1. Place the patient supine on the examination table.
2. Place the legs in the frog-leg position.
3. Locate the full bladder (ultrasound guidance often helpful).
4. Prep and drape the skin.
5. Place a wheal of local anesthetic at the aspiration site.
6. Advance the needle (usually 22-gauge, 3.75- to 8.75-cm length) in the midline through the skin and subcutaneous tissues towards the bladder.
7. Actively aspirate the syringe while simultaneously advancing.
8. If the bladder is entered, urine appears in the syringe.
9. If there is no urine, withdraw the needle to a subcutaneous position and redirect it at a different angle.
10. Following adequate urine collection, withdraw the syringe and needle.

Description

Background

Utilized primarily in young children as an alternate means of urine specimen collection.

Anatomy and Physiology

See following figures.

Pathophysiology

Results in urine specimen collection capable of distinguishing true bacteriuria from contamination.

Indications

In the neonate or the young child, suprapubic aspiration or urethral catheterization can provide the clinician with a sample that is reliable for bacteriologic interpretation. Although disconcerting to some parents, suprapubic aspiration is not a dangerous procedure, and the sensitivity of urinalysis for bacteriuria approaches 100%. However, for many young children, urine can generally be more readily collected by urethral catheterization.

For adult patients, the indications for suprapubic aspiration are more limited because these patients can usually cooperate with the clinician. Men with condom catheters or phimosis, however, may require suprapubic aspiration to minimize urethral contamination. Aspirated cultures, rather than catheterized specimens, may help assess for infection versus contamination in patients with asymptomatic bacteriuria on routine urine collection. In infections caused by organisms that in other circumstances are often discounted as contaminants (e.g., *Staphylococcus epidermidis* or *Candida albicans*), suprapubic

aspiration or a catheterized specimen is required to confirm the presence of such pathogens.

In patients in whom the possibility of infravesical infection is a concern (e.g., patients with chronic infections of the urethra or the periurethral glands), suprapubic aspiration may help distinguish a bladder source from a urethral source.

Contraindications

Skin or soft tissue infection in the area of the proposed anterior abdominal wall puncture site.

Procedure

Place the child supine with the legs in a frog-leg position and restrain as necessary (Fig. 55.27A, step 1). First locate the bladder. A full, palpable, or percussible bladder should be readily apparent, but this can be difficult to discern in all but the thinnest patients. If there is any question about the location or the amount of bladder urine, a quick ultrasound examination is informative. The point of entry in the skin should be 1 to 2 cm above the superior edge of the symphysis pubis. Pass the syringe and needle perpendicular to the abdominal wall toward the bladder, usually at a 10- to 20-degree angle from the true vertical, somewhat cephalad in children (see Fig. 55.27A, step 2) and somewhat caudad in adults (see Fig. 55.27B). Note that the bladder of a newborn is an abdominal organ and that it will be missed if the needle is inserted too close to the pubis or angled toward the feet.

After draping the prepared skin and choosing the point of entry, raise a skin wheal of local anesthesia to reduce discomfort. After anesthetizing the skin, advance a longer, mid-caliber needle (usually 22-gauge, 3.75 to 8.75 cm in length) in the midline through the skin and quickly into the bladder. Advance the needle attached to a syringe and aspirate during advancement. As soon as the bladder is entered, urine will appear in the syringe. A short needle is adequate for virtually all pediatric patients. After collecting the urine, withdraw the syringe and needle. Microscopic hematuria always follows the procedure but gross hematuria is uncommon.

If urine is not obtained, do not remove the needle but withdraw it to a subcutaneous position and redirect it at a different angle. Often, a child may spontaneously start to void after any type of invasive stimulus (e.g., bladder irritation by a probing needle, venipuncture, or lumbar puncture). Hence, prepare to collect a spontaneously voided specimen, should that option arise. Anticipate this before beginning blood or spinal fluid collection during the bacteremic workup of the febrile neonate.

In most patients, an acceptable urine sample can be obtained with the first needle pass. If the needle points too caudad, in an effort to avoid entering the peritoneum, it is possible to enter the retroperitoneal space, skimming the bladder muscle and never penetrating the bladder mucosa.

Aftercare

Following withdrawal of the needle, place a simple bandage over the puncture site.

Complications

Bacteremia does not typically result from this procedure.⁸⁷ Bowel penetration has occurred in children with distended abdomens from gastrointestinal disturbances.⁸⁸ The combination of gaseous bowel distention and relative hypovolemia might displace and flatten the relatively empty bladder against the

pelvic floor. Even when the large bowel has been penetrated, most patients typically recover uneventfully. As a general rule, simple penetration of the bowel with a needle is considered an innocuous event and requires no specific treatment.

Conclusions

Although it can be performed in a patient of any age, suprapubic aspiration is utilized for urine collection in young children only when alternative collection methods are not feasible. It consistently provides a urine specimen that is capable of distinguishing true bacteriuria from contamination. However, in many cases, alternative methods of urine collection are preferred over this procedure.

SUPRAPUBIC CYSTOSTOMY

Introduction

In general, any patient requiring a urethral catheter, but in whom a catheter cannot be safely passed, is a candidate for a suprapubic cystostomy tube (Video 55.3).

Among the most user-friendly devices for suprapubic bladder access is the Cook peel-away sheath unit (Cook Medical, Bloomington, IN).⁸⁹ It uses the Seldinger (guidewire) technique to gain bladder access and allows suprapubic placement of a Foley balloon catheter for definitive bladder drainage. This device is readily suitable for ED use when compared with other suprapubic bladder access approaches, such as trocar-type devices.

When emergency bladder drainage is required and a transurethral Foley catheter cannot be placed, any device suitable for central venous access can be inserted suprapubically using the Seldinger technique (Fig. 55.28).

Procedure Overview

Indications: need for emergency bladder access and drainage.

Contraindications: bladder not readily definable or low bladder volume; relative contraindications include history of previous lower abdominal surgery, intraperitoneal surgery, irradiation, bleeding diathesis, or concurrent antithrombotic use.

Complications: a wide variety of complications have been reported, including bowel or other organ injuries, which serve as reminders that suprapubic cystostomy is not innocuous.

Equipment: Chiou Suprapubic Tube Insertion Kit (Cook Medical) and Foley catheter.

Key Procedure Sequence

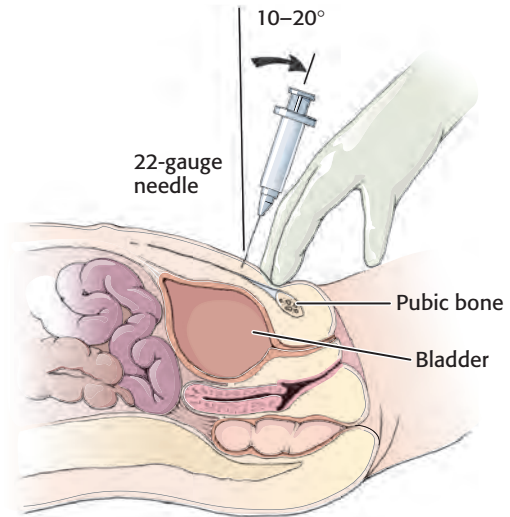

1. Prep and drape the skin for a sterile procedure.
2. Inject local anesthesia ~2 to 3 cm above the pubic symphysis.
3. Locate the bladder by palpation (or ultrasound if available). While aspirating, advance a 22-gauge spinal needle with an attached syringe until urine returns.
4. Keep the needle in place, remove the syringe, and thread the guidewire through the needle into the bladder.
5. Once the guidewire is threaded into the bladder, remove the needle.
6. Make a stab incision at the guidewire/skin interface.
7. Pass a peel-away sheath and indwelling fascial dilator device over the wire.

Suprapubic Aspiration

A. Pediatric

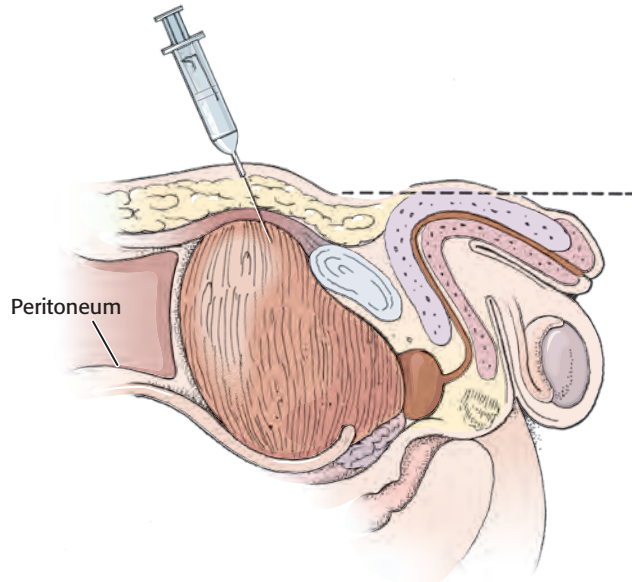

1. Restrain the infant and place her in a frog-leg position. Prepare and drape the skin, and raise a skin wheal with local anesthetic to reduce discomfort. Despite the safety of this procedure, it may be disconcerting for worried parents, and they may wish to leave the room during the aspiration.

2. Puncture the abdominal wall with a 22-gauge needle in the midline approximately 1 to 2 cm cephalad to the superior border of the pubic bone. Keep the syringe perpendicular to the plane of the abdominal wall (usually 10 to 20 degrees from the true vertical). The bladder is an abdominal organ in infants, and placing the needle too close to the pubic bone or angling toward the feet might cause the needle to miss the bladder. Localizing the bladder with bedside ultrasound facilitates this procedure.

B. Adult

In adults, the peritoneum is pushed cephalad by the filled bladder during suprapubic aspiration. Direct the needle slightly caudad.

Figure 55.27 Suprapubic aspiration.

8. Remove the guidewire and fascial dilator, leaving only the sheath in place.
9. Pass a Foley balloon catheter through the sheath, and inflate the catheter.
10. Withdraw the peel-away sheath, leaving only the suprapubic catheter in place.

Description

Background

In situations where emergency bladder access is necessary, the Seldinger (guidewire) technique allows for suprapubic placement of a Foley balloon catheter for definitive bladder drainage.

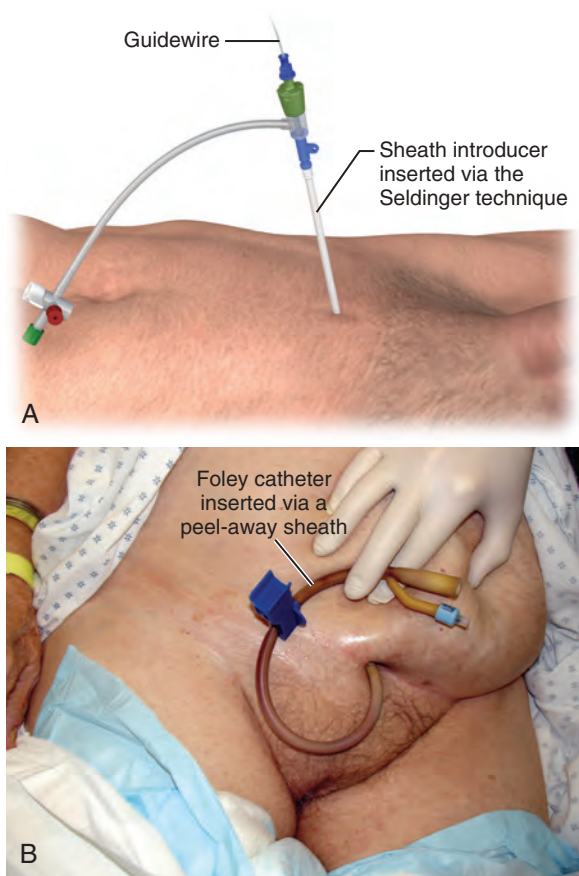

Figure 55.28 Suprapubic cystostomy. **A**, Any catheter that can be used as a central venous catheter can be inserted suprapubically via the Seldinger technique. **B**, The more traditional and more permanent suprapubic cystostomy with a Foley catheter inserted through a Cook peel-away sheath introducer (Cook Medical, Bloomington, IN).

Anatomy and Physiology

See following figure.

Pathophysiology

In emergency situations, the majority of patients requiring suprapubic cystostomy are trauma patients with urethral disruption, or men with severe urethral stricture or complex prostatic disease.

Indications

If time allows, it is prudent to discuss the case with a urologist to explore alternative methods of bladder access and urine drainage prior to initiation of a suprapubic cystostomy. Even in the case of major trauma, many affected patients will require laparotomy for associated injuries, so the suprapubic catheter can be placed intraoperatively.

Contraindications

Because placement of a suprapubic tube involves some risk, proper patient selection is important. Do not perform the procedure in a patient whose bladder is not readily definable. Although no absolute reported minimum bladder volume has ever been established, there must be enough urine in the bladder to allow the needle to fully penetrate the bladder dome without immediately exiting through the base. There must also be enough urine in the bladder to displace the bowel away from

the anterosuperior surface of the bladder and the entrance of the needle. Ultrasound can be helpful in defining bladder anatomy.

Individuals who have a history of previous lower abdominal surgery, intraperitoneal surgery, or irradiation may have developed adhesions or adherence of the bowel to the anterior bladder wall. They are potentially at greater risk for bowel injury during percutaneous suprapubic cystostomy tube placement than those without previous abdominal surgery. Blind suprapubic cystostomy tube placement should be avoided in these patients. The absence of any of these risk factors does not totally exclude the risks of bowel or intraperitoneal injury, but it reduces them significantly.

Patients with bleeding diatheses are at greater risk for postinsertion bleeding, either into the bladder, into the retroperic space, or at the site of skin entry.

Procedure

The following comments concern the placement of the Cook peel-away sheath, as described by Chiou and colleagues.⁹⁰ With modifications, the same principles apply for any type of suprapubic catheter placement.

If necessary, shave the lower abdomen and apply antiseptic topically. Fill a 10-mL syringe with 1% lidocaine, and attach it to a 22-gauge, 7.75-cm or similar spinal needle. Raise a skin wheal in the proposed site (~2–3 cm above the pubic symphysis), and infiltrate the subcutaneous tissue and rectus abdominis muscle fascia at a 10- to 20-degree angle toward the pelvis.

Locate the bladder by advancing the needle in the prescribed direction while aspirating the syringe. Urine is easily aspirated when the bladder is entered (Fig. 55.29, step 1).

Once the bladder has been located, remove the syringe from the needle and advance a guidewire through the needle into the bladder (see Fig. 55.29, step 2). Withdraw the needle, leaving only the guidewire traversing the anterior abdominal wall and positioned inside the bladder. Use a No. 11 or similar scalpel blade to make a stab incision directly posterior to the wire through the skin, subcutaneous tissue, and superficial anterior abdominal wall fascia. Then pass the peel-away sheath and indwelling fascial dilator together over the wire into the bladder (see Fig. 55.29, step 3). Remove the guidewire and fascial dilator, leaving only the peel-away sheath inside the bladder (see Fig. 55.29, step 4). Then pass a Foley balloon catheter through the indwelling intravesical sheath into the bladder (see Fig. 55.29, step 5). Aspirate urine to confirm proper placement. Inflate the Foley balloon with a minimum of 10 mL of air, water, or saline (see Fig. 55.29, step 6). A 5-mL balloon will accommodate 10 mL easily and make accidental catheter distraction less likely. Withdraw the peel-away sheath from the bladder and anterior abdominal wall and literally peel it away from the catheter, leaving only the indwelling suprapubic Foley catheter (see Fig. 55.29, step 7). Withdraw the catheter slowly until the inflated balloon approximates the cystostomy site (see Fig. 55.29, step 8).

Aftercare

Connect the catheter to a drainage bag, and then dress the wound with 4 × 4 gauze pads to complete the procedure. The major difficulty with cystostomy tubes of all designs is securing them to the patient's skin. Those with retention balloons, such as the standard Foley urethral catheter, are the most secure and need only tape to attach them to the anterior abdominal wall.

Suprapubic Cystostomy (Peel-Away Sheath Technique)

1

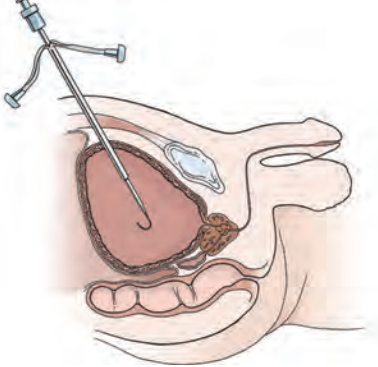

Enter the bladder with a syringe and needle. Confirm location by aspirating urine.

2

Remove the syringe and pass the guidewire through the needle into the bladder.

3

Remove the needle and then pass the dilator and peel-away sheath over the wire into the bladder. A small stab wound in the anterior abdominal fascia may be required to accommodate the dilator and sheath.

4

Remove the dilator and wire and leave only the sheath inside the bladder.

5

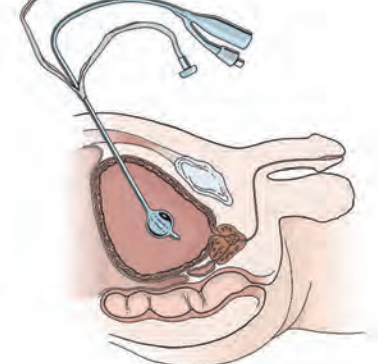

Pass the preselected Foley balloon catheter through the sheath into the bladder. Aspirate urine to confirm location.

6

Inflate the balloon with a minimum of 10 mL of air, saline, or water. A 5-mL balloon will accommodate 10 mL easily and make accidental catheter distraction less likely.

7

Remove the sheath from the bladder, anterior abdominal wall, and cutaneous entry site, and then literally peel it away from the indwelling catheter.

8

Withdraw the catheter until a snug fit is ensured at the cystostomy site.

Figure 55.29 Suprapubic cystostomy using a peel-away sheath. If this equipment is not available, an analogous procedure using any catheter suitable for central venous catheterization may be performed.

BOX 55.5 Complications of Suprapubic Cystostomy

Bowel perforation
 Through-and-through bladder penetration with associated rectal, vaginal, or uterine injury
 Intraperitoneal extravasation (without a previous history of surgery)
 Extraperitoneal extravasation
 Ureteral catheterization
 Obstruction of the tubing (blood, mucus, or kinking)
 Tubing comes out
 Infection
 Hematuria

Complications

A wide variety of complications have been reported, which serve as reminders that suprapubic cystostomy is not innocuous. Occasionally, the suprapubic tube or catheter cannot be positioned or maintained successfully without problems (Box 55.5).

The most serious complications involve perforation of the peritoneum or the intraperitoneal contents. Although finding the bladder using a small-gauge “scout” needle may help reduce bowel injury, even in the most apparently successful of bladder punctures, a complication may still result.

Occasionally, the clinician proceeds with suprapubic cystostomy when the bladder is not palpable and has not been located with a syringe and needle. Injury of adjacent organs is much more frequent in these circumstances. Allowing the bladder to refill over time can be an important consideration, especially if initial attempts to locate the bladder were unsuccessful. Ultrasound guidance may also be helpful for determining bladder size and location.

Conclusions

Suprapubic cystostomy can be readily performed when emergency bladder access is needed. However, the procedure may be associated with significant risks to the patient. As such, when time affords, discussion with a urologist is prudent to explore alternative methods of bladder access and urine drainage.

LOWER GENITOURINARY TRACT IMAGING**Introduction**

Although the signs of GU trauma in general can be quite subtle, lower urinary tract injury can often be quickly identified and thoroughly evaluated radiographically in the ED. Radiologic imaging of the upper urinary tract is generally a less urgent matter and can usually be done in the radiology suite or, when important for emergency operative decision-making, as a single shot intravenous pyelogram (IVP) in the operating room.

The timing of any radiologic evaluation can be challenging in the emergency setting, especially when faced with a critically ill, multiply injured patient. The trauma team of clinicians involved in each resuscitation must determine the priority and extent of such an evaluation on a case-by-case basis.

In patients with urologic trauma, the lower urinary tract should be studied before the upper urinary tract (e.g., study

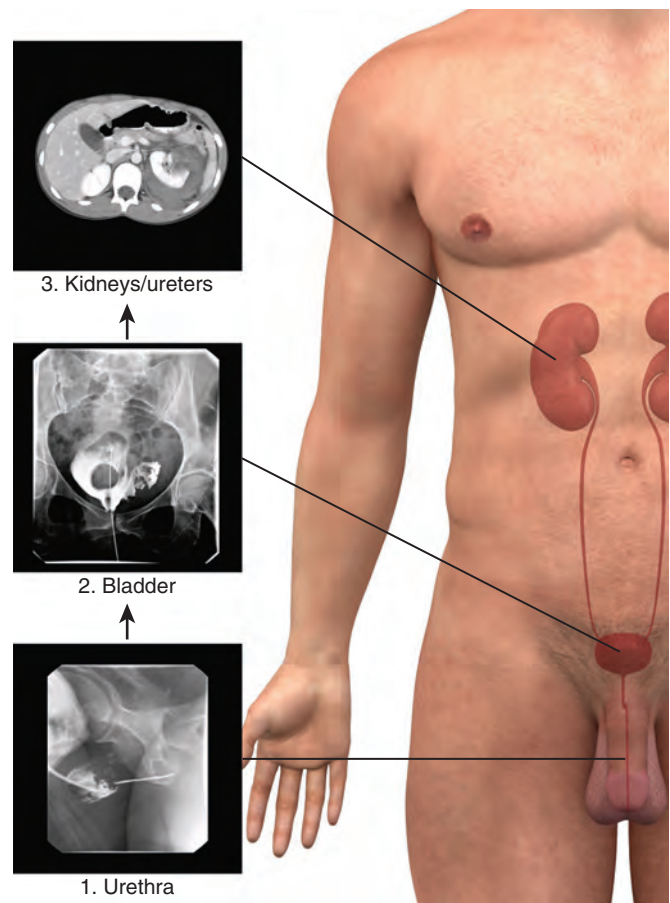

Figure 55.30 Diagnostic approach to genitourinary (GU) tract trauma. The GU tract is studied in a retrograde fashion, proceeding from the urethra (retrograde urethrography) to the bladder (conventional or computed tomographic [CT] cystography) to the kidneys and ureters (CT urography with delayed/excretory images). These studies must be carried out in the proper sequence and in a retrograde fashion to avoid missing potential injuries.

the urethra before the bladder, study the bladder before the kidneys). As such, specific diagnostic studies should be conducted in a retrograde fashion (Fig. 55.30).

RUG and retrograde cystography are the diagnostic procedures of choice to evaluate potential injury to the lower urinary tract. These studies must be carried out in the proper sequence and in a retrograde fashion to avoid missing potential injuries. Retrograde refers to the technique of instilling contrast retrograde through the urethra or by gravity filling of the bladder. It must be distinguished from antegrade filling, in which intravenous contrast for IVP or abdominal computed tomography (CT) is excreted from the kidneys and allowed to fill the bladder passively over time.

Procedure Overview

Indications: RUG is indicated whenever uncertainty exists about the integrity of the urethra; retrograde cystography is indicated any time a bladder injury is suspected.

Contraindications: uncertainty about urethral integrity is a contraindication to blind urethral catheterization; ensuring urethral integrity with a RUG prior to Foley catheter placement is required for retrograde cystography; prior

history of reaction to radiographic contrast material is a precaution.

Complications: tissue irritation from contrast extravasation; progression of urethral injury from overly forceful injection of contrast material.

Equipment: equipment and personnel for plain radiographs (or fluoroscopy), small Foley catheter (or Toomey syringe), contrast material for injection.

Key Procedure Sequence

Retrograde Urethrogram

1. Assemble the items and personnel needed for plain imaging (or fluoroscopy).
2. In case of pelvic fracture, keep the patient supine.
3. In other cases, orient the hips in a slightly oblique position in relation to the stretcher.
4. Gently extend and stretch the penis along the medial thigh to maximize urethral unfolding.
5. Take a plain film (kidneys, ureters, and bladder [KUB]) or fluoroscopy for a reference image prior to injecting the contrast.
6. Retract and secure foreskin/glans with a folded 4 × 4 gauze pad.
7. Hold the penis between the long and the ring fingers of the nondominant hand.
8. Insert a non-Luer-Lok syringe or a small Foley catheter snugly into the meatus.
9. Before injecting contrast, stretch the penis perpendicularly across the patient's thigh.
10. Gently inject 10 to 15 mL of contrast; avoid an overly forceful injection.
11. Immediately following the contrast injection, obtain a radiograph (urethrogram).

Retrograde Cystogram

1. Assemble items and personnel needed for plain imaging (or fluoroscopy).
2. In the case of a pelvic fracture, keep the patient supine.
3. In other cases, orient the hips in a slightly oblique position in relation to the stretcher.
4. Perform a RUG to ensure urethral integrity prior to placement of the catheter needed for the cystogram.
5. Remove the central plunger from a 60-mL catheter-tip syringe and attach the tip to a Foley catheter.
6. Hold the syringe above the level of the bladder and pour contrast material into the syringe.
7. Allow the bladder to fill by gravity instillation, and fill to capacity (~400 mL in an adult).
8. Clamp the catheter, obtain both anteroposterior (AP) and oblique images (or AP and lateral if oblique not feasible).
9. Obtain an AP postevacuation film in all cases after bladder drainage.
10. If bladder injury is detected, keep the catheter in place and consult urology.

