerated by the patient.

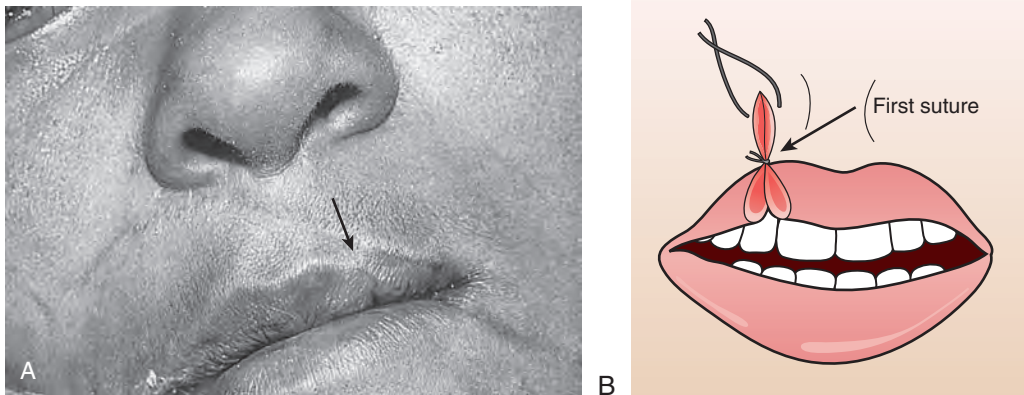

Figure 35.49 **A**, A poorly aligned vermilion border (*arrow*) distorts the lip contour. **B**, To prevent this complication, place the first stitch at the vermilion-cutaneous border to obtain proper alignment.

lacerates the lip as a result of a punch in the face. Check all lip lacerations for retained tooth fragments. In general, small lacerations of the oral mucosa that do not involve muscle heal well without sutures. However, if a mucosal laceration creates a flap of tissue that falls between the occlusal surfaces of the teeth or if a laceration is extensive enough to trap food particles (e.g., ≥ 2 to 3 cm in length), the laceration should be closed. Small flaps may be excised. Accomplish closure with 4-0 Dexon or Vicryl in a simple interrupted suturing technique. These materials are soft and less abrasive than gut sutures, which become hard and traumatize adjacent mucosa. Vicryl Rapide promotes less inflammation than either gut or Dexon sutures.¹⁴³ Nylon sutures have sharp ends that are annoying and painful; thus, this suture material should be avoided inside the mouth. In general, when possible, close muscle and mucosal layers separately. Sutures in the oral cavity easily become untied by the constant motion of the tongue. Tie each of these sutures with at least four square knots. These sutures need not be removed; they either loosen and fall out within 1 week or are rapidly absorbed.^{117,144,145}

Small through-and-through lacerations can be thoroughly cleaned and closed in two layers (skin and mucosa). It is acceptable to leave the mucosal side open if the defect is small (see Fig. 35.48C). Close large through-and-through lacerations of the lip in three layers. With a multilayer closure, approximate the muscle layer with a 4-0 or 5-0 absorbable suture securely anchored in the fibrous tissue located anterior and posterior to the muscle. The vermilion-cutaneous junction of the lip is a critical landmark that, if divided, must be repositioned with precision. Even a 1-mm step-off is apparent and cosmetically unacceptable.

Approximate the vermilion border with a 5-0 or 6-0 nonabsorbable guide stitch before any further closure to ensure proper alignment throughout the remainder of the repair (Fig. 35.49). Close the vermilion surface of the lip and the buccal mucosa with interrupted stitches of 4-0 or 5-0 absorbable suture. Finally, close the skin with 6-0 nonabsorbable suture (Fig. 35.50).¹⁴⁴

Evaluate all lacerations that penetrate the oral mucosa for the presence of tooth fragments, especially if teeth are missing

Figure 35.50 **A**, This patient sustained a large through-and-through lip laceration that will require a layered closure. A submental nerve block may be used, or a local anesthetic (lidocaine with epinephrine) can be injected if it does not distort the tissue landmarks. The muscle layer should be repaired with 4-0 or 5-0 absorbable suture. **B**, The vermilion border (*arrow*) must be repositioned precisely to prevent permanent disfigurement. A 5-0 or 6-0 guide stitch should be placed at the border before any other closure. Nonabsorbable monofilament sutures are then used to close the skin. **C**, Absorbable sutures are used to close the buccal mucosa.

Figure 35.51 **A**, A lacerated tongue usually heals well without sutures, but they were placed in this patient because of a large rent in the middle of the tongue. Dexon (Medtronic), Vicryl (Ethicon), or silk sutures (avoid nylon) are ideal for suturing the surface of the tongue. Bleeding is usually controlled with direct pressure and local infiltration of lidocaine with epinephrine; others require deep sutures for hemostasis. Many seemingly large central tongue lacerations (such as occur during a seizure) heal well with no suturing if the margins of the tongue are intact. **B**, When a forked tongue is possible or flaps are pronounced, the tongue requires anatomic repair. **C**, This laceration will heal well without sutures.

or chipped. Intensify the search if the patient returns with an infection of a sutured wound. Probe the wound with forceps to identify fragments not seen directly in the wound. In the setting of marked facial swelling, take a radiograph of the soft tissue to help identify embedded tooth fragments.

Tongue Lacerations

Some controversy exists regarding when to suture tongue lacerations. Small, simple, linear lacerations, especially those in the central portion of the tongue, heal quickly with minimal risk for infection. Many small tongue lacerations that occur in children or from falls or seizures do not require sutures. In general, lacerations that involve the edge or pass completely through the tongue, flap lacerations, and all lacerations bisecting the tongue need to be sutured¹⁴⁴ (Fig. 35.51). Small flaps on the edge of the tongue may be excised, but large flaps should be sutured. If dilute peroxide mouth rinses and a soft diet are used for a few days, healing can be rapid. Persistent bleeding from minor lacerations brings most patients to the ED, and

closure with deep sutures may be necessary to prevent further bleeding.

Repair of a tongue laceration in any patient is difficult, but in an uncooperative child, the procedure may prove impossible without general anesthesia. A Denhardt-Dingman side mouth gag aids in keeping the patient's mouth open. Anesthetize a localized area of the tongue topically by covering the area with 4% lidocaine-soaked gauze for 5 minutes. Determine the maximum safe dose of local anesthetic and avoid exposure to greater doses. Large lacerations require infiltration anesthesia (1% lidocaine with buffered epinephrine) or a lingual nerve block. If the tip of the tongue has been anesthetized, a towel clip or suture can be used to maintain protrusion of the tongue in an uncooperative patient. Further anesthesia and subsequent wound cleansing and closure are possible while an assistant applies gentle traction on the tongue.

Use size 4-0 absorbable sutures to close all three layers (inferior mucosa, muscle, and superior mucosa) in a single stitch; alternatively the stitch should include half the thickness

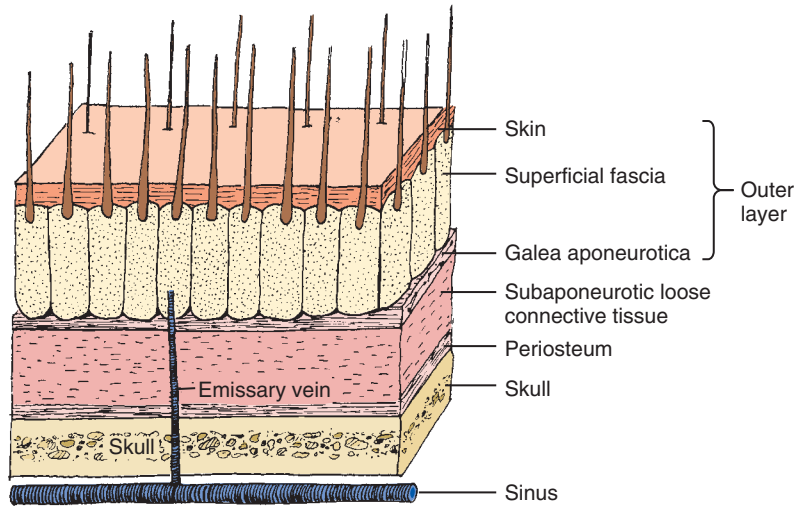

Figure 35.52 Anatomy of the scalp. The skin, superficial fascia, and galea constitute the outer layer. Blood vessels in the fascia are the major source of the bleeding in scalp lacerations.

of the tongue, with sutures placed on the superior and inferior surfaces, as well as on the edge of the tongue. Sutures on the tongue frequently become untied. This problem can be prevented if the stitches are buried. Avoid nylon sutures because the sharp edges are uncomfortable.¹¹⁷ Closure of the lingual muscle layer with a deep absorbable suture alone may be sufficient to control bleeding and return motor function to the lacerated tongue; mucosal healing is rapid.

Scalp Lacerations

The scalp extends from the supraorbital ridges anteriorly to the external occipital protuberances posteriorly and blends with the temporalis fascia laterally. The scalp has five anatomic layers: skin, superficial fascia, galea aponeurotica, subaponeurotic areolar connective tissue, and periosteum (Fig. 35.52). Clinically, however, the scalp may be divided into three distinct layers. The outer layer consists of the skin, superficial fascia, and galea (the aponeurosis of the frontalis and occipitalis muscles), which are firmly adherent and surgically considered as one layer. The subaponeurotic layer and the periosteum form the second and third layers. The integrity of the outer layer is maintained by inelastic, tough, fibrous septa, which keep wounds from gaping open unless all three portions have been traversed. Wounds that gape open signify a laceration extending beneath the galea layer (Fig. 35.53). The galea itself is loosely adherent to the periosteum by means of the slack areolar tissue of the subaponeurotic layer. The galea is firmly attached to the underside of the SQ fascia and is rarely identified as a distinct layer in the depths of a wound. The periosteum covers the skull. The tissue-thin periosteum is often mistakenly identified as the galea, but the periosteum is flimsy and adherent to the skull and cannot be sutured.

Several unique problems are associated with wounds of the scalp. Multiple scalp wounds that are hidden by a mat of hair are easily overlooked. Stellate lacerations are common in this region, not only because the scalp is vulnerable to blunt trauma but also because its superficial fascial layer is inelastic and firmly adherent to the skin. Stellate lacerations pose additional technical problems in closure and have a greater propensity for infection. Shear-type injuries can cause extensive separation

Figure 35.53 **A**, The galea has been transected in wounds that gape open like this one, and to achieve hemostasis and obtain the best closure, the galea should be sutured. **B**, This nongaping wound does not include the galea and can be closed with superficial sutures.

of the superficial layers from the galeal layer. Debris and other contaminants can be deposited several centimeters from the visible laceration; therefore, careful exploration plus cleaning of scalp wounds is important. When scalp wounds are débrided, obviously devitalized tissue should be removed, but débridement should be conservative because closure of large defects on the scalp is difficult.

The presence of a rich vascular network in the superficial fascia results in profuse bleeding from scalp wounds. Severed scalp vessels tend to remain patent because the fibrous SQ fascia hinders the normal retraction of blood vessels that have been cut and allows persistent or massive hemorrhage with simple lacerations. The subgaleal layer of loose connective tissue contains emissary veins that drain through diploic vessels of the skull into the venous sinuses of the cranial hemispheres. In scalp wounds that penetrate this layer, bacteria may be carried by these vessels to the meninges and the intracranial sinuses. Thus, a scalp wound infection can result in osteomyelitis, meningitis, or a brain abscess.¹⁴² Closure of galeal lacerations not only ensures control of bleeding but also protects against the spread of infection.

Profuse bleeding, especially from extensive scalp lacerations, is best controlled by suturing¹³⁰ (see also Chapter 34). Unless the vessels are large or few, ligation of multiple scalp vessels seldom provides effective hemostasis, and considerable blood loss can occur during the attempt. Ask an assistant to maintain compression around the wound while you complete closure of the wound. A simple procedure that often provides hemostasis of scalp wounds is to place a wide, tight rubber band or Penrose drain around the scalp from the forehead to the occiput. You can also control bleeding temporarily in some cases by grasping the galea and the dermis with a hemostat and everting the instrument over the edge of the skin (Fig. 35.54). The disadvantage of this technique is that tissue grasped by the hemostat may be crushed and devitalized.¹³⁰ If the SQ tissue is also everted for a prolonged period, necrosis can occur.

If an assistant is not available to apply direct pressure, use local anesthetics containing epinephrine because this is sometimes effective in controlling persistent bleeding from small vessels in a scalp wound. If bleeding from the edge of the scalp wound is vigorous and definitive repair must be postponed

while the patient is resuscitated, Raney scalp clips or a hemostat can be applied quickly to the edge of the scalp wound to control the hemorrhage.

Before wound closure, visually examine the underlying skull and palpate it for skull fractures (Fig. 35.55). In wounds that can be visualized or explored, more small skull fractures are detected with the clinician's eyes and gloved finger than with radiographs. However, a common error is to mistake a tear in the galea or the periosteum for a fracture during palpation inside the wound. Direct visualization of the area should resolve the issue. Of particular importance are stab or puncture wounds in the scalp and forehead, such as from a nail, spike, screwdriver, knife, or ice pick. Without a laceration to explore, such wounds may seem benign, and the patient can initially appear relatively asymptomatic, yet the skull or brain has been penetrated. When evaluating a puncture or stab wound to the head, a computed tomography scan may provide unexpected findings of a skull fracture, linear or depressed, or an underlying brain injury or early hemorrhage. In wounds that expose bone but do not penetrate the skull, prolonged exposure may leave a nidus of dead bone in which osteomyelitis could develop. If exposed bone is visibly necrosed, consider appropriate consultation with neurosurgery for partial removal of the bone with rongeurs

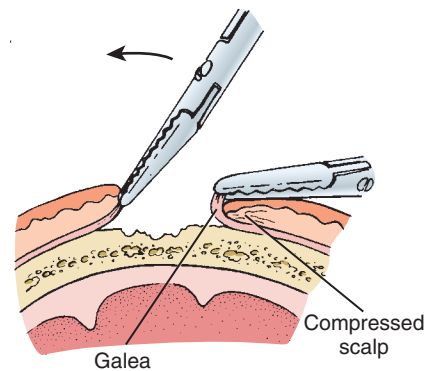

Figure 35.54 To temporarily control bleeding from vessels in the fascia, the galea can be everted to compress the fascia.

Figure 35.55 A, A finger and direct vision can be used to identify skull fractures. Do not mistake a rent in the soft tissues as a fracture. B, Puncture wounds in the forehead and scalp from such objects as a knife, nail, screwdriver, or ice pick can penetrate the skull and brain, and initially the patient appears well and the wound looks benign. This patient was in a bar fight and was “stabbed” in the forehead. He had no complaints. The wound could not be fully explored but appeared to be benign. C, Computed tomography scan demonstrating a depressed skull fracture (arrows).

until active bleeding appears.¹³⁰ Clip hair surrounding the scalp wound far enough from the edge of the wound so that suturing can proceed without entangling the hair or burying it in the wound. As stated in other sections, avoid shaving, and instead clip hair to avoid further injury. If hairs along the wound edges become embedded in the wound, they will stimulate excessive granulation tissue and delay healing.¹⁴⁶ Place Vaseline or tape on stubborn hairs that persistently fall into the wound to help hold them back. Although clipping scalp hair is not popular with some patients, failure to adequately expose an area is a common cause of improper cleaning and closure of scalp wounds. Because of the extensive collateral blood supply of the scalp, most lacerations in this area heal without problem, even after delayed treatment. Nonetheless, wound cleaning must be sufficient to avoid the devastating complication of scalp infection.

With microvascular techniques, large sections of skin avulsed from the scalp can be reimplanted. Some of these same techniques are used to salvage avulsed scalp, similar to those used for amputated extremities.¹⁴⁷

Unlike most wounds involving multiple layers of tissue, scalp wounds can usually be closed with a single layer of sutures that incorporate skin, SQ fascia, and the galea (Fig. 35.56). The periosteum does not need to be sutured; in fact, sutures generally do not hold in this friable, thin tissue. Separate closure of the galea introduces additional suture material into the wound and may increase the risk for infection. However, in extremely large wounds, separate closure may be necessary to provide a more secure approximation of the galea than can be obtained with a large-needle, single-layer closure. In this

situation, an inverted stitch (with an absorbable 3-0 or 4-0 suture) will bury the knot beneath the galea.

In superficial wounds, approximate the skin and SQ tissue with simple interrupted or vertical mattress stitches using nonabsorbable 3-0 nylon or polypropylene suture on a large needle. Avoid smaller suture material because it tends to break when firm knots are being tied. Leave the ends of the tied scalp sutures at least 2 cm long to facilitate subsequent removal. The use of blue nylon rather than black may make suture removal easier. Absorbable sutures may provide similar cosmetic and functional outcomes in scalp laceration repair.¹⁴⁸

Sutured scalp lacerations need not be bandaged. Instruct patients that they can wash their hair in 2 hours (Fig. 35.57). If bleeding persists, use an elastic bandage as a compression dressing. Place gauze sponges over the laceration to provide direct local pressure beneath the elastic bandage.

An easy method of scalp laceration repair is the hair apposition technique (HAT; Fig. 35.58A).¹⁴⁹⁻¹⁵⁴ HAT should not be used in deep wounds as it only apposes the superficial layers of the scalp. Advantages of this technique include cosmetic results similar to suturing, increased speed of repair, no need for clipping of hair, and no need for return visit for suture or staple removal.¹⁵⁵ The HAT technique should not be used with lacerations greater than 10 cm in length, irregular wound margins, hair less than 3 cm in length, and continued bleeding. Wounds between 1 and 3 cm in length may be repaired with the modified HAT technique (see Fig. 35.58B).¹⁵⁶ Care must be taken to place only a small drop of glue onto the twist of hair (not the scalp) to prevent tissue glue from entering the wound.¹⁵⁶ In the HAT technique, the hair is twisted and no

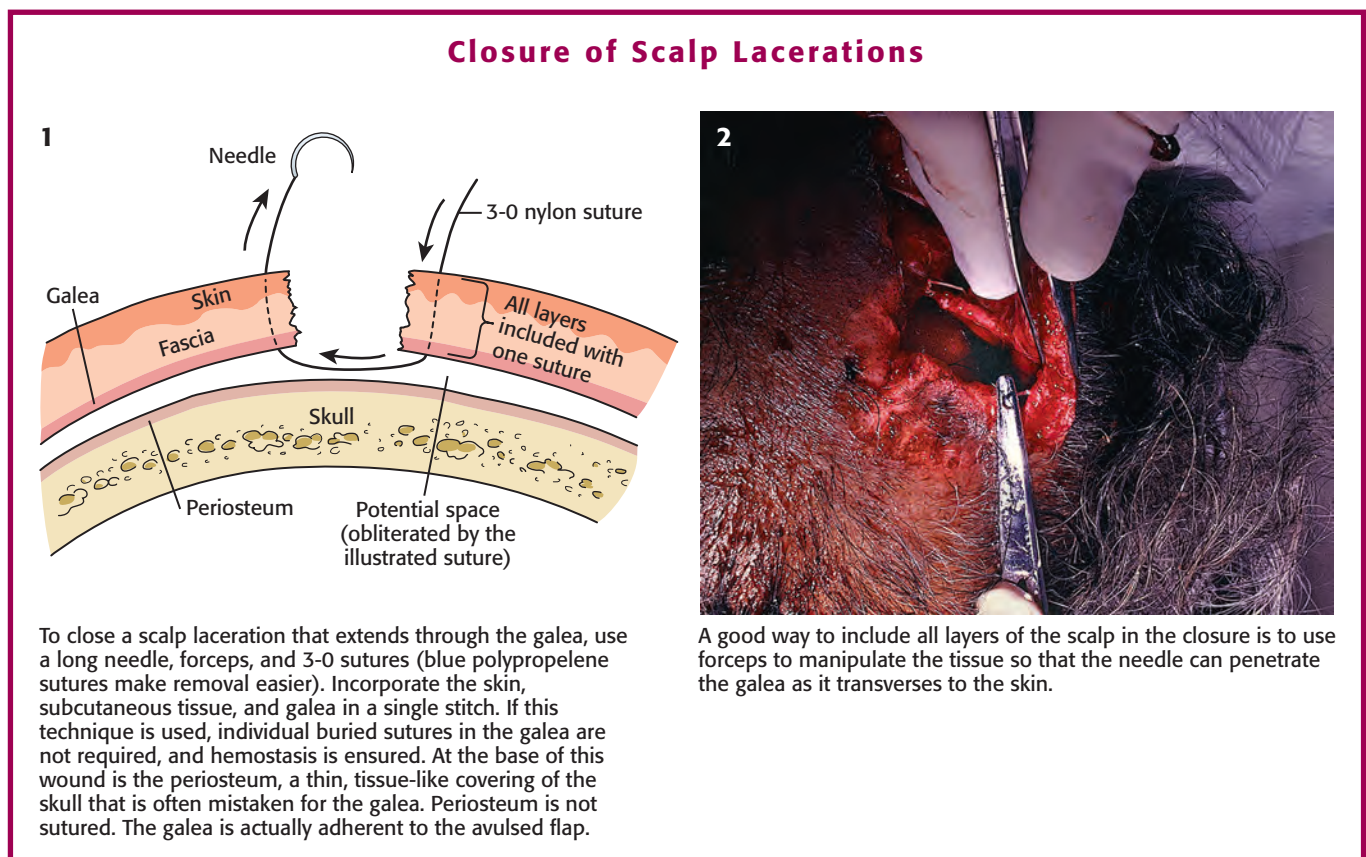

Figure 35.56 Closure of scalp lacerations.

actual knot is tied in the hair. The patient should be instructed to wait two days prior to hair washing. The patient should be informed that the glue will gradually fall off within two weeks. If the drop of glue fails to fall off, it may be simply removed with tweezers or comb.