Description

Background

In the resuscitation of any trauma patient, placement of a Foley catheter is a standard method of monitoring urinary output. Blood at the urethral meatus, however, may indicate

a partial or complete urethral disruption and dictates the need for a RUG to delineate urethral integrity. This study can be done by the resuscitating clinician in the ED or on the operating room table by the trauma surgeon or urologist if the patient requires immediate surgical intervention for life-threatening injuries. RUG is a quick, technically easy study to perform and should be part of every emergency clinician's armamentarium. Similarly, retrograde cystography allows for the evaluation of bladder integrity.

Anatomy and Physiology

The anatomy of the male urethra is demonstrated in Fig. 55.17. The male urethra varies from 17.5 to 20 cm in length for adults and consists of anterior and posterior portions, each of which is subdivided into two parts. The pendulous and bulbous urethral segments are anterior, and the membranous and prostatic segments are posterior. The female urethra is approximately 4 cm long and extends from the bladder neck at the urethrovesical junction to the vaginal vestibule, where it forms the external meatus between the labia minora (see Figs. 55.15 and 55.16).

Pathophysiology

The male posterior urethra, which includes the membranous and prostatic urethra, is injured more frequently than the anterior urethra. The urogenital diaphragm encloses and fixes the membranous urethra; the prostate and prostatic urethra are firmly attached to the posterior surface of the symphysis pubis by the puboprostatic ligaments. Blunt trauma and pelvic fractures, especially in the presence of a full bladder, may result in shearing forces that partially or completely avulse portions of the firmly attached posterior urethra. Usually, the bladder and prostate gland are sheared from the membranous urethra, resulting in a complete urethral disruption (Fig. 55.31). The female urethra, in contrast, is short and relatively mobile and generally escapes injury in blunt trauma. Occasionally, a significant pelvic fracture will result in a laceration or avulsion of the female urethra at the bladder neck. Direct injuries to the female urethra may also occur secondary to penetrating trauma to the vagina or perineum. These injuries often are disclosed by blood at the introitus or an abnormal vaginal examination in the female pelvic fracture patient.⁹¹

Contusions or lacerations of the male anterior urethra occur when the bulbous urethra is compressed against the inferior surface of the symphysis pubis. This happens most commonly as a result of straddle injuries in males but may result from any blunt perineal trauma. Penetrating injuries or urethral instrumentation may also cause injuries to the penile urethra. Anterior urethral injuries may result in extravasation of blood or urine into the penis, scrotum, or perineum or along the anterior abdominal wall, depending on whether Buck's fascia has been violated (Fig. 55.32).⁹² This is in contrast to posterior urethral injuries, in which blood and urine extravasate into the pelvis.

Indications

RUG is indicated whenever uncertainty exists about the integrity of the urethra. The RUG is an anatomic rather than a physiologic examination, but is critical in the identification of a possible urethral injury prior to urinary catheter insertion to preclude a potentially devastating complication.⁹³

The traditional physical indications to perform a RUG in the trauma setting include blood at the urethral meatus, a

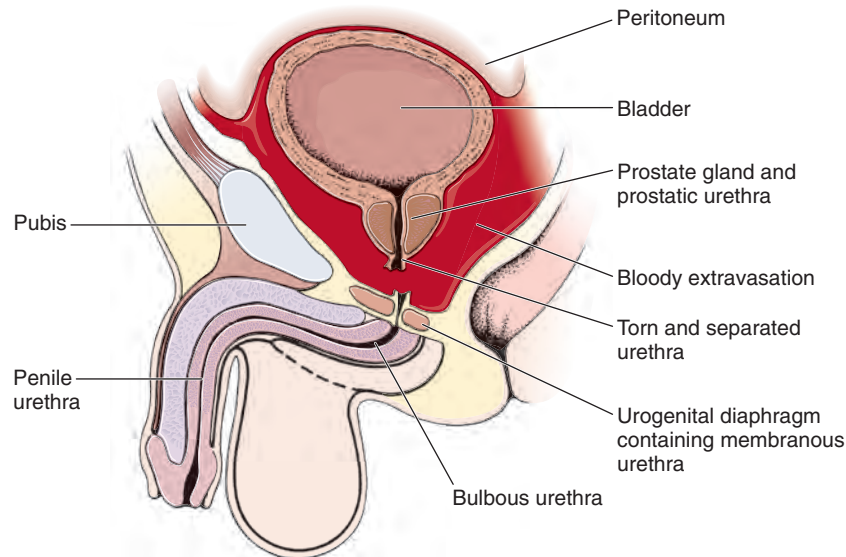

Figure 55.31 Posterior urethral injury. A common posterior urethral injury is disruption of the membranous urethra. In this case, a distended bladder and attached prostate gland are sheared from the fixed membranous urethra. Note the development of a perivesical hematoma and the presence of a high-riding prostate gland. This scenario will prohibit the passage of a catheter.

TABLE 55.6 Common Agents, Dosages, and Administration Information for Contrast-Enhanced Retrograde Urologic Imaging

AGENTS ⁹⁸	USE	PROCEDURE
Diatrizoate (Cystografin, Bracco Diagnostics Inc., Monroe Township, NJ) or Dilute Iohexol (Omnipaque, GE Healthcare Ireland, Cork, Ireland)	Use a stock concentration of solution ^a or Use a one-half stock concentration of solution or Dilute the stock solution with saline in a ratio of 1 part contrast to 10 parts saline (resulting in a < 10% solution)	Urethrography: 10–15 mL of dilute solution injected slowly through the urethral meatus for adults (children: 0.2 mL/kg) Cystography: after a plain film and with the Foley catheter in place, fill the bladder of adults with 400 mL of dilute contrast material introduced under gravity (children: 5 mL/kg)

^aA higher concentration may allow improved image quality; however, extravasation of contrast material into periurethral or perivesical tissues may cause a considerable inflammatory reaction at higher concentrations. Iohexol should be diluted per package insert instructions.

Data from American College of Radiology (ACR) Committee on Drugs and Contrast Media: *ACR manual on contrast media, version 10.1, 2015*, Reston, VA, 2015, American College of Radiology.

nonpalpable or high-riding prostate, or evidence of urethral trauma. However, the value of these findings to the emergency clinician has been called into question, given their low sensitivity.^{94,95}

Perform a retrograde cystogram any time a bladder injury is suspected. It assumes that the urethra is normal before passing the Foley catheter required for retrograde cystography.

Contraindications

Uncertainty about urethral integrity is a contraindication to blind urethral catheterization. As such, urethral integrity must be ensured prior to Foley catheter placement, which is essential for retrograde cystography. History of a prior reaction to radiographic contrast material is a relative contraindication to contrast use, depending on the route of administration selected. Intravenous administration for antegrade imaging carries a much greater risk of serious adverse events as compared with the negligible risks associated with retrograde injection or

instillation of iodinated contrast materials necessary for lower GU tract imaging.

Procedure

Several different iodinated contrast agents are suitable for retrograde studies (urethrography, cystography). Common agents, dosages, and methods of administration are listed in [Table 55.6](#).

RUG and retrograde cystography should ideally be performed under fluoroscopy to provide real-time imaging, but plain films are an acceptable and frequently utilized alternative.

Retrograde Urethrogram

A patient with an associated pelvic fracture should remain supine throughout the entire radiographic examination. In cases of suspected urethral injury not associated with pelvic fracture, it is acceptable to obtain oblique films during the

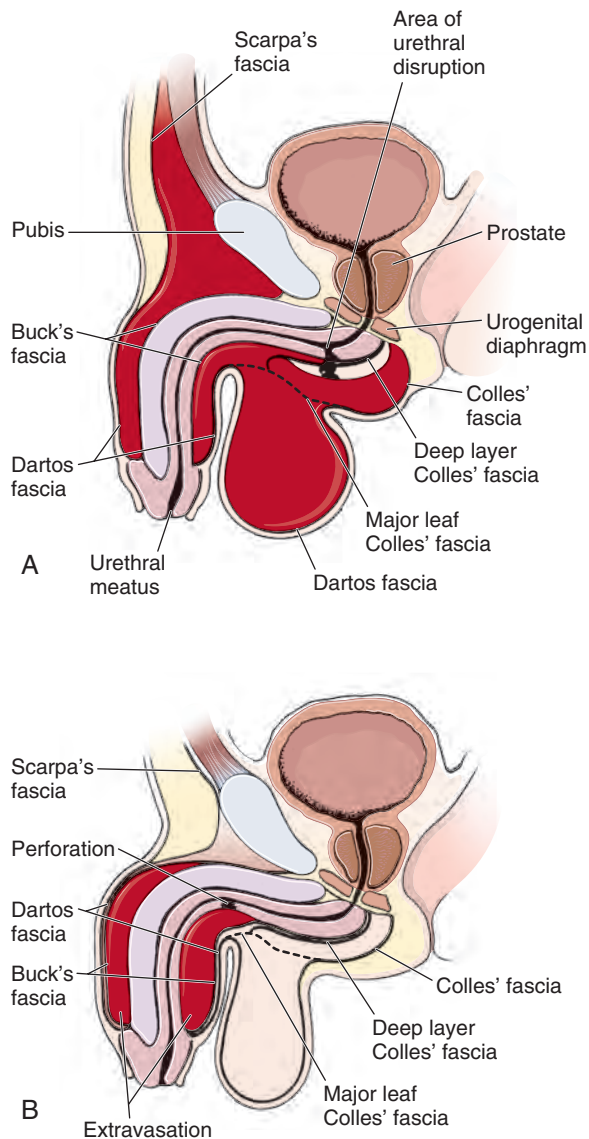

Figure 55.32 Anterior urethral injury. **A**, Disruption of the anterior urethra (bulbous urethra) occurs with straddle-type injuries in a male. Extravasation of urine and blood may occur in the perineum or scrotum or along the anterior abdominal wall. Note that in this diagram Buck's fascia has been penetrated. **B**, Anterior urethral injury in which Buck's fascia remains intact. In this situation, extravasation is confirmed and results in a swollen and ecchymotic penis. Such an injury usually results from instrumentation of the anterior urethra.

study that may complement the examination findings (e.g. supine 45-degree oblique position).

First, take a plain film (KUB) or fluoroscopic image for reference before injecting any contrast material.⁹⁶ Retract and secure the penile foreskin with a folded 4 × 4 gauze sponge. Second, hold the penis between the long and the ring fingers of the nondominant hand to allow a snug fit of the contrast-filled syringe or catheter inside the urethral meatus. Stretch the penis laterally over the proximal thigh with moderate traction to prevent urethral folding (i.e., the double image of the proximal penile and bulbous urethra superimposed on one another) to ensure a high-quality RUG (Fig. 55.33, step 3).

After sterile penile preparation, get ready to inject the dye. A small Foley catheter may be used (see Fig. 55.33, step 1).

Seat the balloon portion of the catheter in the fossa navicularis of the penile urethra, and delicately inflate it with 1.0 to 1.5 mL of saline solution to ensure a snug fit.⁹⁷ Lubrication is not recommended because it may prevent the balloon from remaining in place. Alternatively, apply steady manual pressure of the balloon against the external urethral meatus (distal to the fossa navicularis). Another option is to gently advance a catheter-tipped Toomey irrigating syringe or a regular 60-mL syringe with an attached Christmas-tree adapter or a non-Luer-Lok syringe inside the urethral meatus until a snug fit is ensured (see Fig. 55.33, step 2). Gently squeeze the meatus over the injecting device to prevent leaking.

Inject contrast through the catheter or syringe. If not done carefully, this technique often results in the spillage and deposition of contrast outside the urethra and onto the patient and the examination table, yielding a spurious result. As such, slowly inject anywhere from 10 to 60 mL of contrast material (typically less than 10–20 mL is all that is needed) under constant pressure into the urethra. Not uncommonly, a spasm of the external urethral sphincter will be encountered, preventing filling of the posterior urethra. Use slow, gentle pressure to overcome this resistance.⁹⁸ Overly forceful injection of contrast material may cause intravasation of contrast material into the venous plexus of the urethra, simulating an injury (see Fig. 55.33, step 4). Finally, during the injection of the last 10 mL of contrast, take a film (the urethrogram) (see Fig. 55.33, step 3). Alternatively, view the urethrogram in real time using fluoroscopy.

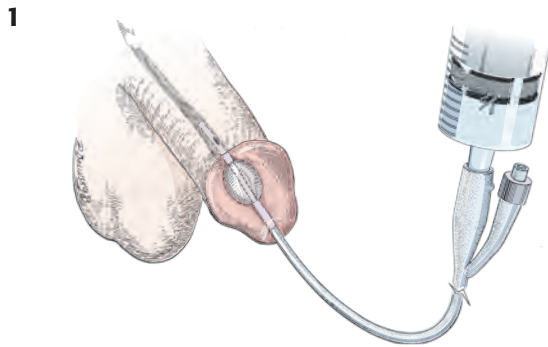

The extravasation of contrast material from a urethral disruption usually appears as a flamelike density outside the urethral contour (see Fig. 55.33, steps 5–7). If any contrast material is seen within the bladder in conjunction with urethral extravasation, a partial rather than a complete urethral disruption is more likely. In a complete urethral disruption, urethral extravasation will be present without evidence of contrast within the bladder. The examiner needs to be certain that the lack of bladder contrast is not secondary to voluntary contraction of the external sphincter. Occasionally, as mentioned previously, intravasated contrast material is seen in the periurethral penile venous plexus (see Fig. 55.33, step 4). It is of no clinical significance and should not be mistaken for urethral extravasation. As expected, penile venous intravasation (venous opacification) will clear spontaneously on any postvoid films, unlike urethral extravasation, which remains in place.

If a Foley catheter has been successfully placed into the bladder and a partial urethral injury is suspected later, such an injury can be readily demonstrated without removing the catheter. Place the lubricated end of a pediatric feeding tube into the proximal penile urethra alongside the existing Foley catheter (Fig. 55.34). Obtain a seal by compressing the glans penis with the nondominant thumb and index finger and gently inject contrast material with the dominant hand. In this way, extravasation can be demonstrated. It should be noted, however, that successful placement of the Foley catheter obviates the need for further treatment of a partial urethral tear in the emergency setting because an indwelling catheter alone is appropriate initial management for this type of injury. The finding of an associated urethral injury must be conveyed to a urologist because it will dictate the duration of definitive Foley catheter drainage.

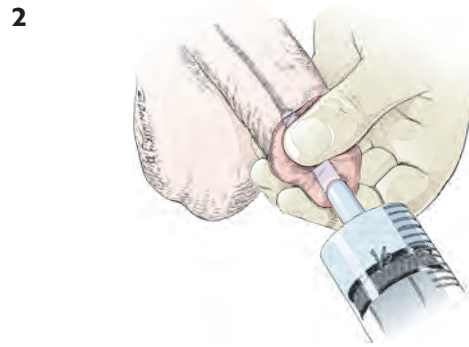

Retrograde Cystogram

As noted, demonstrate that the urethra is normal before passing the Foley catheter required for retrograde cystography.

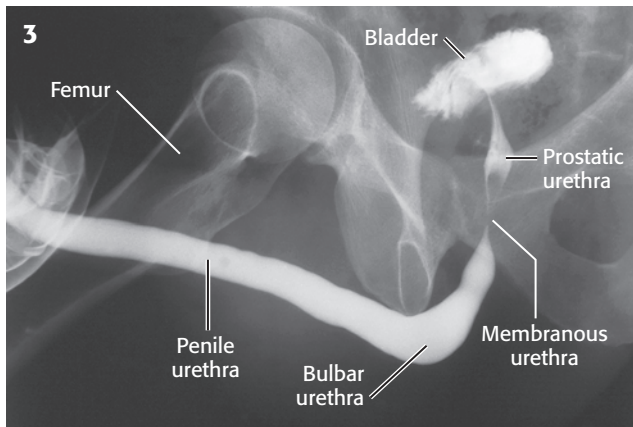

Retrograde Urethrography

1 Insert the balloon portion of a Foley catheter (8 Fr) into the urethra, and slowly inflate the balloon with 2 mL of air or water to create a snug fit. Then slowly inject 10 to 60 mL of a 10% solution of contrast material through the catheter lumen. Usually only 10 to 20 mL is required.

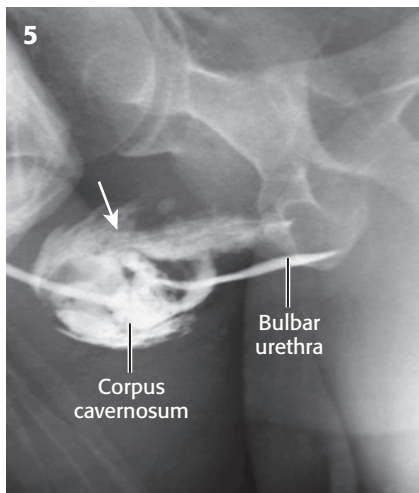

2 Alternatively, use a plain-tipped (non-Luer-Lok) syringe or a catheter-tipped (Toomey) syringe in the urethra. Squeeze the glans around the syringe to prevent spillage of the contrast material. Inject slowly.

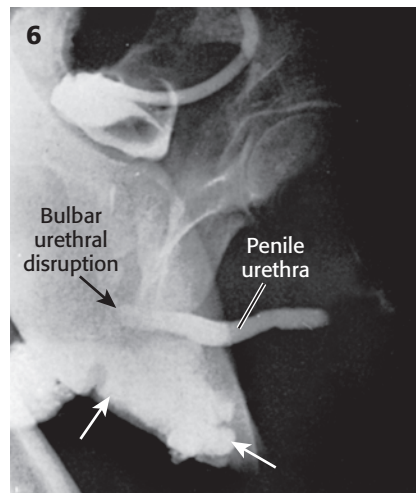

3 **Normal retrograde urethrogram.** Note that penis is pulled taut over the proximal part of the thigh to prevent urethral folding. After injection of contrast material, the entire urethra can be visualized and inspected for injury.

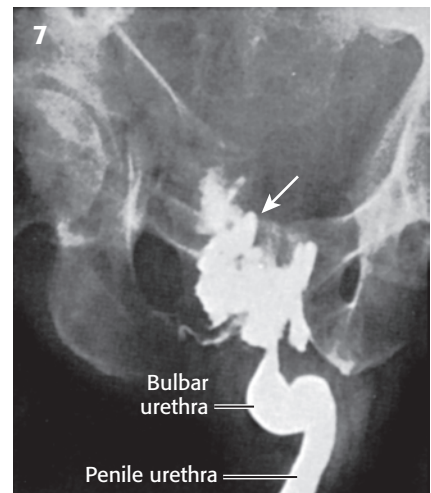

4 Inject the contrast material slowly. Injecting too fast causes venous intravasation (arrows). This may mimic urethral extravasation but it clears immediately, as opposed to actual extravasation, which remains indefinitely. If unsure, take another film in 10 minutes. The presence of intravasation is benign but can confuse the clinician.

5 **Penile urethral disruption.** Extravasation of contrast material (arrow) is seen in the corpus cavernosum.

6 **Bulbar urethral disruption.** Extravasation of contrast material (white arrows) is seen in the scrotum.

7 **Supramembranous urethral disruption.** Extravasation of contrast material (arrow) is noted superiorly.

Figure 55.33 Retrograde urethrography. (Step 4, From Richter MW, Lytton B, Myerson D, et al: Radiology of genitourinary trauma, *Radiol Clin North Am* 11:626, 1973; step 7, from Morehouse DD, MacKinnon KJ; Posterior urethral injury: etiology, diagnosis, initial management, *Urol Clin North Am* 4:74, 1977.)

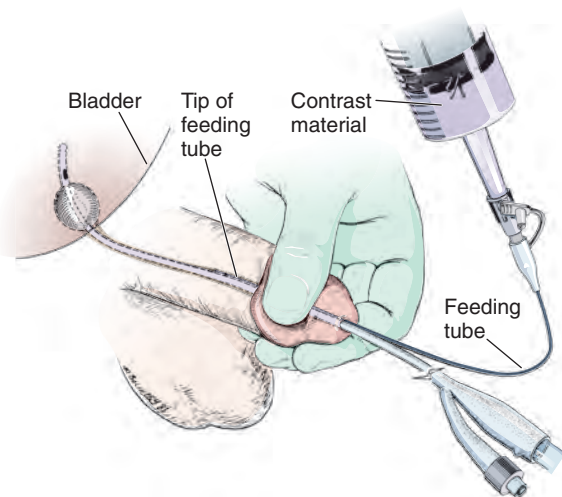

Figure 55.34 Evaluation of a urethral injury with a Foley catheter in place. A lubricated pediatric feeding tube has been advanced into the urethra beside the indwelling Foley catheter.

Obtain a preliminary KUB or fluoroscopic image to serve as the reference film for the entire examination. Next, fill the bladder under direct operator supervision by gravity instillation of contrast material. After removing the central plunger from a 60-mL catheter-tip syringe, attach the catheter-tipped end of the syringe to the Foley catheter and hold it above the level of the patient's bladder. Pour the contrast material into the syringe and allow it to fill the bladder by gravity instillation to one of three end points: (1) 100 mL with evidence of gross extravasation on fluoroscopy or on plain film (if the examiner elects to check at this point); (2) 400 mL in an adult or any child aged 11 years or older. In children younger than 11 years, bladder capacity, and therefore appropriate contrast volumes, are estimated based on this formula $([age\ in\ years + 2] \times [30])^{99}$; or (3) the point of initiating a bladder contraction (see later), then add an additional 50 mL by hand injection under gentle but steady pressure.

Obtain AP and complementary oblique projections if feasible (Fig. 55.35A1). In the presence of a pelvic fracture, obtain all films with the patient in the supine position for the same reasons that were elucidated for RUG. A lateral film may be informative when oblique films are not possible (see Fig. 55.35A2). Obtain an AP postevacuation film in all cases after bladder drainage to disclose posterior perforation, especially in cases of penetrating trauma (see Fig. 55.35A3). A dilute solution of contrast material (see Table 55.6) may be used, rather than full-strength contrast. Some authors recommend a dilute solution of contrast material ($\leq 10\%$) because extravasation into the periurethral or perivesical tissues may cause considerable inflammatory reaction at higher concentrations. The dilute solutions do not appear to compromise the quality of the study, but this must remain a consideration. Retrograde cystography done by any technique other than hand-poured gravity instillation is subject to inadequate bladder filling or connector tubing-catheter disconnection. Both conditions will result in spurious examination results, which may adversely affect important patient management decisions.

It must be stressed that in the absence of initial gross extravasation, the bladder must be filled to 400 mL in an adult, or to an appropriate capacity in a child, and the catheter clamped with a Kelly clamp. Volumes less than 400 mL have been

associated with false-negative findings, especially in penetrating bladder injuries.¹⁰⁰ At times, the patient may have difficulty cooperating with bladder filling because of a head injury or associated pain; and in the case of severe injury, the patient may have involuntary bladder contractions, causing contrast material to back up into the syringe. If this occurs, refill the bladder to the point of initiating a bladder contraction, clamp the Foley catheter, remove the initial syringe and replace it with a 60-mL contrast-filled syringe, unclamp the catheter, hand-inject the additional 50 mL under pressure, and reclamp the catheter. The goal is to overdistend the bladder. Once the filled-bladder films have been obtained and reviewed, unclamp the Foley catheter and allow the contrast material to drain into a bedside drainage bag. Then obtain the AP postevacuation film to visualize any posterior extravasation that may have been hidden by the distended bladder during the AP filled-bladder film (see Fig. 55.35B2 and B3). Once again, take care to ensure that contrast material is not spilled onto the patient or the examination table during the procedure.

Extravasation from an injured bladder may be intraperitoneal, extraperitoneal, or both. Extraperitoneal extravasation is usually seen as flame-like areas of contrast material confined to the pelvis and projecting laterally to the bladder (see Fig. 55.35B1 and B4). If the contrast material extravasates intraperitoneally, it tends to fill the paracolic gutters and outline intraperitoneal structures, particularly the bowel, spleen, or liver (see Fig. 55.35B5). It is important to distinguish extraperitoneal from intraperitoneal injury because the treatment options differ significantly: surgical repair is required for all intraperitoneal injuries and for those extraperitoneal injuries that extend into or primarily involve the bladder neck, especially in women. Most other extraperitoneal injuries can be managed confidently by Foley catheter drainage alone.

Retrograde cystography may be done in conjunction with contrast-enhanced abdominal CT scanning (Fig. 55.36). The bladder must be filled just as if a conventional retrograde cystogram were being obtained. Clamp the catheter and seek evidence for contrast ascites on the CT scan. When this is encountered, bladder injury with extravasation must be further evaluated with selective images of the pelvis.

Aftercare

Foley catheter placement following demonstration of urethral integrity with a RUG. Consult urology to aid in decision making in any case of urethral or bladder injury.

Complications

Contrast extravasation into periurethral or perivesical tissues in the case of urethral or bladder injury, respectively, may cause considerable inflammatory reaction, particularly contrast materials of higher concentrations.

Conclusions

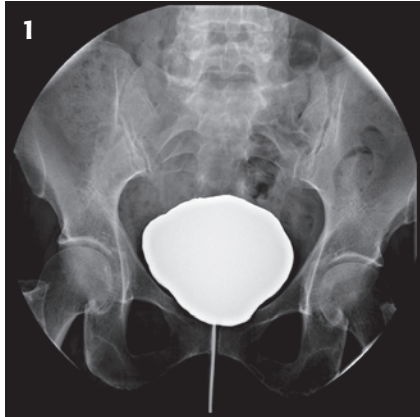

RUG and retrograde cystography are the diagnostic procedures of choice to evaluate potential injury to the lower urinary tract. These studies must be carried out in the proper sequence and in a retrograde fashion to avoid missing potential injuries.

UPPER GENITOURINARY TRACT IMAGING

Once the lower GU tract has been exonerated with RUG and retrograde cystography, the upper tract (kidneys and ureters)

Retrograde Cystography

A. Normal Examination

AP view. Fill the bladder with at least 400 mL (see text for details). The normal bladder has a smooth outer contour and no extravasation of contrast material is seen.

Lateral view. Obtain a lateral or oblique view to assess for posterior extravasation because the opacified bladder would prevent visualization of this injury on the AP view.

Postvoid film. Always perform a postvoid film to assess for subtle posterior perforation, especially in the case of penetrating trauma.

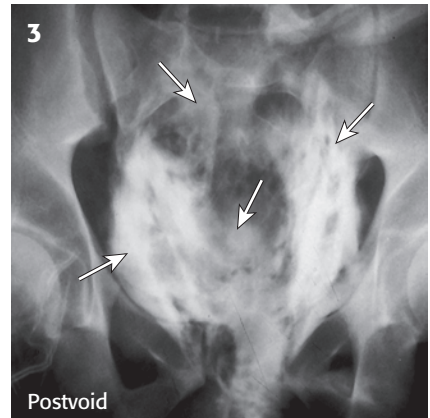

B. Abnormal Examinations

Extraperitoneal bladder perforation. Contrast material is seen adjacent to the bladder neck. The bladder itself is displaced rightward by an adjacent hematoma.

Posterior injury. On this AP film, the bladder appears normal, and no extravasation of contrast material is noted. However, postvoid films are required to rule out posterior injury.

The postvoid film demonstrates substantial posterior extravasation of contrast material. This injury would have been missed if only the AP study were performed.

Extraperitoneal bladder rupture. Extravasated contrast material is seen surrounding the bladder (*arrows*) but no loops of bowel are outlined. This injury can typically be treated conservatively with a Foley catheter.

Intraperitoneal bladder rupture. Note the contrast material outlining the paravesical space, tracking up the right paracolic gutter and outlying loops of bowel (*arrows*). This typically requires operative repair.

Pelvic hematoma. Note the "open-book" pelvic fracture (*arrows*). No extravasation of contrast material is seen, however, the pear-shaped bladder indicates the presence of a pelvic hematoma.

Figure 55.35 Retrograde cystography. AP, Anteroposterior.

Retrograde Computed Tomographic Cystography

Extraperitoneal bladder perforation. Retrograde cystography may be performed in conjunction with abdominal CT scanning. Fill the bladder in the same fashion as for conventional cystography (obtaining delayed images with IV contrast material collected in the bladder is not sufficient). Above, extravasation of contrast material is noted adjacent to the left side of the bladder (*arrow*).

Intraperitoneal bladder perforation. This patient complained of abdominal pain after routine cystoscopy. Standard IV and oral contrast-enhanced CT imaging of the pelvis revealed nonspecific inflammatory changes in the right pelvis. CT cystography was required to diagnose the bladder perforation, as evidenced by extravasation of contrast material into the peritoneal cavity (*arrow*).

Figure 55.36 Retrograde computed tomographic cystography. *CT*, Computed tomography; *IV*, intravenous.

BOX 55.6 American Association for the Surgery of Trauma Classification System for Renal Injuries

GRADE 1 INJURIES

Hematuria with normal imaging
Contusions
Subcapsular, nonexpanding hematoma without parenchymal laceration

GRADE 2 INJURIES

Nonexpanding perinephric hematomas confined to the retroperitoneum
Renal cortical lacerations less than 1 cm in depth without urinary extravasation

GRADE 3 INJURIES

Renal cortical lacerations greater than 1 cm in depth without urinary extravasation

GRADE 4 INJURIES

Parenchymal laceration extending through the renal cortex/medulla and into the collecting system
Main renal artery or vein injury with contained hemorrhage
Segmental infarction without associated laceration

GRADE 5 INJURIES

Shattered or devascularized kidney
Complete avulsion or thrombosis of the main renal artery or vein
Avulsion of the ureteropelvic junction

From Moore EE, Shackford SR, Pachtter HL, et al: Organ injury scaling: spleen, liver, and kidney, J Trauma 29:1664–1666, 1989.

should be evaluated. For adult blunt trauma patients with gross hematuria or hypotension (systolic pressure lower than 90 mm Hg), upper tract imaging is indicated.¹⁰¹ Data show that 12.5% of such patients will have a major renal injury as compared with only 0.2% of adults with microscopic hematuria and normal blood pressure.¹⁰² In the presence of a major mechanism of injury or other extenuating circumstances, inclusion criteria for upper tract imaging may be broadened. It should be noted that these criteria are not intended for use in pediatric populations, and opinions regarding diagnostic strategies in children remain controversial.

Contrast-enhanced CT is the gold standard for evaluating patients with suspected renal trauma.¹⁰² Parenchymal injuries, vascular injuries, and urinary extravasation can all be readily identified on CT (Fig. 55.37, plates 1 and 2). Traumatic renal injuries are graded on a 5-point scale (Box 55.6). For patients with a mandate for emergency laparotomy, upper tract imaging can be performed in the operating room with an excretory urogram (see Fig. 55.37, plate 3).

Ureteral injuries can also be identified on contrast-enhanced CT imaging; however, it is essential to obtain delayed images (i.e., approximately 10 minutes after the initial intravenous

Upper Genitourinary Tract Imaging

Grade 3 renal laceration. This contrast-enhanced CT scan reveals a renal laceration >1 cm in depth without urinary extravasation (*arrow*) and hence a grade 3 injury.

Grade 4 renal injury. This laceration extends through the renal parenchyma and into the collecting system. Extravasation of contrast material is seen (*long arrow*), thus making this a grade 4 injury. Note the large perinephric hematoma (*short arrows*).

Urethral transection. This intraoperative excretory urogram reveals extravasation (*arrow*) in the upper part of the right ureter consequent to a stab wound. No contrast material is seen in the ureter below the site of injury, a finding indicative of complete transection.

Normal CT urogram. A coronal projection of a CT urogram in the excretory phase demonstrates opacification of the proximal and middle section of the ureters (*arrows*) without evidence of extravasation of contrast material.

Distal ureter injury. This patient suffered a gunshot wound to his abdomen. After emergency laparotomy and bowel resection, abdominal pain worsened. The initial arterial phase CT demonstrated a large fluid collection in the inferior recesses of the peritoneum (*arrow*).

Delayed images revealed extravasation of contrast material from the distal end of the ureter (*arrow*) into the fluid collection. This part of the ureter was not explored during the initial operation.

Figure 55.37 Upper genitourinary tract imaging. *CT*, Computed tomography. (*Step 3*, from Wein AJ, Kavoussi LR, Novick AC, et al, editors: *Campbell-Walsh Urology*, ed 10, Philadelphia, 2011, Saunders; *step 4*, from Haaga JR, Dogra VS, Forsting M, et al, editors: *CT and MRI of the Whole Body*, ed 5, St. Louis, 2008, Mosby; *steps 5 and 6*, from Jankowski JT, Spirnak JP: Current recommendations for imaging in the management of urologic traumas, *Urol Clin North Am* 33:365–376, 2006.)

contrast bolus) (see Fig. 55.37, plates 4.6). This delay allows the contrast material to become concentrated in the kidneys and excreted through the ureters. Ureteral injury can then be identified by extravasation of contrast material into adjacent tissues.

Emergency Childbirth

Samreen Vora and Valerie A. Dobiesz

BACKGROUND

Of the more than 3.9 million births in the United States in 2013, 98.6% were delivered in a hospital setting. Although a physician was present for 91.7% of these births, the percentage of these births that occur in the emergency department (ED) setting is unknown.¹ Childbirth is a relatively rare occurrence in the ED but ‘complications of pregnancy, childbirth, and puerperium’ is one of the twenty leading primary diagnoses seen in the ED.² Emergency delivery of an infant continues to be one of the most challenging and stress-inducing procedures facing emergency physicians (EPs). The clinician needs to assess the mother and fetus, prepare for delivery, and anticipate potential difficulties or complications during and after the birthing process.

In institutions where on-site and timely obstetric services are available, the primary duty of the EP may be only to determine that labor is active and delivery imminent. However, in the case of unavailable obstetrics, precipitous delivery, or delayed arrival, the EP may be required to solely manage a patient in active labor. This role includes handling both maternal and neonatal resuscitation.

ANATOMY AND PHYSIOLOGY

Labor is the process by which the fetus is expelled from the uterus. It begins with a sequence of regular and effective uterine contractions that result in effacement and dilation of the cervix.³ Identification of true labor versus false labor is best determined in a dedicated obstetric unit, often with external uterine monitoring.

Labor can also be divided into *phases*. The latent phase of labor is the period between its onset and when labor becomes active, which generally requires 80% effacement and cervical dilation of greater than 4 cm.⁴ Active labor is normally divided into three progressive stages. The first stage begins with cervical effacement and dilation and ends when the cervix is completely dilated. In multiparous women, this stage of labor typically lasts approximately 5 to 8 hours, as opposed to 7 to 13 hours in nulliparous women, but with much individual variation.^{3,4} The second stage of labor begins when dilation of the cervix is complete and ends with delivery of the infant. The duration of this stage is also variable, with a median of 50 to 60 minutes in nulliparas and 15 to 20 minutes in multiparas.^{3,4} The third stage of labor begins after delivery of the infant and ends with delivery of the placenta. The fourth stage of labor refers to the 1 hour immediately after delivery, the period in which postpartum hemorrhage (PPH) is most likely to occur.³ It is recommended that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first hour to rapidly detect any ongoing hemorrhage.³

IDENTIFICATION OF LABOR

It is not uncommon for women to have contractions late in pregnancy, although not all are true or effective labor contractions. Brief Braxton-Hicks contractions of the uterus, usually confined to discomfort in the lower abdominal region and groin, are typically irregular in timing and strength. These pains do not cause any change in the cervix or result in descent of the fetus. Although these pains usually stop spontaneously, they can rapidly convert to true labor contractions; if they occur, a period of observation may be necessary.

True labor is characterized by a regular sequence of uterine contractions with progressively increasing intensity and decreasing intervals between contractions. The interval between contractions gradually diminishes from 10 minutes at the onset of labor to as short as 1 minute or less in the second stage of labor. This should be accompanied by effacement and dilation of the cervix, along with descent of the fetal presenting part into the pelvis. The onset of true labor can be difficult to identify given that patients are far more likely to be at home than in a hospital when labor begins.

Show or *bloody show* is a sign of approaching labor. The normal mucous plug sealing the cervix discharges as the cervix dilates. Show consists of a small amount of blood-tinged mucus discharged from the vagina and indicates that labor is already in progress or will probably occur during the next several hours to a few days. The mucous color can be pink or brown tinged as a result of minor bleeding. However, if more than a small amount of blood escapes with the mucous plug, an abnormal cause such as placental abruption or placenta previa should be considered. Digital vaginal examination under these circumstances is generally contraindicated.³

Spontaneous rupture of membranes can occur during the course of active labor, typically evident by a sudden gush or continuous leakage of a variable amount of clear or slightly turbid vaginal fluid. Rupture of membranes before the onset of labor at any stage of gestation is referred to as *premature rupture of membranes* (PROM). Term PROM complicates approximately 8% of pregnancies.^{5,6} In the majority of cases it is followed by the onset of labor and delivery within 5 hours. The most significant maternal risk associated with term PROM is intrauterine infection (chorioamnionitis and endometritis). Fetal risks associated with PROM include umbilical cord compression and ascending infection.⁶ The ideal management of PROM should be deferred to the consulting obstetrician.⁷

Membrane rupture occurring before 37 weeks of gestation is called *preterm premature rupture of membranes* (pPROM). Birth within 1 week generally occurs regardless of management or the clinical findings. The most significant maternal risk related to pPROM is intrauterine infection. The most significant risks to the fetus are complications related to prematurity. Preterm delivery occurs in approximately 12% of all births in the United States and is the leading cause of perinatal morbidity and mortality.⁶

Accurate diagnosis of PROM is helpful in further management. Suspected PROM should be confirmed by an examination that minimizes the risk of introducing infection. Avoid digital cervical examination unless the patient is in active labor or delivery is imminent. A sterile speculum examination can be performed to look for amniotic fluid extruding from the cervical os or pooling in the posterior fornix, as well as to inspect for fetal or umbilical cord prolapse and assess cervical effacement and dilation.^{3,6}

Figure 56.1 Amniotic fluid has an *alkaline* pH, whereas normal vaginal secretions are acidic. Both **A**, Nitrazine or pH paper and **B**, an indicator swab (Amnicator device/Amnicator.com) will turn yellow when placed in a sample in the absence of amniotic fluid and dark blue in the presence of amniotic fluid within a few seconds.

Amniotic fluid may be differentiated from vaginal fluid by testing the pH of the fluid with Nitrazine paper or similar swab devices (Fig. 56.1). The pH of vaginal fluid is generally 4.5 to 6.0, whereas amniotic fluid has a pH of 7.0 to 7.5. The yellow testing paper turns blue-green to deep blue in the presence of amniotic fluid. With vaginal secretions, the Nitrazine paper remains yellow.³ False-positive results may occur with blood, semen, bacterial vaginosis, or alkaline urine. If rupture of membranes is documented in the ED, notify the patient's obstetrician and plan for hospital admission or possible transfer.

The biomarker fetal fibronectin (fFN), a glycoprotein produced by amniocytes and cytotrophoblast found in cervicovaginal secretions, may also be used as a screening tool for preterm labor as an adjunct to maternal/fetal monitoring and pelvic examination.^{8,9} The detection of increased levels of fFN between 22 and 37 weeks gestation can be considered an indicator of preterm birth.¹⁰ fFN has an excellent negative predictive value (99%) in determining the likelihood of delivery within one week. The test is done with a vaginal swab but must be done before any digital exam. The test is not reliable if the patient has had sexual intercourse within 24 hours, associated bleeding, or has used a gel.

EVALUATION OF LABOR

When a woman is initially seen with contractions, the general condition of both the fetus and mother should be assessed quickly. Under the federal Emergency Medical Treatment and Labor Act (EMTALA), hospitals with an ED must conduct an appropriate screening examination to rule out true labor.

Figure 56.2 Assessment of fetal heart rate. **A**, Fetal assessment is often done via bedside ultrasonography in the emergency department. **B**, Traditional methods, such as external Doppler, are also acceptable. The normal baseline fetal heart rate is 110 to 160 beats/min.

In addition, under EMTALA, a woman in labor is considered unstable for interhospital transfer unless done so at the direction of the patient or a physician who certifies that the benefits outweigh the risks of transfer.³ In this case, conduct a brief obstetric history, including the onset and frequency of contractions, the presence or absence of bleeding, possible loss of amniotic fluid, previous prenatal care, and due date. In the absence of active vaginal bleeding, perform a sterile vaginal examination and palpate the maternal abdomen to determine the stage of labor, as well as the position, presentation, and lie of the fetus. Monitor fetal well-being by evaluating the fetal heart rate, particularly immediately after a uterine contraction. In an ED setting, fetal assessment is increasingly done via bedside ultrasonography, which can assess fetal movement and heart rate (Fig. 56.2). The traditional approaches of using external Doppler or auscultation are also acceptable. The normal baseline fetal heart rate is 110 to 160 beats per minute.

Lie refers to the relationship of the long axis of the fetus to the long axis of the uterus. It is either longitudinal, transverse, or oblique (Fig. 56.3). Oblique lies are unstable and will convert to a longitudinal or transverse lie during labor. Longitudinal lies occur in more than 99% of pregnancies at term.³ Transverse lies generally cannot be safely delivered vaginally.⁴

The presentation, or presenting part, refers to the portion of the body of the fetus nearest to or foremost in the birth canal and is most commonly the occiput or vertex of the head. The

presenting part can be felt through the cervix on sterile vaginal examination. In longitudinal lies, the presenting part is the fetal head, the buttocks (breech), or the feet (footling breech). With a transverse lie, the presenting part is the shoulder. The presentation can be cephalic, breech, shoulder, or compound (a fetal extremity with another presenting part). All presentations except cephalic are considered malpresentations.¹¹

Cephalic presentations are classified by the bony leading landmark of the fetal skull. Ordinarily, the head is sharply flexed so that the occipital fontanelle is the presenting part. This is referred to as a *vertex* or *occiput presentation*. Less commonly, the neck is fully extended and the face is foremost in the birth canal; this is termed *face presentation*. A partially flexed or partially extended neck position results in *sinciput* and *brow presentations*, respectively. Sinciput and brow presentations associated with preterm infants are almost always unstable and convert to either an occiput or face presentation as labor progresses.

Breech presentations are classified as frank, complete, or incomplete (Fig. 56.4). A fetus presenting with the buttocks

and hips flexed and the legs extended is termed a *frank breech*. Presentation of the buttocks with flexion of the fetal hips and knees results in a *complete breech* presentation. When one or both feet or knees are lowermost in the canal, an *incomplete* or *footling breech* results.

At or near term, 97% of fetuses will be vertex and 3% will be breech.³ The incidence of breech delivery is approximately 25% at 28 weeks, 17% at 30 weeks, and 11% at 32 weeks.^{3,12,13}

Position refers to the relationship of the presenting part to the maternal pelvis and may be either left or right. The occiput is the reference point in cephalic presentations, whereas the sacrum is the determining part in breech presentations. The vertex occiput anterior position is the most common and is considered normal. The other position is occiput posterior.

LABOR MOVEMENTS: VERTEX PRESENTATION

Full dilation of the cervix signifies the second stage of labor and heralds delivery of the infant. Typically, the patient begins to bear down, which coincides with descent of the presenting part. Uterine contractions may last 1.5 minutes and recur after a resting phase of less than 1 minute. Delivery of a vertex-presenting infant usually occurs spontaneously. The role of the clinician or attendant is principally to provide control of the birth process by preventing forceful, sudden expulsion or extraction of the infant with resultant fetal or maternal injury.

The mechanism of labor in vertex presentations consists of engagement of the presenting part, flexion, descent, internal rotation, extension, external rotation or restitution, and expulsion (Fig. 56.5).³ These are often referred to as *cardinal movements* of labor. The mechanism of labor is determined by the pelvic dimensions and configuration, the size of the fetus, and the strength of the uterine contractions. Essentially, the fetus will follow the path of least resistance by adaptation of the smallest achievable diameter of the presenting part to the most favorable dimensions and contours of the birth canal.

The sequence of movements in vertex presentations is as follows:

1. *Engagement* refers to the mechanism by which the greatest transverse diameter of the head, the biparietal diameter in occiput presentations, passes through the pelvic inlet. A fetus is engaged when the presenting part is at 0 station. In a primiparous patient, it usually occurs in the last 2 weeks

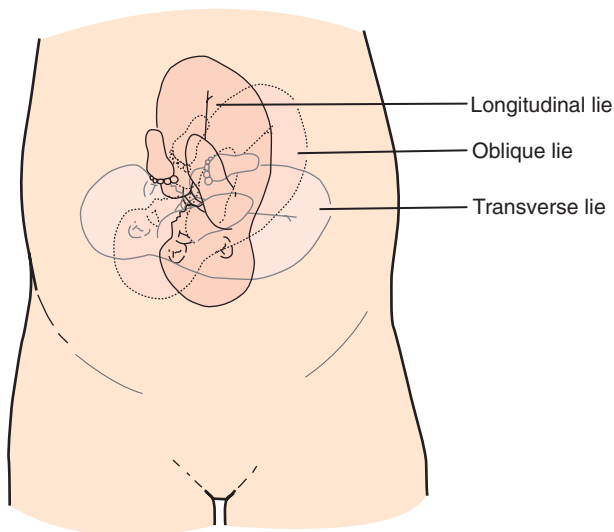

Figure 56.3 Examples of different fetal lie. (From Gabbe SG, Niebyl JR, Simpson JL, editors: *Obstetrics: normal and problem pregnancies*. Philadelphia, 2007, Churchill Livingstone.)

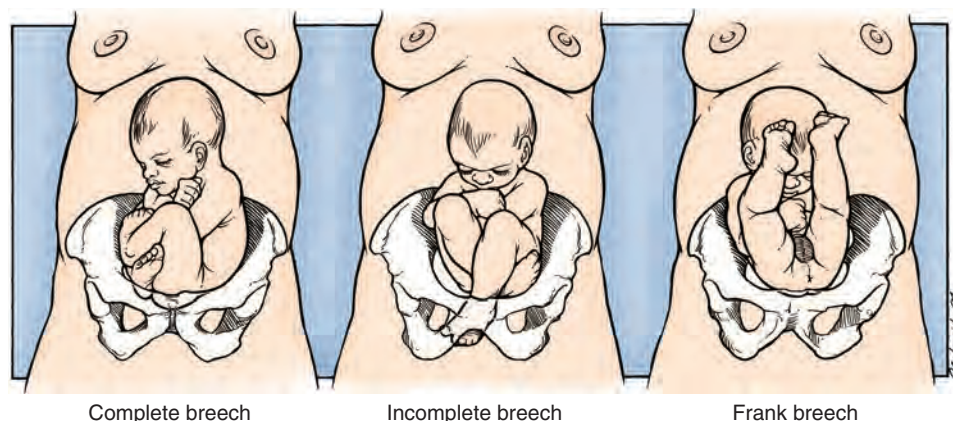

Figure 56.4 A fetus in a complete breech presentation is flexed at the hips and at the knees. An incomplete breech shows incomplete deflexion of one or both knees or hips. With a frank breech presentation, the fetus is flexed at the hips and extended at the knees.

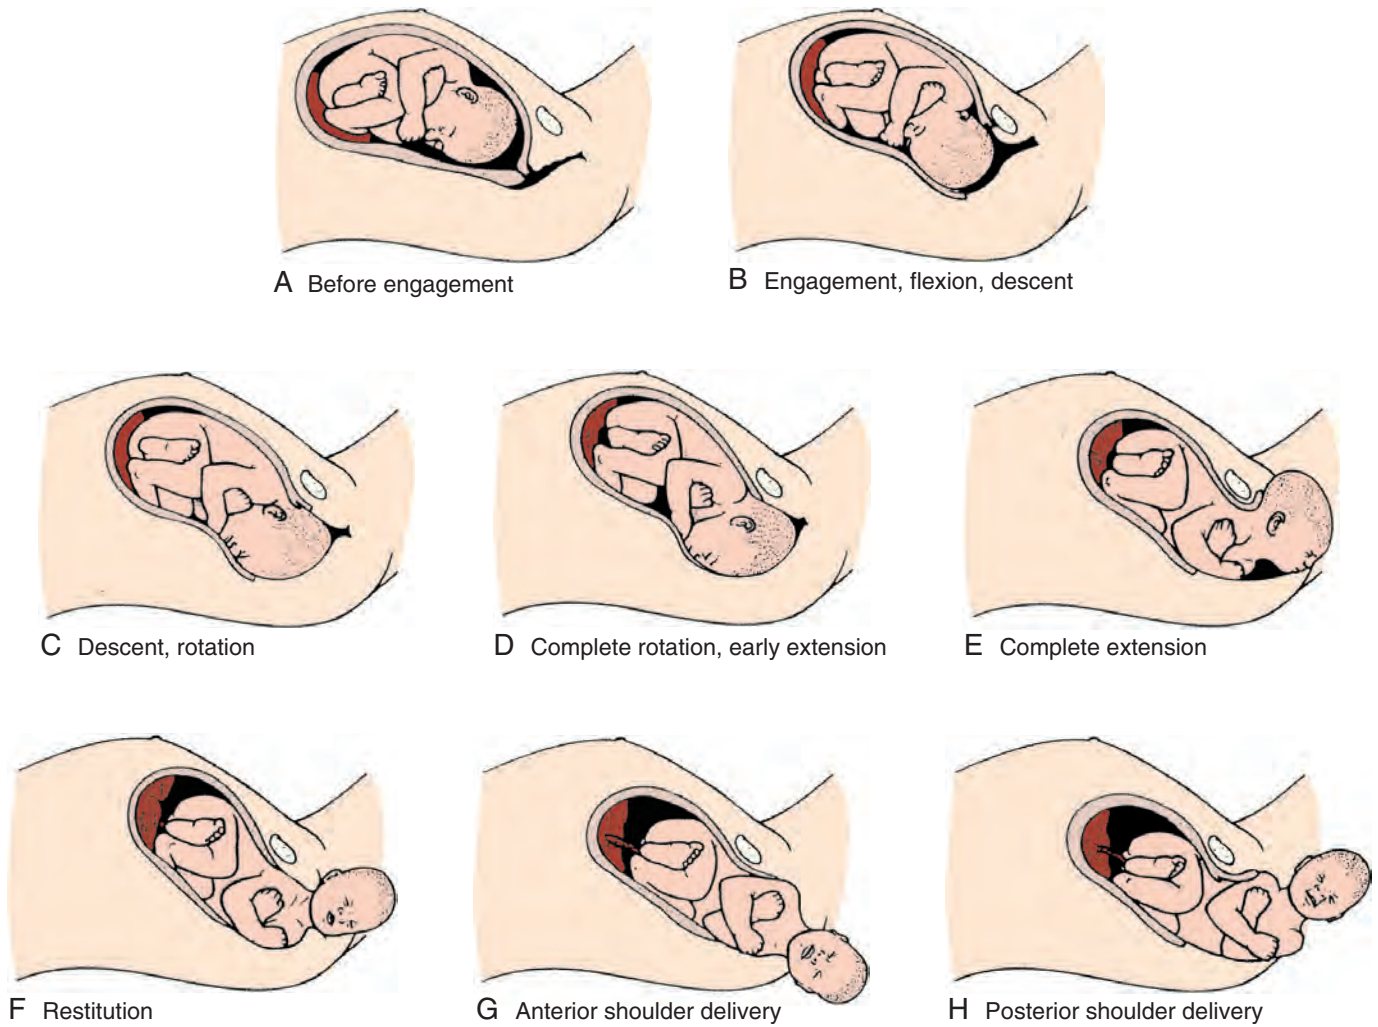

Figure 56.5 A–H, Cardinal movements of labor. (From Gabbe SG, Niebyl JR, Simpson JL, editors: *Obstetrics: normal and problem pregnancies*, ed 5, Philadelphia, 2007, Churchill Livingstone.)

of pregnancy; in a multiparous patient, it can occur at the onset of labor.