Nail Bed Lacerations

Injuries to the nail and nail bed (also called the nail matrix) are common problems in emergency medicine, yet controversy

Figure 35.57 Once the scalp is sutured, the patient is encouraged to wash the hair at home that day to remove blood and debris. Prohibiting bathing with sutures in place in any part of the body has no scientific merit.

exists over proper management (Fig. 35.59). As a general rule, repair nail bed lacerations unless they are well approximated. An exception is a nail bed laceration that causes a simple subungual hematoma.

Subungual Hematomas

Subungual hematomas develop from a nail bed laceration. Some nail bed lacerations are minor and of no consequence, whereas others portend a poor outcome unless the bed is repaired.^{157,158} A simple subungual hematoma (even in the presence of a tuft fracture) in which the nail is firmly adherent and disruption of the surrounding tissue is minimal, is not an indication to remove the nail to search for nail bed lacerations (Fig. 35.60).¹⁵⁹ Despite the presence of a nail bed laceration, a good result can be expected as long as the tissue is held in anatomic approximation by the intact fingernail. Nail trephination is discussed in Chapter 37.

Suture the nail bed if a large subungual hematoma is associated with an unstable or avulsed nail. Remove the nail completely and repair the nail bed under a bloodless field (Fig. 35.61). Always use absorbable sutures in the nail bed so they do not have to be removed. A good outcome depends on maintaining the space under the eponychium (cuticle) as the laceration heals and the new nail grows out, which is a slow process.

Partial Nail Avulsions

If the nail is partly avulsed (especially at the base) or loose, lift the nail to assess and potentially repair the nail bed. If the nail is intact, it is best to leave it in place if the nail bed laceration

Figure 35.58 **A**, Hair apposition technique (HAT) for superficial scalp lacerations in which hair is greater than 3 cm in length. 1, Select 4 to 5 hair strands on each side of the laceration; separately twist each group of hair strands to form bundles. 2, Cross the bundles using artery forceps. 3, Twist the bundles around each other once; there is no need to form an actual knot. 4, Place one small drop of glue on the twist of hair (not on the scalp) to secure. Repeat, every 1–2 cm along the wound, bisecting the wound just as if using sutures. **B**, Modified HAT, which is useful for hair lengths of 1 cm to 3 cm. 1, On each side of the wound, a bundle of 5 to 15 hairs is grasped by a clamp and the clamps are twisted around one another. 2, Tighten the twist of hairs to appose the wound margins. 3, One small drop of tissue glue is placed on the twist of hairs. 4, Repeat this every 1 to 1.5 cm to secure the entire laceration. (**A**, from Ong M, Ooi S, Saw, et al: A randomized controlled trial comparing the hair apposition technique with tissue glue to standard suturing in scalp lacerations (HAT study), *Ann Emerg Med* 40:21, 2002. **B**, from Karaduman S, Yurukrumen A, Guryay S, et al: Modified hair apposition technique as the primary closure method for scalp lacerations, *Am J Emerg Med* 27:1050, 2009.)

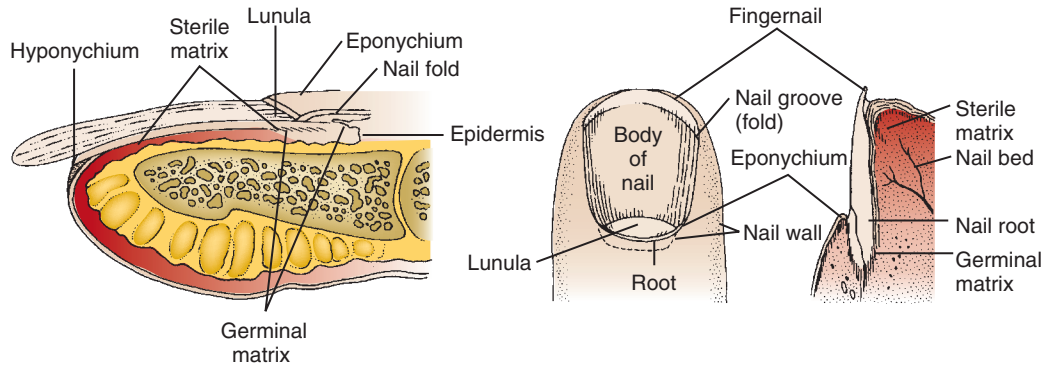

Figure 35.59 Anatomy of the fingernail. The fingernail rests on the nail bed, also termed the matrix. The distal end of the nail covers the sterile matrix; the proximal end arises from and covers the germinal matrix. The tissue adherent to the proximal dorsal surface of the nail is the eponychium (also termed the cuticle), and the potential space between the nail and the eponychium is the nail fold.

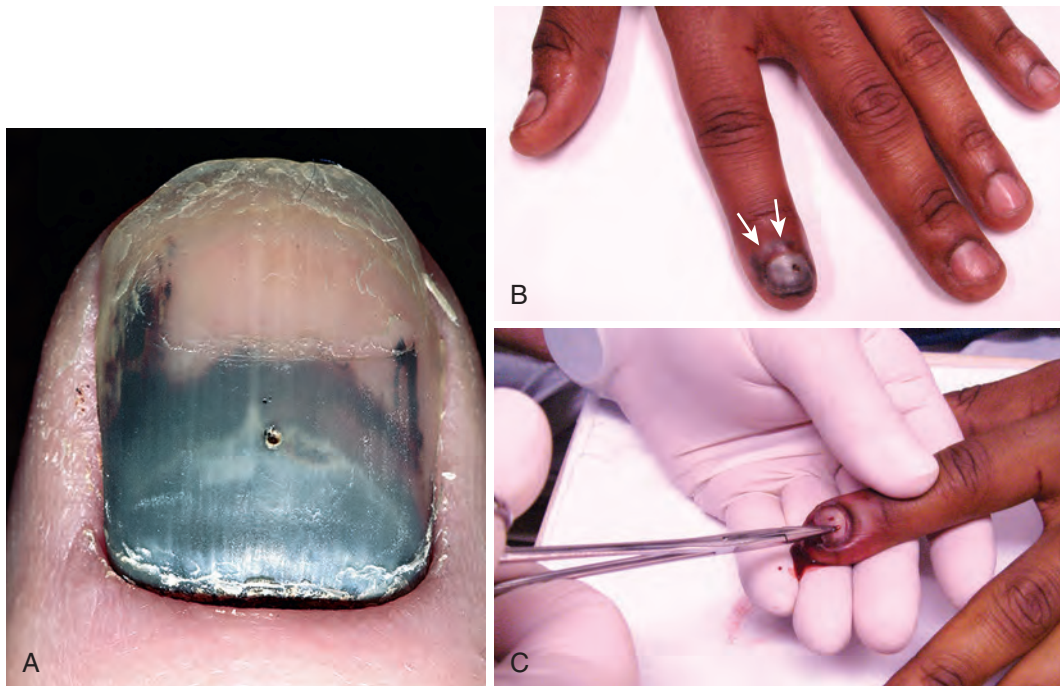

Figure 35.60 **A**, This subungual hematoma occupies most of the nail and should be drained by simple nail trephination. The injury does not require nail removal or repair of the nail bed because the nail is still firmly attached to the matrix. Even though a nail matrix laceration (the source of the bleeding) is present, the cosmetic result will be excellent. The presence of an underlying digital tuft fracture does not change management. This hole is too small and did not evacuate all the blood. **B**, There are two issues with this injury. First, an inadequately sized hole was placed (too small) and did not drain the subungual hematoma. All blood should be drained in the emergency department before discharge to ensure proper treatment. Note the subtle ecchymosis under the eponychium (*arrows*). This can occur only if the nail base was avulsed. The base of the nail is lying just under the skin. Compare it with **A**, where no blood is seen in the paronychia area as the nail base remains intact. **C**, After the hole is enlarged and the blood is totally drained, and without removing the nail, a hemostat is used to pull the nail forward and manipulate the base back into its proper position under the eponychium.

can be repaired (Fig. 35.62). The method for atraumatically removing a nail is demonstrated in Fig. 35.67.

Nail Bed Repair

When the integrity of the nail bed is significantly disrupted, a rippled nail may develop (see Fig. 35.62F). Anatomic repair

of the nail bed may minimize subsequent nail deformity. Approximate a simple nail bed laceration with 6-0 or 7-0 absorbable suture (to obviate the need for suture removal); either Vicryl Rapide or chromic gut may be used for nail bed repair.^{160,161} If available, use loupe magnification and a finger tourniquet to maintain a bloodless field (Fig. 35.63). Repair

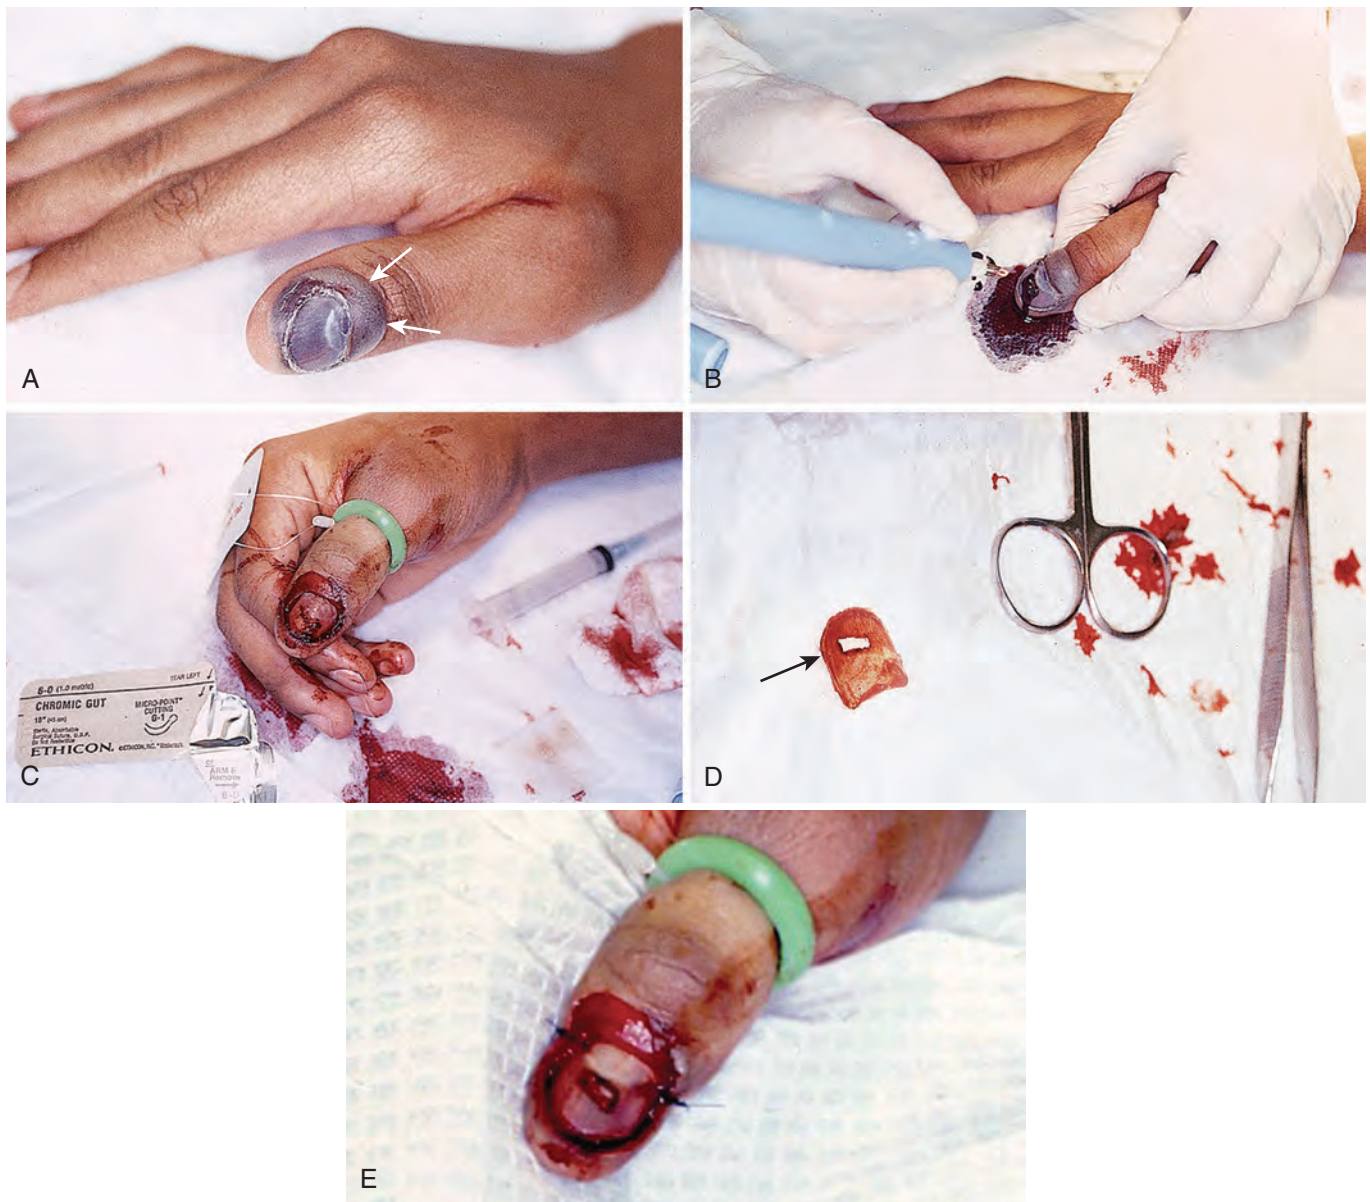

Figure 35.61 **A**, Classic “finger slammed in a door” with forced flexion and avulsion of the base of the nail. This large subungual hematoma can be misleading, but it is associated with blood under the cuticle (*arrows*) proximal to the nail, a clue that this is not a simple injury. **B**, When the blood is drained, the extent of the injury is more obvious. **C**, Careful removal of the nail exposes a laceration of the nail bed, which is sutured with absorbable suture. **D**, A drainage hole is placed in the nail (*arrow*) because it will be used as a temporary splint for the nail bed and to keep the cuticle space open to prevent scarring. **E**, The avulsed nail is placed under the eponychium to its base and sutured in place for 3 to 4 weeks while a new nail grows. This replaced nail may be removed, or it is pushed out by the new nail.

the proximal and lateral nail (onychial) folds first. Attach a sturdy needle to a 4-0 thread for suturing lacerated nails. Insert the needle perpendicularly to the nail because the needle penetrates most easily in this position. The point of the needle carves a rigid path through the nail. Unless the entire length of the needle is allowed to follow this path as it passes through the nail, the needle is likely to bend or break. Alternatively, use an electrical cautery instrument or a heated paper clip to perforate the nail and permit easy passage of the needle.

Protect the exposed nail bed by reapplying the avulsed nail (best choice) or by applying a sterile nonadherent dressing,

such as Silastic sheet, sterile polypropylene foil (obtained from the sterile infusion reservoir used on IV tubing), or gauze packing for approximately 2 to 3 weeks. Reinsertion of the nail occasionally results in infection, so clean the nail carefully. After cleaning, suture the avulsed nail in place or secure it with wound closure tape or tissue glue. If only the distal portion of the nail has been avulsed, it can still be used as a temporary splint or “dressing” to protect and maintain the integrity of the underlying nail bed (see [Fig. 35.63](#)).

The figure-of-eight technique can be used to secure the nail, which minimizes additional trauma to the nail bed and

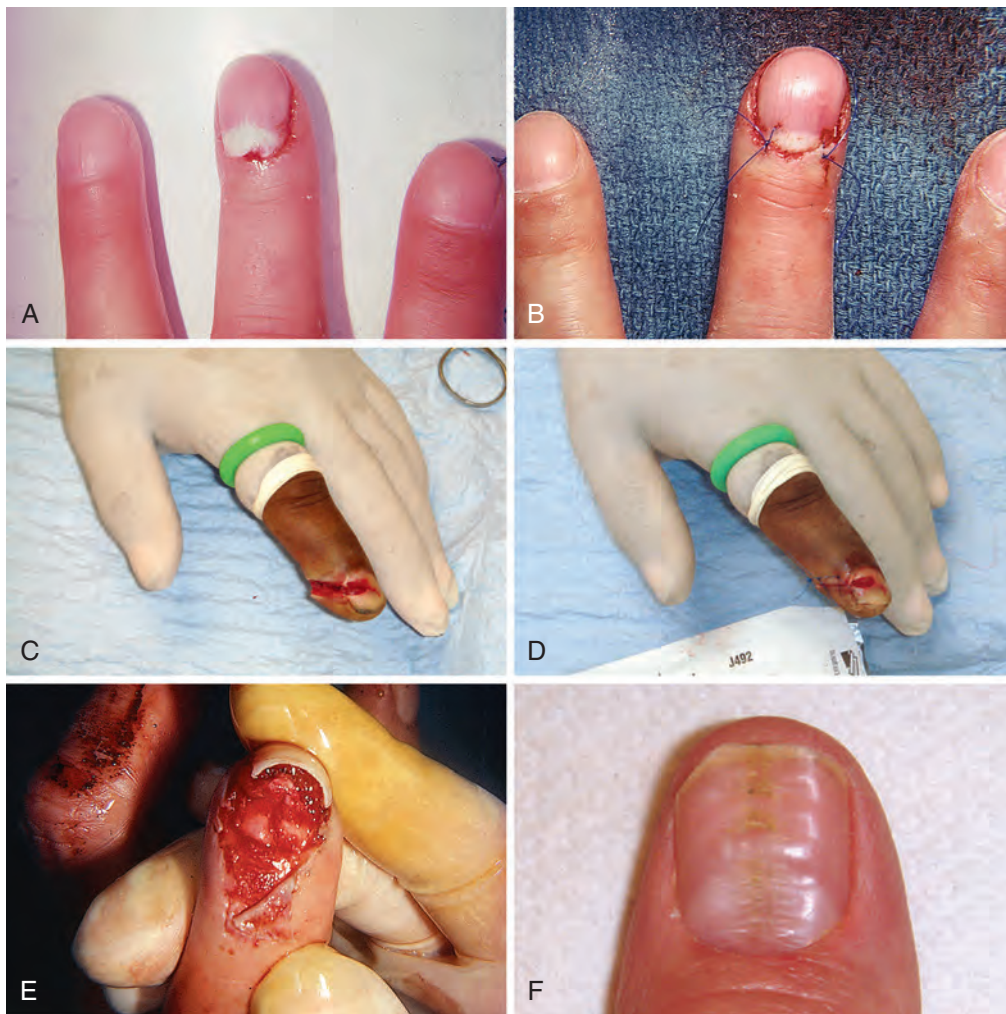

Figure 35.62 **A**, This fingernail was avulsed at the base, a common result of having a door slam on the digit. The nail is tightly adherent to the nail bed, so it is not removed but simply replaced under the eponychium to its former position. **B**, Sutures are placed in the nail to keep it stable. This nail may simply start to grow on its own. **C**, A saw-induced laceration of the fingertip with an open fracture, nail bed laceration, and skin laceration. **D**, Only part of the nail was removed and the nail bed repaired through the window. The skin is closely approximated. Such injuries usually heal well with attention to detail, and infection is unusual despite the open fracture. Oral antibiotic therapy for 5 to 7 days is reasonable. **E**, Because this avulsed nail is unstable and subungual bleeding is present, the nail can be removed and the nail bed inspected. Any large nail bed laceration should be repaired meticulously with absorbable suture (6-0). After repair of the nail bed, a drainage hole is placed in the nail, and the nail is replaced under the eponychium (cuticle) and fixed in place with sutures that incorporate the nail edge and the skin bilaterally. In 2 to 3 weeks, the new nail will begin to push out the old nail (usually growing under it while maintaining the eponychium), and the old nail is removed. The exposed nail bed will be sensitive for a while. See [Fig. 35.67](#) for a simple technique to remove the fingernail. **F**, This nail is permanently deformed with ridges. Although crush injury to the nail bed is probably responsible for this deformity, repair of the nail bed might have minimized the resultant deformity.

eponychium ([Fig. 35.64](#)).¹⁶¹⁻¹⁶³ This technique has also been used to secure sterile polypropylene foil in the event that the nail is too injured to be replaced ([Fig. 35.65](#)).¹⁶³

Tissue adhesive is a time-saving option for repairing nail bed lacerations in both adult and pediatric patients ([Fig. 35.66](#)).^{164,165} Tissue glue obviates the need for suture removal and produces similar cosmetic and functional results.¹⁶⁴ Tissue glue is applied on nail bed lacerations after meticulous alignment. The glue can also be used to secure the nail plate under

the eponychial fold. A tourniquet is often necessary to maintain a bloodless field during tissue adhesive application.