2. *Flexion* of the head is necessary to minimize the presenting cross-sectional diameter of the head during passage through the smallest diameter of the bony pelvis. In most cases, flexion is necessary for both engagement and descent and occurs passively.
3. *Descent* is the downward passage of the fetal presenting part. It is gradually progressive but is not necessarily continuous. Descent is affected by uterine and abdominal contractions, as well as by straightening and extension of the fetal body.
4. *Internal rotation* occurs with descent and is necessary for the head or presenting part to traverse the ischial spines. This movement essentially turns the head such that the occiput gradually moves from its original, more transverse position anteriorly toward the symphysis pubis or, less commonly, posteriorly toward the hollow of the sacrum. This is known as occiput anterior or occiput posterior, respectively.
5. *Extension* occurs as the flexed head reaches the anteriorly directed vaginal introitus. The occiput reaches the inferior aspect of the pubic symphysis. The head is born by further

extension as it rotates around the pubic symphysis and the occiput, bregma, forehead, nose, mouth, and finally, the chin pass successively over the anterior margin of the perineum. Immediately after its birth, the head drops downward such that the chin lies over the maternal anal region.

6. *External rotation* or restitution is return of the head to the correct anatomic position with respect to the fetal torso. It follows delivery of the head as it rotates to the transverse position that it occupied at engagement. This is also a passive movement.
7. *Expulsion* of the remainder of the fetal body then occurs. The shoulders descend in a path similar to that traced by the head (i.e., rotating anteroposteriorly for delivery). First, the anterior shoulder is delivered beneath the symphysis pubis followed by the posterior shoulder across the perineum.

LABOR MOVEMENTS: BREECH PRESENTATION

The mechanism of labor for breech presentations varies (see Fig. 56.4). The widest diameter that is engaged is the bitrochanteric diameter. Usually, the hips engage in one of the

oblique diameters of the pelvic inlet. As descent occurs, the anterior hip generally descends more rapidly than the posterior hip. Internal rotation occurs as the bitrochanteric diameter assumes the anteroposterior (AP) position. Lateral flexion takes place as the anterior hip catches beneath the symphysis pubis, which allows the posterior hip to be born first. The infant's body then rotates to allow engagement of the shoulders in an oblique orientation. Gradual descent occurs, with the anterior shoulder rotating to bring the shoulders into the AP diameter of the outlet. The anterior shoulder follows lateral flexion to appear beneath the symphysis, with the posterior shoulder being delivered first as the body is supported. The head tends to engage in the same diameter as the shoulders. Subsequent flexion, descent, and rotation of the head occur to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

Breech delivery is associated with a greater incidence of prematurity, prolapsed cord, and increased perinatal morbidity and mortality.^{3,14,15} Cesarean section can reduce the morbidity and mortality associated with breech delivery, but a planned vaginal delivery may be the method of choice in carefully selected cases and may be beneficial in low resource settings.¹⁶⁻¹⁸ The emergency clinician should be cognizant of the imminent vaginal delivery of a breech infant in any presentation: frank, complete, or footling. However, a breech presentation is always problematic for any clinician, even under the best of circumstances. It is not expected that the EP will always be able to successfully deliver a breech presentation.

Types

There are three types of vaginal breech deliveries. *Spontaneous breech* is a breech delivery in which the infant is delivered spontaneously without any manipulation or traction other than supporting the infant. This form of delivery is rare with term infants, and there is little associated traumatic morbidity. *Partial breech extraction* occurs when the infant is delivered spontaneously as far as the umbilicus and the remainder of the body is extracted. *Total breech extraction* occurs when the entire body of the infant is extracted by the clinician.

Similar to cephalic presentations, the role of the clinician is to assist the mother in the birthing process and allow maternal expulsive efforts to effect delivery of the infant. Premature or aggressive assistance or traction can significantly increase the risk for fetal or maternal morbidity.

To perform any vaginal breech delivery, the birth canal must be sufficiently large to allow passage of the fetus without trauma and the cervix must be completely effaced and dilated.

▶ If these conditions do not exist, cesarean section (Videos 56.1 and 56.2) is indicated. To ensure full cervical dilation in a footling or complete breech, it is important that the feet, legs, and buttocks advance through the introitus to the level of the fetal umbilicus before the clinician intervenes and further delivery is attempted. The mere appearance of the feet through the vulva is not in itself an indication to proceed with delivery. This may be a footling presentation through a cervix that is not completely dilated. In this case there may be time to transfer the patient to the labor and delivery suite, preferably in the knee-chest position to minimize the risk for cord compression.¹⁹ Similarly, if the breech is frank, cervical dilation and outcome are improved if the infant is allowed to deliver to the level of the umbilicus. Before this, as with complete and footling presentations, there may be time to safely transfer the mother

to the labor and delivery area. Tocolytics such as subcutaneous terbutaline may be considered to inhibit labor until such patients can be safely transferred.¹⁹

VAGINAL EXAMINATION

Cleanse the perineum with an antiseptic and use a sterile lubricant to decrease potential contamination. A sterile vaginal (not speculum) examination is performed to identify the fetal presentation and position and assess the progress of labor, except in cases of suspected bleeding. During the digital examination, take care to avoid the anal region and potential fecal contamination. Assess cervical effacement and dilation, as well as fetal station, presentation, and position.³ Do not withdraw the finger from the vagina until the examination is complete. The number of vaginal examinations during labor correlates with infectious morbidity, especially in cases of early membrane rupture.³

Cervical effacement refers to the process of cervical thinning that occurs before and during the first stage of labor as the cervical canal shortens from a length of approximately 2 cm to a circular opening with almost no length remaining (Fig. 56.6). Effacement is expressed as a percentage from 0% (unefaced and thick) to 100% (completely effaced). Assess the degree of cervical effacement by palpation and determine the palpated length of the cervical canal in comparison to that of an unefaced, or normal, cervical canal.

Determine *cervical dilation* by estimating the average diameter of the internal cervical os. Sweep the examining finger from the cervical margin on one side across the cervical os to the opposite margin. Express the diameter in centimeters. Ten centimeters constitutes full cervical dilation. A diameter of less than 6 cm can be measured directly. A cervix that accommodates one index finger is 1 cm, and one that accommodates two fingers is dilated approximately 3 cm. For a diameter greater than 6 cm, it is frequently easier to determine the width of the remaining cervical rim and subtract twice that measurement from 10 cm. For example, if a 1-cm rim is felt, dilation is 8 cm.

Figure 56.6 Effacement of the cervix. **A**, None. **B**, Partial. **C**, Complete. (A–C, From Romney S, Gray MK, Little AB, et al, editors: *Gynecology and obstetrics: the health care of women*. New York, 1975, McGraw-Hill.)

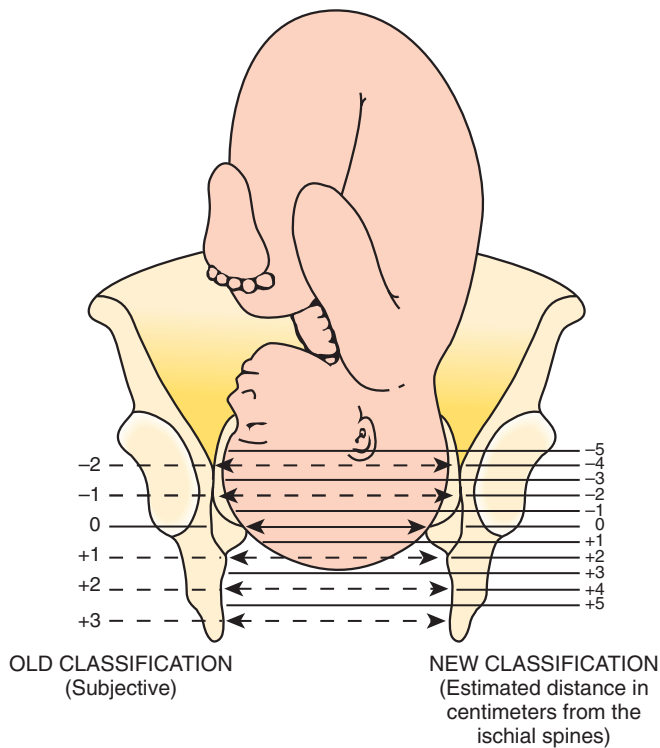

Figure 56.7 The relationship of the leading edge of the presenting part of the fetus to the plane of the maternal ischial spines determines the station. Old and new classification are included. (From Gabbe SG, Niebyl JR, Simpson JL, editors: *Obstetrics: normal and problem pregnancies*, ed 5, Philadelphia, 2007, Churchill Livingstone.)

Station refers to the level of the presenting fetal part in the birth canal relative to the ischial spines, which lie halfway between the pelvic inlet and the pelvic outlet (Fig. 56.7). Zero station is used to denote that the presenting part is at the level of the ischial spines. When the presenting part lies above the spines, the distance, estimated in centimeters ranging from 1 to 5, is stated in negative figures (–5, –4, –3, –2, –1). Below the ischial spines, the presenting fetal part passes +1, +2, +3, +4, and +5 stations to delivery. This measurement is made by simple palpation.³ The ischial spines can be palpated at roughly the 8 and 4 o'clock positions on the vaginal examination.

Three maneuvers are used to determine fetal presentation and position. First, introduce two fingers into the vagina and advance them to the presenting part to differentiate face, vertex, and breech presentations. In vertex presentations, move your fingers up behind the symphysis pubis and then sweep them posteriorly over the fetal head toward the maternal sacrum to identify the course of the sagittal suture. Define the positions of the two fontanelles, which are located at opposite ends of the sagittal sutures, by palpation. The anterior fontanel is diamond shaped; the posterior fontanel is triangular. In breech presentations, the fetal sacrum is the point of reference, whereas in face presentations the fetal chin is used.

FETAL WELL-BEING

Auscultation

Make the initial determination of fetal well-being by assessing the fetal heart rate with a fetoscope, bedside ultrasound, or a

fetal Doppler ultrasound device. Place the device firmly on the maternal abdominal wall overlying the fetal thorax and reposition it until fetal heart tones are heard. When a Doppler device is used, apply a conducting gel to the abdominal wall to interface with the Doppler receiver. To avoid confusion of the maternal and fetal heart sounds, palpate the maternal pulse as the fetal heart rate is auscultated.

The normal baseline fetal heart rate is 110 to 160 beats/min and varies considerably from a baseline measured for a minimum of 2 minutes in a 10-minute segment of time.^{20,21} Rates above or below this range may indicate fetal distress. Accelerations in the fetal heart rate lasting longer than 10 seconds and less than 2 minutes commonly occur during labor and are probably a physiologic response to fetal movement.^{3,20,21} Persistent fetal tachycardia occurs most frequently in response to maternal fever or amnionitis but may also indicate fetal compromise.^{3,20}

As with brief accelerations in the fetal heart rate, a gradual decrease in the fetal heart rate in association with a uterine contraction with an onset to nadir of 30 seconds or more (with the nadir coinciding with the peak of contraction) is termed an *early deceleration*. Such decelerations are physiologic and probably the result of vagal nerve stimulation secondary to compression of the fetal head. Decelerations that occur independent of uterine contractions, are abrupt, or last between 15 seconds and 2 minutes are known as *variable decelerations*. Variable decelerations are relatively common, can be classified according to their severity, and may be temporarily corrected by maternal repositioning. *Late decelerations* are those that are delayed in timing with respect to a contraction, with the nadir of the deceleration occurring after the peak of the contraction. Late decelerations can be an ominous sign and may represent cord compression or uteroplacental insufficiency and may necessitate emergency delivery.^{20,21}

Changes in the fetal heart rate that indicate fetal distress are usually evident immediately after a uterine contraction, and therefore the fetal heart rate is optimally assessed at this time. Formal monitoring of labor should ideally be performed in an obstetrics unit (Fig. 56.8).^{3,20}

Management of Fetal Distress

Definitive evaluation of fetal distress should be performed in the obstetric unit by the delivery team. There is no role for sophisticated fetal monitoring in the ED. In the absence of a dedicated obstetric unit, transfer to another hospital is the only option, albeit a less than ideal one. An EP working in an ED without adequate obstetric backup can do little to effect a positive outcome in high-risk situations. Eclampsia, bleeding, and abnormal fetal presentation may be identified, but the EP needs to focus attention on maternal well-being while expediting transfer, referral, or both. The EP has limited options for managing fetal distress.

If fetal distress is suspected on the basis of the resting fetal heart rate or changes after contractions, change the maternal position, typically into the left lateral decubitus position, and reevaluate. Administer supplemental oxygen to the mother to optimize fetal oxygenation. In the absence of bleeding, perform a vaginal examination to rule out the possibility of umbilical cord prolapse.^{20,22} *Cord prolapse* usually occurs at the same time as rupture of the membranes and is diagnosed by palpation of the umbilical cord on vaginal examination or by visualization of the cord protruding through the introitus.

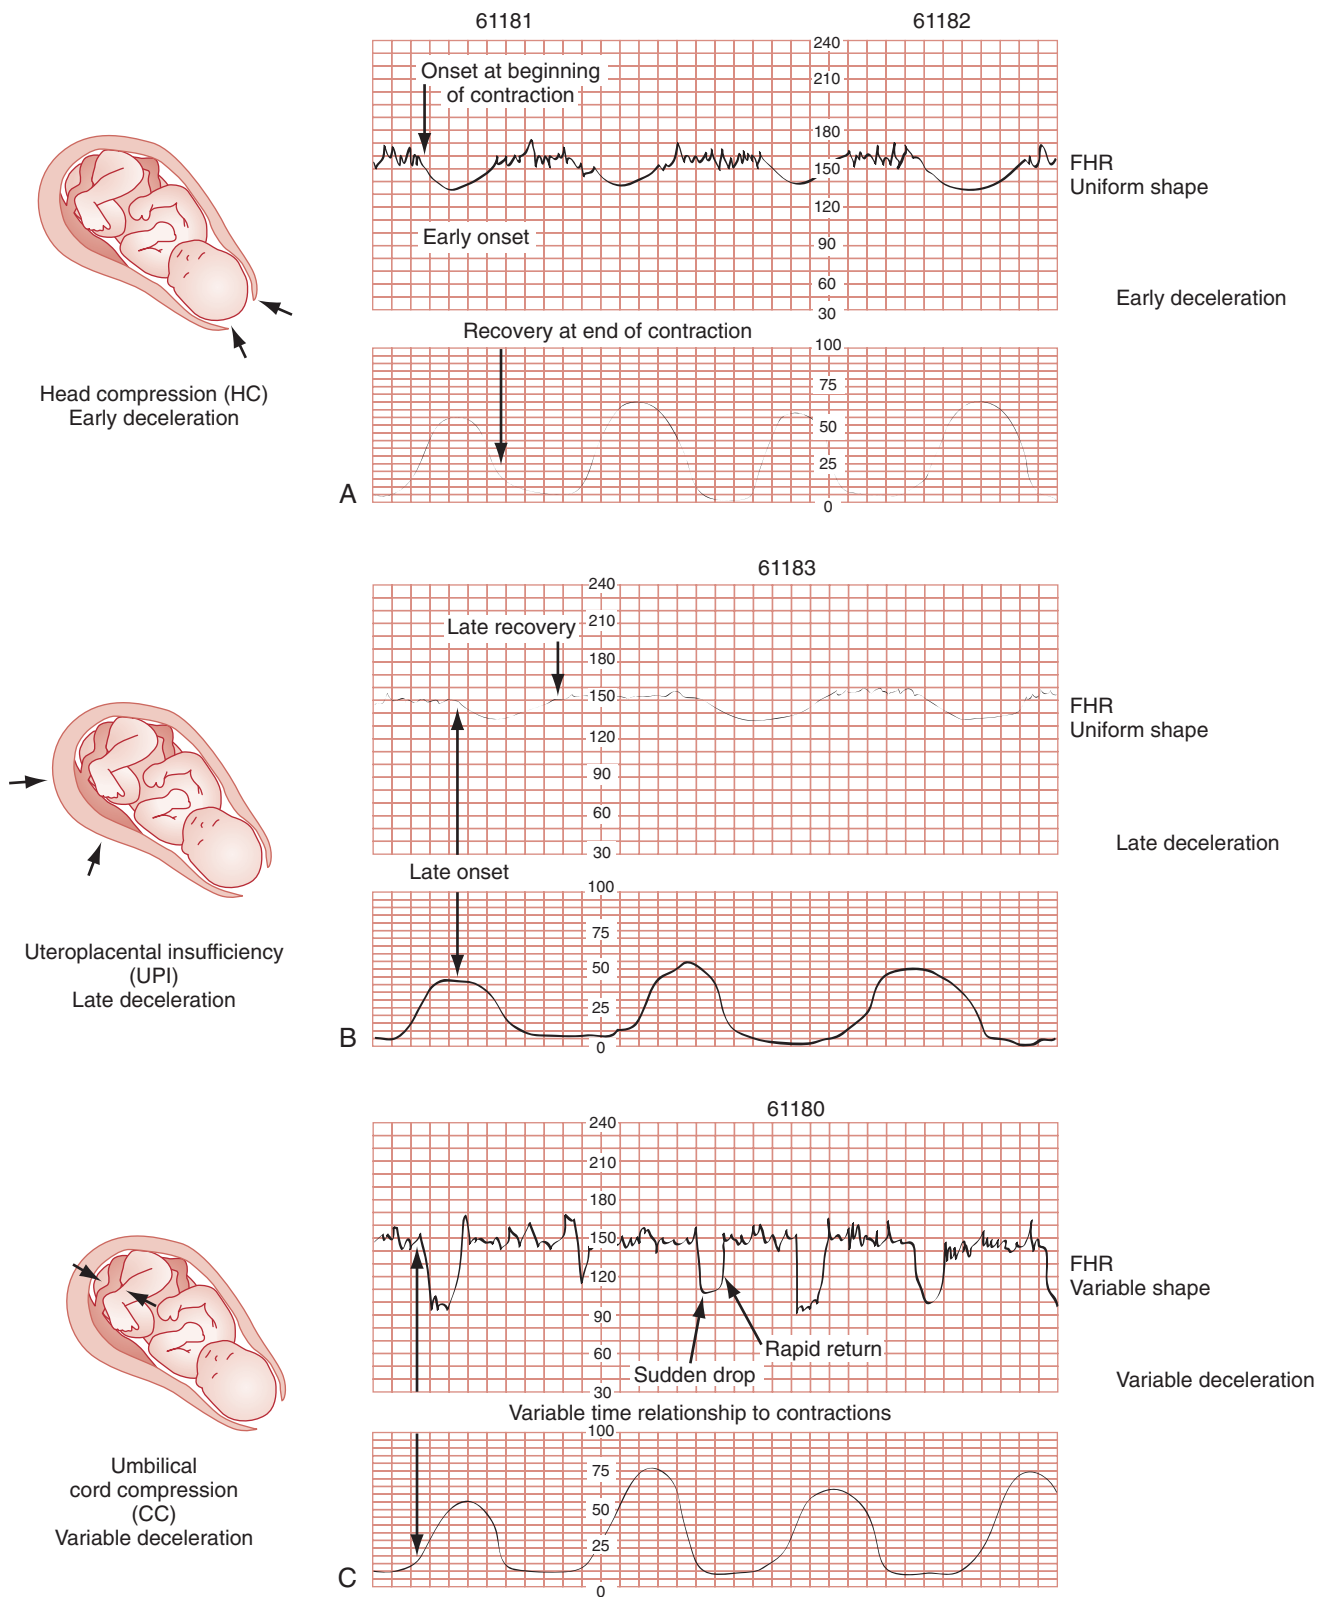

Figure 56.8 Deceleration patterns of the fetal heart rate (FHR). **A**, Early deceleration caused by head compression. **B**, Late deceleration caused by uteroplacental insufficiency. **C**, Variable deceleration caused by cord compression. Note: fetal monitoring is not done in the emergency department; this figure is supplied for completeness. (Modified from Lowdermilk DL, Perry SE, Bobak IM, editors: *Maternity and women's health care*, ed 6, St. Louis, 1997, Mosby.)

Cord prolapse is associated with several risk factors such as malpresentation, grand multiparity, and prematurity, as well as iatrogenic causes.^{22–24}

Management of cord prolapse is directed at sustaining fetal life until delivery is accomplished. In situations with the cord prolapse and evidence of fetal distress, unless immediate delivery is feasible or the fetus is known to be dead, prepare for an emergency cesarean section. If immediate obstetric services are not available, four temporizing measures can be undertaken. (1) Place the patient in the knee-chest or deep Trendelenburg position, and keep the patient in this position until delivery.^{22,23,25} (2) Minimize compression of the umbilical cord by inserting a sterile gloved hand and exerting manual pressure in the vagina to lift and maintain the presenting part away from the prolapsed cord. (3) After manual elevation of the presenting part, instill 500 to 700 mL of saline into the bladder to raise the presenting part and maintain cord decompression. Once the bladder is filled, remove the vaginal hand.^{23,25} (4) Tocolytic therapy can be administered to decrease uterine contractions and improve fetoplacental perfusion in cases of fetal bradycardia or pathological decelerations.^{23,25} Unfortunately, outcomes of true obstetric emergencies managed solely in the ED are often bleak and essentially out of the hands of the EP.

Tocolytic Therapy

Tocolytics are drugs used to suppress uterine contractions for women in preterm labor and are rarely indicated or instituted in the ED. However, under extremely limited circumstances and preferably under obstetric guidance, this intervention may be initiated in the ED. The goal of delaying delivery is to enable administration of antenatal corticosteroids for lung maturation and magnesium sulfate ($MgSO_4$) for neuroprotection, as well as to permit maternal transport (if indicated) to a tertiary facility.^{26–29} Preterm birth is a major contributor to perinatal mortality and morbidity globally.³⁰

Before instituting pharmacologic tocolytic therapy for either preterm labor or fetal distress, initiate basic maneuvers to improve maternal and fetal status. Because uterine hypoxia may induce uterine contractions, administer supplemental oxygen and infuse 500 mL of crystalloid intravenously. Place the mother in the left lateral decubitus position to improve uterine perfusion.³¹ Because uterine, cervical, or urinary tract infections account for 20% to 40% of cases of preterm labor, search for a specific cause and treat infections appropriately.³² If the contractions persist and cervical changes are documented despite these basic interventions, consider pharmacologic therapy.^{33,31} Although tocolytic agents are commonly used and have been shown to prolong pregnancy by 2 to 7 days, data suggest that tocolysis does not improve neonatal outcomes.^{3,28,31} In addition, none of the commonly used tocolytic medications are approved for use by the U.S. Food and Drug Administration (FDA) for this indication. General contraindications to tocolytic therapy include severe preeclampsia, placental abruption, intrauterine infection, advanced cervical dilation, and evidence of fetal compromise or placental insufficiency.³¹

There are no clear first-line tocolytic agents to manage preterm labor (Table 56.1). Clinical circumstances and preferences should dictate treatment. Agents such as calcium channel blockers (CCBs) and the prostaglandin inhibitor indomethacin have shown varying efficacy in clinical trials.^{3,20,31} The most commonly used tocolytic agents in the United States are the CCB nifedipine, $MgSO_4$, and the β_2 -receptor agonist terbutaline.

TABLE 56.1 Tocolytics for the Emergency Management/Cessation of Preterm Labor

Drug	Dose	End Point
Indomethacin	50–100 mg PO or 50 mg PR	May repeat 25–50 mg PO q 6 hr for a maximum of 48 hr
Terbutaline	0.25 mg SC	May repeat q 20–60 min Cessation of uterine contractions Intolerable maternal side effects
Magnesium sulfate	4–6 g IV over 20 min followed by an infusion at 1–3 g/hr IV	Cessation of uterine contractions Signs of magnesium toxicity (e.g., respiratory depression, hypotension, somnolence)
Nifedipine ^a	10 mg PO	May repeat q 15–20 min Cessation of uterine contractions Harmful maternal side effects, e.g., hypotension Maximum dose, 40 mg

^aVariable doses have been used.

IV, Intravenously; PO, orally; PR, per rectum, q, every; SC, subcutaneously.

CCBs are the tocolytics preferred by the World Health Organization (WHO).³³

β_2 -Receptor Agonists

The most commonly used β_2 -adrenergic tocolytic agent is terbutaline. The β -mimetic agents react with adrenergic receptors to reduce intracellular ionized calcium levels and prevent the activation of myometrial contractile proteins.³ Although terbutaline stimulates β_2 -receptors primarily, it has some β_1 -activity, and this is responsible for its cardiovascular side effects.

Terbutaline is commonly used for the treatment of preterm labor.^{3,34} Administer terbutaline subcutaneously in a 0.25-mg dose and repeat it every 20 to 60 minutes until contractions cease or intolerable maternal side effects occur.^{31,35,36} In 2011 the FDA required the addition of a *Boxed Warning and Contraindication* (“black box warning”) against the use of injectable terbutaline for the prevention or prolonged treatment of preterm labor beyond 48 to 72 hours because of adverse effects, including maternal death.³⁷ Use terbutaline with caution in patients with cardiovascular disease, hypertension, hyperthyroidism, diabetes, and seizures and in those taking other sympathomimetic amines.^{31,38} The general clinical side effects of arrhythmias, myocardial ischemia, and pulmonary edema are related to its

inherent activity as a β -mimetic drug. Treatment of the majority of side effects is supportive; severe cardiovascular effects may be treated with β -blocking agents.^{35,38}

MgSO₄

MgSO₄ is not approved in the United States for use as a tocolytic agent and has been shown to be ineffective at delaying birth or preventing preterm birth, has no apparent advantages as a tocolytic agent, and it may be associated with an increased risk of fetal, neonatal, or infant mortality.³⁹ Even though the use of MgSO₄ as a tocolytic has fallen out of favor, benefits have been shown for antenatal use for its fetal neuroprotective effects.^{40–41} The mechanism of action is not fully understood; magnesium probably decreases myometrial contractility through its role as a calcium antagonist.³ Its fetoprotective effects probably result from noncompetitive antagonism of the *N*-methyl-D-aspartate receptor or through antiapoptosis and prevention of neuronal cell loss.⁴²

MgSO₄ is generally administered at a loading dose of 4 g intravenously over a period of 20 to 30 minutes, followed by a maintenance intravenous infusion beginning at 1 g/hr.^{31,43} Infusion of MgSO₄ often produces sweating, warmth, and flushing. Rapid parenteral administration may cause transient nausea, vomiting, headache, or palpitations.^{31,44} The major side effect of magnesium therapy is impairment of the muscles of respiration with subsequent respiratory arrest, an effect not usually seen until the serum magnesium level exceeds 10 mEq/L. At levels of 12 mEq/L or greater, respiratory arrest may occur.³⁸

The first sign of magnesium toxicity, a decrease in the patellar reflex, typically occurs as serum magnesium levels exceed 4 mEq/L, with loss of the reflex as levels increase further. The dosing and ongoing maintenance of magnesium therapy should be guided by the clinical status of the patient rather than by laboratory values. Monitor the patellar reflex throughout therapy. Because magnesium is almost totally excreted by the kidney, it is contraindicated in the presence of renal failure. Monitor urinary output and renal function throughout therapy. If respiratory depression develops, inject 10 mL of a 10% solution of calcium gluconate or calcium chloride over a 3-minute period as an antidote. For severe respiratory depression or arrest, prompt endotracheal intubation may be lifesaving.³

Calcium Channel Blockers

Calcium antagonists inhibit the influx of calcium ions through the muscle cell membrane and reduce uterine vascular resistance. The decrease in intracellular calcium also results in decreased myometrial activity. CCBs, mainly nifedipine, have demonstrated benefits in postponement of birth compared to β -mimetics with respect to prolongation of pregnancy, serious neonatal morbidity, and maternal adverse effects. CCBs may have some benefits over oxytocin receptor antagonists and magnesium sulfate, although oxytocin receptor antagonists had fewer maternal adverse effects. No difference has been noted in perinatal mortality.³⁰

Although dosing regimens vary, nifedipine is frequently given as an initial loading dose of 30 mg orally and then 10 to 20 mg every 4 to 6 hours.^{31,35} The CCB-induced decreased vascular resistance can lead to maternal hypotension and thus decreased uteroplacental perfusion.⁴⁵

Cyclo-Oxygenase Inhibitors

Cyclo-oxygenase (COX) inhibitors inhibit uterine contractions, are easily administered and appear to have few maternal side effects, although adverse effects have been reported in the fetus and newborn.⁴⁶ Indomethacin is administered as an initial oral or rectal dose of 50 to 100 mg followed by 25- to 50-mg doses every 6 hours for a total of 48 hours.³¹ Ketorolac can be used as an alternative with a 60-mg intramuscular loading dose, followed by 30 mg intramuscularly every 6 hours for 48 hours.³¹ Side effects include oligohydramnios and premature closure of the ductus arteriosus.

Steroids

In addition to tocolytics, patients in preterm labor at less than 34 weeks' gestation are candidates for antenatal steroid administration. This may reduce the incidence of neonatal respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis.³¹ Appropriate patients should receive betamethasone, 12 mg intramuscularly every 24 hours for a total of two doses, or dexamethasone, 6 mg intramuscularly every 12 hours for a total of four doses. Dexamethasone may have benefits compared to betamethasone such as fewer intraventricular hemorrhages and decreased lengths of stay in the neonatal intensive care unit (NICU). The intramuscular route may be more advantageous than the oral route.⁴⁷

VAGINAL BLEEDING DURING THE THIRD TRIMESTER

Bleeding during the third trimester should always be considered an emergency because shock may occur within minutes. Prepare for the two most typical causes of bleeding in late gestation, placenta previa and placental abruption (Fig. 56.9). *Placenta previa* refers to implantation of the placenta in the lower uterine segment with varying degrees of encroachment on the cervical os. Placenta previa is classically characterized by vaginal bleeding with little or no abdominal or pelvic pain. *Abruptio placentae* refers to separation of the placenta from its site of implantation in the uterus before delivery of the fetus. Although the clinical signs and symptoms with placental abruption can vary considerably, abruptio placentae is typically associated with varying degrees of abdominal pain and uterine irritability or contractions.^{3,48}

Stabilization of a patient with third-trimester bleeding should be initiated with large-bore intravenous access. Blood should be drawn for a complete blood count with platelets and a type and crossmatch. If abruption is suspected, clotting studies, including a fibrinogen level and a toxicology screen for cocaine, may be indicated because of the association of abruption with disseminated intravascular coagulation and cocaine abuse, respectively. Until the diagnosis of placenta previa is excluded, digital vaginal examination is *contraindicated* because of the possibility of tearing or dislodging a placenta previa, which may result in profuse, potentially fatal hemorrhage.³ The simplest and most precise method of placental localization is by transabdominal ultrasound, which has an accuracy in locating placenta previa of approximately 96%. In contrast, ultrasonography has limited sensitivity in detecting abruptio placentae, with a reported negative predictive value of between 63% and 88%.³ Therefore negative findings on

Abnormalities of Placental Implantation

ultrasound should not be used to exclude placental abruption. Immediately transfer the patient to the care of an obstetrician for further evaluation.

PROCEDURE

Technique for Uncomplicated Delivery

Although complete sterility is not always possible especially during emergency conditions, when time permits, use sterile technique and equipment. Wear sterile gloves, a gown, mask, and eye protection. Clean the perineum and vulva as for a vaginal examination and drape with sterile towels so that only the immediate area about the vulva is exposed. Be careful to avoid fecal contamination of the infant or perineum.

Ideally, place the patient on a delivery table in the dorsal lithotomy position to increase the diameter of the pelvic outlet (Fig. 56.10, *step 1*). Alternatively, position the patient on a stretcher with her hips and knees partially flexed, her thighs abducted, and the soles of her feet placed firmly on the stretcher. Additional personnel may assist in keeping the patient in this position. If the foot of the bed cannot be removed, enhance the delivery position by placing the underside of a bedpan under the patient's buttocks to provide additional space between the bed and the perineum.

Spontaneous Vertex Delivery

Spontaneous delivery of a vertex-presenting infant is divided into three phases: delivery of the head, delivery of the shoulders, and delivery of the body and legs.

Delivery of the Head

Anticipate delivery when the presenting part reaches the pelvic floor. With each contraction, the perineum bulges further and the vulvovaginal opening becomes more and more dilated by the fetal head. Just before delivery, *crowning* occurs, which is when the head is visible at the vaginal introitus and the widest portion, or the biparietal diameter of the head, distends the vulva.

Gentle, gradual, controlled delivery is desirable. Avoid explosive delivery of the head. Once the fetal head distends the vaginal introitus to 5 cm or more during a contraction, place the palm of one hand over the occipital area and provide gentle pressure to control delivery of the head (see Fig. 56.10, *step 2*). With the other hand preferably draped with a sterile towel to prevent contamination from the anus, exert upward pressure on the chin of the fetus through the perineum just in front of the coccyx in a modified Ritgen maneuver (Fig. 56.11). This maneuver extends the neck at the proper time such that the smallest diameter of the head passes through the introitus and over the perineum to protect the maternal perineal musculature. It is not uncommon for the vagina and perineum to tear with expulsive maternal effort during delivery of the head. If maternal expulsive efforts are insufficient to allow delivery of the head, an episiotomy may be considered at this time.³

Gently support the head during subsequent delivery of the forehead, face, chin, and neck. With delivery of the neck, pass a finger around the infant's neck to determine whether it is encircled by one or more coils of the umbilical cord. If a loop of cord is felt, loosen it carefully and gently slip it over the

infant's head (Fig. 56.12). If this cannot be done easily, clamp the cord doubly, cut the cord between the clamps and promptly deliver the infant.

Delivery of the Shoulders

Just before external rotation the head usually falls posteriorly, almost bringing it into contact with the mother's anus. If maternal defecation occurs, avoid fecal contamination of the fetus. As rotation takes place, the head assumes a transverse position and the transverse diameter of the thorax rotates into the AP diameter of the pelvis. In most cases the shoulders are born spontaneously. Aid delivery by grasping the sides of the head and exerting *gentle* downward (posterior) traction until the anterior shoulder appears beneath the symphysis pubis (see Fig. 56.10, *step 3*). Gently lift the head upward to aid in delivery of the posterior shoulder (see Fig. 56.10, *step 4*). The remainder of the body usually follows without difficulty.

If delivery of the body is delayed after the shoulders have been freed, assist by providing *moderate* traction on the exposed fetal body. To avoid injury to the brachial plexus, do not hook the fingers in the axilla during delivery. Always exert traction in the direction of the long axis of the infant. If traction is applied obliquely, bending of the neck and excessive stretching of the brachial plexus may occur.^{3,19}

Clearing the Airway

Once the head has been delivered, quickly wipe the infant's face and mouth. Routine suctioning is not indicated for vigorous newborns. Although it may be counterintuitive, current recommendations no longer advise routine oropharyngeal and nasopharyngeal suctioning of infants with meconium staining by amniotic fluid. Studies have shown that this practice offers no benefit if the infant is vigorous. A vigorous infant is one who has strong respiratory effort, good muscle tone, and a heart rate greater than 100 beats/min.⁴⁹ Routine intubation for tracheal suction of infants with meconium staining is also no longer recommended.⁴⁹ Per 2015 American Heart Association (AHA) guidelines, infant resuscitation should be initiated with air (21% oxygen at sea level), particularly for preterm infants less than 35 weeks, then titrated as necessary.⁴⁹

Clamping the Cord

The infant should be positioned at or slightly below the level of the vaginal introitus during clamping of the cord.¹⁹ Cut the umbilical cord with scissors between two Kelly clamps placed 4 to 5 cm from the infant's abdomen (see Fig. 56.10, *step 6*). Delayed clamping of the umbilical cord, no earlier than 1 minute after birth, in infants who do not require resuscitation can improve the short- and long-term hematologic and iron status of full-term infants.⁴⁹⁻⁵² Later, apply an umbilical cord clamp 2 to 3 cm from the infant's abdomen. Collect blood samples from the placental end of the cord for infant serology, including Rh determination.¹⁹

After cutting the umbilical cord, evaluate the infant and, if necessary, initiate resuscitation as described in the later section on The Newborn. Rapidly assess the infant by determining the following:

- Was the baby born after a full-term gestation?
- Does the baby have good muscle tone?
- Is the baby breathing or crying spontaneously?

If the answer to these questions is "yes," the baby will probably not need resuscitation.^{49,52}

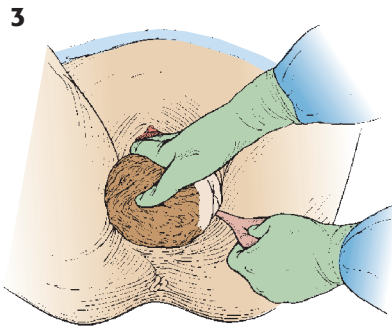

Spontaneous Vertex Delivery

1 Place the patient in the dorsal lithotomy position. Anticipate delivery when *crowning* occurs; the fetal head will be visible at the vaginal introitus.

2 Place one hand over the occiput and provide gentle pressure to control delivery of the head. Use your other hand to exert pressure on the chin of the fetus through the perineum (the modified Ritgen maneuver).

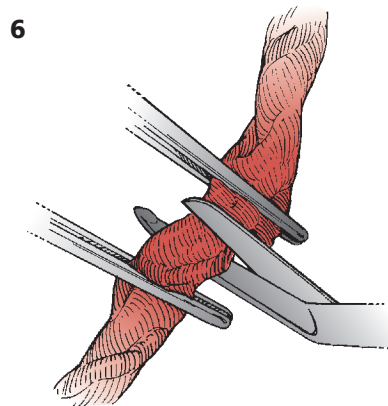

3 Apply gentle downward (posterior) traction until the anterior shoulder appears beneath the symphysis pubis.

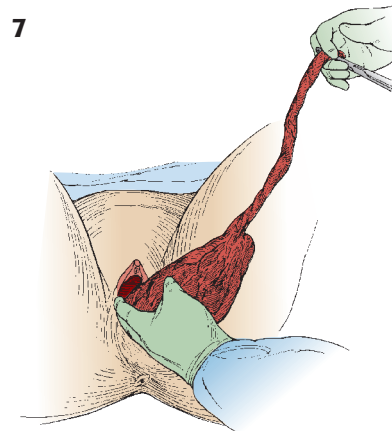

4 Gently lift the head upward to aid in delivery of the posterior shoulder.

5 The remainder of the body usually delivers spontaneously without difficulty. Routine suctioning is not indicated for vigorous newborns.

6 Position the infant at or slightly below the level of the vaginal introitus during clamping of the cord. Cut the cord with scissors between two Kelly clamps placed 4 to 5 cm from the infant's abdomen.

7 Deliver the placenta (placental separation usually occurs within 5 minutes after delivery). Ask the mother to bear down to aid in delivery.

Figure 56.10 Spontaneous vertex delivery. (Adapted from *Ferri's clinical advisor 2013*. St. Louis, 2013, Mosby.)

Figure 56.11 For controlled and gentle delivery of the head, use the modified Ritgen maneuver. (From Seils A, Noujaim S, Davis K, et al, editors: *Williams obstetrics*, ed 22, New York, 2005, McGraw-Hill Medical.)

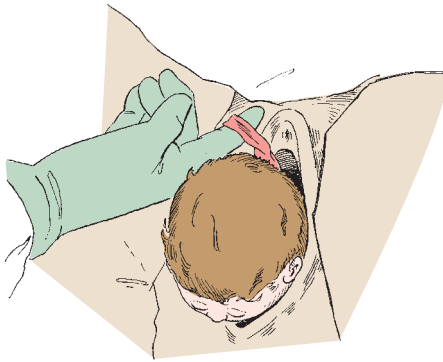

Figure 56.12 As the head is delivered, use a finger to determine whether the umbilical cord is encircling the neck. If a loop of cord is felt, loosen it carefully and gently slip it over the infant's head.

Delivery of the Placenta

Placental separation usually occurs within approximately 5 minutes after delivery of the infant, although it may take longer. It can be recognized by the following signs:

1. The uterus becomes globular and firmer as it contracts.
2. There is a sudden gush of blood as the placenta separates from the uterine wall.
3. The umbilical cord lengthens and protrudes further out of the vagina.

Ask the mother to bear down; the increased intraabdominal pressure produced by this maneuver may be enough to effect complete expulsion of the placenta (see Fig. 56.10, step 7). If maternal force alone is insufficient, aid in the delivery of the placenta. After ensuring that the uterus is firmly contracted and placental separation has occurred, use one hand to exert gentle pressure through the abdominal wall to lift the uterine fundus cephalad while keeping the umbilical cord slightly taut with the other hand (Fig. 56.13). Repeat this maneuver until the placenta reaches the introitus. At this time, stop uterine pressure and gently lift the placenta upward and out of the vagina. Never force expulsion of the placenta before placental separation has occurred, and never use forceful traction to pull the placenta out of the uterus. Such maneuvers may result

Figure 56.13 Delivery of the placenta and fetal membranes by exerting controlled traction on the cord and suprapubic pressure with the abdominal hand to prevent uterine inversion. Care should be taken to avoid avulsion of the cord. Active management with uterotonic agents such as oxytocin administered at delivery hastens delivery of the placenta and may reduce the incidence of postpartum hemorrhage and total blood loss. (From Gabbe SG, Niebyl JR, Simpson JL, editors: *Obstetrics: normal and problem pregnancies*, ed 5, Philadelphia, 2007, Churchill Livingstone.)

in separation of the cord from the placenta or uterine inversion with potentially catastrophic hemodynamic consequences. Examine the placenta for completeness and save it for later evaluation by the obstetrician.^{3,19}

Examine the vulva, vagina, and cervix for traumatic lacerations. Cervical lacerations most typically occur at the 9 or 3 o'clock position; vaginal lacerations typically occur at the point of the ischial spines. The most common areas for lacerations are the vagina, hymen, and perineum. Based on the availability of resources and the clinical setting, definitive repair of uncomplicated or minor obstetric lacerations may be performed in the ED by the EP, but this is often done by a consultant obstetrician.

After delivery of the placenta, the primary mechanism by which hemostasis is achieved at the placental site is through myometrial contraction. Agents such as oxytocin, methylergonovine, and ergonovine may be used to stimulate myometrial contraction. In an effort to prevent uterine atony and subsequent bleeding, oxytocin is often administered after delivery of the placenta.

Oxytocin is the most commonly used oxytocic drug and is usually given by continuous intravenous infusion. Add 20 units of oxytocin to 1 L of normal saline and administer the solution at a rate of 10 mL/min for several minutes until the uterus remains firmly contracted and bleeding is controlled. At this point, reduce the infusion rate to 1 to 2 mL/min.^{3,19} Alternatively, ergot derivatives such as methylergonovine maleate, 0.2 mg, or ergonovine maleate, 0.2 mg, may be given intramuscularly.³ Because of their vasoconstrictive properties, ergot preparations are relatively contraindicated in patients with hypertension, including pregnancy-associated hypertension or preeclampsia.³ The synthetic prostaglandin misoprostol can also be given as an 800- to 1000- μ g rectal dose. In the United States, oxytocic agents are not generally administered before delivery of the placenta because of concerns that the resultant uterine contraction may entrap the placenta or trap an undiagnosed twin within the uterus.^{3,19} Even when oxytocics are administered, the hour after delivery of the placenta is the time during which PPH secondary to uterine atony is most

likely to occur. For this reason, palpate the uterus frequently to ensure that it is well contracted. A normally contracted uterus will feel firm with its upper margin just below the maternal umbilicus. If the uterus is flaccid or bleeding, gently massage it through the abdominal wall. Occasionally, the placenta may fail to separate completely, resulting in a retained placenta or placental fragments with persistent uterine bleeding. Support the patient with intravenous fluids and blood transfusions as indicated until definitive therapy is available. Constant firm uterine massage can lessen hemorrhage and may be lifesaving.

COMPLICATIONS

Complex Deliveries

Shoulder Dystocia

Shoulder dystocia refers to impaction of the fetal shoulders in the pelvic outlet after delivery of the head and occurs in 0.6% to 1.4% of deliveries (Fig. 56.14).⁵³ Shoulder dystocia is associated with several risk factors, including fetal macrosomia, maternal diabetes, obesity, multiparity, and postterm pregnancy.

Impaction of the fetal shoulders and thorax in the maternal pelvis prohibits adequate respiration, and compression of the umbilical cord frequently compromises the fetal circulation. For these reasons, shoulder dystocia is a serious and potentially fatal complication of delivery.^{19,45} Fetal complications include brachial plexus injury, clavicular and humeral fractures, and rarely, death.^{45,49}

Management

The techniques used to treat shoulder dystocia frequently require an assistant, and delivery can result in fetal injury or hypoxia, as well as increased rates of PPH.⁵⁴ Call for emergency assistance from a pediatrician, an obstetrician, and an anesthesiologist. Complications such as a fetal fracture or nerve injury are not unusual with shoulder dystocia during any delivery technique.

Figure 56.14 Shoulder dystocia. When delivery of the fetal head is not followed by delivery of the shoulders, the anterior shoulder has often become caught behind the symphysis.

Although a variety of techniques have been described to free the anterior shoulder from its impacted position beneath the symphysis pubis, the initial technique of choice is the McRoberts maneuver because of its ease and potential for success (Fig. 56.15A).⁵⁵ In one study, approximately 40% of shoulder dystocias were relieved with the McRoberts maneuver alone.⁵⁶ To perform the McRoberts maneuver, place the mother in the extreme lithotomy position with her hips completely flexed so that her knees rest alongside her chest. This causes a flattening of the lumbar lordosis, rotates the maternal pelvis cephalad, and frequently frees the impacted anterior fetal shoulder.^{3,45,55} If the McRoberts maneuver fails to effect delivery, ask an assistant to apply moderate suprapubic, not fundal, pressure to the maternal abdomen while providing gentle downward traction on the fetal head (see Fig. 56.16B).^{45,53}

If these initial maneuvers fail to effect delivery, several other techniques exist, the choice of which will depend on clinician preference and experience. In the first maneuver, place two fingers in the vagina and exert pressure on the fetal scapula to rotate the *posterior* shoulder 180 degrees in a clockwise or counterclockwise fashion, depending on the orientation of the torso (*reverse Wood's screw*), to free the entrapped anterior shoulder (see Fig. 56.15C). Other maneuvers include the Rubin maneuver, in which rotation is achieved by applying pressure on the posterior aspect of the anterior shoulder, or the Wood's screw maneuver, in which pressure is placed on the anterior aspect of the posterior shoulder. This may cause release of the impacted anterior shoulder and result in progression of delivery.^{45,57} Alternatively, attempt to deliver the posterior arm (see Fig. 56.15D). In this maneuver, insert the hand along the hollow of the maternal sacrum to the level of the fetus' posterior elbow. Exert pressure at the antecubital fossa, flex the posterior forearm of the fetus, and grasp the hand or forearm. Next, carefully sweep the posterior arm of the fetus across its chest to effect delivery of the posterior arm and shoulder. Rotate the shoulder girdle into one of the oblique diameters of the pelvis and subsequently deliver the anterior shoulder.^{3,55} No particular maneuver has a higher correlation to neonatal morbidity and mortality, but the use of multiple maneuvers does increase the chance for neonatal complications.^{55,58} Preliminary data suggests delivery of the posterior arm should be considered immediately following the McRoberts maneuver/subrapubic pressure.⁵⁵

If all these strategies fail, it may be necessary to perform a controlled destructive procedure, such as fracture of the fetal clavicle, or the cephalic replacement maneuver (Zavanelli) with subsequent cesarean delivery.^{3,19} The Zavanelli maneuver should be a last resort. An episiotomy is not useful during the management of shoulder dystocia.⁵⁹

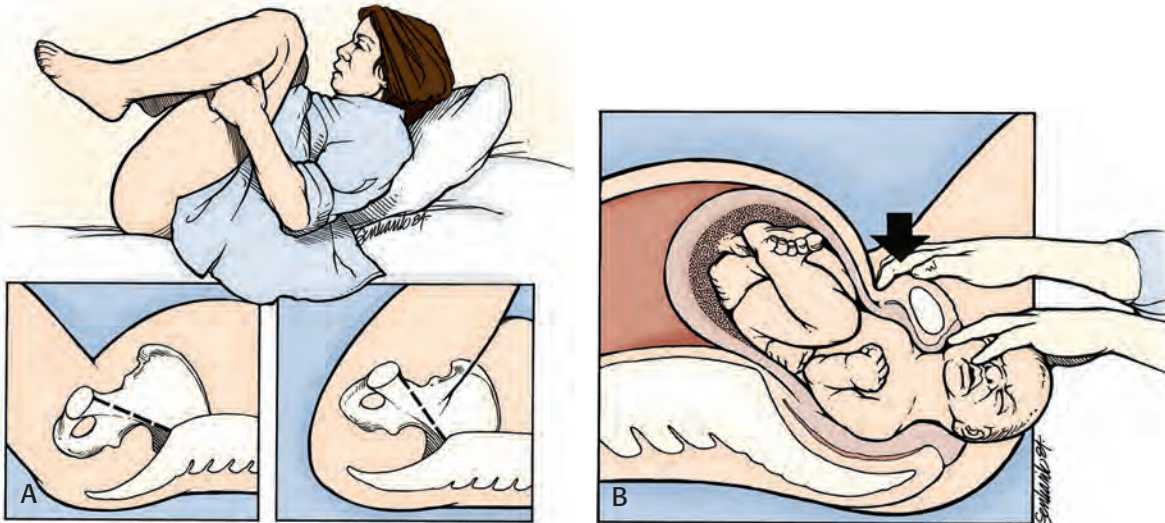

Breech Delivery

Technique

If a breech delivery becomes necessary in the ED, an episiotomy may need to be performed but is not recommended routinely. As the breech progressively distends the perineum, the posterior hip will be delivered, usually from the 6 o'clock position (Fig. 56.16, *step 1*). The anterior hip will then be delivered, followed by external rotation to the sacrum-anterior position. Ideally, two attendants should be available for a breech delivery.