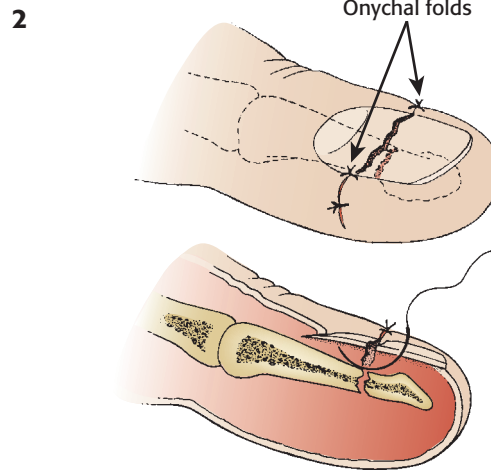

Complete Nail Avulsions

If the entire nail is avulsed but intact, it should be replaced after repairing the nail bed laceration for three reasons: (1) it acts as a splint or mold to maintain the normal anatomy of the nail bed, (2) it covers a sensitive area and facilitates dressing changes, and (3) it maintains the fold for new nail

Nail Bed Repair

A laceration involving the nail bed, germinal matrix, and skin fold must be carefully approximated. First, the nail is completely removed. **A**, Fine, absorbable sutures are used to repair the nail bed under a bloodless field provided by a finger tourniquet. The avulsed nail (trimmed at the base) or a gauze pack is gently placed between the matrix and the eponychium for 2 to 3 weeks to prevent scar formation. **B**, If the original nail is replaced (the best option), it may be sutured or taped in place. A large hole in the nail will allow drainage. The old nail is gradually pushed out by a new one. If the nail matrix is replaced quickly and atraumatically, the nail may act as a free graft and grow normally. Note: Only absorbable sutures are used to repair the nail bed.

Repair of a distal finger laceration involving the nail and the onychial fold. In this case, the nail is still adherent to the nail matrix and acts as a natural splint. If the nail is loose or completely transected, it is prudent to remove the entire nail and then carefully suture the nail bed under direct vision.

This nail was removed and the nail bed repaired with absorbable suture.

Because the nail was macerated and unable to be replaced, gauze is used to maintain the eponychial space for 2 to 3 weeks. A small piece of gauze is placed with forceps to gently pack open the space to prevent scar formation.

Figure 35.63 Nail bed repair. (Plate 2, from Dushoff IM: Handling the hand, *Emerg Med* 8:111, 1976. Reproduced by permission.)

growth. If the proximal portion of the nail is not replaced, either of two complications may result: (1) longitudinal scar bands may form between the proximal nail fold and the germinal matrix and cause a permanent split or deformity of the nail, or (2) the space between the proximal nail fold and the germinal matrix of the nail bed may be obliterated within a few days.¹⁶⁶ Consequently, splints over proximal nail beds should be maintained for 2 to 3 weeks. The proximal portion of the traumatized nail often needs to be trimmed so that it will fit more easily into the nail fold. It is usually necessary to suture or glue the nail in place. A replaced nail may grow normally and act as a free graft, but it is often dislodged by a new nail. If the nail was lost or irreparably destroyed, insert a piece of nonadherent, petrolatum-impregnated gauze (such as Adaptic [Acelity, San Antonio, TX] or Xeroform [DeRoyal, Powell, TN]) between the proximal nail fold and the germinal matrix. Nails grow at a rate of 0.1 mm/day, and

approximately 6 months is required for a new nail to reach to the fingertip.

Complicated Nail Bed Injuries

If the germinal matrix of the nail bed is avulsed but intact, reimplant the nail with a 5-0 or 6-0 absorbable suture using a mattress stitch.^{117,167} If an open fracture exists, do not allow any part of the matrix to remain trapped in the fracture line.¹⁶⁸

If the nail bed is found to be extensively lacerated, it may be prudent to refer the patient to a hand surgeon, who can raise a flap of tissue extending from the proximal nail fold, explore the wound for foreign bodies, and clean under the nail bed. A fingertip avulsion that involves the germinal matrix or an isolated nail bed avulsion should not be allowed to heal on its own (i.e., by secondary intention). If the exposed germinal matrix is left open to granulate, it will form scar tissue that could produce a distorted and sensitive digit. If part of the

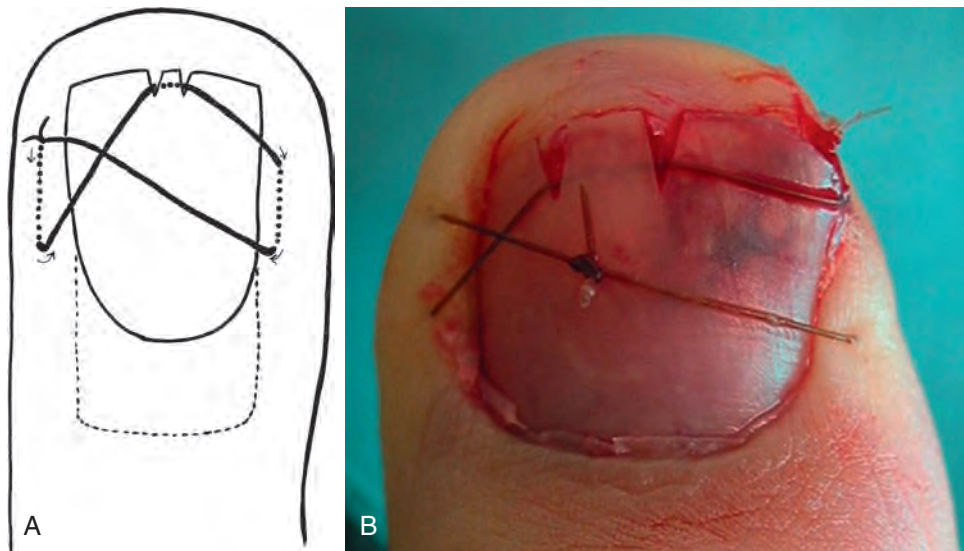

Figure 35.64 Transverse figure-of-eight suture for securing the nail. Two small wedges are cut into the distal aspect of the nail and the nail is placed under the eponychial fold. A 4-0 (5-0 in children) absorbable or nonabsorbable suture is placed distal-to-proximal on one side of the paronychium. Suture is slid through the wedges of the distal nail, placed distal-to-proximal in the opposite paronychium, and then tied, resulting in a figure-of-eight pattern. The distal entry point is about the midpoint of the exposed nail plate and may be used even if the nail is only partially intact. The finger should be dressed with a bulky, nonadherent dressing. (From Bristol S, Verchere C: The transverse figure-of-eight suture for securing the nail, *J Hand Surg Am* 32:125, 2007.)

germinal matrix has been lost, refer the patient to a surgical consultant for a matrix graft.^{117,169,170}

Recheck wounds 3 to 5 days after repair. At that time, remove and replace any nonadherent material that was inserted under the proximal nail fold, and assess the wound for infection. The use of absorbable suture for nail bed repair makes suture removal unnecessary. Sutures that were used to reattach the nail are removed in 2 weeks, and the old nail is allowed to fall off as the new nail grows. The value of antibiotics is unproven. Advise all patients with nail injuries of a possible cosmetic defect in the new nail that may occur regardless of the repair technique.

Removal of a Nail

▶ If a partially avulsed or intact nail requires removal (Video 35.10), take care to not injure the nail bed. The nail is usually firmly attached to the bed but can be separated by advancing and opening small scissors in the plane between the nail and the bed. Once loosened, pull the nail from its base with a hemostat (Fig. 35.67).

Tuft Fractures

Once the nail bed has been lacerated, a tuft fracture is considered an open fracture. The use of antibiotics for nail bed laceration is controversial. Most injuries do well with good wound care and reasonable follow-up. Antibiotics are not used after nail trephination, even in the presence of a tuft fracture. Infection is rare, but antibiotics may be considered for significant crush or highly contaminated injuries. The approach to an open tuft fracture varies from formal operating room débridement and intravenous antibiotics to thorough ED cleaning and oral antibiotics with early follow-up. Consultation with a hand specialist is warranted. Splinting is protective. Search for a traumatic mallet finger with flexion or crush injuries.

Drains in Sutured Wounds

Drains are used primarily to keep wounds open for drainage of existing purulence or blood that may otherwise collect in the wound. Drains do not prevent infection. When no infection exists, the use of drains in soft tissue wounds “prophylactically” is rarely required in the ED setting. Drains in uninfected wounds may wick surface bacteria into the wound and impair resistance of the wound to infection.¹⁰² Drains placed in experimental wounds contaminated with subinfective doses of bacteria behave as foreign bodies by enhancing the rate of infection, regardless of whether the drain is placed entirely within the wound or brought out through the wound.¹⁷¹

If the wound is considered to be at high risk for infection, instead of suturing the wound with a drain in place (in anticipation of infection), it may be more prudent to leave the wound open and consider delayed primary closure later when the risk for infection subsides. Drains should not serve as substitutes for other methods of achieving hemostasis in traumatic wounds.

Lacerations Over Joints

Lacerations over joints may enter the joint itself or injure adjacent tendons or muscle groups. It may be difficult to determine whether the joint has been violated. A plain radiograph of a large joint such as the knee may demonstrate air within the joint, which is evidence of joint penetration (Fig. 35.68). If a wound penetrates the joint cavity, open débridement may be required, but the approach varies with the joint involved.

Fingertip Amputations

Treatment of fingertip amputations has undergone evolution from complicated grafts and flaps to nonsurgical follow-up and primary healing (Figs. 35.69 and 35.70). If bone is not

C, Fingernail substitute trimmed to fit in the nail bed and to provide the nail bed protection while healing. D, Secured fingernail substitute. E, Clinical outcome at one year. (From Tos S, Artiaco S, Coppolino S, et al: A simple sterile polypropylene fingernail substitute, *Chirurgie de la main* 28:144, 2009.)

Figure 35.66 Dermabond (Ethicon) use for securing the nail to the nail bed. (Courtesy Michelle Lin, MD. From Rezaie S: Trick of the trade: nail bed repair with tissue adhesive glue, *Acad Life Emerg Med* 2014. Available at: <http://www.aliem.com/trick-trade-nail-bed-repair-tissue-adhesive-glue/>. Accessed 2016.)

Figure 35.68 A, This laceration looks benign but may involve the knee joint or quadriceps tendon. A radiograph to look for air in the joint or a saline arthrogram (see [Chapter 53](#)) should be performed. B, Air in the joint space (*arrows*) on a plain radiograph proved joint space violation.

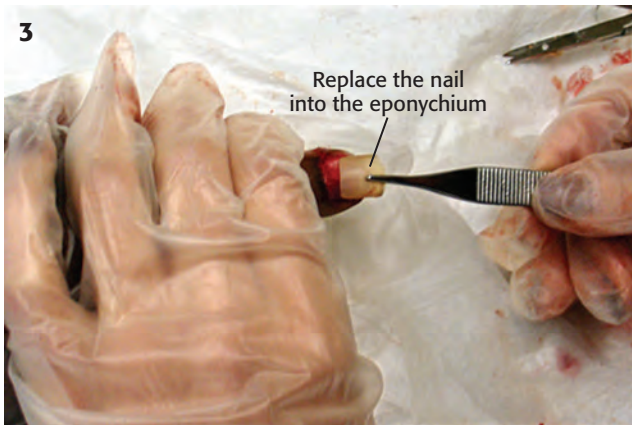

Nail Removal

To remove a fingernail or toenail atraumatically, the blades of iris scissors are held parallel to the nail bed to avoid lacerating the matrix. A digital block is necessary. The closed blades are slowly advanced in the plane between the nail and the nail bed and then gently spread to loosen the nail. The scissors are advanced and spread in stages until the base of the nail is reached and the entire nail is loose. The nail is grasped with a hemostat and pulled from the base.

Once the nail is removed, repair any nail bed lacerations with absorbable suture.

Replace the nail into the eponychial fold.

Suture the nail in place with nonabsorbable stitches.

Figure 35.67 Nail removal.

Figure 35.69 A and B, Guillotine amputation of the fingertip through the distal end of the nail (*arrow*). The distal phalanx is not involved. Approaches vary widely, and referral can be made in a few days if not immediately available. C, Although it is tempting to replace the amputated tip, many would allow this wound to heal spontaneously, albeit slowly (8 to 12 weeks), and not perform skin grafts or flaps. D, The amputated nail is placed under the eponychium and sutured into place. A rounded but shortened tip with sensation can be expected. Periodic débridement and use of the nail as a splint resulted in a good final appearance. E and F, In only 4 weeks, this amputation has nearly healed to the original length and contour with only dressing changes and minimal débridement. Note that a new nail is growing (*arrow*) and the replaced nail has been removed.

Figure 35.70 A and B, This macerated tip has islands of skin left and good tissue volume and will do quite well with sutures to restore the basic anatomy. Healing will take 4 to 5 weeks.

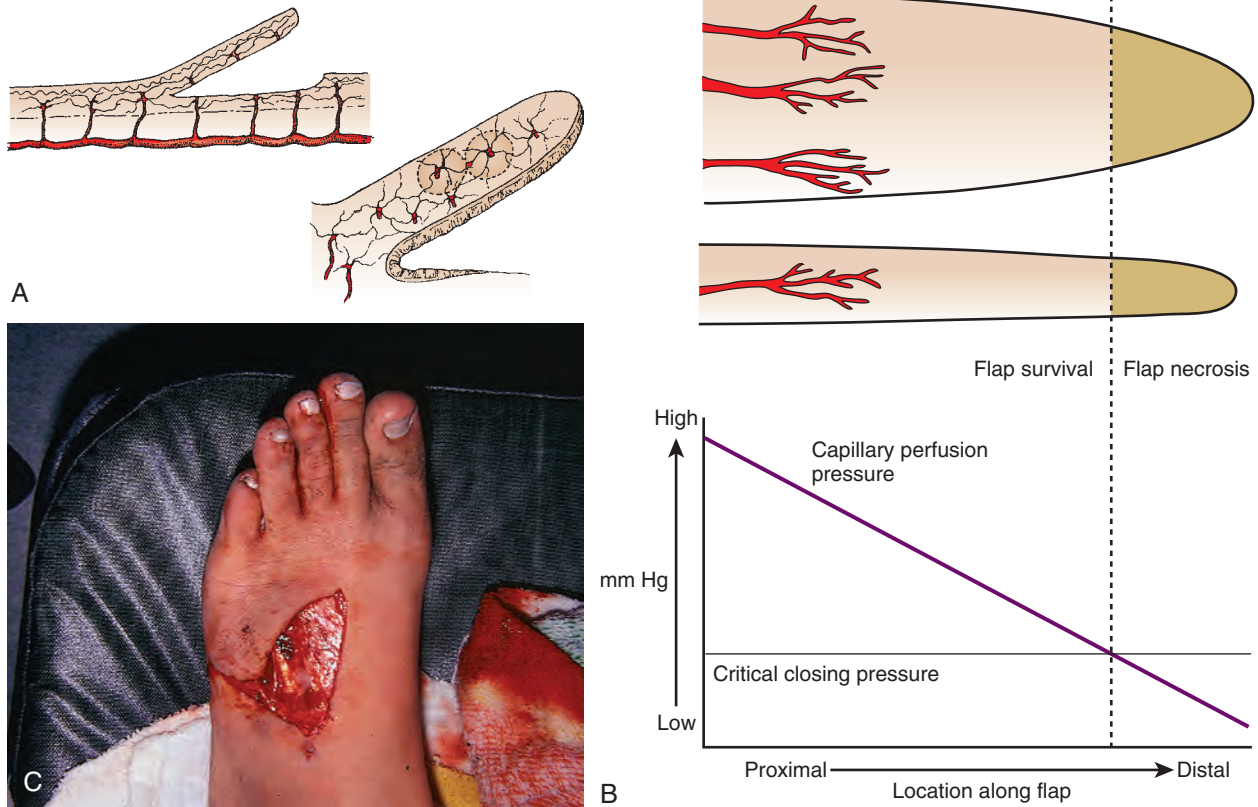

Figure 35.71 A, Vascular territories in skin flaps. Multiple perforating vessels exist and are interconnected at the periphery of their vascular territory. When some of these vessels are cut, the blood supply can be replaced with nearby perforating vessels, and then tissue necrosis does not occur. B, Fallacy of the length-to-width ratio. The slope of decreasing perfusion pressure versus length does not change with the incorporation of additional vessels (flap a versus flap b) at the same perfusion pressure. Flap necrosis occurs when perfusion pressure decreases below the critical closing pressure of the capillary bed. C, This distally based flap is at risk for necrosis because of impaired venous and lymphatic drainage rather than from loss of the arterial supply. As with all flap repairs, it should be replaced by undermining the base to relieve tension (if possible), a compression dressing to limit movement and fluid buildup under the flap, and elevation of the extremity. Even if only a portion survives, closure can be performed in the emergency department. Impaired venous drainage from a proximally based flap is less problematic.

involved, a good result can be expected with attentive wound care, occasionally minimal débridement, and protective dressing changes. It may take 6 to 12 weeks for healing to occur, but acceptable length, function, and sensation can be expected. A motivated patient and follow-up with a knowledgeable specialist are required. There are no data or standard that mandates long-term antibiotics for such injuries, but it is reasonable to provide gram-positive antibiotic coverage for 7 to 10 days.

DISTALLY AND PROXIMALLY BASED FLAP LACERATIONS

Minor flap lacerations can be managed primarily in the ED. Large flaps, such as scalping lacerations, are best handled by a consultant. Both proximally and distally based flaps are not always simple lacerations. The major problem is vascularity: venous drainage at the end of a distally-based flap and the potential for ischemic necrosis in any flap configuration. The body has the ability to augment the circulation in some flaps

(Fig. 35.71A). The length-to-width ratio of the flap is not the main variable in survival of the flap (see Fig. 35.71B). Perfusion pressure is the most critical factor. Intravascular perfusion pressure decreases along the length of the flap. If intravascular perfusion pressure is less than interstitial pressure at the distal end of the flap, capillaries will collapse (the *critical closing pressure*). As edema is generated by ischemia and inflammation, interstitial pressure increases, which decreases chances for tissue survival.

Many proximally and distally based flaps (see Fig. 35.71C) may be closed in the ED and monitored on an outpatient basis. Healing of a distally based flap is hampered by loss of venous and lymphatic drainage and by subsequent edema of the flap, which decreases capillary flow. Warn the patient about the possibility of flap necrosis and the need for revision or even skin grafting at a later date. Partial flap survival is better than total loss of the flap, so flaps with questionable viability should not be removed. Flaps are similar to free skin grafts, and the keys to a more successful outcome include undermining the flap to relieve tension, limiting buildup of fluid under the

Figure 35.72 A–C, These patients had minor lacerations and were brought to the emergency department simply for tetanus prophylaxis or for other vague or unrelated reasons. These are characteristic of self-inflicted wounds that are representative of serious underlying psychiatric issues, and further evaluation is required. D, These cigarette burns are also self-inflicted, though the patient initially stated that she was burned with grease while cooking.

flap with a compression dressing, and decreasing movement of the flap as it heals. Cautious minor defatting may be performed on the underside of the flap. Tissue adhesive instead of multiple sutures can be helpful.

Self-inflicted wounds with a vague or inaccurate history may be encountered in the ED. Characteristic self-injury

patterns are depicted in Fig. 35.72. These patterns of injury should be recognized and appropriate psychiatric follow-up provided.

Foreign Body Removal

Daniel B. Stone and David J. Scordino

EVALUATION AND DIAGNOSIS

A foreign body (FB) is any substance that is not naturally part of the body. These cases are common in the clinical setting. An FB should be suspected whenever the skin is broken. A thorough history and physical examination are essential to assess the risk for an FB. During assessment, FBs may not be obvious especially when the wound may appear closed, but they should be considered whenever the history is particularly concerning. For example, a patient with an apparent “sprained foot” who was walking without shoes and experienced a sharp, sudden pain in the foot may have a needle, toothpick, or any other similar type of FB (Fig. 36.1). Certain mechanisms of injury, such as punching or kicking out a window or stepping on an unknown object while walking in a field or stream, are often associated with a retained FB. Mechanisms that make FBs less likely include lacerations from metal objects; however, if considerable force was applied during the injury and the object is not available for inspection, radiographic imaging may be warranted because bone may have been encountered and a small section might have splintered off the offending object. The history should also include whether the patient perceives or suspects an FB. Steele and associates found that the negative predictive value of patient perception was 89% but that the positive predictive value was just 31%.¹ Importantly, the patient’s past medical history should be explored for allergies to local anesthetics, bleeding diatheses, diabetes mellitus, vascular disease, uremia, immunocompromised state, or other diseases that would affect wound healing or management.

Before the physical examination, be sure to have enough examination time, as well as proper space and equipment. It is important to confirm that the patient is willing to undergo the procedure because cooperation is essential to optimize success. Attempts at removing an FB in an overtly uncooperative patient, such as one who is intoxicated, drugged, cognitively limited, or confused, are potentially injurious to both the examiner and the patient. In most noncritical situations, if a patient is uncooperative, perform the examination again when the patient is able to cooperate. In benign cases, follow-up can occur a few days later.

During the physical examination, carefully palpate the periphery of all wounds to elicit tenderness because retained FBs often produce pain during palpation. In addition, some FBs can migrate away from the wound or perceived entry point. Some superficial FBs may be palpated through the skin, but surprisingly large FBs may be found in seemingly minor wounds without much external evidence. In some cases, the external characteristics of the wound do not yield firm evidence regarding the presence or absence of an FB. Deeper FBs may not be palpable and must be localized by other techniques.

Exploration is an important part of the bedside evaluation, whether done initially or after further imaging studies (Fig. 36.2). This requires adequate pain control, good lighting, proper

equipment, a bloodless field, a cooperative patient, and appropriate positioning to visualize as much of the wound as possible (Figs. 36.3 and 36.4). A metal probe may help identify the FB by feel or sound. Glass, as an example, is difficult to identify by sight in soft tissue, but touching it with metal causes a characteristic grating sound. Probing a wound with a gloved finger to locate or identify an FB is strongly discouraged because of the risk of the FB penetrating the glove and exposing the clinician to infection such as human immunodeficiency virus (HIV) and hepatitis (Fig. 36.5). Alternatively, some authors have suggested injecting the entrance wound with methylene blue to outline the track of the FB.² The blue line of injected dye is followed into the deeper tissues. This technique is of limited value because the track of the FB often closes tightly and does not allow passage of the methylene blue.

Augmenting the Physical Examination: Imaging Techniques

Many emergency clinicians mistakenly believe that in the absence of adipose tissue, if the base of the wound can be clearly visualized and explored, an FB can always be ruled out. Orlinsky and Bright found the reliability of exploration to be related to the depth of the wound.³ In their study, only 2 of 133 superficial wounds, deemed adequately explored, had an FB on plain films, but 10 of 130 wounds had FBs beyond the subcutaneous fat despite negative explorations. Anderson and coworkers reported that 37.5% of the foreign bodies were initially missed by the treating physicians.⁴ In many of these cases, a radiograph of the injured area was not taken. Avner and Baker detected glass with routine radiographs in 11 of 160 wounds (6.9%) that were inspected and believed by the clinician to be free of glass.^{5,6} Clinicians evaluating for FBs should maintain a low threshold for ordering or performing imaging studies. Options for imaging include plain radiographs, ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and fluoroscopy. See Table 36.1 for a summary.

Plain Radiography

Plain radiographs are readily available, are easily interpreted, and cost significantly less than CT, formal US, or MRI.⁷ The ability of plain films to detect FBs in soft tissue depends on the object’s composition (relative density), configuration, size, and orientation (Fig. 36.6). Detection of FBs on plain films can be enhanced by requesting an underpenetrated soft tissue technique and by obtaining multiple views to prevent FBs from being obscured by superimposed bone or soft tissue folds.⁸ Plain films are often sufficient; however, digitized radiographs may be manipulated to enhance identification of a suspected FB. Indirect evidence of an FB may include trapped or surrounding air, a radiolucent filling defect, or secondary bony changes such as periosteal elevation, osteolytic or osteoblastic alterations, or pseudotumors of bone.⁸

Metallic objects are readily visualized on radiographs. Despite a common misconception that glass must contain lead to be visualized on a plain radiograph, almost all glass objects in soft tissue (bottles, windshield glass, lightbulbs, microscope cover slips, laboratory capillary tubes) are at least somewhat radiopaque and can be detected by plain radiographs unless they are obscured by bone or are very small (< 1 mm) (Fig. 36.7).^{7,9,10} The absence of a glass FB on multiple projections is strong, though not absolute evidence that glass is not contained in a

Figure 36.1 **A**, A common foreign body (FB) in the foot is a splinter, toothpick, pin, or needle that is impaled while walking barefoot on a carpet. This sewing needle (*arrow*) was obvious, but in the absence of a history of an FB, some FBs may be mistaken for a simple puncture wound, heel spur, stress fracture, contusion, or tendinitis. **B**, Postoperative radiographs demonstrate complete removal. **C**, This patient fell, landed on a metal pipe, and suffered a deep laceration in the thigh. A radiograph was taken to rule out a fracture, and the key was seen but thought to be an artifact (i.e., an item left on the backboard). During the examination, the key was found embedded in the wound. It had been in the patient's pants pocket and was forced into the wound by the pipe during the injury.

wound. Other nonmetallic objects readily visualized include teeth, bone, pencil graphite, asphalt, and gravel.^{7,11} Aluminum, which has traditionally been deemed radiolucent, can occasionally be visualized on plain films if the object is projected away from the underlying bone. Ellis demonstrated that pure aluminum fragments as small as $0.5 \times 0.5 \times 1$ mm could be identified in a chicken wing model simulating a human hand or foot.¹² Ellis cautioned that other aluminum FBs, such as pull tabs from cans, may not be visualized in other parts of the body such as the esophagus or stomach.¹²

Certain FBs such as vegetative material (thorns, wood, splinters, and cactus spines) are radiolucent and not readily visualized on plain radiographs. These materials absorb body fluids as they sit in situ and become isodense with the surrounding tissue. Because of their varying chemical composition and density, plastics may or may not be visible on plain films.¹³

Besides simply diagnosing FBs, radiographs can also be used to estimate the general location, depth, and structure of radiopaque FBs. If one strategically attaches a marker (needle or paper clip) to the skin surface at the wound entrance before taking a radiograph, the FB will be seen in relation to the

entrance wound (Fig. 36.8). This also helps identify the path that leads to the FB and the relative distance from the surface to the FB.¹⁴ Needles at two angles may also be used to aid in localization (Fig. 36.9).

Liberal use of plain film radiography makes sound clinically relevant medicolegal practice. A review of 54 wound FB claims against 32 physicians from 22 institutions found glass, a radiopaque substance, to be the most common material. However, in only 35% of the cases involving glass were plain films taken. Cases with a glass FB without a radiograph ordered were associated with unsuccessful defense (60%) and higher indemnity payments.¹⁵

US

US has become the modality of choice for imaging radiolucent FBs such as wood and thorns because most soft tissue FBs are hyperechoic on US. In addition, if in place for more than 24 hours, most FBs will be surrounded by a hypoechoic area corresponding to granulation tissue, edema, or hemorrhage, which may aid in making the diagnosis.¹⁶ Metal will leave a linear trail of echoes deep to the FB, referred to as the *comet*

Figure 36.2 Some wound mechanisms are classic for the presence of a foreign body (FB). Note that even small pieces of all types of glass are readily seen on a plain radiograph. **A**, This intoxicated patient kicked out a window and sustained seemingly minor puncture wounds. He did not believe that glass was in the wound, there was little pain, and no FB could be palpated externally. **B**, A radiograph revealed a large shard of glass (*arrows*) deeply embedded in the wound. **C**, The shard of glass was removed, but only after 20 minutes of exploration. **D**, Another classic scenario for a retained glass FB is putting the arm through a window. An FB was not suspected or sensed by the patient or clinician. **E**, When a radiograph was taken, a large shard of glass (*arrow*) was readily detected. Despite its size, removal was difficult and time-consuming.

Figure 36.3 **A**, This patient has an obvious wooden foreign body (FB) on the dorsal aspect of the proximal part of the forearm. **B**, Manual removal of the object was not difficult. **C**, However, thorough exploration of the wound cavity via an incision over the entire length of the FB tract revealed multiple small wooden fragments. Wood fragments retained in a wound will always cause an infection. Proper exploration requires adequate analgesia, good lighting, hemostasis, and a cooperative patient. Use of a metal probe may help identify the foreign object by feel or sound (see [Fig. 36.17](#)).

Figure 36.4 A windshield forehead injury usually harbors multiple retained pieces of glass that are difficult to find. Probing with a needle or forceps in each wound to feel or hear contact with the fragments may help find them. A supraorbital nerve block is ideal to facilitate probing.

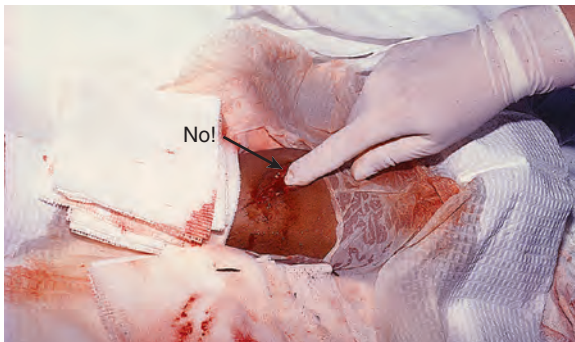

Figure 36.5 What's wrong here? Though historically suggested as a useful technique to find foreign bodies, probing the depths of a wound with a gloved finger may result in a puncture wound in the operator. The practice is strongly discouraged because of the prevalence of hepatitis and human immunodeficiency virus infection.

tail artifact. A wooden object leaves an acoustic shadow without artifact.^{17,18}

US may be performed at the bedside. To do so, use a high-frequency transducer (at least 7.5 MHz, such as a high-frequency linear vascular probe) because most FBs are small and superficial. A lower frequency may also be necessary if a deeper FB is suspected, but it may miss small FBs.¹⁹ A spacer may be needed to adjust the “focal zone” (i.e., where the beam is the narrowest and signal intensity is the highest). US may be particularly difficult in the hand or foot, which have many echogenic structures and web spaces that may limit visualization when the FB is adjacent to bone.^{16,18,20} Keep in mind that the presence of air, scars, calcification, sutures, and sesamoid bones in surrounding tissue may lead to false-positive results.^{20,21}

Advantages of US include low cost, no ionizing radiation, the ability to define the object in three dimensions, and real-time bedside imaging, which may be used during removal.⁸ Many studies report that US is highly sensitive for the detection of FBs by adequately trained personnel, either radiologists, technicians, or emergency physicians.³ It is difficult to cite a precise sensitivity or specificity because of the wide variation in these studies with regard to FB size, material, and location; operator experience; and the models used in these studies.^{21–23}

Figure 36.6 Radiographic appearance of various foreign bodies. Arrows point to **A**, glass **B**, pencil lead (graphite, but not wood, is radiopaque), and **C**, a metallic pin. Plain radiographs should be taken in multiple projections. Do not ignore subtle soft tissue irregularities. Generally absent on radiographs are aluminum, plastic, wood, thorns and other organic objects, such as fish spines, and small pieces of gravel.

Figure 36.7 Almost all glass is visible on a plain radiograph, regardless of its lead content. Do not ignore small white specs on a radiograph. If glass is superimposed on bone, it may be missed, so multiple projections are recommended. Plain film radiography shows sharp corners characteristic of glass. Proximity of the foreign body to the bone may be deceiving.

CT

CT depends on x-ray absorption; thus, it generally visualizes the same material detected on plain films, but subtle differences in soft tissue densities may help identify FBs not seen on radiographs.^{7,11} In addition, CT produces a better

TABLE 36.1 Imaging Summary

	RADIOGRAPHY	US	CT	MRI	FLUOROSCOPY
Materials visualized	Metal Glass Graphite Plastic (variable)	Wood Thorns Organic matter Metal Glass	Metal Glass Wood (late) Plastic (variable) Organic material (variable)	Glass Plastic Organic matter	Metal Glass Plastic (variable)
What type of material cannot be visualized	Wood Thorns Organic matter Plastic (variable)	Deep FBs	Wood (early) Plastic (variable) Organic material (variable)	Wood (variable) METAL!	Wood Thorns Organic matter Plastic (variable)
Pros	Cheap Available Easy to interpret	Bedside use for real-time extraction Relatively inexpensive	3D images with some improved visualization of FBs vs. plain film	Improved detection of radiolucent objects vs. CT	Useful for real-time bedside extraction
Cons	Unable to visualize all material May miss small FBs in areas adjacent to bone	Results vary based on operator experience Difficult visualization in the hands and potential for false positives	Expensive Increased exposure to ionizing radiation	Expensive Not readily available in all EDs Dangerous for metallic FBs	Unfamiliar technique to most ED clinicians Not widely available
Conclusions	Reasonable initial approach, particularly for metal and glass Obtain multiple views via a soft tissue technique	Recommended for radiolucent structures such as vegetative material (wood, thorns, etc.) Allows direct visualization Can assist with operative removal Potentially a bedside procedure depending on the clinician's skill level	Recommended approach for intracranial, intraorbital FBs Has a role for repeated visits and concerns for retained FBs Limited role during initial evaluation	Role limited on initial evaluation Has a role with repeated visits and concern for retained FBs	Use limited to individual clinicians with experience and availability

3D, Three dimensional; CT, computed tomography; ED, emergency department; FB, foreign body; MRI, magnetic resonance imaging; US, ultrasonography.

A reasonable initial approach for localizing nonvisualized FBs in the ED is to obtain multiple-projection plain radiographs with a soft tissue technique. This technique will visualize the majority of FBs, especially metal and glass. US should be considered for objects known to be radiolucent, such as wood or thorns. The role of CT and MRI for evaluation of FBs in the ED is limited, but they are the definitive imaging tests in confusing cases. For suspected intraorbital or intracranial FBs, CT is recommended. CT or MRI is also warranted *when a previously negative explored wound exhibits recurrent infection, poor healing, or persistent pain*. CT or MRI may be the appropriate initial test for patients with nonspecific swelling to define FBs and possible alternative diagnoses such as abscesses, masses, or other inflammatory processes.⁶ Bedside US and fluoroscopy (for radiopaque FBs) may be used to guide difficult FB extractions if initial attempts at removal are unsuccessful and the proper equipment and experienced personnel are available.

three-dimensional image than plain films do and may visualize objects embedded in or behind bone. However, CT is more costly and exposes the patient to more ionizing radiation than radiography or US does, and its use should therefore be judicious.

As an example, wood is unlikely to be visible initially on CT, but after 1 week, the wood absorbs surrounding blood products and may become higher in attenuation than muscle and fat. It may then appear on CT as a linear area of increased attenuation on a wide window setting such as a bone window.⁶

MRI

Although MRI is expensive and not as readily available to emergency clinicians as plain films and CT are, it may be superior to CT in detecting small, nonmetallic, radiolucent FBs such as plastic, particularly in the orbit.²⁴ MRI may not visualize wood, which may appear as a linear signal with associated inflammation and looks hypointense with respect to muscle on T1- and T2-weighted sequences, on which it appears as a signal void.⁶ Plastic is more easily visualized with MRI than with CT. MRI cannot be used for metallic objects and gravel, which contain various ferromagnetic particles that

Figure 36.8 **A**, This patient had an obvious diabetic foot abscess. **B**, A radiograph was taken to rule out osteomyelitis or soft tissue gas. To everyone's surprise, including the patient's, a sewing needle (*arrow*), origin and timing unknown, was the source of the infection. **C** and **D**, A paper clip was taped to the skin to localize the depth and position of the foreign body (FB; *arrow*) on the radiograph. An anteroposterior radiograph (not shown) also localized the FB. **E**, For orientation, the outline of the paper clip was traced on the foot. A dot marks a possible entrance site. **F**, A generous incision was made over the projected site of the FB. **G**, The needle (*arrow*) was felt and extracted with a hemostat. **H**, The wound was left open and packed with a cotton wick.

Figure 36.9 When a small entrance wound (*A*) is noted but the foreign body (FB) is not seen, noninvasive localization is preferable to blind probing. Metal markers taped to the skin or needles inserted close to the FB under local anesthesia (*B*) and radiographed at different angles provide a guide to localization and extraction of the FB. (Reproduced from *Hospital Medicine*, January 1981, with permission of Cahner's Publishing Co.)

produce signal artifacts and a theoretical risk of shifting within the magnetic field and causing structural damage.⁷ This is particularly important when evaluating FBs in the eye, brain, or deep structures of the neck, face, or extremities. FBs may be difficult to differentiate from other low-signal structures on MRI, such as tendon, scar tissue, and calcium.²⁵

Fluoroscopy

More recently, portable, low-power, C-arm fluoroscopy has become available in some emergency departments (EDs), particularly for orthopedic reductions. Its use has also been reported for the removal of BB pellets, metal, glass, and coins from patients.²⁶ Like radiography, fluoroscopy can visualize objects that are radiopaque but not radiolucent such as wood

Ultrasound Box 36.1: Foreign Body Removal

Christine Butts, MD

Many foreign bodies are radiopaque and can easily be seen with traditional radiography. Such foreign bodies include glass, metal, and some plastics. Other foreign materials, such as splinters, spines, and thinner plastics, are radiopaque and easily missed on radiographs. Ultrasound is an optimal modality for both identifying retained foreign bodies and aiding in their removal. A number of studies have evaluated the sensitivity and specificity of ultrasound in identifying foreign bodies in soft tissue. The findings have been variable, depending on the type and size of foreign body.¹⁻³

General Considerations

A preliminary radiograph may be helpful in narrowing down the area to be evaluated with ultrasound, particularly when there is a large area where the foreign body may be found. Asking the patient to identify the point of maximal tenderness may also be helpful in narrowing down the overall area to be examined. Once the area has been clarified, a high-frequency (10 to 12.5 MHz) transducer should be selected. Higher frequencies will convey sufficient resolution to distinguish foreign material from normal soft tissue structures.

Each type of foreign body has specific identifiable characteristics; however, certain general findings suggest the presence of foreign material. The finding of soft tissue edema, represented by anechoic (black) or hypoechoic (dark gray) areas within the normal soft tissue, is highly suggestive of recent tissue disruption (Fig. 36.US1).

The area in question should be evaluated from a number of different angles to find the object in its long axis. A small foreign body may easily be overlooked if only a small portion of it is seen.

Additionally, the use of a "stand-off" pad may be helpful, especially when dealing with superficial structures such as the hand or foot. A slim, fluid-filled structure, such as a 100-mL bag of saline or a glove filled with water, is placed over the area of interest. The transducer is then placed on top of this pad. This extra layer creates an acoustic window to allow greater resolution and eliminate some superficial artifacts that may impede the examination.

Metallic foreign bodies are strongly echogenic and are very straightforward to locate. They will appear bright white and often give off strong reverberation artifacts (Fig. 36.US2).

Glass foreign bodies appear very similar to metallic objects in that they are highly echogenic (white). Glass may cause a reverberation artifact but more typically will cause acoustic shadowing to extend deep to the object (Fig. 36.US3).

Figure 36.US1 Wooden foreign body in the foot. The foreign body is hyperechoic (*arrow*), whereas the surrounding hypoechoic region (*arrowhead*) is indicative of edema or pus. (From Rumack CM: *Diagnostic Ultrasound*, ed 4, St. Louis, 2010, Mosby.)

Figure 36.US2 Metallic foreign body identified as a brightly echogenic (*white*) object (*arrow*) with a comet tail artifact seen extending deep into the soft tissue (*arrowhead*).

Ultrasound Box 36.1: Foreign Body Removal—cont'd

Figure 36.US3 Glass foreign body (*arrow*) identified as a hyperechoic (*white*) object causing a strong shadow (*arrowhead*) within the otherwise normal-appearing soft tissue.

Wooden objects (such as splinters) are more challenging to locate, particularly with very small foreign bodies. Wooden foreign bodies do not create as strong an echogenic focus as other types of material do and may appear only slightly brighter than normal tissue (Fig. 36.US4). Very subtle shadowing may be seen extending deep to the object. The presence of surrounding edema is often key to locating the FB.

Removal

Once the object has been localized, it can be removed either blindly or under direct sonographic guidance.

Another technique that may be helpful, particularly with smaller objects, is to insert two 25-gauge needles under sonographic

Figure 36.US4 Sonographic appearance of a retained wooden foreign body (*arrow*).

guidance. These needles should be inserted at right angles to each other so that the tips of each of them rest at the foreign body. The clinician can then cut the skin and overlying soft tissue and dissect down to the intersection of these two needles.

and plastic.^{26,27} By using correct technique and shielding, radiation scatter to imaging personnel is minute, less than 0.0001 R/hr.²⁸ Fluoroscopy also offers the advantage of real-time bedside imaging.^{26,28} Fluoroscopic image-intensifying equipment may be used to follow a wound's entrance, localize the material, grasp the FB, and remove it without making a larger incision. Ariyan described a technique in which two needles are placed in the soft tissue from opposite directions and pointing toward the FB.²⁹ The extremity is rotated while the clinician watches the image under the image intensifier to obtain a three-dimensional effect. An incision is made perpendicular to the plane of the needles, and the object is removed. Although the technique to use fluoroscopy is relatively easy to learn, the lack of instruction and availability is the major limitation to its use in the ED.^{28–30}

FB REMOVAL

Removal Decisions

One should judiciously evaluate and manage each FB scenario individually. The composition and location of an FB, as well

as the patient's medical status and vocational and avocational activities, greatly affect decision making related to FB removal, including the best time and place for removal. Reactive material, such as wood, should be removed immediately when accessible because retained wood will invariably lead to inflammation and infection. Other inert material, such as glass or plastic, may often be removed on an elective basis. Some innocuously located glass and metallic FBs may frequently be left permanently embedded in soft tissue. With deeply embedded, small, inert material (BB, bullets, etc.) that is not located near any vital structures, the time, effort, and trauma involved in removal may be excessive when compared with the possible adverse effects of the foreign material remaining in place. An ill-conceived extended search for an elusive but otherwise harmless FB often results in frustration for the clinician and discomfort, dissatisfaction, and possible injury for the patient.

If localization is certain and removal can be accomplished within a manageable period without worsening of the injury, an attempt at removal is generally indicated on the initial visit (given the availability of clinicians and support staff).

When reviewing the decision regarding when and how to remove the FB, the possibility of the FB migrating to involve vital structures, though quite remote, should be discussed with

the patient. Cases of reported missile embolization in the vascular system are influenced by missile caliber, impact velocity, physical wound characteristics, point of vessel entrance, body position and movement, and velocity of blood flow.³¹ Retained bullets usually remain in soft tissue but can rarely make their way into the vascular system. Schurr and colleagues reported a paradoxical bullet embolization from the left external iliac vein to the left iliac artery via a patent foramen ovale.³² When clinicians first examined the patient, a bullet was noted on the chest radiograph, and an isolated chest wound was suspected. However, the bullet had apparently entered the chest, traversed the abdomen to the iliac vein, and then embolized back to the chest and arterial system.