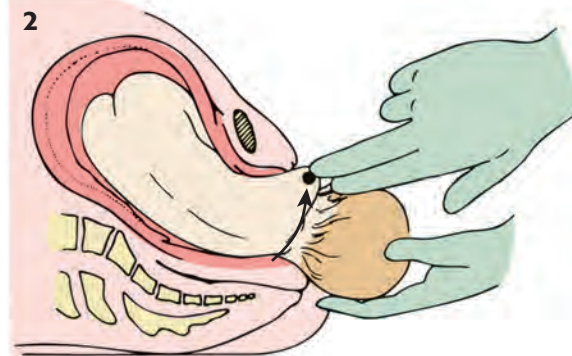

Delivery of the Presenting Part and Body. Many breech infants deliver spontaneously with maternal expulsion efforts alone. Avoid fetal traction and apply fetal manipulation only

Management Of Shoulder Dystocia

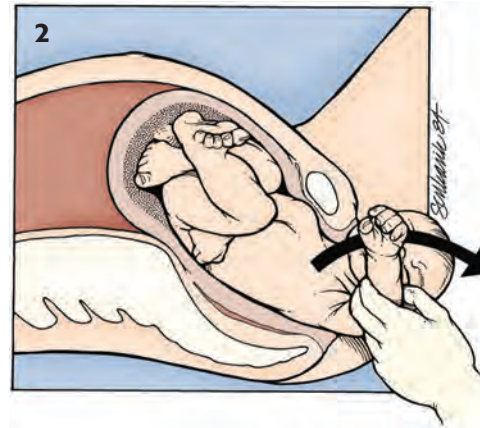

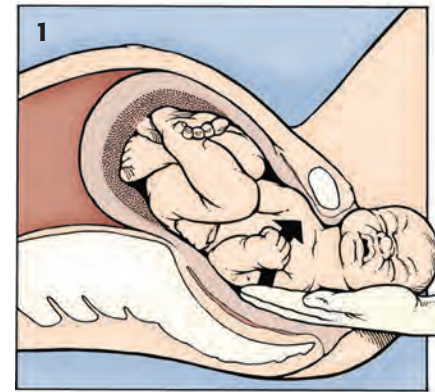

The McRoberts maneuver is the least invasive maneuver to disimpact the shoulders in shoulder dystocia. Position the patient in the extreme lithotomy position with the hips completely flexed (knee-chest position); this may free the anterior fetal shoulder.

Moderate suprapubic pressure will often disimpact the anterior shoulder. Desperate traction on the fetal head is not likely to facilitate delivery and might lead to trauma. Delivery of an infant with shoulder dystocia often results in fracture of the clavicle or humerus to accomplish delivery.

C Rubin or reverse Wood's screw maneuver. 1, Rotate the posterior shoulder. 2, Deliver the rotated shoulder.

D Posterior shoulder delivery. Insert a hand and sweep the posterior arm across the chest and over the perineum. Take care to distribute the pressure evenly across the humerus to avoid unnecessary fracture.

Figure 56.15 Management of shoulder dystocia. (A, B, and D, From Gabbe SG, Niebyl JR, Simpson JL, editors: *Obstetrics: normal and problem pregnancies*, ed 5, Philadelphia, 2007, Churchill Livingstone.)

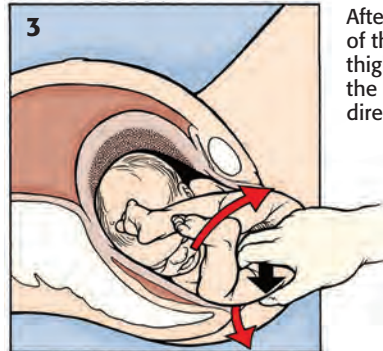

Breech Delivery

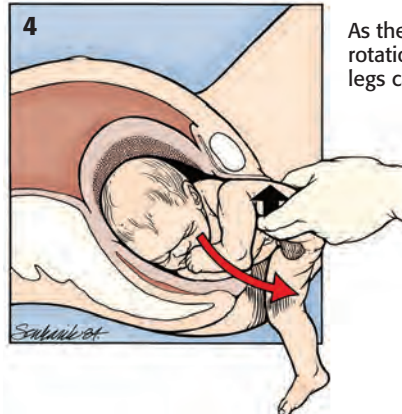

1 As the fetus begins to emerge, the posterior hip will deliver, usually from the 6-o'clock position.

2 Avoid premature aggressive traction, which increases the risk for head entrapment or nuchal arm entrapment.

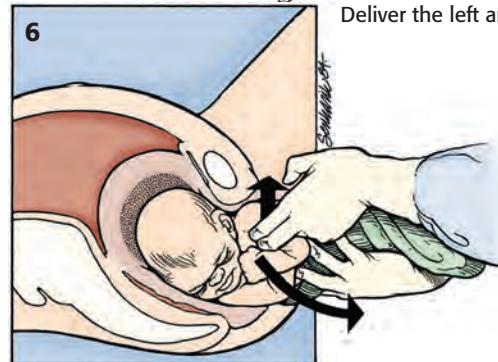

3 After spontaneous expulsion of the umbilicus, rotate the thigh externally and rotate the pelvis in the opposite direction.

4 As the knees flex during the rotational maneuvers, the legs can be delivered.

5 When the scapulae appear under the symphysis, reach over the left shoulder and sweep the arm across the chest.

6 Deliver the left arm.

7 Gently rotate the shoulder girdle to facilitate delivery of the right arm.

8 Rest the fetal body on your palm and forearm.

Place your index and middle fingers over the infant's maxilla to maintain head flexion. Apply downward traction on the shoulders, and then elevate the body of the fetus to deliver the head.

Figure 56.16 Breech delivery.

after spontaneous delivery to the level of the umbilicus. Continued descent of the fetus will allow delivery of the legs, which may be aided by splinting the medial part of the thighs of the fetus with the fingers positioned parallel to the femur and exerting pressure laterally to sweep the legs away from the midline (see Fig. 56.16, steps 2 to 4). After delivery of the legs, grasp the fetal bony pelvis with both hands, with the fingers resting on the anterior superior iliac crests and the thumbs on the sacrum. Because the fetal body is slippery and difficult to hold, wrap it in a towel to assist delivery. Use the maternal expulsive efforts in conjunction with gentle downward traction. Rotate the fetal pelvis to bring the fetal sacrum into the transverse position to effect delivery of the scapulae. Two methods of shoulder delivery are commonly used (see Fig. 56.16, steps 5 to 7). In the first, with the scapulae visible, rotate the trunk so that the anterior arm and shoulder appear at the vulva and can easily be released and delivered. Next, rotate the body of the fetus in the reverse direction to deliver the other shoulder and arm beneath the symphysis pubis. In the second method, if trunk rotation is unsuccessful, deliver the posterior shoulder. Grasp the feet in one hand and draw them upward over the mother's groin. Exert leverage on the posterior shoulder, which will slide out over the perineal margin, usually followed by the arm and hand. Deliver the anterior shoulder, arm, and hand beneath the symphysis pubis by downward traction on the fetal body.

Occasionally, spontaneous delivery of the arm and hand does not follow delivery of the shoulder. If this occurs, provide upward traction on the fetal body after delivery of the posterior shoulder. Pass two fingers along the fetal humerus until the fetal elbow is reached. Using the fingers to splint the fetal arm, sweep it downward and deliver it. Deliver the anterior arm by depression of the fetal body alone. In some cases it may be necessary to sweep the anterior arm down over the thorax by using two fingers as a splint.

Delivery of the Head. After the shoulders appear, the head usually occupies one of the oblique diameters of the pelvis, with the chin directed posteriorly. Extract the head by using the Mauriceau maneuver as follows. With the fetal body resting on the clinician's palm and forearm, place the index and middle fingers of one hand over the infant's maxilla, not the mandible, to maintain flexion of the fetal head (see Fig. 56.16, step 8). Hook two fingers of the other hand over the fetal neck and, while grasping the shoulders, apply downward traction until the suboccipital region appears under the symphysis pubis. Elevate the body of the fetus toward the mother's abdomen, and the fetal mouth, nose, brow, and eventually the occiput will emerge over the perineum. Avoid excessive elevation of the fetal torso to prevent hyperextension of the neck. If available, have an assistant apply suprapubic pressure to help deliver the head. If delivery of the head is not affected by the Mauriceau maneuver, forceps delivery may be necessary but is beyond the scope of this text and most ED practitioners. Once the breech baby is delivered, further management proceeds as for a normal vertex delivery.

Rarely, *breech extraction* of an infant becomes necessary and is indicated only if there is a definite diagnosis of fetal distress unresponsive to routine maneuvers, if obstetric services are unavailable, and if cesarean section cannot be performed promptly. To perform the extraction, introduce the hand into the vagina and grasp both feet of the fetus, with the index finger placed between the fetal ankles. Apply gentle traction

until the feet are pulled through the vulva. Continue gentle downward traction while grasping successively higher portions of both legs and thighs. When the breech appears at the vulva, apply gentle traction until the hips are delivered. As the buttocks emerge, rotate the fetal back anteriorly. Place the thumbs over the sacrum and the fingers over the hips and deliver the remainder of the breech as described earlier. At times, delivery of a frank breech may be necessary. Facilitated by an episiotomy, allow the breech to deliver spontaneously as far as possible. Place a finger on each side of the fetal groin and exert moderate traction. Once the knees appear outside the birth canal, flex the legs slowly to assist in delivery, and proceed with delivery as described earlier.

Episiotomy

Routine use of episiotomy is no longer recommended.^{60,61} Selected indications include breech delivery, shoulder dystocia, occiput-posterior presentations, and imminent perineal tear, but generally is not indicated and when done in these circumstances is an independent risk factor for third- or fourth-degree perineal tears.⁶⁰ Episiotomy may be necessary to expedite delivery in situations of fetal distress. Two types of episiotomy are used: median (midline) and mediolateral (Fig. 56.17). The median approach is the easiest type to perform and repair, and results in the least amount of blood loss, heals more rapidly with minimal discomfort, and is generally more common in the United States. A major complication of median episiotomy is potential inadvertent extension of the incision into the anal sphincter or rectum, which results in third- and fourth-degree lacerations, respectively.^{3,19,62,63} A mediolateral episiotomy seldom results in extension into the anal sphincter, but blood loss is greater, repair is more difficult, and healing may be more painful.^{3,19}

Technique

With vertex presentations, perform the episiotomy during the second stage of labor, when the fetal head begins to distend the perineum and becomes visible to a diameter of 3 to 4 cm during a contraction.³ Anesthesia for episiotomy in the ED is usually limited to local infiltration of the perineum with 1% or 2% lidocaine.

Make the incision with Mayo scissors through the skin and subcutaneous tissue, the vaginal mucosa, the urogenital septum, and the superior fascia of the pelvic diaphragm (see Fig. 56.17). Make the incision up to half the length of the perineum, and extend it 2 to 3 cm upward into the vaginal mucosa. If the incision is in the midline, extend the incision through the lowermost fibers of the puborectalis portion of the levator ani muscles. As the head crowns, place the index and middle fingers inside the vaginal introitus to expose the mucosa, posterior fourchette, and perineal body. Use tissue scissors to incise the median raphe of the perineum halfway to the anal sphincter. For a mediolateral episiotomy, direct the incision downward and outward in the direction of the lateral margin of the anal sphincter either to the right or to the left.

Repair the episiotomy after delivery of the infant and placenta. Repairs are usually performed by the obstetric consultant in the delivery suite but can be done by an EP experienced in the procedure (see Fig. 56.17). The goals of episiotomy repair are to restore both anatomy and hemostasis with a minimal amount of suture material. Perform the closure after delivery of the placenta and following inspection and

Episiotomy And Repair

Midline Episiotomy

Make the incision through the lowermost fibers of the puborectalis portion of the levator ani muscles. Incise the median raphe of the perineum halfway to the anal sphincter.

A major complication of midline episiotomy is incision of the anal sphincter or rectum, which leads to third- and fourth-degree lacerations.

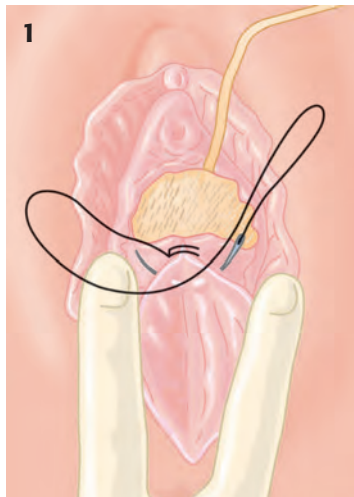

Mediolateral Episiotomy

Make the incision through the lowermost fibers of the puborectalis portion of the levator ani muscles. Direct the incision downward and outward in the direction of the lateral margin of the anal sphincter.

The mediolateral approach rarely extends into the anal sphincter but may be associated with greater blood loss and more difficult repair.

Episiotomy Repair

1

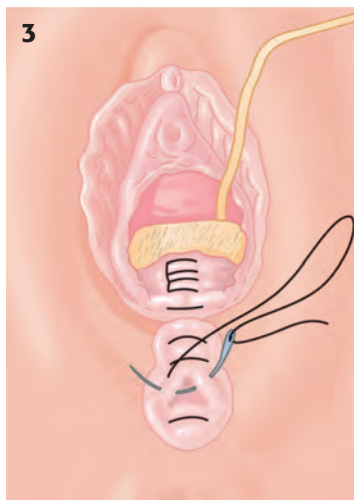

Place a taped sponge in the upper part of the vagina. Expose the full extent of the episiotomy with the left hand. Place the first suture 1 cm cephalad to the most superior margin of the episiotomy or laceration to ensure hemostasis of the repair. Use continuous locked absorbable suture to close the vaginal epithelium from the apex of the laceration to the hymenal ring.

2

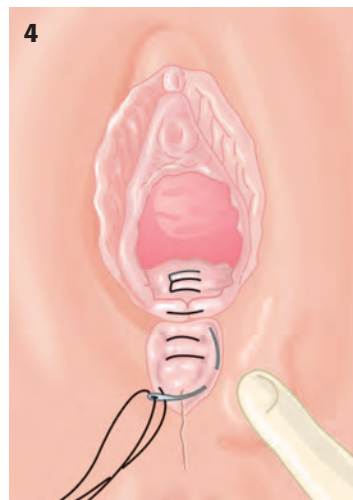

Use simple interrupted (absorbable) suture to close the deep perineal fascia and underlying levator ani muscles (*black arrows*).

Bring the vaginal epithelial suture below the skin into the subcutaneous tissue (*white arrow*).

3

Use the vaginal epithelial suture to close the superficial fascia down to the edge of the episiotomy.

4

Use the same suture again as a subcuticular stitch coming back to the hymenal ring, where it is tied off.

Remove the vaginal sponge.

Figure 56.17 Episiotomy and repair. Routine episiotomy is no longer advised, but the procedure is often performed. Simple repairs may be done in the emergency department (ED), but this is often performed by the obstetrician or in the delivery room after an ED birth. (From Hacker NF, Gambone JC, Hobel CK, editors: *Hacker & Moore's essentials of obstetrics and gynecology*, ed 5, Philadelphia, 2009, Saunders.)

repair of the cervix and upper vaginal canal if indicated. The principles of repair are the same regardless of the type of episiotomy.

Because there is minimal tension on the closed wound, use 2-0 or 3-0 absorbable suture, such as chromic catgut or polyglycolic acid, on a large atraumatic needle. The first step is to close the vaginal mucosa with a continuous suture from just above the apex of the incision to the mucocutaneous junction to reapproximate the margins of the hymenal ring (see Fig. 56.17, *step 1*). Ligate large actively bleeding vessels during closure with separate absorbable sutures. Next, reapproximate the perineal musculature with three or four interrupted sutures (see Fig. 56.17, *step 2*). Close the superficial layers by one of two methods. In the first method, use a continuous suture to close the superficial mucosa from the mucocutaneous junction outward and then continue it upward as a subcuticular skin closure, with the suture returning to and ending at the mucocutaneous junction (see Fig. 56.17, *steps 3 and 4*). Alternatively, place several interrupted sutures through the skin and subcutaneous fascia and tie them loosely. This last method of skin closure avoids burying two layers of suture in the more superficial layers of the perineum.^{3,19}

The most common complication of episiotomy is hematoma formation, which requires evacuation and drainage. Infection is an infrequent complication that usually responds to sitz baths, good hygiene, and antibiotic therapy.

Immediate PPH

PPH is the leading cause of maternal mortality globally. It is primarily seen in developing countries, but the incidence is increasing in the United States.^{64,65} PPH is generally defined as blood loss of more than 500 mL following vaginal delivery and more than 1000 mL following cesarean delivery. The average blood loss with a vaginal delivery is estimated to be approximately 500 mL but clinicians consistently underestimate actual blood loss.⁶⁴ PPH is divided into early hemorrhage, which occurs within 24 hours of delivery, and late hemorrhage, which occurs after 24 hours and up to 6 weeks after delivery.

PPH may be sudden and massive but is frequently characterized by persistent moderate bleeding until serious hypovolemia

develops. Observe carefully for blood loss, including evaluation of uterine size and consistency, during the early postpartum period. The most common cause of early PPH is uterine atony, which is involved in up to 80% of cases.⁶⁵ Less common causes include lacerations of the lower genital tract, retained placenta or placental fragments, coagulation disorders, uterine rupture, uterine inversion, and placental site bleeding.⁴

Management

Management of PPH is similar to management of any acute blood loss. It consists of replacing intravascular volume with crystalloid and blood products, and using massive transfusion protocols as needed, and to correct the underlying cause of the hemorrhage. The diagnosis of uterine atony, the most common cause of bleeding, is made when uterine palpation reveals a soft “boggy” uterus. The diagnosis may be suspected on the basis of abdominal examination with confirmation made on bimanual examination as atony may be localized to the lower uterine segment.

Uterine atony is initially managed with firm manual massage of the uterine fundus through the abdominal wall in conjunction with the administration of oxytocic agents (Table 56.2). If bleeding persists, bimanual uterine compression is indicated. Use one hand to compress and massage the uterus through the abdominal wall while using the fist of the other hand to gently massage the anterior aspect of the uterus through the vagina (Fig. 56.18). Avoid vigorous downward massage, which can result in acute uterine inversion or can injure the blood vessels in the broad ligament.

Oxytocics

Oxytocin is the usual first-line drug for PPH secondary to uterine atony.⁶⁶ Administer oxytocin as an intravenous infusion. A typical initial dose is 20 to 40 units in 1 L of crystalloid infused at a rate of 200 to 500 mL/hr. Titrate to sustain uterine contractions and control uterine hemorrhage. Slowing of hemorrhage should be observed within minutes of administration. If an intravenous line is not available, administer 10 units of intramuscular or intrauterine oxytocin.³⁸ Do not administer oxytocin as an intravenous bolus because this can cause severe hypotension.⁶⁷

TABLE 56.2 Drugs for the Management of Immediate Postpartum Hemorrhage

Drug	Dose	Comments
Oxytocin ^a	20–40 units in 1 L of crystalloid initially infused at 200– 500 mL/hr and then titrate to sustain uterine contractions and control hemorrhage	Do not administer as an IV bolus. First-line therapy. If IV access is unavailable, may use 10 units IM.
Methylergonovine maleate or ergonovine maleate	0.2 mg IM	Avoid in patients with hypertensive disease, including preeclampsia
Carboprost tromethamine	0.25 mg IM Repeat q 15 min until uterine hemorrhage is controlled or a maximum dose of 2 mg	Concurrent use of antiemetics and antidiarrheals recommended to control side effects
Misoprostol	800–1000 µg PR	Single dose; can give PO. May cause tachycardia.

^aNote the increased concentration of oxytocin when used for the treatment of postpartum hemorrhage versus that given to stimulate uterine contractions after uncomplicated delivery.

IM, Intramuscularly; IV, intravenous; PO, orally; PR, per rectum; q, every.

If bleeding and poor uterine tone persist despite oxytocin therapy, consider additional therapy. Second-line therapy includes ergot derivatives such as methylergonovine or a prostaglandin. Give methylergonovine as a 0.2-mg dose intramuscularly every 2 to 4 hours, with uterine contractions occurring within 2 to 5 minutes of administration and lasting regularly for several hours.⁶⁸ Though not the route of choice, methylergonovine can also be given via the oral route. Because of their tendency to cause severe hypertension, avoid administering ergot preparations to women with hypertensive disease, including preeclampsia.^{68,69} Alternatively, give 15-methylprostaglandin F₂₀ (carboprost tromethamine) to stimulate uterine contractions.⁶⁸⁻⁷⁰ Administer carboprost at a dose of 0.25 mg intramuscularly, repeated at 15- to 90-minute intervals as determined by the clinical course, but not to exceed 2 mg.^{68,71} Misoprostol, a synthetic prostaglandin E₁ analogue, can also be given as an 800- to 1000- μ g rectal dose. Clinical trials using tranexamic acid in PPH are being conducted and show promise but evidence on efficacy is insufficient to recommend use at the present time.^{66,72}

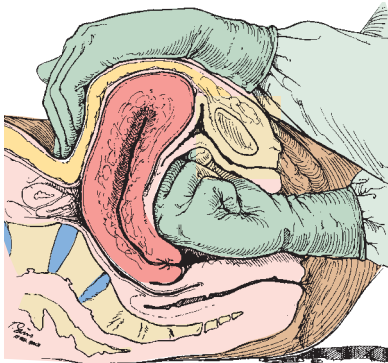

Figure 56.18 Use uterine massage to control postpartum bleeding. Insert one hand into the vagina to compress the anterior uterine wall while massaging the posterior aspect of the uterus through the abdominal wall with the other hand.

If bleeding continues despite these measures, consider uterine tamponade with sterile gauze packing, insertion of an intra-uterine balloon tamponade catheter (Bakri balloon [Cook Urological Inc., Spencer, IN] or BT-cath balloon tamponade catheter [Utah Medical Products, Inc., Midvale, UT]), or placing a Foley catheter into the atonic uterine cavity until surgical intervention or arterial embolization can be performed.^{68,73}

If vaginal bleeding persists despite a firmly contracted uterus, search for additional causes of bleeding. The lower genital tract should be inspected for lacerations. Control bleeding by direct pressure or by gentle application of ring forceps to bleeding cervical lacerations. Use absorbable suture to control bleeding from accessible lacerations. Adequate visualization of the upper part of the vagina and cervix can be difficult, and repair of lacerations may require general anesthesia and obstetric intervention regardless of the location. Genital tract hematomas may also be a significant cause of hemorrhage but are not generally recognized until several hours after delivery.⁵³ Also consider retained placental fragments and coagulopathy. Retained placental fragments may be removed by gentle manual extraction. Use one hand to follow the path of the umbilical cord and find the maternal placental plane and use the other hand to steady the uterine fundus through the maternal abdomen. The plane should feel velvety and irregular and should be gently dissected with side-to-side motion of the fingers until the placenta separates. This procedure is painful and associated with increased risk of infection, so analgesia and antibiotics should be administered.