After the initial history, examination, and preoperative and preanesthetic documentation of the neurovascular status of the patient, a decision must be made regarding the time and place of removal. Thirty minutes is a reasonable self-imposed limit for the provider when attempting removal of an FB in the ED. More difficult procedures should be referred. Many FBs appear superficial on radiographs, thus suggesting that removal will be quite easy. However, surprisingly large or presumed superficial FBs still often prove quite elusive.

If an FB is left in place, inform the patient why it was not removed. If the patient is referred for delayed removal, this should also be carefully explained and documented. Regardless of whether the FB is removed, clean all wounds appropriately and update tetanus prophylaxis if indicated.

Equipment and Preparation

Good space and lighting, a comfortable patient and operator position, a standard suture tray, and a scalpel are usually adequate equipment for the removal of most simple FBs (Fig. 36.10). Tissue retractors, special pickups, and loupes may be added if needed.

Local soft tissue injection or selected nerve blocks with buffered bupivacaine or lidocaine (or both) are the recommended anesthesia for the removal of most soft tissue FBs. Judicious use of sedation (parenteral, rectal, or oral) is advised if the clinician senses undue apprehension or anxiety in the

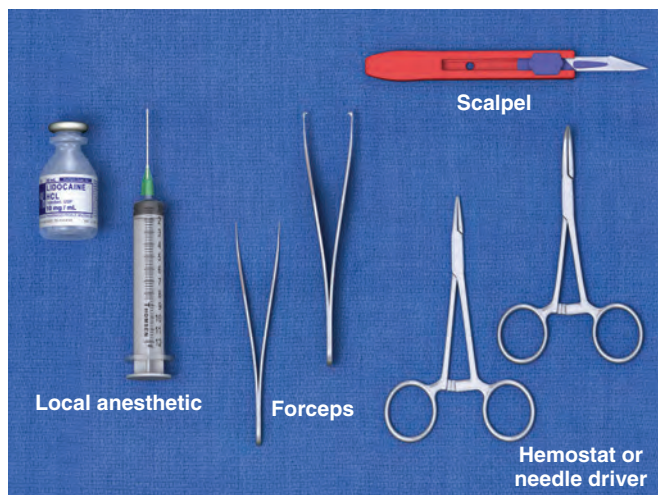

Figure 36.10 The contents of a standard suture tray, with the addition of a scalpel, are usually adequate for the removal of most foreign bodies.

patient. Sedation may be especially helpful in children, with ketamine often being an excellent choice. If the patient is totally uncooperative, postpone exploration to a more appropriate time and setting (e.g., under regional or general anesthesia in the operating room).

To successfully remove an FB in the soft tissue of an extremity, a time-limited arterial tourniquet can help provide a bloodless field. Inflate a blood pressure cuff or portable self-contained pneumatic cuff above arterial pressure on the upper part of the arm, forearm, leg, or thigh. To limit bothersome backbleeding, elevate the extremity and wrap it with an elastic bandage to exsanguinate the extremity before inflating the tourniquet. A Penrose drain or specialized tourniquet may be used as a tourniquet at the base of a finger or toe. Alternatively, use a sterile glove as a finger tourniquet. Cut the fingertip of the glove on the involved finger and roll the glove down to the base of the finger. Most patients can tolerate an ischemic tourniquet for 15 to 30 minutes, and it is safe to stop the circulation to an extremity for this length of time.

Operative Technique

The specific technique for removal of an FB is tailored to each clinical situation (Videos 36.1 to 36.4). In general, FBs should be removed only under direct vision. Grasping blindly into a wound with a hemostat to remove an FB should be avoided. This technique is especially dangerous in the hand, foot, neck, or face, where sensitive or vital structures may easily be damaged.

After obtaining appropriate informed consent and following sterile preparation, consider enlarging the entrance wound with an adequate skin incision because it can be advantageous. Numerous techniques are used, depending on the clinical scenario (Fig. 36.11). Attempting to remove an FB through a puncture wound or an inadequate skin incision is a common error that is both frustrating and self-defeating. After a proper skin incision, explore the wound carefully by spreading the soft tissue with a hemostat. Frequently, the FB can be felt with an instrument before it can be seen (see Fig. 36.11, *plate 1*). After placing a tourniquet on an extremity, follow the track of the FB, although it often cannot be identified when surrounded by muscle or fat. If the FB, such as one that is made of fiberglass or plastic, is difficult to visualize, is located in the superficial soft tissue, or has contaminated the surrounding soft tissue, excising a small block of tissue rather than removing the FB alone may be necessary. Excise the block of tissue only under direct vision and after nerves, tendons, and vessels have been identified and excluded from the excision area.

If an FB such as a thorn or needle enters the skin perpendicularly, a linear incision may pass to one side or the other of the FB, and it may be difficult to determine where the FB lies in relation to this incision (see Fig. 36.11, *plate 2*). For this reason, the search must then be extended into the walls of the incision rather than simply through the skin.³³ In such cases, excise a small ellipse of skin and undermine the skin for 0.5 to 1.0 cm in all directions. Next, compress the tissue from the sides in the hope that the FB will extrude and can then be grasped with a hemostat.

After removal of the FB, it is important to irrigate and cleanse the wounds. If a small incision has been made in a noncosmetic area (such as the bottom of the foot), leave the incision open and bandaged. The area may be periodically soaked in hot water for a few days. A return visit is necessary

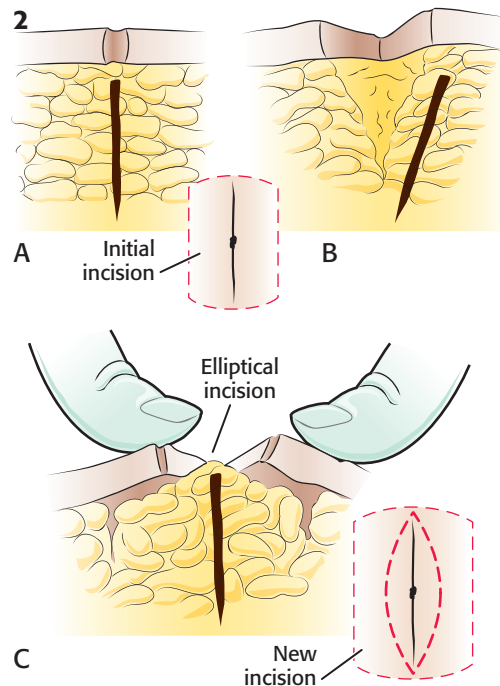

Foreign Body Removal Techniques

1

A, A sewing needle completely embedded below the surface is easily located with a radiograph. **B**, After the application of local anesthesia, a small incision over the superficial end permits removal with a hemostat. **C**, The hemostat is introduced through an adequate incision, spread to open the tissue, and used to “feel” the FB as the hemostat is advanced.

2

If a linear skin incision is used to locate a mobile FB that is perpendicular to the skin in subcutaneous fat (**A**), the FB may be displaced (**B**). **C**, A modified elliptical incision is made and the skin edges are undermined to displace the FB into the middle of the wound. Pressure with the thumbs may be applied to the skin to force the FB into view.

3

FBs in deep fat (**A**) may be approached by making a small elliptical incision around the entry point (**B**). **C**, The incision is then laterally undercut and grasped (without pulling) with forceps. **D**, The ellipse is then further undercut until contact with the FB is made. **E**, The FB may be grasped and removed along with the entry tract and the soiled local fat.

Figure 36.11 Foreign body (FB) removal techniques. (1 and 3, Reproduced from *Hospital Medicine*, January 1981, with permission of Cahner’s Publishing Co; 2, From Rees CE. The removal of FBs: a modified incision. *JAMA*. 113:35, 1939. Copyright 1939, American Medical Association. Reproduced with permission.)

only if signs of infection develop. If a large incision has been made, the skin may be sutured primarily as long as no other contraindications are present. In cases in which gross contamination has occurred or there is significant tissue injury, do not close the wound on the initial visit. Leave the wound open but packed. Suture the skin after 3 to 5 days if the wound is free of inflammation or infection (known as delayed primary closure; see [Chapters 34](#) and [35](#) for details).

Special Scenarios and Techniques

Puncture Wounds in the Sole of the Foot

Puncture wounds in the feet from unknown objects and under unknown circumstances present problems to the clinician. In general, puncture wounds in the feet are at risk for retained FBs and infection. It is impossible to adequately explore a puncture wound. In noncosmetic areas, therefore, a puncture

Figure 36.12 This patient stepped on “something” while walking through a polluted urban creek, a setup for a foreign body and infection. Mandatory radiographs were negative. **A**, Under proper lighting (and a calf blood pressure cuff for a tourniquet), the patient is placed prone. Local lidocaine with epinephrine is infiltrated *through the cut skin edges*, not via the intact sensitive skin. (Alternatively, a posterior tibial nerve block could be used.) **B**, Inspection reveals a dirty skin flap that is cut off. **C**, Because a puncture wound cannot be explored or irrigated, this wound should be lengthened with a scalpel to allow further care. **D**, The depths of the wound are explored. **E**, An assistant holds the wound open with a hemostat so that copious irrigation can be accomplished. This wound should be *packed open* and checked in 24 to 48 hours, *not closed primarily with sutures*. Delayed closure can be performed in 4 to 5 days if necessary, but this injury healed well without sutures. Prophylactic antibiotics are of no proven value but may be given.

wound can be converted to a laceration to adequately explore and clean it (Fig. 36.12). Under most circumstances, delayed primary closure is recommended (see Chapter 34). This topic, including stepping on a nail and puncture wounds in the sole of the foot, is discussed extensively in Chapter 51.

Subungual FBs

Once a subungual FB has been identified, perform a digital block before manipulation of the nail or nail bed. Pay special attention to deeply embedded subungual FBs.³⁴ Some cases may require removing a small portion of the nail with double-pointed heavy scissors to expose the FB and grasp the foreign material with splinter forceps (Fig. 36.13).

One technique is to bend the tip of a sterile hypodermic needle and slide it under the nail. The needle is used to hook the FB and then remove it. Alternatively, slide a 19-gauge hypodermic needle under the nail to surround a small splinter. Bring the needle tip against the underside of the nail and secure the splinter. Remove the needle and splinter as a unit.³⁵ Another possible technique is to shave the overlying nail plate with a No. 15 scalpel blade via light strokes in a proximal-to-distal direction. This creates a U-shaped defect in the nail and exposes the entire length of the splinter.³⁶

Wooden splinters are commonly embedded under the fingernail. Such FBs must be removed completely because of the high risk of subsequent infection. If complete removal

cannot be achieved with the techniques described earlier, remove the entire nail (see [Chapter 35](#)). This allows all the fragments to be visualized and removed. The proximity of the distal phalanx to the subungual area is a constant concern for the development of osteomyelitis and requires follow-up.

Metallic Fragments and Bullets

High-velocity fragments (e.g., bullets, BBs) are easy to visualize radiographically and relatively simple to remove if embedded in areas that are anatomically accessible ([Fig. 36.14](#)). Before removal, assess the area in which the fragments are embedded to determine which structures are involved and which structures might be encountered during removal. Defer removal of deeply embedded metallic FBs unless symptoms of infection develop. Infection is rare because such FBs usually become encysted over time.

Surgery is rarely performed solely for the purpose of removing bullets. Retained bullets rarely cause complications or infection, and aggressive attempts to find and remove bullets generally cause more harm than good. Retrieval is often quite difficult unless the fragments are very superficial. Gunshot wounds themselves need no intervention beyond simple cleaning and perhaps minor débridement of the entrance or exit wound. Gunshot wound tracks do not need débridement unless there

Figure 36.13 For a foreign body (FB) deep in the nail bed, take as small a wedge of nail as will allow access to the proximal end of the splinter, and then extract the FB with splinter forceps. All wood particles should be removed. A digital nerve block is usually necessary.

is gross contamination or significant tissue devitalization. Entrance or exit wounds should not be closed. Antibiotics are usually unnecessary for minor uncomplicated gunshot wounds in otherwise healthy patients, but may be beneficial in patients with multiple injuries, multiple comorbidities, gross wound contamination, significant tissue devitalization, large wounds, or delays in treatment.

There is a concern about lead toxicity from bullet fragments. If a bullet is bathed in synovial, pleural, peritoneal, or cerebrospinal fluid, the lead may leach out over time and produce a significant elevation in blood lead levels. Though rare, lead fragments in contact with synovium are a reason for concern and potentially a reason for removal (see the previous discussion). In one study, Farrell and associates found that patients with retained lead FBs had statistically significant elevated blood lead levels.³⁷ The study did not differentiate the location of the FB and whether patients were, in fact, symptomatic from plumbism. Nevertheless, it may be prudent for the patient's primary care provider to monitor blood lead levels in patients with known lead FBs to prevent the future development of lead toxicity. The value of routine prophylactic antibiotics for metallic FBs left in soft tissue has not been proved and antibiotics are generally not used.

For superficial metallic FBs, a sterile magnet can be used to facilitate the removal of small metallic fragments.³⁸ Introduce the magnet into the entry site, with a small scalpel and hemostat used to extend and open the wound as needed. When the magnet comes in contact with the metal, a click is heard and the FB is removed while attached to the magnet. If resistance to extraction occurs, exploration can be done with the FB attached to the magnet. Sometimes, instead of introducing the magnet directly into the wound, it can be placed on the overlying skin to guide superficial small FBs out of the wound.³⁹ Try not to grasp or touch the bullet because it can interfere with ballistics evidence during any subsequent legal investigation.

FBs in Fatty Tissue

FBs in fatty tissue can be removed by making an elliptical incision around the entrance wound. Grasp the incised skin loosely with Allis forceps. Undercut the incision until the FB is contacted. Remove the FB, skin, and entrance track in one

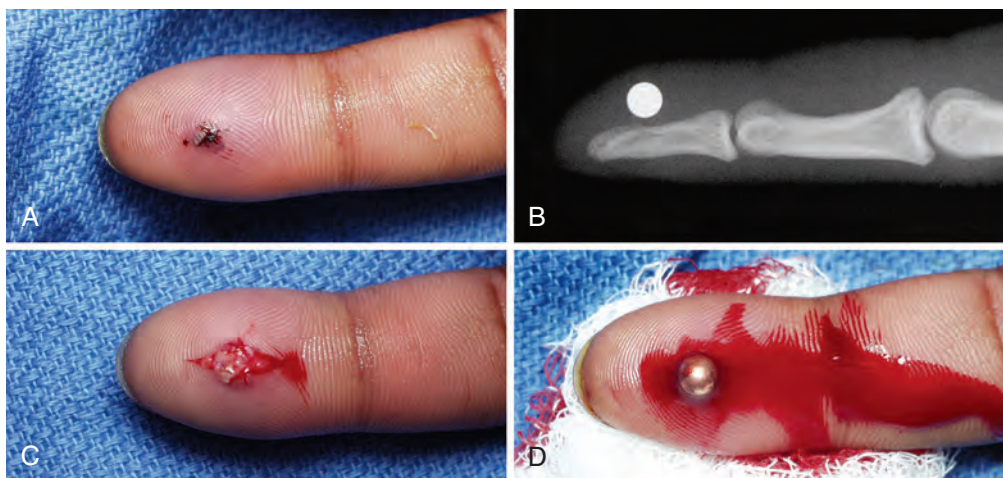

Figure 36.14 A and B, High-velocity fragments such as bullets or BBs are often easy to locate and visualize radiographically. Here, a BB is found embedded in the volar tuft of a finger. C, After a digital block, a small linear incision is made with a scalpel. D, The BB is removed without difficulty.

block. Remove a small portion of subcutaneous fat along with the FB to minimize infection. FBs in fat are very mobile, and probing may displace them even further. FBs that are embedded in fat and are perpendicular to the skin can also be removed, as shown in Fig. 36.11. As always, the removal of soft tissue, including adipose, should be done in as conservative a manner as possible, as any tissue removal may have implications in scar formation.

Pencil Lead/Graphite

Use careful judgment in removing pencil graphite when it is lodged in the skin. Graphite invariably leaves a pigmented tattoo in the soft tissue, and it is preferable to excise the material en bloc (see Fig. 36.11) when pencil lead is found in a cosmetic area. The graphite specks cannot be irrigated or scrubbed off, and tattooing results if they are not removed. Furthermore, a pencil lead FB may resemble a malignant melanoma over time. US has been shown to be useful in differentiating between pencil lead FBs and melanoma.⁴⁰

Fishhooks

Traditionally, four fishhook removal techniques (see Video 36.1) have been described: advance and cut, string-yank, needle cover, and retrograde.⁴¹ The preferred method depends on the type of fishhook, location, depth of penetration, and conditions under which the removal is to take place (Fig. 36.15).⁴²⁻⁴⁴ Initially, note whether the fishhook is single or multiple and determine the number and location of barbs. Remove or cover any remaining exposed hooks to prevent subsequent injury. As with most injuries, document the patient's vascular and neurologic status before and after removal. As with all wounds, administer tetanus prophylaxis if indicated. Prophylactic antibiotics are not generally necessary.

Advance and Cut Technique

To perform the advance and cut technique for removal, advance the fishhook and cut proximal to the barb (Fig. 36.16, plate

1). This method is particularly well suited for superficially embedded fishhooks. Generally, infiltrate local anesthetic (1% lidocaine) into the tissue overlying the barb. Force the barb through the surface of the anesthetized skin and clip it off. Move the rest of the hook retrogradely, along the direction of entry. Because this technique is almost always successful, it can be considered a first-line option.

String-Yank Technique

In the field or stream, removal of a fishhook may be accomplished without local anesthesia by using the string-yank technique. This technique may be used in the ED as well. Some clinicians prefer to use local 1% lidocaine to facilitate removal. For the “stream” technique (see Fig. 36.16, plate 2), pass a looped string or fishing line around the belly of the hook at the point where it enters the skin. Wrap approximately 1 ft of string around the dominant hand to provide strong traction. Hold the shank of the hook parallel to and in approximation to the skin with the index finger of the opposite hand. Use the thumb and middle finger of the opposite hand to stabilize and depress the barb, which helps the index finger disengage the barb from the subcutaneous tissue. When the barb has been disengaged, give a sharp pull (i.e., a quick tug with a snapping motion) with the dominant hand to remove the hook. Take care to keep bystanders out of the expected path of the hook because it often flies out of the patient.

Needle Cover Technique

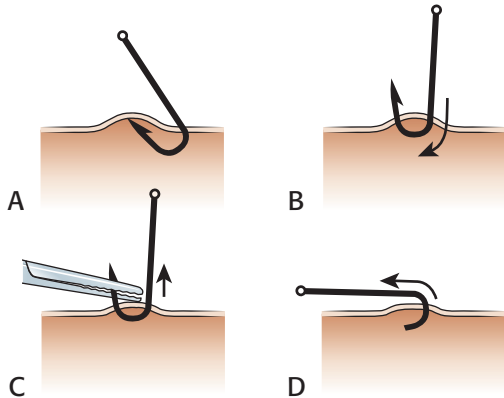

For this technique use an 18-gauge needle to cover the barb (see Fig. 36.16, plate 3). After adequate local anesthesia has been achieved, pass the needle through the entrance wound of the hook parallel to the shank of the hook to sheath the barb and allow the hook to be backed out while the barb is covered. An alternative to this procedure is to insert a No. 11 blade parallel to the shank of the hook down to the barb and use the point of the blade to free the subcutaneous tissue that is engaged on the barb. Cover the barb with the point of the

Figure 36.15 Fishhooks. **A**, Fishing lure embedded in the nasal ala. This type of injury may occur while casting the line. **B**, Fish hook embedded in the distal tuft of the finger. Note that the barb is completely embedded in subcutaneous tissue, thus making removal by simply pulling the hook out impossible. **C**, This patient cut off the portion of the embedded hook external to the skin before coming to the emergency department. Patients will commonly do this; however, it makes removal more difficult because there is very little hook exposed that can be manipulated during attempts at removal.

Fishhook Removal

1 Advance and Cut Technique

Method of removing an embedded fishhook when anesthesia is available and the point of the fishhook (**A**) is close to the skin. **B**, Force the point through the anesthetized skin. **C**, Clip off the barb. **D**, Remove the rest of the hook by reversing the direction of entry.

2 String-Yank Technique

Method of removing an embedded fishhook when anesthesia is unavailable or when the barb of the fishhook lies too deep to force it out through a second wound without causing significant additional damage. **A**, Loop a piece of string (or thick suture material) around the belly of the hook and hold it down against the skin with the index finger of the left hand. **B**, Depress the shaft of the hook against the skin with the middle finger and thumb while applying light downward pressure with the index finger of the left hand to disengage the barb from subcutaneous tissue (**B**), and pull sharply on the ends of the string with the right hand (**C**) to remove the hook through its entry wound. Be careful of the flying hook.

3 Needle Cover Technique

Method of removing an embedded fishhook using anesthesia when the hook is large and not too deep in the skin. **A**, After anesthetizing the area with 1% lidocaine, insert a short-bevel 18-gauge needle through the entry wound of the hook and attempt to sheathe the barb of the hook within the needle. **B**, If this is done correctly, the hook and needle may then be backed out together.

4 Retrograde Technique

This is the simplest but least effective method. **A**, First apply downward pressure on the shank of the hook to disengage the barb. **B**, Pull the hook out. If resistance is encountered, abandon the attempt and try another technique.

Figure 36.16 Fishhook removal. (Reproduced from *Hospital Medicine*, July 1980, with permission of Cahner's Publishing Co.)

No. 11 blade and back the hook out, with the blade protecting the barb.

Retrograde Technique

This is the simplest, but least effective method. By applying downward pressure on the shank of the hook, disengage the barb to allow successful removal (see [Fig. 36.16, plate 4](#)). If resistance is encountered, abandon the procedure and attempt removal with another technique. If the barb is not already protruding from the skin, the retrograde technique may cause less tissue trauma.

Wooden Splinters

Removal of wooden splinters is a common FB removal procedure. By simply grasping the end of a superficial, protruding splinter, it may be adequately removed, but care should be taken to not leave small pieces of material in the wound. Some splinters cannot be visualized at the point of entry but can easily and readily be palpated beneath the skin. When a wood FB is in subcutaneous tissue, it is advisable to cut down on the long axis of the FB to remove it via a skin incision rather than pulling it out through the entrance wound ([Figs. 36.17 and 36.18](#)). Although an incision may seem extensive and creates

a laceration where only a puncture wound existed, opening the track allows thorough cleaning and removal of all the small pieces of the splinter that might otherwise remain. Any remaining piece of wood can lead to infection. The deeper the splinter, the more likely that small pieces of the splinter will remain in the deep part of the wound. If the incision is linear, it may be sutured. Occasionally, the fastest method of removing small wooden splinters is to completely excise the entrance track and the FB en bloc, followed by linear closure. Particular mention should be made of certain wood splinters that are

pliable and reactive, such as California redwood and northwest cedar. Any wood that is easily fragmented requires meticulous care to ensure removal of all material.

Traumatic Tattooing

Ground-in foreign material or tattooing of the skin is a difficult problem because permanent disfigurement may occur (Fig. 36.19). These injuries occur most often from falls on blacktop surfaces or asphalt or falls from bicycles or motorcycles on a variety of surfaces. Many cases may be managed

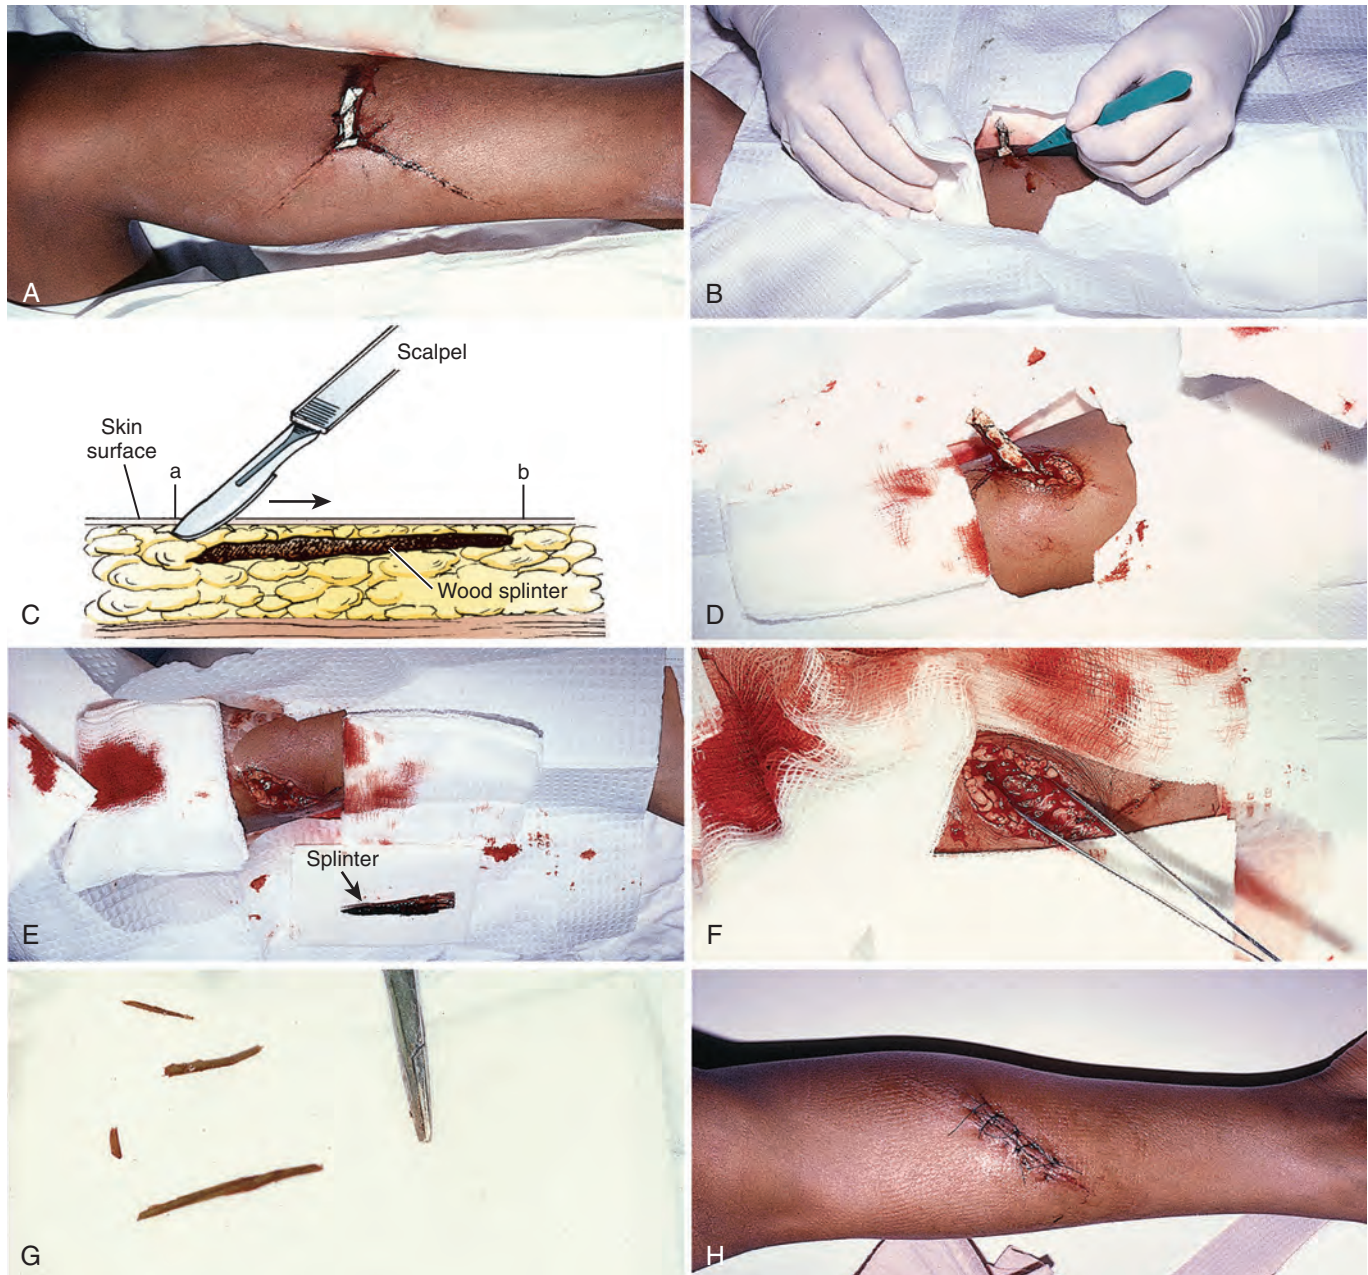

Figure 36.17 A, The course and depth of penetration of this large wooden splinter in the leg are uncertain, but it is axiomatic that all pieces of wood must be removed to prevent infection. B-D, To ensure complete removal of foreign bodies, an incision is made over the entire course of the splinter. E-G, All pieces of wood are carefully removed under direct vision. H, The laceration is sutured primarily. Although it may be tempting to simply pull the splinter out and irrigate the puncture track, such actions often lead to retained particles and complications.

Figure 36.18 **A**, A splinter was removed from the foot of this 3-year-old 7 days earlier, and a few days after removal it began to swell. A retained foreign body (FB) was suspected. Plain radiographs were negative. A small pyogenic granuloma is seen. After ketamine sedation, a 5-mm core of tissue was removed, but no FB was found on extensive exploration. This was an abscess from the puncture. The wound was packed open and cephalexin was given. **B**, It healed well (1 week later), but if it recurs, computed tomography or magnetic resonance imaging would be indicated to search for an occult FB.

Figure 36.19 Traumatic tattoos. **A**, This patient was seen approximately 1 week after a blast injury. Traumatic tattoos are evident. The patient subsequently underwent successful laser removal of most of the pigment. **B**, Traumatic tattoo of the chin. Bluish discoloration and slight erythema, predominantly caused by silica, are apparent. (**A**, From Flint PW, Haughey BH, Lund VJ, et al, editors: *Cummings Otolaryngology: Head & Neck Surgery*, ed 5, St. Louis, 2010, Mosby; **B**, From Bolognia JL, Jorizzo JL, Shaffer JV, editors: *Dermatology*, ed 3, St. Louis, 2012, Saunders.)

with adequate local anesthesia and meticulous débridement with a sponge, scrub brush, or toothbrush. If all foreign material cannot be removed with these methods, give careful consideration to secondary excision of the tattooed area and primary closure with subsequent plastic surgery to repair the defect. However, it is usually impossible to completely remove traumatic tattooing in the ED. Referral for more extensive surgical treatment after local wound care is quite acceptable. Dermabrasion may be an acceptable delayed treatment when the tattooing is superficial.⁴⁵ An alternative is to refer patients to a dermatologist for laser removal of traumatic tattoos. Certain lasers, such as a yttrium-aluminum-garnet (YAG) laser, have proved to be an excellent alternative.⁴⁶ The process is more specific in removing embedded material without harming the surrounding tissue. The type of material will determine the

number of treatments required. Not all tattoos can be removed completely.⁴⁷

Marine FBs

Although most marine FBs, such as shell fragments, may be treated like other FBs, a number of marine animals carry toxins and may leave FBs that require special consideration. Saltwater marine FBs may be contaminated with *Vibrio* species, which are usually sensitive to tetracyclines, aminoglycosides, or third-generation cephalosporins. Even if all foreign material has been removed, stings from marine animals may initiate a prolonged local irritation that simulates cellulitis. However, the presence of a wound infection on a subsequent visit strongly raises concern for an occult retained FB rather than the simple conclusion that the wound is merely infected by bacteria

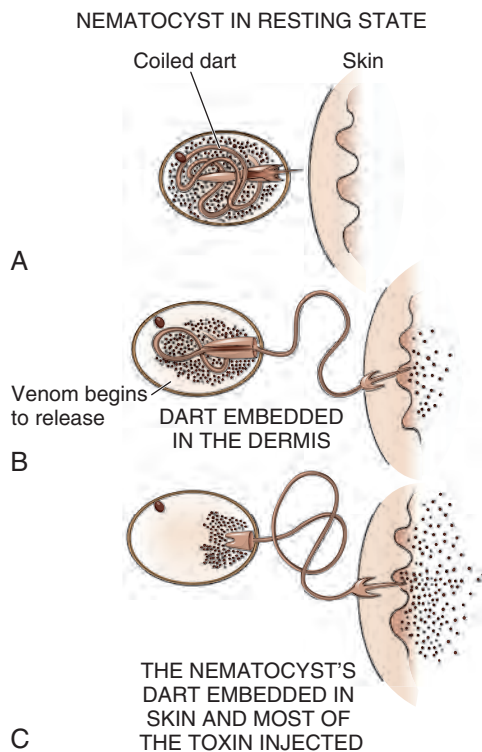

Figure 36.20 **A**, Magnified view of a venom-containing nematocyst in its resting or “cocked” state. **B**, After contact with the skin, a dartlike tail is extended and penetrates the dermis, and **C**, venom is injected. Further stimulation of the attached nematocyst can expel more venom (see text for the decontamination and removal technique).

introduced during the initial insult. Wound infections that appear to be progressive despite antibiotic therapy should be evaluated for retained FBs.

Coelenterates

Coelenterates, including the Portuguese man-of-war, true jellyfish, fire coral, box jellyfish, and sea anemones, inject several different toxins that are responsible for many marine envenomations by embedding venom-containing organelles, called *nematocysts*, into the victim’s skin (Fig. 36.20). The tentacles of coelenterates may contain thousands of nematocysts, which allows many to be deposited by even minor skin contact. After deposition, nematocysts discharge their venom. Reactions may be local or systemic, and the pain may be severe and is often described as “shocklike,” “itching,” “burning,” or “throbbing.” Substances such as tetramine, histamine, and 5-hydroxytryptamine are thought to be responsible for this localized reaction, whereas proteinaceous substances are implicated in the systemic response. Systemic reactions usually consist of fever, chills, and muscle spasm, but severe reactions may result in neurologic sequelae ranging from malaise and headache to paralysis and coma. Potential cardiopulmonary manifestations include dysrhythmias, hypotension, syncope, bronchospasm, laryngeal edema, and cardiorespiratory failure.^{48,49}

Initial wound care should focus on decontamination and removal of unfired nematocysts, which will decrease the pain and systemic reactions. Vinegar (5% acetic acid) is the initial decontaminating agent of choice because it will inactivate the unfired nematocysts of most (but not all) species of jellyfish, Portuguese man-of-war, and sea anemones.^{48,50,51} Apply it

continuously for 30 minutes or until the pain is gone.⁴⁹ *Do not apply fresh water* to the area because the osmotic shock will activate any remaining unfired nematocysts and cause them to discharge toxin and increase pain and toxicity. Other suggested, but unproven, remedies include meat tenderizer, ammonia, baking soda, urine, olive oil, sugar, and papaya latex.

After the wound has been decontaminated, remove any remaining tentacle fragments. Extract large fragments with forceps; however, individual nematocysts are very small (< 1 mm in length) and are not easily visible. To remove the remaining nematocysts, scrape the skin with a hard edge, such as a credit card held perpendicular to the skin. An alternative is to apply shaving cream and shave the area gently to eliminate the remaining fragments.⁴⁹ Do not use sand to remove nematocysts because sand can increase the discharge of venom. If the pain persists, it should be assumed that organelles still remain and further cleansing is required.

After decontamination, use topical anesthetics or steroids, but prophylactic antibiotics are not necessary. Follow routine wound care. Treat allergic and systemic reactions appropriately. The application of warm or cold packs to the area has not been shown to reduce pain.⁵⁰ Antivenin is available only for box jellyfish envenomation, but its use remains incompletely understood and controversial.

In summary, a 2013 Cochrane review found inconclusive evidence defining the most effective treatment for jellyfish envenomation, but a 2016 article suggested several interventions may be effective for nematocyst inhibition. These authors wrote that topical vinegar for at least 30 seconds for some species while seawater, baking soda slurry and water warmed to 42°C to 45°C can help, along with oral analgesics.^{52,53} Ultimately species-specific interventions are the most effective, but there is inadequate research to make definitive recommendations.

Coral

Coral is composed of a calcium carbonate core and thousands of small marine animals. Fire coral, a specific type of coral, is another type of coelenterate that produces toxicity with stinging nematocysts. After contact, a burning and intense pruritus may occur along with a series of skin eruptions. Within minutes of contact, pruritus, erythema, and urticaria-like lesions may appear, and blister formation may result within hours (Fig. 36.21). Eventually, the lesions will become lichenoid, but complete resolution may not take place for 15 weeks after contact. Ultimately, hyperpigmented areas will form at the point of initial contact. Immediate care with oral antihistamines and topical steroids tends to reduce, but not prevent, the symptoms.

“Coral cuts,” which can be deep lacerations, occur in divers and snorkelers exploring coral reefs. With these wounds, delayed healing may take place with the secondary development of cellulitis or ulceration, perhaps as a result of contamination of the wound with bacteria or microparticles of coral.⁴⁸ Treatment consists of copious saline irrigation. Hydrogen peroxide may be used to help remove small coral particles from the wound.⁴⁸ Do not close the wound; wet-to-dry dressings are advised instead.

Sponges

Sponges produce both an irritant and a contact dermatitis. The irritant dermatitis occurs as a result of sponge spicules embedded in the victim’s skin. Remove the spicules with adhesive tape (applied to the skin and then peeled back), and then bathe

the area with vinegar.⁴⁸ Contact dermatitis, which is believed to be caused by a toxin, produces erythema, pruritus, and vesicles similar to those with poison oak.⁴⁸ Treatment is initial immersion in vinegar followed by local steroid creams.

Sea Urchins and Starfish

Sea urchins and starfish are free-living echinoderms covered with venomous, sharp, brittle spines and with venom-secreting pincers located near the mouth. If sea urchins or starfish are

Figure 36.21 Fire coral stings. (From James WD, Berger TG, Elston DM, editors: *Andrews' diseases of the skin: clinical dermatology*, ed 11, St. Louis, 2011, Saunders.)

handled or inadvertently stepped on, these spines may become embedded in the patient and a severe local reaction may result from venom in the spines. Systemic symptoms occur and include muscle weakness; paralysis of the lips, tongue, and face; hypotension; abdominal pain; and respiratory distress. Local pain responds quite well to immersion in hot water (43.3°C to 46.1°C [110°F to 115°F]) for 30 to 90 minutes. Retained spines may become infected or cause delayed (≤ 1 to 2 months) FB granulomas. This reaction is not adequately understood, but it may be due to an intense and persistent inflammatory reaction. Spines that penetrate joints may induce synovitis. Echinoderm spines may discharge a purple dye that may be mistaken for a retained spine (Fig. 36.22).⁴⁹ Spines are usually visible on radiographs and should be removed if possible, although they are brittle and can break off in the skin. A YAG laser may be an effective alternative to remove sea urchin spines. If spines are located in a joint or near a nerve, surgical extraction using an operative microscope may be necessary.⁴⁸ Otherwise, if removal is difficult, leave the spine in place until it is resorbed or a local reaction takes place. If appropriate, open the wound and drain it to allow it to close by secondary intention.

Catfish

Several species of catfish in North America contain toxic venom, and a sting from the dorsal or pectoral spines can embed an FB. The spine secretes venom from an epidermal gland at its base.⁵⁴ The pain is usually ephemeral, and because no specific antitoxin exists, treatment consists of local care and analgesics. Immerse the affected part in hot water ($\approx 43.3^\circ\text{C}$ [110°F]) for at least 30 minutes if the pain is severe. This is believed to provide relief of symptoms by decreasing vascular and muscle spasm.⁵⁵ Local injection of the wound with alkalized bupivacaine provides local analgesia and may also neutralize the toxin.⁵⁴ Inspect the wound and remove any remaining spines (Fig. 36.23). A radiograph may be taken to confirm the absence of FBs, but catfish spines and cartilage may be radiolucent. Bedside

Figure 36.22 A, Multiple sea urchin punctures in the hand soon after injury and following a soak in hot water. B, The same hand after 6 days without intervening therapy other than soaking. Lack of discoloration indicates absorption of dye from the sea urchin spines and probable absence of retained fragments. (From Auerbach PS, editor: *Wilderness Medicine*, ed 6, St. Louis, 2011, Mosby.)

Figure 36.23 To ensure total removal, remove the spine of a catfish by incising the puncture site as opposed to simply pulling it out.

US may be helpful, depending on the clinician's level of experience. Thoroughly clean and irrigate the wound. Update the patient's tetanus prophylaxis if necessary. Some authors recommend empirical antibiotic therapy to cover gram-negative bacilli (e.g., *Aeromonas hydrophila*), but infection is quite rare and routine antibiotic prophylaxis is not standard.⁵⁴

Stingrays

Stingray envenomation usually occurs in a person who accidentally steps on a creature that is resting on the bottom in shallow water and covered by sand (Fig. 36.24). This causes the stingray to lash out its whiplike caudal appendage, or tail, which contains one to four venom-containing serrated spines. Portions of the spine may become buried in the victim's skin. Each spine is covered with a sheath containing venom glands, and in addition to immediate toxin-induced pain, pieces of the spine or sheath may remain embedded in the wound. These fragments, though often difficult to locate, do not dissolve and must therefore be removed. Persistent pain and inflammation, even weeks to months after the attack, mandate consideration of a retained FB, but a persistent and difficult-to-treat irritative process can occur in the absence of a retained spine or sheath. Immediate local and systemic reactions develop as a result of injection of a complex toxin. Systemic reactions may be severe and can include muscle cramps, vomiting, seizures, hypotension, arrhythmias, and (rarely) death.⁵⁶

Treatment consists of irrigation with saline followed by immersion in hot water at 42°C to 45°C for 30 to 90 minutes to inactivate the heat-labile toxin. Local digital blocks without vasoconstrictors provide effective analgesia for hand wounds. Explore and débride all wounds, and remove all remnants of the spine and integumentary sheath.⁴⁸ Wounds should heal by secondary intention. The venom can cause significant local tissue necrosis, and surgical débridement may be required.