Rarely, PPH is due to uterine inversion, with an estimated incidence of one in several thousand deliveries.⁷⁴ Consider uterine inversion especially when there is severe pelvic pain, absence of a palpable fundus, brisk excessive PPH, and maternal hemodynamic instability. Shock develops in up to 40% of patients.^{69,75-77} The diagnosis is made by visualization or palpation of the uterine fundus in the vaginal vault or protruding through the introitus. On abdominal examination, no mass representing the uterus may be palpated, or when palpated, the uterus may have a cuplike dimpling of the fundus.^{69,71,76,77} Treat with crystalloid intravenous fluids to maintain cardiovascular stability. Reposition the uterus immediately (Fig. 56.19). Conscious sedation and general anesthesia may be necessary.

Figure 56.19 Manual replacement of an inverted uterus. Uterine inversion should be suspected with the sudden onset of brisk vaginal bleeding in association with an absent palpable fundus abdominally and maternal hemodynamic instability. It may occur before or after placental detachment. The diagnosis is made clinically with bimanual examination, during which the uterine fundus is palpated in the lower uterine segment or within the vagina. Use sonography to confirm the diagnosis if the findings on clinical examination are unclear.

Use tocolytic agents such as terbutaline or $MgSO_4$ for uterine relaxation and repositioning, and stop all oxytocic drugs.^{3,68,69,77}

To reposition the uterus, insert one hand into the vagina with the tips of the fingers at the uterocervical junction and hold the uterine fundus firmly in the palm of the hand. Gently apply pressure to the uterine fundus in the direction of the umbilicus. Do not initially exert pressure centrally on the fundus because this will cause the uterus to become compressed and force more “layers” of the uterus to lie within the relatively tight cervical ring.⁷⁵⁻⁷⁷ General anesthesia and laparotomy may be necessary for uterine positioning.

PERIMORTEM CESAREAN SECTION

Cardiopulmonary arrest is a rare event during pregnancy with the exact incidence unknown. Perimortem cesarean section (PCS) or resuscitative hysterotomy is a surgical procedure with the potential to save a viable fetus and improve maternal circulation in cases of maternal cardiopulmonary arrest.⁷⁸ The time from when maternal circulation ceases to extraction of the neonate is the critical factor in determining maternal and fetal outcome. Delivery of the fetus increases maternal venous return and cardiac output by 25% to 30% and may lead to survival benefit for the mother.^{79,80} PCS should be considered in any woman who suffers a cardiac arrest after 24 weeks’ gestation (uterine size exceeding the level of the umbilicus) and initiated within 4 minutes of onset of maternal cardiac arrest and the absence of spontaneous circulation.^{80,81}

Evidence suggests the early initiation of PCS in cases of cardiac arrest may increase the restoration of hemodynamic status and likelihood of return of spontaneous circulation in the mother.^{82,83}

Indications

Although the lower limit of fetal viability varies among institutions, performance of PCS before approximately 24 weeks is not generally indicated. If the duration of gestation is not known from the history, estimate fetal maturity quickly by calculating gestational age on the basis of the date of the patient’s last normal menstrual period or by measuring the height of the uterine fundus. Between 18 and 30 weeks’ gestation, the age of the fetus in weeks will correspond to the distance in centimeters from the uterine fundus to the symphysis pubis (e.g., at 28 weeks’ gestation the fundus lies approximately 28 cm above the symphysis pubis or halfway between the umbilicus and the costal margin).⁸⁴

Survival of the infant is directly related to the time elapsed from maternal cardiac arrest to delivery, prompt performance of cardiopulmonary resuscitation (CPR) on the mother, the maturity of the fetus, pre-arrest health status of the mother, and in certain circumstances, the availability of neonatal intensive care facilities.⁸⁵⁻⁸⁷ In accordance with advanced cardiac life support guidelines, initiate CPR immediately on recognition of maternal arrest and continue it until the infant has been delivered. The anatomic and physiologic changes of pregnancy will inhibit the effectiveness of CPR on the mother. Aortocaval occlusion by the gravid uterus may occur after 20 weeks’ gestation. It can reduce venous return and compromise maternal cardiac output, especially in the supine position. CPR should be performed in the left lateral, head-down position or with an assistant manually displacing uterus away from the inferior

vena cava.⁸⁸ In addition, the decreased functional residual capacity of the lungs may impede ventilation efforts. Under these conditions, CPR generates only 30% to 40% of normal cardiac output, which severely compromises placental perfusion. The potential for infant survival decreases and the chance of neurologic damage increases as the time from maternal cardiac arrest to PCS rises. Neonatal outcome is best when PCS is performed within 4 minutes and poor if done after 20 minutes. Make every attempt to begin PCS within 4 minutes of cardiopulmonary arrest and complete the procedure within 5 minutes of arrest.^{84,87} Fetal prognosis is generally better in the later stages of pregnancy and after the sudden death of a previously healthy mother rather than death secondary to chronic illness.^{84,85} CPR should continue during and after the procedure. PCS in itself may represent the most important variable for successful maternal resuscitation.^{85,89} The decision to perform this procedure may be one of the most challenging that an EP will encounter. In the absence of immediate obstetric backup, it is reasonable to proceed with PCS within 4 minutes if initial maternal resuscitation efforts are unsuccessful. Prolonged attempts to resuscitate the mother are unlikely to benefit either the mother or the fetus.

Technique

The most experienced person present should perform the PCS, preferably an obstetrician. Under ideal circumstances a neonatologist should also be in attendance. Do not delay the procedure to allow time for arrival of consultants. Time should not be wasted searching for fetal heart tones or attempting to evaluate fetal viability with ultrasonography.

Extract the infant rapidly while avoiding fetal and maternal injury in the ED (Fig. 56.20). Hence, do not waste time preparing a sterile operating field or transporting the patient to an operating suite outside the ED. Use a large (e.g., No. 10) scalpel blade and make a midline vertical incision through the abdominal wall extending from the symphysis pubis to the umbilicus. Carry the incision through all abdominal layers into the peritoneal cavity. In most gravid women, the hyperpigmented “linea nigra” is apparent, and when present, use this as a guide for the incision. If available, place retractors in the abdominal wound and draw them laterally to expose the anterior surface of the uterus. Reflect the bladder inferiorly. If full, aspirate the bladder to evacuate it and permit better access to the uterus. While avoiding injury to fetal parts, make a small (≈5 cm) vertical incision through the uterus until amniotic fluid is obtained or the uterine cavity is clearly entered. Insert the index and long fingers into the incision and use them to lift the uterine wall away from the fetus. Use bandage scissors to extend the incision vertically to the fundus until a wide exposure is obtained. Gently deliver the infant, clamp and cut the cord, and evaluate and resuscitate the newborn as clinically indicated. Because the incision is relatively high in the uterus, the infant’s head may not be readily accessible to the clinician. In this case, grasp the infant’s feet and deliver the infant through maneuvers similar to those used for a breech delivery.

THE NEWBORN

Approximately 10% of newborns require some degree of assistance to begin breathing at birth (e.g., some sort of

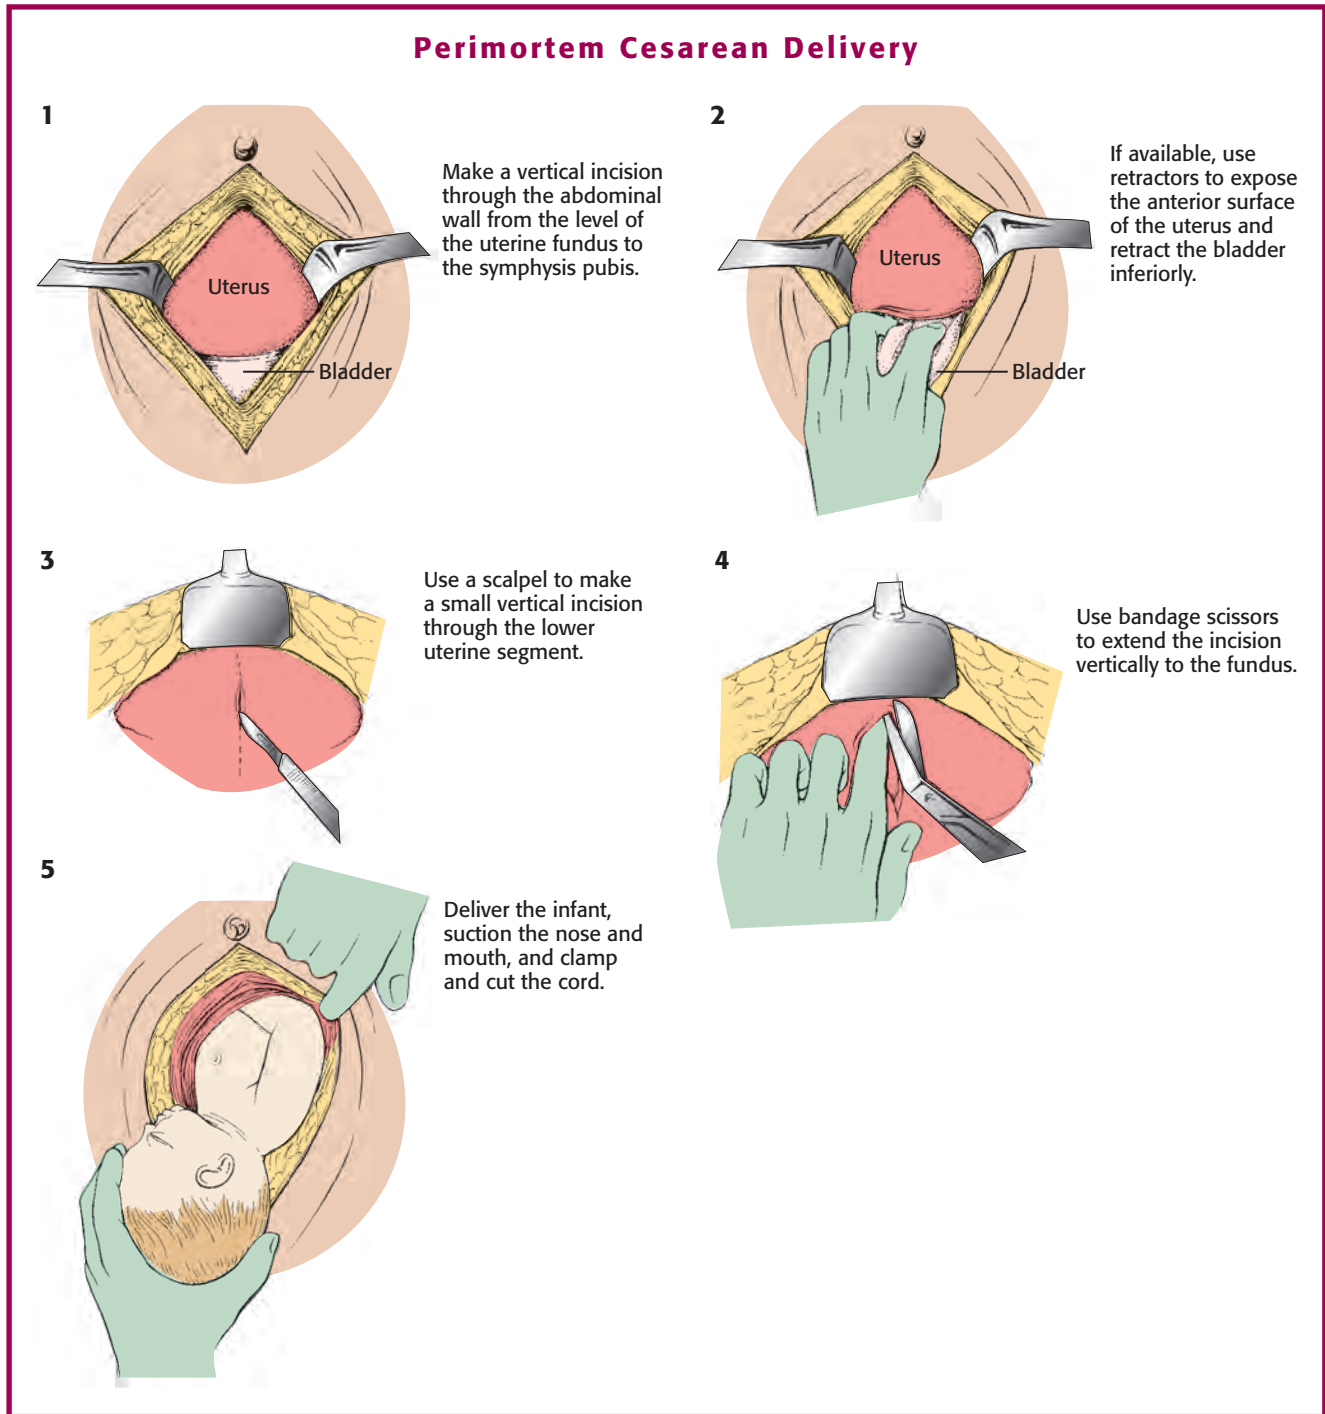

Figure 56.20 Perimortem cesarean delivery.

stimulation to breathe), but less than 1% require extensive resuscitation.⁴⁹ Evaluation of the newborn begins before delivery with assessment of maternal well-being and identification of risk factors for fetal distress: multiple pregnancies of less than 35 weeks, maternal infection or hypertension, oligohydramnios, preterm delivery at less than 36 weeks, breech presentation, meconium-stained amniotic fluid, non-reassuring fetal heart rate, emergency caesarean section, shoulder dystocia, and opiate use in normal labor.^{52,90}

Newborn resuscitation can be divided into four categories of action: (1) initial assessment and stabilization; (2) ventilation,

including bag-valve-mask (BVM) or bag-tube ventilation; (3) chest compressions; and (4) administration of medications or fluids. Although most newborns require no resuscitation or only basic steps such as warming, drying, and stimulation, others will require further intervention. The most crucial action of neonatal resuscitation is establishment of adequate ventilation.⁴⁹

Evaluation

Traditionally, the Apgar scoring system, applied at 1 and 5 minutes after birth, has been the standard of newborn evaluation

TABLE 56.3 Apgar Scoring System

Sign	0	1	2
Heart rate (beats/min)	Absent	Slow (< 100)	> 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Blue, pale	Body pink, extremities blue	Completely pink

(Table 56.3).^{3,52} In general, the higher the score, the better the condition of the infant. Waiting for the traditional 1-minute Apgar score to indicate the need for resuscitation has been replaced by the concept of “the golden minute.” Begin basic resuscitation maneuvers, reevaluation, and positive pressure ventilation (PPV), if required, by the first 60 seconds after birth. Use the heart rate and respiratory effort to guide resuscitation efforts because skin color does not reliably predict oxygenation status in the newborn period.⁴⁹

Respiration

Normally, the newborn begins to breathe and cry almost immediately after birth.³ After initial respiratory efforts, the newborn should be able to establish regular respirations sufficient to improve color and should be able to maintain a heart rate higher than 100 beats/min. Generally, drying and stimulation (rubbing the back or flicking the soles of the feet) are enough to induce effective respirations in the newborn.⁴⁹ Gasping and apnea after 30 seconds of stimulation are signs indicating the need for assisted ventilation and continuous pulse oximetry monitoring.^{49,52,91} It is important to note that even in healthy newborns, oxygen saturation does not reach extrauterine levels until 10 minutes after birth. Studies have demonstrated potential harmful effects from both excessive and insufficient supplemental oxygen versus room air during neonatal resuscitation. For term and preterm infants requiring ventilation, the current recommendation is to begin with room air and avoid the use of supplemental oxygen.⁴⁹ The application of supplemental oxygen should be guided by normal newborn oxygen saturation ranges (Table 56.4). Establishing adequate ventilation and oxygenation will restore vital signs in the vast majority of newborns.⁴⁹

Heart Rate

The heart rate may be determined by auscultation or palpation of the pulse at the base of the umbilical cord. If available, a three-lead ECG may be a more accurate and rapid measurement of neonatal heart rate during resuscitation.⁴⁹ The heart rate should consistently be greater than 100 beats/min in an uncompromised newborn. If after 30 seconds the heart rate is less than 100 beats/min, initiate PPV. If the heart rate is less than 60 beats/min despite adequate ventilation and oxy-

TABLE 56.4 Targeted Preductal SpO₂ After Birth

1 min	60%–65%
2 min	65%–70%
3 min	70%–75%
4 min	75%–80%
5 min	80%–85%
10 min	85%–95%

Note that oxygen administration to the newborn *is not recommended* after a routine delivery, even when there is early cyanosis. Excessive oxygenation may be toxic. For term and preterm infants requiring ventilation, the current recommendation is to begin with room air and avoid the use of supplemental oxygen. It is important to note that even in healthy newborns, oxygen saturation does not normally reach extrauterine levels until 10 minutes after birth. From Kattwinkel J, Perlman JM, Aziz K, et al: Neonatal resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, *Pediatrics* 126:e1400–e1413, 2010.

genation for 30 seconds, commence chest compressions. Because chest compressions may diminish the effectiveness of ventilation, do not initiate them until lung inflation and ventilation have been established.^{49,92}

Color

An uncompromised newborn will be able to maintain a pink color of the mucous membranes without supplemental oxygenation. Central cyanosis is determined by examining the face, trunk, and mucous membranes, but it is not a reliable method of determining oxygen saturation in the immediate neonatal period. Acrocyanosis is usually a normal finding in the newborn and not a reliable indicator of hypoxemia. It may, however, indicate other conditions such as cold stress.^{49,52,93}

Stabilization Technique

Following delivery of the infant and cutting the umbilical cord, place the newborn on the side in the sniffing position with the neck in a neutral or slightly extended position.^{49,52} Place a rolled blanket or towel under the back and shoulders of the supine infant to elevate the torso 2 to 2.5 cm because this may help maintain head position.⁵² Prevent heat loss in the newborn because cold stress can increase oxygen consumption and impede effective resuscitation.⁵² Avoid hyperthermia, however, because it is associated with perinatal respiratory depression.^{49,52} Place the infant under a radiant warmer, rapidly dry the skin, and wrap the infant in warmed blankets to reduce heat loss.^{49,52} Alternatively, use the mother’s body as a heat source for the newborn. If initial evaluation indicates that the infant is stable, dry and place the infant skin to skin on the mother’s chest or abdomen, and cover both with blankets.^{49,52}

Vigorous newborns should not be routinely suctioned after delivery, even those delivered through meconium-stained fluid.^{49,52,92,93} Reserve suctioning (including suctioning with a bulb syringe) immediately after birth for babies who exhibit obvious obstruction to spontaneous breathing or require PPV. Endotracheal intubation and suctioning is no longer recommended for nonvigorous babies born through meconium-stained amniotic fluid.⁴⁹ If airway obstruction necessitates suctioning, first clear secretions from the mouth and nose with a bulb

TABLE 56.5 Medications Commonly Used in Neonatal Resuscitation

Drug	Dose	Indications	Comments
Epinephrine ^a	0.01–0.03 mg/kg (0.1–0.3 mL/kg of a 1:10,000 solution)	Bradycardia, asystole	May be repeated every 3–5 min as indicated
			High-dose epinephrine in newborns is contraindicated
Volume expanders (normal saline or Ringer's solution)	10 mL/kg IV over 5–10 min	Suspected hypovolemia, shock, or blood loss	May be repeated after determination of clinical response
Bicarbonate	1–2 mEq/kg of a 0.5-mEq/mL solution given over at least 2 min	Prolonged arrests unresponsive to other therapy	Not indicated during brief periods of CPR Should be used only after adequate ventilation and perfusion are established

^aThe intravenous route is now strongly preferred, but one can consider administering epinephrine via an endotracheal tube in doses of 0.05 to 0.1 mg/kg while obtaining intravenous access.

CPR, Cardiopulmonary resuscitation.

From Kattwinkel J, Perlman JM, Aziz K, et al: Neonatal resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, *Pediatrics* 126(5):e1400–e1413, 2010; and Pediatric Working Group of the International Liaison Committee on Resuscitation. Neonatal resuscitation, *Circulation* 102:343, 2010.

syringe or suction catheter (8- or 10-Fr). Aggressive pharyngeal suctioning can cause laryngeal spasm and vagal bradycardia, so limit the depth and duration of suctioning and do not exceed a negative pressure of 100 mm Hg.^{49,52}

For newborns who do not quickly respond to conservative measures, PPV is indicated within 1 minute of birth. Most newborns who require PPV can be adequately ventilated with a bag and mask. Perform assisted ventilations at a rate of 40 to 60 breaths/min (30 breaths/min if mechanical compressions are being performed). As of the 2015 AHA guidelines, higher inflation pressures and longer inflation times for the first several breaths are not recommended due to insufficient data.⁴⁹ Visible chest expansion is a more reliable indicator of appropriate inflation pressure than a specific manometer reading.^{49,52} Heart rate measurement can be used to assess adequacy of ventilation after 60 seconds of visible chest rise with PPV.⁹³ Because BVM ventilation can produce gastric distention and impede respiration, insert an orogastric tube (8-Fr) in infants undergoing prolonged PPV.⁵²

Endotracheal intubation may be indicated when BVM ventilation is ineffective, when the airway is obstructed, when chest compressions are performed, or when prolonged PPV is required.^{49,91} Alternatively, a neonatal laryngeal mask airway may provide effective airway management, especially in the case of ineffective BVM ventilation or failed endotracheal intubation.⁴⁹

Monitor the heart rate during neonatal evaluation and stabilization by either direct auscultation over the chest, palpation of the pulse at the base of the umbilical cord, or a three-lead ECG. A readily discernible heartbeat of 100 beats/min or greater is acceptable. If the heart rate is less than 60 beats/min despite adequate ventilation and oxygenation for 30 seconds, institute chest compressions while continuing to ventilate.⁴⁹ Deliver chest compressions on the lower third of the sternum and not over the xiphoid to avoid damage to the liver.^{49,91}

There are two techniques for performing chest compressions in the newborn. In the preferred method, position two thumbs side by side over the lower third of the sternum just below the nipple line. If the infant is large or the resuscitator's hands are too small to encircle the chest, use two-finger compressions with the ring and middle fingers.^{49,91} Compress to a depth that is approximately one third of the AP diameter of the newborn's chest so that a palpable pulse is generated.⁴⁹ Coordinate compressions and ventilations to avoid simultaneous delivery, which may compromise the efficacy of ventilation. Use a compression-to-ventilation ratio of 3:1 with 90 compressions and 30 breaths to achieve approximately 120 events/min.⁴⁹ If the heart rate remains less than 60 beats/min despite these interventions,⁴⁹ establish an umbilical or intravenous line and initiate appropriate drug therapy. Alternatively, use intraosseous access, but this may not be as effective in a preterm infant.⁵² The medications most commonly used during neonatal resuscitation are listed in [Table 56.5](#).^{49,52}

Gynecologic Procedures

G. Richard Braen and John Kiel

PELVIC EXAMINATION

In an emergency department (ED) there are several reasons to perform a pelvic examination: lower abdominal pain, vaginal discharge, vaginal bleeding, suspected sexually transmitted disease (STD), retained foreign body, and possible Bartholin abscess (BA) of the vulva. Emergency physicians do not routinely screen for cervical cancer. The evaluation of sexual assault victims is discussed in [Chapter 58](#).

Before performing a pelvic examination, the examiner must have a basic understanding of female pelvic anatomy ([Fig. 57.1](#)). The vulva is made up of the labia majora, labia minora, clitoris, hymen, and vulvar vestibule. The labia majora extend from the mons veneris anteriorly to the perineal body and are filled with fatty tissue that varies in thickness with age – proportionately thicker in children and thinner as a woman passes through menopause. The labia minora are generally covered completely by the labia majora and are more delicate, pink, and hairless. Anteriorly the labia minora form a hood for the clitoris and posteriorly join with the labia majora to form the fourchette. The urethral meatus is just posterior to the clitoris. The hymen separates the external genitalia from the vagina and may be obscured by the labia. There are two Bartholin

glands which lie below the fascia, one on each side of the lower, posterior third of the vagina. These glands secrete lubrication through ducts located at the lower pole of the labia minora. Normal Bartholin glands are rarely palpable. Healthy vaginal mucosa is reddish pink, but during pregnancy may become dusky, almost cyanotic-appearing. The cervix faces posteriorly (80%) but may face anteriorly (20%). The non-parous cervical diameter is 2 to 3 cm with a length of 2 to 4 cm. The cervix is normally pink. The cervical os changes with vaginal delivery from being smooth and circular to being fissured, oval, and slightly irregular.

Preparation for a Pelvic Examination

Before beginning an internal pelvic examination assemble the appropriate equipment. This equipment includes: a stretcher with stirrups or knee holders, various sizes of vaginal speculums, gloves, surgical lubricant, appropriate lighting, swabs, ring forceps or a Kelly clamp for the removal of foreign bodies or products of conception, transport medium for chlamydia and gonorrhea testing, pH paper, slides, coverslips, “eye dropper” bottles of 10% potassium hydroxide (KOH), and normal saline for testing vaginal discharge ([Fig. 57.2](#)). Speculums may be plastic and disposable, or may be metal (warmed to body temperature before insertion), but must be sized to the patient; a pediatric speculum for women with a narrow introitus (elderly women and young adolescents), a Smith-Pederson speculum for virginal women, a standard speculum for most, and a Graves speculum for obese women and multiparous women. Note that if stirrups or leg supports are not available, the patient can have a padded bedpan under her buttocks with the bottoms of her feet together and her knees separated. When examination in a lithotomy position is not possible, an examination may be performed with the patient in a knee-chest position.