Tetanus and Antibiotic Therapy

Prophylactic antibiotic therapy for marine injuries is common, although there are no convincing data to support or refute this practice. Unlike other soft tissue infections, marine injuries become infected with unusual gram-negative organisms, particularly *Vibrio* species. Although few studies have evaluated the effects of specific antibiotics, it is recommended that quinolones, trimethoprim-sulfamethoxazole, tetracyclines, third-generation cephalosporins, or aminoglycosides be used in lieu of penicillin, ampicillin, erythromycin, or first-generation cephalosporins.⁴⁹ It is always difficult to differentiate chronic inflammation caused by toxins and foreign material from

Figure 36.24 **A**, Stingray resting on the bottom of the ocean, usually covered by a layer of sand. **B**, An unsuspecting victim steps on the stingray, and the whiplike tail impales the foot (even through a heavy boot) with one or more spines. **C**, The spine has backward-facing barbs covered by a sheath with venom-containing cells, which causes a toxic envenomation and the potential for multiple foreign bodies.

true infection, and surgical exploration is often required in persistent cases. Administer tetanus prophylaxis as per routine recommendations.

Cactus Spines

The size of cactus spines fluctuates considerably. The difficulty of removal is generally inversely proportional to the size of the FB.⁵⁷ Larger embedded cactus spines are managed like

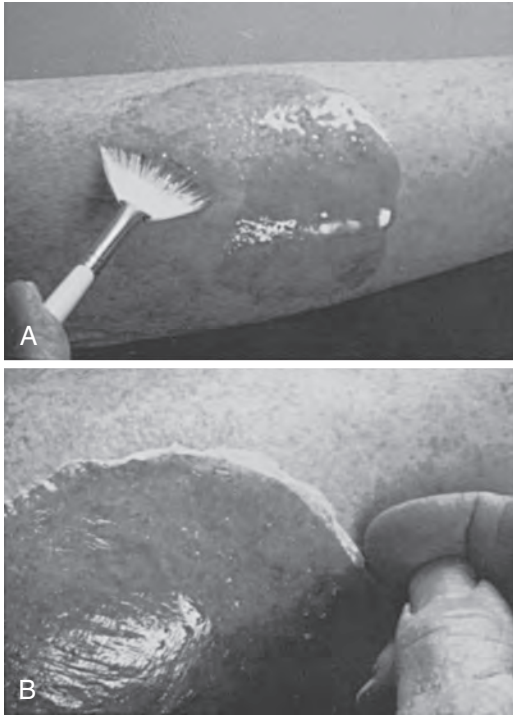

Figure 36.25 A thousand or more glochids may become affixed to the skin by contact with a single pad of polka dot cactus. **A**, To remove them, professional facial gel is spread with a fan brush, thin at the edges. **B**, The gel rollup is started by picking at the edge with the fingernails. When the gel is peeled off, all the very small spines come with it. (From Lindsey D, Lindsey WE: Cactus spine injuries, *Am J Emerg Med* 6:362, 1988. Reproduced by permission.)

wood splinters and sea urchin spine FBs. More advanced imaging techniques (US, CT, or MRI) may be required for localization of deeply embedded spines.

Deeply embedded cactus spines generally produce granulomatous reactions, but infections are rare.⁵⁸ Dermatitis from embedded cactus spines is a well-described phenomenon. Hence, make an effort to remove deeply embedded spines after carefully weighing the benefit and potential harm related to deep exploration, especially in a sensitive location.⁵⁷ Using forceps, remove superficially embedded, medium to large cactus spines by direct axial traction on each spine. Smaller spines (glochids) may be difficult and tedious to remove individually. Apply an adherent facial mask gel to remove the spines en masse with the gel (Fig. 36.25). Depilatory wax melted in a microwave oven and applied warm, commercial facial gels, and household glue (Elmer's Glue-All, Borden, Inc., Columbus, OH) have all been recommended for this purpose.^{57,59-61} Over-the-counter "home use" facial mask gels are not adherent enough to be effective without multiple (eight or more) applications.

Ring Removal

Frequently, a ring must be removed to prevent laceration of tissue or vascular compromise. Thoroughly lubricate (with a water-soluble lubricant—e.g., K-Y jelly) the finger and use a circular motion with traction on the ring. However, the string-wrap method or physically cutting the ring off may be necessary. Preferably, remove all rings before the edema is extensive enough to cause pain or vascular compromise.

String-Wrap Method

An occasional patient can remain calm during this procedure, but if the swelling is significant or the digit has been traumatized, anesthesia is necessary. Perform a proximal digital or metacarpal block to provide sufficient anesthesia and to minimize tissue distention at the ring site. Before removal of the ring, wrap a wide Penrose drain circumferentially in a distal-to-proximal direction to reduce the soft tissue swelling (Fig. 36.26). Leave the wrap in place for a few minutes to reach the maximum effect. Some nonanesthetized patients panic during the procedure because of increasing pain from compression and unwinding.⁶²

First, pass a 20- to 25-inch piece of string, umbilical tape, or thick silk suture between the ring and the finger. Shorter lengths are discouraged because one may need to repeat the wrapping procedure midway. If marked soft tissue swelling is present, pass the tip of a hemostat under the ring to grasp the string and pull it through. Wrap the distal string clockwise around the swollen finger (proximal to distal) to include the proximal interphalangeal (PIP) joint and the entire swollen finger. Start the wrapping next to the ring. Wrap it snugly enough to compress the swollen tissue. Place successive loops of wrap next to each other to keep any swollen tissue from bulging between the strands. When the wrapping is complete, carefully unwind the proximal end of the string in the same clockwise direction to force the ring over that portion of the finger that has been compressed by the wrap. The PIP joint is the area that is most difficult to maneuver over and causes the most pain.

Occasionally, the finger must be rewrapped if it was not done carefully the first time. It is not uncommon to produce abrasions or other kinds of trauma in the skin during this procedure. If the finger with the ring is lacerated or there are underlying fractures, it is prudent to cut the ring off instead of attempting this technique.

Certain rings are made of extremely hard material such as tungsten carbide or ceramic. In these cases, cracking the material with standard locking pliers can break the ring. Place the pliers on the ring and adjust the jaws to fit tightly, and then remove and readjust them while increasing tension with each subsequent adjustment. Continue until the material cracks and falls apart. Some rings may be lined with a metal band. Use a standard ring cutter to remove the band.

Ring Cutter

A ring cutter should be used when the swelling is excessive or other methods fail (Fig. 36.27). A ring cutter has a small hook that fits under the ring and serves as a guide for the saw-toothed wheel that cuts the metal. The cut ends of the ring are spread with large hemostats (e.g., Kelly clamps), and the ring is removed. If the tension is too great to spread the ring, another cut 180 degrees apart from the original ring cut can be performed. This will allow the ring to fall off in two pieces. A jeweler can subsequently repair cut rings.

Certain hardened metal rings, such as tungsten carbide, may not be amenable to the use of a ring cutter. Case studies have demonstrated that a dental-tipped drill or dental volvere can be used successfully. However, because of the nature of these instruments and the possibility of injury from them, such as lacerations from the blade, thermal burns, or ocular FBs, take precautions to limit further damage to the finger, as well as the use of eye protection to shield the patient's and operator's eyes.

Ring Removal: String-wrap Method

1 Lessen the edema by compressing the finger with a Penrose drain left tightly wrapped for 3 to 5 minutes.

2 Slide a small hemostat under the ring, grab a long piece of umbilical tape, and pull it under the ring.

3 Begin to carefully wrap the tape around the finger in a proximal-to-distal fashion.

4 Continue winding the distal strand to compress the skin distal to the ring. Take time to place successive loops next to each other, and keep tissue from bulging between the strands.

5 Remove the ring by unwrapping the proximal strand in the same direction that it was wrapped. The most difficult area to negotiate is the proximal interphalangeal joint. You may have to repeat the wrapping procedure to totally remove the ring.

6 Successful removal of the rings.

Figure 36.26 Ring removal: string-wrap method.

Body Piercing and Removal

The art of body piercing predates most history books. Over the past decade an enormous increase in the practice of body piercing has occurred. Accordingly, so have the complications associated with the practice.⁶³ For centuries the ears were the

most common place. Today, the lips, tongue, eyebrow, nose, navel, nipples, and genital areas have become sites of body piercing. To date, there are only a limited number of studies on infection after piercings in areas other than the ears. Three major types of jewelry are used: (1) barbell studs, which are

Ring Removal: Ring Cutter Method

1

This ring is too tight to be removed by the string-wrap technique. Note that the skin is deeply indented.

2

An electric ring cutter is the best option.

3

When the ring is cut through, grab the cut ends with hemostats and separate the sides. This ring can be repaired by a jeweler to a nearly new condition.

4

Note the macerated tissue under the ring.

Figure 36.27 Ring removal: ring cutter method.

straight bars with a ball threaded onto both ends; (2) labret studs, which are straight bars with a ball threaded on one end and a disk permanently fixed on the other end (more commonly used on the lips); and (3) a captive bead ring, which consists of a bead with small dimples on opposite sides and an incomplete ring with rounded ends to fit into the dimples (Fig. 36.28). The bead is held “captive” by tension from both sides of this incomplete ring. The bead ring is a variation of this: one bead is permanently fixed to one end, and an opening is made by removing the free end of the ring.⁶⁴

The most common reason for removal is infection (Fig. 36.29). Other symptoms such as bleeding, edema, allergic reaction, and keloid formation may also prompt removal. Occasionally, tongue piercings must be removed to permit intubation. To remove barbell- and labret-type studs, hold the bar with forceps and unscrew the bead on the other end. To remove a captive bead ring, hold the ring on both sides of the captive bead to release tension on the bead. This will dislodge the bead from the ring, which is holding it in place. If the jewelry is near the mouth or nose, take care to prevent aspiration

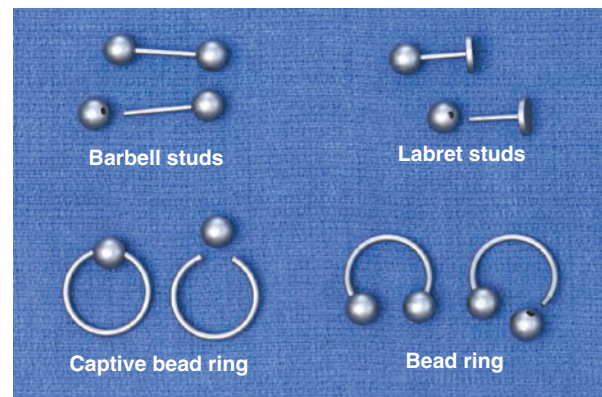

Figure 36.28 Various types of piercing jewelry. To remove a barbell stud or labret stud, unscrew the ball that is threaded onto the bar. To remove a captive bead ring, snap the ball out of the incomplete ring (it is held in place simply by tension and is not screwed in). You may need to insert needle-nose pliers into the center of the ring and spread it to pry the ring open. To remove a bead ring, unscrew the ball from one end of the ring.

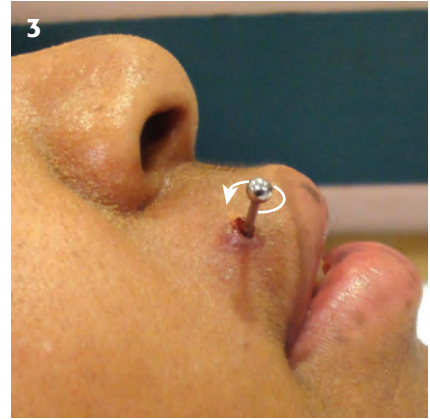

Body Piercing Removal

This patient has a labret stud piercing. Note that the ball is visible externally (*short arrow*); however, the disk portion has migrated internally and the buccal mucosa has closed over it (*long arrow*).

Infiltrate the region with local anesthetic. Alternatively, an infraorbital nerve block could be used (see Chapter 30).

Next, unscrew the ball on the end of the bar.

Make an incision in the buccal mucosa over the embedded disk.

Use a hemostat to find and remove the bar from the lip.

The labret stud, successfully removed and reassembled.

Figure 36.29 Body piercing removal. This piercing became infected when the mucosal portion of the metal bar migrated into tissue. An incision was required to find and grasp the metal bar.

of the bead. The complete microbiology of infections related to body piercing has not yet been determined. However, organisms such as *Staphylococcus epidermidis* and *Staphylococcus aureus*, along with *Pseudomonas aeruginosa*, have been commonly implicated pathogens. Other infectious complications from body piercing such as septic arthritis, endocarditis, hepatitis B and C, and HIV have been reported.^{65,66}

Most commonly, however, local wound infections predominate and can be managed with warm compresses, antibacterial soap, and topical antibacterial ointment once the FB is removed. The possibility of leaving the piercing in place while treating the infection has yet to be studied.

Postoperative Suture Removal

FBs in the form of nonabsorbed suture material are frequently encountered in the postoperative period. Drainage, localized pain, tenderness, and an inflammatory reaction along the suture line are characteristic of a retained FB (suture abscess). In this

instance, probing the wound with a sterilized needle bent into the shape of a crochet hook is frequently successful. Hooking the suture material through the sinus tract and removing it allows the wound to heal over the tract.

Tick Removal

It is important to remove ticks early because of tick-borne disease, including the hard tick of the Ixodid family. Rocky Mountain spotted fever, Lyme disease, tularemia, and ascending paralysis are among the many infections identified as tick-borne diseases. It is important to note that the rate of disease transmission before 48 hours of attachment is exceedingly low.⁶⁷ Removal of Ixodid ticks is difficult because the mouthparts become cemented within 5 to 30 minutes of contact with the host's skin. Removal will become more difficult the longer the tick is attached. Inadequate or partial removal of the tick may cause infection or chronic granuloma formation. Removal by mechanical means is recommended.⁶⁸ Nonmechanical, traditional, and

Tick Removal

Ticks should be removed as soon as possible to minimize the transmission of tick-borne pathogens and to limit their fixation to the skin by a secreted cement compound. This engorged tick has been attached for about a day and has burrowed under the skin. Most home remedies are worthless.

A recommended approach is to grasp the tick with forceps near its head where it enters the skin (avoid the soft body) and gently pull it out. Some advise twisting the head counterclockwise, but this has not objectively been found to be more effective.

If pieces of the tick remain (*arrow*), they should be dug out. Anesthetize the area and use a scalpel with a No. 11 blade to excise the embedded mouthparts. The erythema surrounding this tick bite is not erythema migrans (which is characteristically an oval-shaped rash, with or without central clearing), but rather local irritation from the initial removal attempt.

Figure 36.30 Tick removal.

folk methods of forcing the tick to disengage (e.g., the use of petroleum jelly, fingernail polish, a hot match, or alcohol) are not advised and can cause the tick to regurgitate, thereby increasing the possibility of transmission of infection.

The use of straight or curved forceps or tweezers is the recommended method of removal. If these instruments are not available, use a gloved hand. Grasp the tick as close to the patient's skin surface as possible and gently apply steady axial traction (**Fig. 36.30**). Take care to not squeeze, crush, twist, or jerk the tick's body because this may expel infective agents or leave mouthparts in the skin. If mouthparts are left behind after removal of the body, they may be removed with tweezers. If one is still unable to remove the mouthparts, consider excision under local anesthesia to prevent local infection.

Many patients have great anxiety about the development of tick-borne diseases after tick removal. Some studies have demonstrated that single-dose doxycycline (200 mg) may prevent the development of Lyme disease.⁶⁷ Children younger than 8 years may be given a single dose of doxycycline (4 mg/kg). However, prophylactic antibiotic treatment of all tick bites is not recommended. Amoxicillin prophylaxis is not effective. When a patient is in an area where the incidence of Lyme disease is high or when a partially engorged deer tick in the nymphal stage is discovered on the body, the patient is more likely to benefit from prophylaxis. Regardless of whether prophylaxis is given, instruct patients about the symptoms and signs of Lyme disease and encourage them to return or seek medical evaluation if these symptoms develop.

Zipper Entrapment

The skin of the penis may become painfully entangled in a zipper mechanism (**Fig. 36.31**). Unzipping the zipper frequently

Figure 36.31 Penile skin caught in a zipper creates a rather painful and embarrassing situation for the patient. Instead of anesthetizing and excising the skin, consider cutting the zipper as demonstrated in **Fig. 36.32**.

lacerates the skin and increases the amount of tissue caught in the mechanism. Although the clinician may anesthetize the skin and excise the entrapped tissue, a less invasive method can be considered.

Cutting the median bar between the faceplates of the zipper mechanism remains the most common method. The interlocking teeth of the zipper then fall apart when the median bar (diamond or bridge) of the zipper is cut in half (**Fig. 36.32**), and the skin is subsequently freed. A bone cutter or wire clippers and a

Figure 36.32 Zipper removal. (From *Emergency Medicine*, October 15, 1982, p. 215. Used by permission.)

moderate amount of force may be required to break the bar. The addition of mineral oil followed by traction has been demonstrated to achieve some success. Patients with penile lacerations warrant urologic follow-up to assess for urethral injury.

Infiltration of Radiographic Contrast Material

The infiltration of high-osmolality intravenous contrast material has the potential to cause skin necrosis, but the use of low-osmolality dye, which is well tolerated in soft tissues, has essentially eliminated this problem (Fig. 36.33). The use of high-pressure power injectors, with the technologist out of the room, calls for careful inspection of the intravenous site before injection. However, because of the high-pressure rapid auto-injection of contrast material and the absence of a technician in the room, extravasation of contrast material is not a rare event and occurs even with meticulous technique. Infiltration occurs in approximately 0.5% to 1% of auto-injections. Once contrast material has infiltrated, no intervention has been demonstrated to ameliorate the local reactions, which are usually mild. Swelling, erythema, and mild discomfort at the infiltration site may occur. It is best to resist the temptation to use excessive heat or cold. Elevation of an extremity is appropriate but of unproven value. Injection of steroids and other agents has no known benefit. Low-osmolality dye is usually totally resorbed in a few days, with no serious consequences in the vast majority of cases. Progress of the dye's egress may be followed with radiographs. The majority of contrast material extravasations resolve with no long-term consequences with conservative management. If large volumes of contrast material are injected (> 75 to 100 mL), especially in confined areas such as the dorsum of the hand, it is possible that skin necrosis from the pressure or a compartment syndrome

may develop, but this is rare. The clinician should resist attempts to routinely remove even large volumes of extravasated contrast material by incision or aspiration. Although some contrast material may be removed with surgical techniques during fasciotomy, the actual benefit is unknown. Surgical intervention is rarely required and is based on measurement of compartment pressure and clinical evaluation. Patients with small-volume and minimally symptomatic extravasations may be discharged. Large-volume extravasations warrant consultation or further observation.

TASER Darts

The Thomas A. Swift Electric Rifle, or TASER, is a conducted electrical weapon used in many areas by police to subdue violent patients (see Chapter 70). The TASER fires two barbed electrodes on long copper wires (Fig. 36.34). The barbs attach to skin or clothing and create an arc that delivers an electrical jolt that causes overwhelming pain and involuntary muscle contraction and incapacitates the subject. The electricity is of such high frequency that it is believed to stay near the surface and not penetrate to the depth of internal organs. The barbs are designed to not penetrate deeper than 4 mm, and police are taught to remove them by stretching the surrounding skin and tugging sharply. If this fails, cutting down on the dart after local anesthesia should facilitate removal.^{69,70} Patients may need medical evaluation after ED removal of the darts for the underlying state of agitation that required the use of a TASER, complications of electrical injury, injury from the fall after incapacitation, and injury from the barb, especially if struck in the mouth, eye, neck, or groin. Most patients do well with minimal intervention and proper wound management if the patient is not unduly agitated and the TASER did not involve the critical areas of the body just mentioned.

Figure 36.33 The entire volume (100 mL) of nonionic low-osmolality contrast material (Isovue) for a computed tomography scan was pressure-injected into the antecubital soft tissue when the intravenous line infiltrated. High-volume injections are automatically administered by a programmed auto-injector; the technician is not in the room to stop it. **A**, There was only mild pain but considerable soft tissue swelling, and most of the redness and blistering occurred when the technician taped an unprotected ice pack directly to the skin and nearly caused frostbite. **B**, X-ray evidence of the infiltration. **C**, Within 36 hours, the dye was absorbed, without further treatment. No skin necrosis occurred, as has been seen when older ionic high-osmolality agents infiltrate. There is no known way to ameliorate the potential soft tissue injury. The antecubital fossa is the preferred site for an intravenous line for injection of contrast material, and such an extravasation on the dorsum of the hand may be more serious. Do not attempt to remove the contrast material by aspiration or surgical incisions.

Human and Animal Bite FBs

The most common FB after a human bite is a piece of tooth. These FBs can be difficult to find and may not be appreciated if the patient does not admit or disclose the bite wound. Usually, the bite puncture is small and not easily cleaned or visualized. The puncture can be widened with a formal incision to aid in cleaning and evaluation for tendon integrity, injury to the joint capsule, fracture, or an FB (Fig. 36.35). Occasionally, small pieces of teeth can become embedded in a wound, such as with dog, cat, or snake bites (Fig. 36.36). Radiographic detection is variable, and exploration is often the only alternative.

Figure 36.34 **A** and **B**, Barbed TASER darts can be removed by a quick pull or through a small incision made over the barb.

Figure 36.35 This human bite puncture wound was enlarged with an incision to aid in cleaning and search for a foreign body, usually a piece of tooth. Even though this wound appears clean, it should not be closed with sutures.

Pyogenic Granuloma (Lobar Capillary Hemangioma)

A pyogenic granuloma is a benign acquired polypoid, friable vascular lesion of the skin (hand, neck, foot, fingers, and trunk) and mucous membranes (Fig. 36.37). They are common in children; in pregnancy, the lesion is termed *epulis gravidarum* (pregnancy tumor). The cause is unknown, but there is some association with topical retinoids and the protease inhibitor indinavir; they are not due to infection, and they are not granulomas. They grow rather rapidly over a period of a few weeks, are occasionally associated with minor trauma, have a glistening dark red appearance, and may bleed. Histologically, a pyogenic granuloma is a hemangioma. A variety of topical therapies (silver nitrate, cryotherapy), laser, or cautery are available, but removal by sharp dissection with primary suturing

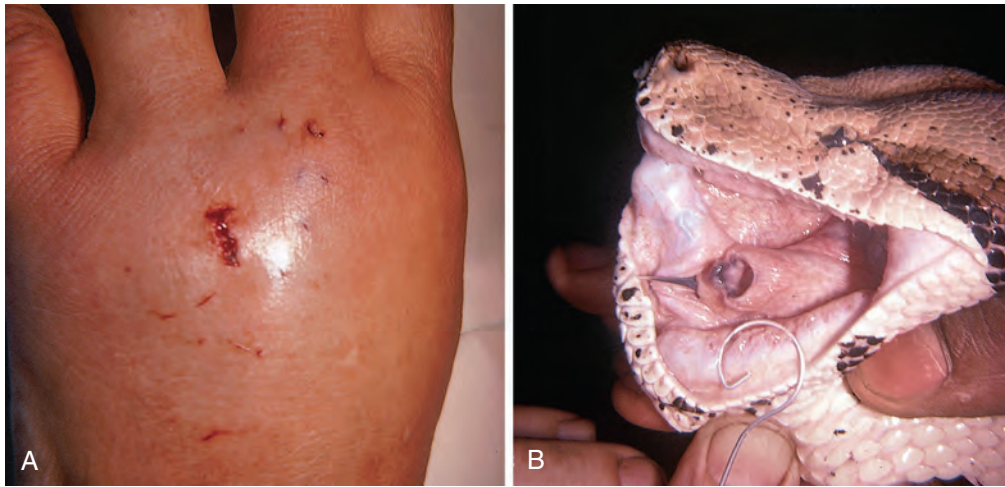

Figure 36.36 A and B, The bite of a boa constrictor, though not poisonous, may contain small tooth fragments. As with cat and dog bites, radiographic evaluation is variable and exploration may be required.

Figure 36.37 Pyogenic granuloma. Despite their name, these lesions are neither pyogenic (i.e., infectious) nor granulomas. Rather, they are a type of hemangioma. Pyogenic granulomas can develop rapidly over a period of weeks and are common in pregnant women.

is usually curative (Fig. 36.38). The recurrence rate may be as high as 40% with nonsurgical intervention.⁷¹

Hair-Thread Tourniquet

Hair or thread fibers adherent to infants' clothing occasionally become tightly wrapped around a child's digits or genitals (Fig. 36.39).⁷² If they are left in place, amputation may eventually occur. The offending fibers may be difficult to visualize, and the child is often brought for evaluation only after signs of distal ischemia appear. Occasionally, the fiber can be grasped with toothless forceps or a small hemostat and then unwrapped. More commonly, fibers cannot be identified because they are deeply embedded in swollen tissue. Removal not requiring minor surgery includes use of a chemical depilatory, such as the over-the-counter product Nair (calcium thioglycolate), to dissolve or weaken the hair. A generous amount of depilatory cream is worked into the involved area and allowed to dissolve

or weaken the hair, which is then removed mechanically. If a depilatory is not successful in 30 to 60 minutes, surgical removal is indicated.

A No. 11 blade can be used to cut the constricting bands under a regional nerve block.⁷³ It may be difficult to identify individual hairs that are deeply embedded in a swollen digit and even more difficult to assess the success of the intervention. Frequently, multiple hairs are involved. Because the bands may be quite deep, the incision should avoid known neurovascular tracts. Barton and coworkers recommend a dorsal, rather than a lateral, incision on the digits.⁷² If the soft tissue on the distal end of the digit has been rotated after a circumferential dermal laceration from the tourniquet, the distal tissue can be realigned with the proximal tissue and two dorsolateral sutures placed or tissue adhesive glue applied to maintain the digit in alignment.

Generally, conservative wound care is sufficient once the band has been removed. Application of an antibiotic ointment may enhance healing and allow easier removal of serous drainage from the circumferential laceration. Clinical reassessment in 24 hours will indicate whether any constricting bands remain.

DISPOSITION MANAGEMENT

Tetanus

Wounds with FBs should be considered contaminated wounds, and tetanus status should be updated according to the recommendations for patients with contaminated wounds.

Antibiotics

There is no consensus or standard for the use of antibiotics after removal of wound FBs. Antibiotics may be indicated for immunocompromised patients, but there are no data to support the routine use of antibiotics in patients with wounds that have been thoroughly cleaned and from which all foreign material has been extracted. Prophylaxis may be considered if there was excessive time between injury and removal or obvious contamination or when it is difficult to adequately clean the

Figure 36.38 A-D, Pyogenic granuloma removed by sharp dissection under ketamine anesthesia and primary suturing.

Figure 36.39 This child has multiple hair tourniquets compromising the circulation to two toes. The hairs are deeply embedded in the skin creases and cannot be visualized. An over-the-counter depilatory (such as Nair) smeared into the fold may dissolve the hair in 30 to 45 minutes, but if unsuccessful, an incision must be performed. The best way to ensure removal of the constriction is to cut the depth of the folds with a scalpel blade (using a dorsal incision to avoid the neurovascular bundle) and attempt to extricate individual fibers. A digital nerve block may be performed for anesthesia. Return of circulation should be obvious by the change in temperature and color in the affected digit or digits before it is assumed that all the fibers have been cut.

wound. Under these circumstances, it is more prudent to opt for an open wound and delayed closure.

If prophylactic antibiotics are prescribed, a first-generation cephalosporin or penicillinase-resistant penicillin has traditionally been the first-line choice. In patients with contraindications to penicillins and cephalosporins and with the increasing incidence

of community-acquired methicillin-resistant *S. aureus* in many areas, clindamycin, trimethoprim-sulfamethoxazole, or tetracycline may provide alternative coverage.⁷⁴ However, infections associated with FBs are not likely to be from methicillin-resistant *S. aureus*. Under certain circumstances, alternative antibiotics may be indicated. For infected plantar punctures through a shoe, a fluoroquinolone to cover *P. aeruginosa* is appropriate coverage, although most *Pseudomonas* infections are complex and may need extensive débridement and intravenous antibiotics. Saltwater marine FBs may be contaminated with *Vibrio* species, which are usually sensitive to tetracyclines, aminoglycosides, or third-generation cephalosporins. Freshwater FBs, on the other hand, are more likely to harbor *A. hydrophila*, which can be treated with tetracyclines.

FB Reactions

If the FB is not removed or cannot be removed, an FB reaction may occur. Some FBs produce an inflammatory reaction or infection a few days after introduction into the body. Other objects may not cause problems for weeks, months, or even years until they flare up for no apparent reason. The primary factors that affect the extent of tissue reactions are contamination and whether the material is inert or reactive with human tissue. Reactive FBs, such as wood, will generally produce inflammation eventually, whereas inert FBs, such as bullets, rarely do. Some inert FBs carry dirt particles, pieces of clothing, or other sources of bacterial contamination. Expedient removal may be necessary, even if the FB itself is relatively small and unlikely to cause a reaction.

A purulent bacterial infection may develop in the presence of any FB; therefore, any abscess or cellulitis that recurs or wounds that do not heal as expected should always be investigated for retained FBs.^{75,76} Karpman and coworkers found a 15% rate of infection (*S. aureus* and Enterobacteriaceae) in a series of 25 patients treated for cactus thorn injuries on the extremities.⁵⁸ Certain thorns (black thorns, rose thorns), redwood and northwest cedar splinters, toothpicks, hair, and stingray or sea urchin spines are noted for their ability to initiate chronic FB reactions. Sea urchin spines and other marine FBs are covered with slime, calcareous material, and other debris that commonly initiate an FB granuloma. The inflammatory reaction seen with cactus thorns may be an allergic reaction to fungus found on the cactus plant.

Many FB reactions are thought to result from an inflammatory response to organic material, or they may represent infection from bacteria introduced at the time of the wound. Clinically evident reactions may be delayed for weeks or even years after injury (Fig. 36.40). The chronic infection or inflammatory reaction may not be accompanied by the production of pus, but it may be quite painful or result in loss of function. FBs may also be associated with the formation or development of a chronic pseudotumor, a sinus tract, or an osteomyelitis-like lesion of bone and soft tissue.⁷⁵ In addition, organic material has been noted to induce chronic tenosynovitis, chronic monarticular synovitis, and chronic bursitis.

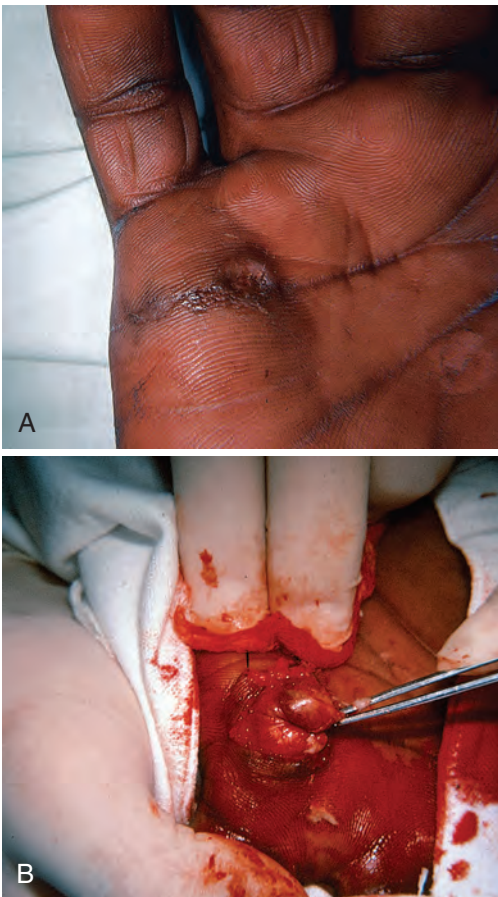

Figure 36.40 This foreign body (FB) granuloma developed after the FB was stable for 6 months. There was no gross infection and it was dissected en masse.

Rapidly traveling projectiles with considerable inherent heat (e.g., bullets) are less likely to cause infection but are more apt to cause other difficulties. Damage to surrounding areas can occur during passage through tissue. Rarely do retained lead FBs, such as bullets or shotgun pellets, leach out lead into the general circulation and produce systemic lead poisoning unless they are in contact with synovium (Fig. 36.41). If this process does occur, it may take years to develop and can result in vague or nondescript symptoms (e.g., fatigue, arthralgia, headache, or abdominal pain) many years after the initial injury.

Figure 36.41 There is no need to routinely remove retained bullets. Most lead foreign bodies are well tolerated, but if a bullet is bathed in synovial, pleural, peritoneal, or cerebrospinal fluid (CSF), the lead may leach out over time and produce a significant elevation in blood lead levels. The symptoms are often vague, and the relationship between the retained lead and the patient's clinical scenario may be difficult to sort out. **A**, This patient had chronic neurologic findings, including wristdrop, and was wheelchair bound. **B**, The symptoms were due to chronic lead poisoning from a 20-year-old retained bullet (arrows) in or near the spinal canal, possibly being bathed by CSF. **C**, Note the lead lines in the gingiva, indicative of lead poisoning.

Elevated blood lead levels are more likely to occur if body fluids such as joint, pleural, peritoneal, or cerebrospinal fluid bathe the lead. Bullets retained in muscle or other soft tissue are not likely to produce any sequelae related to their lead content. However, Farrell and colleagues reported unsuspected elevated lead levels in patients with retained lead fragments who were seen in the ED with a variety of complaints.⁷⁷ Lead levels of up to 50 µg/dL were reported. Levels greater than 45 µg/dL are generally considered an indication for chelation therapy. The relationship between the retained lead and the symptoms was unclear, but this report verifies the observations of others that retained lead FBs in selected areas can significantly elevate blood lead levels and may produce symptomatic plumbism.

Discharge Instructions

The patient should be informed that despite every effort there can be no absolute guarantee that all foreign material has been identified or extracted, regardless of whether some or any FB was removed during the initial exploration. Prudent clinicians

should always suggest close follow-up and should leave open the possibility that an occult FB may still remain in the wound. Discharge instructions should also include the signs and symptoms of problems related to retained material. Some centers routinely add this caveat on all discharge instructions to patients treated for lacerations or soft tissue defects. Written instructions should inform patients that additional steps may be undertaken if foreign material is subsequently suspected. Discharge instructions should indicate that close, continued and careful follow up is important with any evaluation for FB, FB removal, and post-FB removal assessment.

ACKNOWLEDGMENT

The authors and editors wish to thank Ted Koutouzis and Matthew Levine for contributions to this chapter in previous editions.

Incision and Drainage

Gina Ambrose and Donald Berlin

▶ **I**ncision and drainage (I&D) procedures (Videos 37.1–37.5) in the emergency department (ED) are most commonly performed for soft tissue abscesses (Fig. 37.1).^{1,2} The total number of ED visits increased from 90 million to 115 million over a 10-year period, with visits for abscess-related complaints increasing faster than overall ED visits.³ Of an estimated 34.8 million ambulatory visits for skin and soft tissue infections, 33% are seen in EDs.⁴

The emergence and predominance of methicillin-resistant *Staphylococcus aureus* (MRSA) as the cause of cutaneous abscesses during the past several decades have necessitated major revisions in long-standing guidelines for antibiotic administration. In light of this significant etiologic change, MRSA should be considered as a probable cause in most skin and soft tissue infections.

ABSCESS ETIOLOGY AND PATHOGENESIS

Localized pyogenic infections may develop in any region of the body. Abscesses generally begin as a localized superficial cellulitis. Some organisms cause necrosis and liquefaction, as well as the accumulation of leukocytes and cellular debris. This is followed by loculation and subsequent walling off of these products, all of which result in the formation of one or more abscesses. Any process or event that causes a breach in the skin's defensive epithelial barrier increases risk for the development of an abscess. This includes primary dermatologic conditions as well as trauma. The lymphatic tissues may be involved in this form of lymphangitis or “streaking.”

An isolated abscess is often associated with local symptoms only, lacking fever, systemic complaints, or abnormal blood tests. Systemic signs of toxicity or fever suggest deeper tissue involvement, bacteremia, or both. As the process progresses, the area of liquefaction increases until it “points” and eventually ruptures into the area of least resistance. This may be toward the skin or the mucous membrane, into the surrounding tissues, or into a body cavity. If the abscess is particularly deep, spontaneous drainage may not occur. In some cases, a fistulous tract can arise and lead to the formation of a chronic draining sinus. This development—or the recurrence of an abscess that was previously drained—should broaden the etiologic differential. For example, recurrent abscesses in the perineal or lower abdominal area should raise suspicion for inflammatory bowel disease as the trigger, and recurring abscesses in the axilla or groin should raise the possibility of hidradenitis suppurativa (HS). Chronic abscesses may be associated with an immunocompromised state or intravenous drug use (IVDU), and recurrent abscesses may suggest the possibility of a retained foreign body, underlying osteomyelitis, or the presence of an atypical or drug-resistant organism (Fig. 37.2).

Various organisms that colonize normal skin can cause necrosis and liquefaction with subsequent accumulation of

leukocytes and cellular debris. Loculation and subsequent walling off of these products leads to abscess formation. The cause of an abscess depends on its anatomic location and flora indigenous to that area. Different organisms cause disease based on environmental exposure. For example, direct inoculation of extraneous organisms may occur during a mammalian bite (e.g., *Eikenella*, *Pasteurella*), exposure to saltwater (e.g., various *Vibrio* strains) or freshwater (e.g., *Aeromonas*), or meat or fish exposure (e.g., *Erysipelothrix rhusiopathiae*). *Pseudomonas* folliculitis has been associated with the use of a hot-tub, as this organism thrives in a warm, wet environment.⁵

Staphylococcal strains, which are normally found on the skin, produce rapid necrosis, early suppuration, and localized infections with large amounts of creamy yellow pus, the typical manifestation of an abscess. Conversely, group A β -hemolytic streptococcal infections tend to spread through tissues and cause a more generalized infection characterized by erythema, edema, a serous exudate, and little or no necrosis, typical manifestations of cellulitis. Anaerobic bacteria, which proliferate in the oral and perineal regions, produce necrosis with profuse brownish, malodorous pus⁶ and may cause both abscesses and cellulitis.

Normal skin is extremely resistant to bacterial invasion, and few organisms are capable of penetrating intact epidermis. In a normal healthy host with intact skin, the topical application of even very high concentrations of pathogenic bacteria does not result in infection. The requirements for infection usually include a high concentration of pathogenic organisms, such as in hair follicles in the adnexa; occlusion of glands or other structures that prevent desquamation and normal drainage; a moist environment; adequate nutrients; and trauma to the corneal layer, which allows organisms to penetrate into deeper tissues.⁷ Tissue perfusion may also play a role in the ability to prevent infection. Trauma may be the result of abrasions, shaving, insect bites, hematoma, injection of chemical irritants, incision, or occlusive dressings that macerate the skin. The presence of a foreign body can potentiate skin infections by enabling a lower number of bacteria to establish an infection. For example, abscesses occasionally develop at suture sites in otherwise clean wounds. In addition, abscesses can develop at any site used for body piercing. Ear piercings through the cartilage of the pinna seem to be at particular risk for infection because of the avascularity of auricular cartilage.⁸

When favorable factors are present, the normal flora that colonize cutaneous areas flourish and infect the skin and deeper structures. In persons performing manual labor, the arms and the hands are infected most frequently. In women, the axilla and submammary regions are frequently infected because of minor trauma from shaving, contact with undergarments, a moist environment, and an abundance of bacteria in these areas. Infections may develop anywhere on the body in intravenous (IV) drug users, although the upper extremities are most commonly affected.^{9–11} Deep soft tissue abscesses can be caused by an addict's attempts to access deep venous structures when peripheral venous access sites are exhausted.¹² In addition, areas with compromised blood supply are more prone to infection because normal host defenses, including cell-mediated immunity, are less available.⁸

Bacteriology of Cutaneous Abscesses

Although most abscesses contain bacteria, 5% of abscesses are sterile, especially those associated with IVDU. Clinically, sterile

Figure 37.1 Cutaneous soft tissue abscesses such as this are commonly encountered in the emergency department. Incision and drainage are required for definitive treatment; antibiotics alone are not sufficient. Multiple recurrent abscesses in the same area raise suspicion for a foreign body or underlying osteomyelitis. This abscess, located on the hip of a prison inmate, began to spontaneously drain, releasing purulent contents. The abscess was caused by methicillin-resistant *Staphylococcus aureus* (MRSA). (Courtesy Public Health Image Library. <http://www.cdc.gov/mrsa/community/photos/photo-mrsa-8.html>.)

abscesses cannot be differentiated from those caused by bacteria. They are caused by injected irritants that are not fully absorbed, causing local inflammation at the site of injection. Somewhat atypical abscesses develop in parenteral drug users. Injection of a cocaine-heroin mixture (“speedball”) may predispose users to abscesses by inducing soft tissue ischemia.¹³ Jenkins and colleagues compared the microbiology of abscesses in IVDU-patients versus patients without a history of IVDU and found that streptococcal species and anaerobes were identified more commonly than *Staphylococcus* in IVDU-patients.¹¹

The microbiology and the underlying cause of skin and soft tissue abscesses are related to their location. Abscesses involving the extremities are generally the result of a breach in the skin’s integrity from trauma such as cuts, abrasions, or needle punctures. Abscesses involving the head, neck, and perineal region are usually associated with obstruction of the apocrine sweat glands. These types of abscesses increase in frequency after puberty because of the increased apocrine and sebaceous gland activity. Perirectal abscesses are typically the result of bacterial spread from adjacent anal glands. Vulvovaginal abscesses usually result from obstruction of a Bartholin gland, which then causes duct and gland edema and subsequent infection. Pilonidal abscesses are hypothesized to be caused by sacrococcygeal infections from ingrown hairs in the intergluteal cleft.

In 2002, Brook¹⁴ compiled the findings from more than 15 bacteriologic studies of 676 polymicrobial abscesses. *S. aureus* and group A β -hemolytic streptococci were the most prevalent aerobes in skin and soft tissue abscesses and were isolated in specimens from all body sites. Gastrointestinal and cervical flora (enteric gram-negative bacilli and *Bacteroides fragilis*) were found most often in intraabdominal, buttock, and leg lesions. Group A β -hemolytic streptococci, pigmented *Prevotella*, *Porphyromonas* species, and *Fusobacterium* species—all normal residents of the oral cavity—were most commonly found in lesions of the mouth, head, neck, and fingers.

In a study of the bacteriology of cutaneous abscesses in children, Brook and Finegold¹⁵ found aerobes (staphylococci and group A β -hemolytic streptococci) to be the most common isolates from abscesses of the head, neck, extremities, and trunk, with anaerobes predominating in abscesses of the buttocks and perirectal sites. Mixed aerobic and anaerobic flora was found in the perirectal area, head, fingers, and nail bed. This study noted an unexpectedly high incidence of anaerobes in non-perineal abscesses. Anaerobes were found primarily in areas adjacent to mucosal membranes (e.g., the mouth), where these organisms tend to thrive, and in areas that are easily contaminated (e.g., by sucking fingers, which causes nail bed and finger infections or bite injuries).