Culdocentesis

Indications

Diagnosis of acute pelvic conditions when ultrasound is not available or clinically feasible, including:

- Ruptured viscus (ectopic pregnancy or corpus luteum cyst)
- Pelvic inflammatory disease
- Other intraabdominal infections
- Splenic or liver injuries
- Ruptured aortic aneurysm

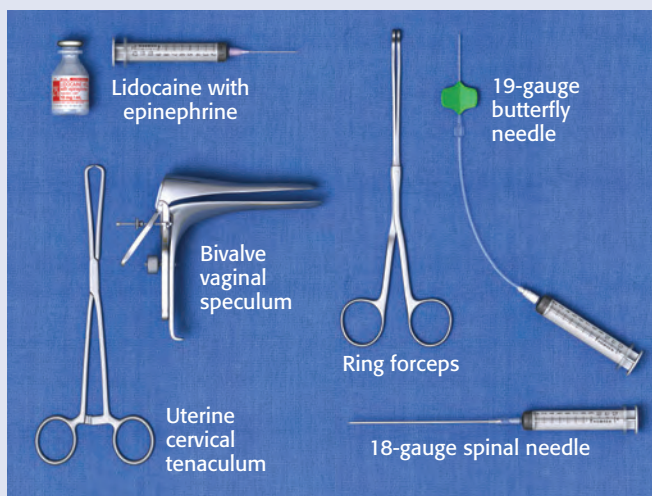

Contraindications

- Uncooperative patient
- Pelvic mass detected on bimanual examination
- Nonmobile retroverted uterus
- Coagulopathies

Complications

- Rupture of unsuspected tuboovarian abscess
- Bowel perforation
- Pelvic kidney perforation
- Bleeding

Equipment

Review Box 57.1 Culdocentesis: indications, contraindications, complications, and equipment. Not shown is optional prepuncture topical anesthetic, such as a topical anesthetic-soaked cotton ball.

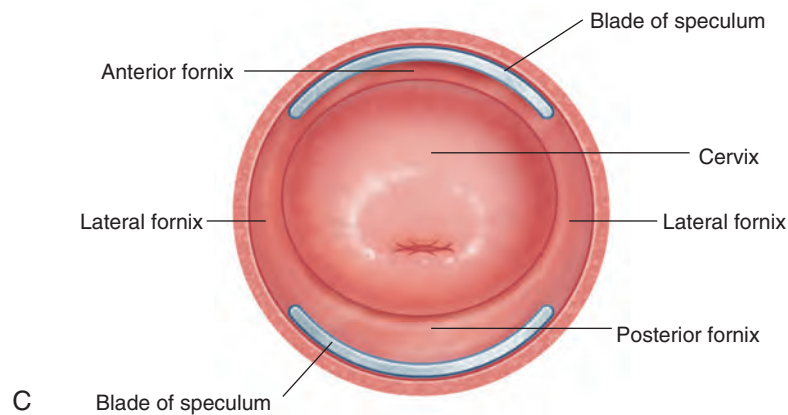

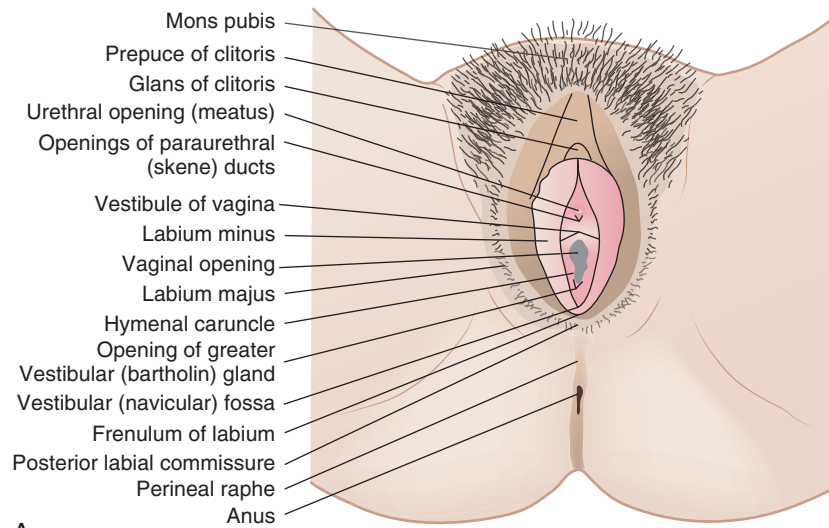

Figure 57.1 Anatomy of the female external genitalia, vagina, and rectouterine pouch (pouch of Douglas). **A**, Female external genitalia. **B**, Cross sectional view of female genitalia demonstrating the rectouterine pouch (Douglas’ pouch). **C**, Anatomy of cervix and posterior fornix as seen through speculum. (Modified from Drake RL: *Gray’s anatomy for students*, ed 2, Philadelphia, 2010, Elsevier, Fig. 5.56.)

Figure 57.2 Equipment for routine gynecologic examination. *A*, Light source; *B*, speculum; *C*, water-soluble lubricant; *D*, transport media for chlamydia and gonorrhea testing; *E*, glass slide and cover slip; *F*, pH paper; *G*, ring forceps; *H*, swabs.

A pelvic examination should be done with the patient in a lithotomy position. She should be gowned and should have an empty bladder. Privacy should be assured and the patient should be fully informed by the examiner. Chaperones are commonly used during the examination. The examiner should glove and should touch the patient, reassuring her prior to each phase of the pelvic examination.

Performance of the Pelvic Examination

The vulva is examined visually for any lesions, and then by palpation. Women with a BA have acute, painful swelling of the posterior vulva that usually has developed over 2 to 3 days, making it difficult for them to sit or walk. The abscess appears erythematous, swollen, and forms a tender, spherical (3 to 4 cm in diameter) mass just lateral to the posterior fourchette. A Bartholin cyst is usually not tender and there is no associated erythema or swelling, differentiating it from an abscess. The treatment of a BA is similar to other abscesses in that incision and drainage is often required.

After examination of the vulva, separate the labia majora to expose the introitus and look for lesions, discharge, or blood. Next, insert a speculum with good lighting. If cervical cancer screening is anticipated, lubricate the speculum with water only. Otherwise, use surgical lubricant. Spread the labia, insert the speculum to its full length, and open the speculum. If the cervix is not seen, withdraw the speculum and palpate the location of the cervix with one finger, remove the finger, and follow with a second redirected speculum insertion. Inspect the cervix for blood, discharge and any lesions, particularly at the squamocolumnar junction (where the red columnar tissue of the endocervix changes to the reddish-pink squamous epithelium of the vagina). If there is a white lesion at the squamocolumnar junction that does not wipe off with a swab, consider dysplasia, carcinoma in situ, or condyloma accuminatum. Collect samples for STD and vaginitis prior to withdrawal of the speculum (see later section on [Vaginal Discharge and Suspected STD Sampling](#)). Additionally, remove any foreign body or material found (see later section on [Vaginal Foreign Body Removal](#)). Withdraw the speculum slowly while inspecting

the walls of the vagina. Close the speculum just prior to exiting the introitus.

A bimanual examination of a woman with a small vagina can be accomplished with one gloved, lubricated index finger. Two fingers can be used when the introitus is larger. Gently place your opposite hand on the patient's abdomen. After palpating the labia majora, separate them, and inspect the introitus. Insert the fingers to locate the cervix. When using two fingers, place one on each side of the cervix. Pain with side to side cervical motion may indicate pelvic inflammatory disease (PID). Using the hand on the abdomen and the intravaginal fingers, evaluate the size and shape of the uterus. An asymmetric uterus may be an indication of a fibroid tumor. After moving both fingers to one side of the cervix, palpate the adnexa of that side between the intravaginal fingers and the abdominal hand. Gently palpate the pelvic adnexa since firm palpation of normal organs may cause pain and can be misleading to the examiner. If an adnexal mass is found, try to estimate a 3-D size in centimeters along with the degree of firmness, the degree of fixation to adjoining organs, and the degree of tenderness. Masses that can be detected with the bimanual examination include pedunculated fibroids, paraovarian cysts, tuboovarian abscesses (TOAs), and ectopic pregnancies.

Many examiners follow the bimanual examination with a rectal examination looking for firmness or nodules between the uterus and rectum, suggestive of tumors or uterosacral ligamentous endometriosis. Rectal material should be guaiac tested for blood, which may be falsely positive for gastrointestinal bleeding if blood is present in the vagina.

Bartholin Abscess (BA)

As stated previously, the BA is an acute painful swelling located in the posterior part of the vaginal introitus ([Fig. 57.3](#)). The inflammatory swelling can be small or quite large and painful. BA occurs in about 2% of women, usually in the reproductive years.¹ The pathogenesis of the abscess is unclear, but is thought to be the result of a blocked or partially obstructed Bartholin duct leading to accumulation of material with subsequent infection. As with any abscess, the evaluation must include consideration of the patient's comorbidities and willingness to consent for the procedure.

In most cases, a BA can be treated in the ED, but close follow-up with gynecology is needed. These abscesses can recur and the gynecologist may elect to do a marsupialization of the area which reduces the recurrence rate. If the abscess is very large, if the diagnosis is uncertain, or if there are other masses, significant cellulitis, or significantly distorted tissue, involvement of the gynecologist is warranted. In addition, if the patient has significant comorbidities, has unstable vital signs, has a bleeding dyscrasia, or is immunocompromised, the patient should be seen by the consulting gynecologist to manage the abscess.

Incision and Drainage ([Fig. 57.4](#))

Incision and drainage of a BA can be painful and anxiety-provoking for many patients.

It is an invasive procedure that requires a written, witnessed, and signed consent form from the patient, parent, or guardian and should be witnessed with a notation made in the medical record documenting that the procedure was described, complications were discussed, and any alternatives such as antibiotics or warm compresses were offered when appropriate.

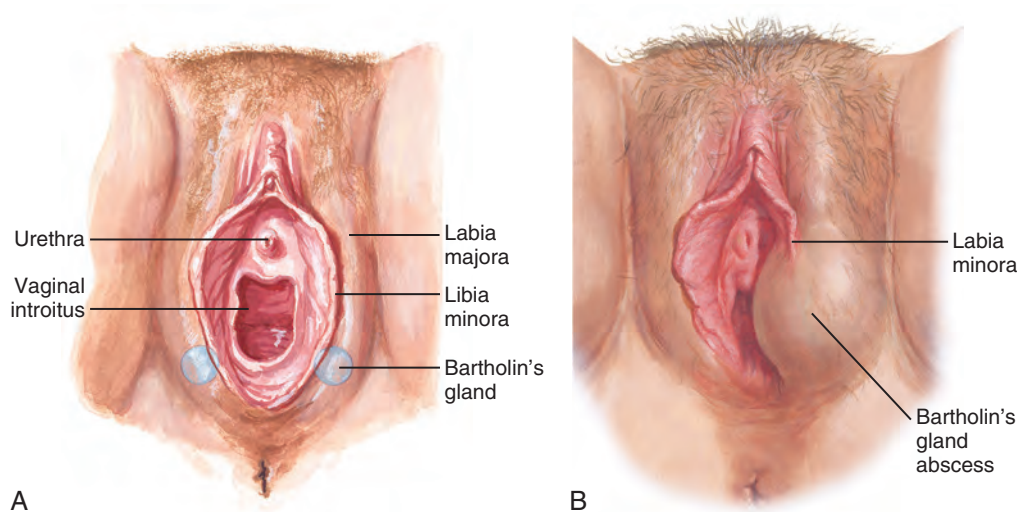

Figure 57.3 Bartholin gland and abscess. **A**, Anatomy of the female external genitalia. Note the location of Bartholin glands at 5 and 7 o'clock. **B**, Bartholin gland duct cysts and abscesses are recognized by the presence of a fluctuant mass of variable size within the posterior vestibule, with the labia minora transecting the cyst. (Netter illustration from www.netterimages.com. © Elsevier Inc. All rights reserved.)

Once written consent is obtained, place the patient in the lithotomy position. Place the patient's feet in stirrups. Generously premedicate with intravenous opioids, or sedatives when appropriate. Administration of nitrous oxide analgesia is also an accepted practice. Procedural sedation with propofol, etomidate, or benzodiazepines can be considered, especially for those patients who are extremely uncomfortable.

1. Use universal precautions with gown, gloves, and mask. The contents of the abscess may be under pressure and can spray when incised.
2. Clean the affected area in the usual sterile way.
3. Apply topical analgesia to the mucosal surface of the introitus where the swelling is most evident. Note that the abscess incision is made on the mucosal, not on the skin surface. Applying viscous lidocaine to this area for 10 minutes can help reduce discomfort.
4. Administer a local anesthetic using a 25- or 27-gauge needle and 2% lidocaine. Note that the abscess contents may be under pressure and may leak during this step.
5. Approach the abscess from the vaginal introitus and, using an 11-blade scalpel, make a 5-mm stab incision *through the mucosal surface, not the skin*, to evacuate the contents of the abscess. If the abscess is larger, the incision can be lengthened to the diameter of the abscess, but in most cases 5 mm is sufficient (Fig. 57.5).
6. After irrigating and cleaning the area, the wound can be packed or left open. Iodoform strips can be used to pack the wound. Do not pack the wound too tightly and leave just enough material to fill the base of the wound with a small tail (0.5 to 1 cm) extending from the cavity.
7. Some authors recommend inserting a small balloon catheter into the wound rather than packing. The Word catheter (Cook Medical Inc., Bloomington, IN) is often recommended (Fig. 57.6). Insert the Word catheter cautiously and fill it with 3 mL of saline. Be careful not to fill it too much because the resulting pressure in the abscess cavity can be uncomfortable. This should be sufficient to hold

the catheter in place. On rare occasions, it is necessary to suture the catheter in place. The Word catheter is usually left in place for 2 to 4 weeks.

8. Close follow-up with gynecology is recommended for a repeat examination and evaluation within the next 3 days.
9. Antibiotics are usually not necessary unless there is fever, significant cellulitis, multiple comorbidities, or the patient is immunocompromised in any way. If these conditions are present, the patient may need observation and gynecology consultation prior to performing the procedure.
10. Counsel the patient that the Word catheter is usually left in place for up to 4 weeks, but close gynecology follow-up and monitoring is needed throughout that time.
11. If the patient is well enough to be discharged, prescribe analgesics, including nonsteroidal antiinflammatory medications. Advise patients that they can resume most of their normal activities pending repeat follow-up evaluation by gynecology.

COMMON CAUSES OF VAGINAL BLEEDING IN ADULT WOMEN

Common causes of vaginal bleeding in adult women include menstruation, oral contraceptive use, anovulatory cycles, spontaneous abortion, ectopic pregnancy, intrauterine contraceptive devices, persistent corpus luteum, gynecologic malignancy, vaginal or cervical injury, vaginal foreign bodies, gestational trophoblastic diseases, placenta abruptio, placenta previa, vasa previa, and uterine rupture. A good history along with beta human chorionic gonadotropin (β -hCG) testing and ultrasound (US) help differentiate among some of these, but pelvic examination should be considered for most of these potential conditions, except, most notably, placenta previa, where it can cause catastrophic hemorrhage. In general, avoid a pelvic examination in late third trimester bleeding.

Bartholin Abscess Drainage (Word Catheter)

Place the patient in the dorsal lithotomy position and identify the abscess, which will be located at either the 5- or 7-o'clock position, with the labia minora transecting the abscess.

Cleanse the area with antiseptic solution. While stabilizing the abscess with your thumb and index finger, inject local anesthetic through the mucosal surface (not through the skin).

Use a No. 11 scalpel blade to make an incision in the mucosal surface of the abscess. Make the incision large enough to accommodate the catheter, but small enough to prevent extrusion of the inflated balloon.

Alternatively, a hemostat can be used to puncture the abscess cavity. Stabilize the abscess with your thumb and index finger and skewer the abscess onto the hemostat (see Fig. 37.21).

Once the abscess has been entered (heralded by a palpable pop or the free flow of pus), insert the Word catheter to the hilt and inflate with 3 to 4 mL of saline. Use a 25-gauge needle to fill the balloon.

The catheter is left in place for 2 to 4 weeks to form a fistula. Antibiotics are of no proven value once drainage is performed, but practice varies.

Figure 57.4 Drainage of a Bartholin abscess (Word catheter [Cook Medical Inc., Bloomington, IN] method.) Note that the mucosal surface, not the skin, is the site of abscess drainage.

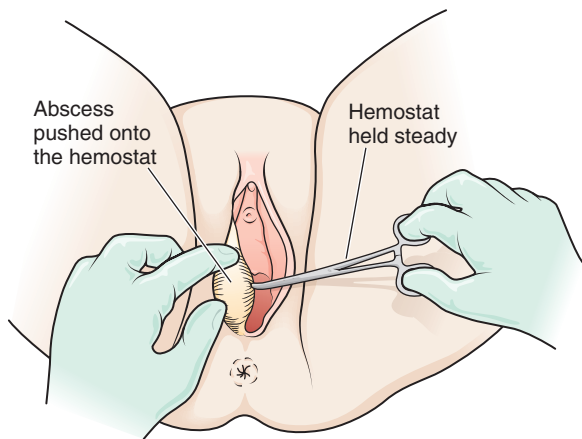

Figure 57.5 It is technically easier to enter the Bartholin gland abscess cavity if the hemostat is held steady and the mucosal surface of the abscess, held with the thumb and index finger, is skewered onto the hemostat. Attempting to puncture a deep immobilized abscess by stabbing with the hemostat may be more difficult. Expect a palpable pop or drainage of frank pus when entering the abscess. Note that the mucosal surface, not the skin, is the site of abscess drainage.

Early Pregnancy Bleeding

One fifth of pregnant women have vaginal bleeding during the first half of pregnancy, and 2% of women have an ectopic pregnancy, with the potential of hemorrhagic shock and maternal death. Evaluation of ectopic pregnancy is discussed in the later section on [Culdocentesis](#).

One of the most common reasons to perform a speculum examination in early pregnancy bleeding is to evaluate a possible miscarriage, looking for cervical dilatation or the presence of products of conception. Some emergency physicians simply palpate the os intravaginally to determine the status of cervical dilatation and feel that speculum examination adds little to either the diagnosis or the plan of treatment, with the exception of early pregnancy bleeding associated with shock where the removal of obstructing products of conception is a resuscitative measure. Ultrasonography and β -hCG levels generally give the information needed to manage a patient with early pregnancy bleeding, and some practitioners feel that vaginal examination does not improve the accuracy of the diagnosis.^{2,3}

Pelvic and Lower Abdominal Pain

Pelvic examination, particularly bimanual examination, is often performed for pelvic and lower abdominal pain. The pain can be caused by problems in the urinary tract, intestinal tract and the reproductive tract (in both pregnant and nonpregnant patients). Urinary tract conditions include ureteral colic, cystitis and pyelonephritis. Intestinal tract conditions include appendicitis, diverticulitis, inflammatory bowel disease, bowel obstruction or ischemia, and a perforated viscus. Reproductive tract conditions include ectopic pregnancy, threatened abortion, endometritis, endometriosis, corpus luteal cyst, salpingitis (PID and TOA), ovarian cyst, ovarian torsion, round ligament pain, uterine fibroids, and uterine perforation. Later in pregnancy three conditions of importance are ectopic pregnancy, placenta previa (which is most often painless), and placenta abruption, all of which are suggested by vaginal bleeding. Conditions

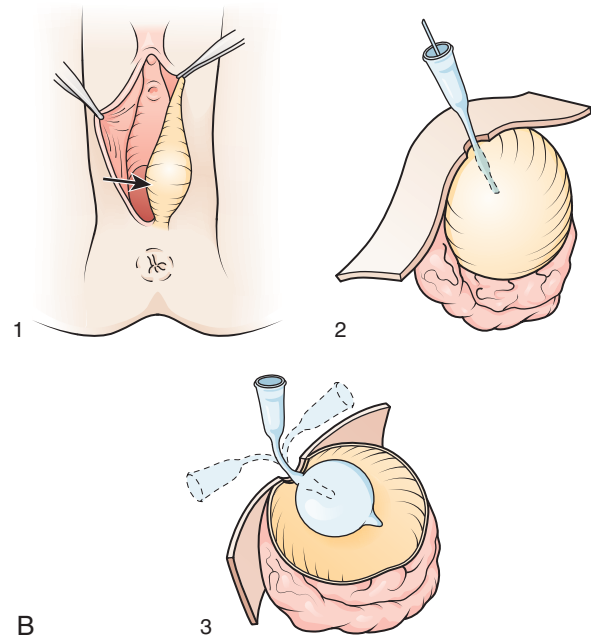

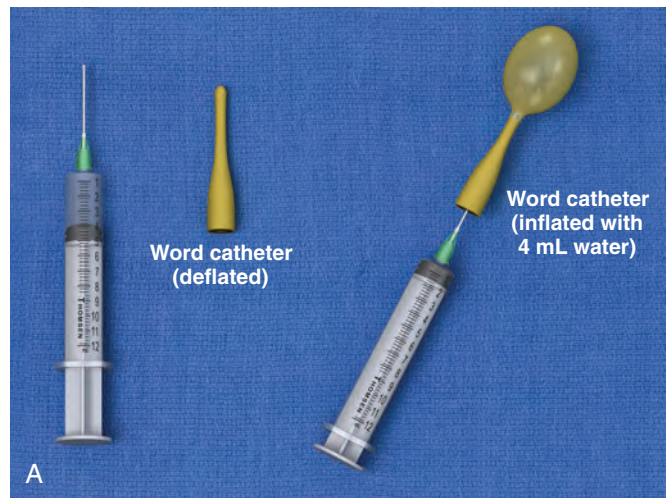

Figure 57.6 Word catheter (Cook Medical Inc., Bloomington, IN). **A**, Inflatable bulb-tipped catheter. *Left*, uninflated; *right*, inflated with 4 mL water. **B**, Use of the Word catheter for outpatient drainage of a Bartholin gland abscess. This is a fistulization procedure rather than standard incision and drainage. *1*, A stab incision is made on the mucosal surface. *2*, The catheter is inserted into the cyst cavity. *3*, The catheter is filled with 3 to 4 mL of water. The Word catheter is left in place for 2 to 4 weeks. (**B**, From Word B: Office treatment of cyst and abscess of Bartholin gland, *JAMA* 190:777, 1964.)

that may cause pain in the nonpregnant patient include salpingitis (PID), TOA, ovarian cyst, ovarian torsion, endometriosis, round ligament pain, uterine perforation, or uterine fibroids. Painless third trimester bleeding may be caused by placenta previa, in which a separated placenta is near or at the cervical os. Because manipulation of the uterus may further dislodge the placenta, defer rectal examination, speculum examination, and manual examination of the vagina to an obstetric professional. PID and TOA are often associated with vaginal discharge and fever. Endometriosis is often associated with dyspareunia and dysmenorrhea.

Vaginal Foreign Body Removal

Retained vaginal foreign bodies can cause pain or bleeding and may lead to a foul-smelling vaginitis. Common vaginal foreign bodies in adults include retained tampons, broken parts of condoms, pessaries, contraceptive diaphragms, drug smuggling devices, and sexual stimulation devices. Women with psychiatric illness sometimes insert vaginal foreign bodies (vaginal polyembolokoilamania). The removal of these foreign bodies, once located, may be accomplished using a speculum and ring forceps, or a Kelly clamp. Imbedded foreign bodies may require removal in an operating room. Once the foreign body is removed, the vaginal walls should be inspected for lacerations and infection. Bleeding vaginal lacerations can be tamponaded with surgical dressing prior to repair. Deep lacerations may require operative repair by a gynecologist.

It is not uncommon for a tampon to be lodged in a horizontal position in the upper vagina, commonly following intercourse. There is frequently a foul odor. The tampon can be removed by trapping it between two gloved examining fingers. Withdraw the tampon while inverting the examining glove with the tampon inside, placing the encased tampon in the palm of the opposite glove and then inverting the second glove over the first, followed by disposal.

Vaginal Discharge and Suspected STD Sampling

History and physical exam are critical for diagnosing infectious pathology of the external genitalia, vagina, cervix, or reproductive tract. However, given the often nonspecific symptoms, laboratory evaluation is mandatory to target appropriate therapy. Diagnostic options include Gram stain, culture, nucleic acid amplification tests (NAATs), and antigen-detecting immunochromatography. Culturing is done to assess the effectiveness of antibiotics on targeted bacteria, particularly when there has been treatment failure. According to the Centers for Disease Control and Prevention, “the performance of NAATs with respect to overall sensitivity, specificity, and ease of specimen transport is better than that of any of the other tests available for the diagnosis of chlamydial and gonococcal infections.”⁴

Bacterial Vaginosis (BV) and Candidiasis. The vaginal discharge of BV is homogeneous, thin, and white and when obtained from a speculum examination, can aid in diagnosis. pH paper applied to the vaginal fluid can suggest BV when the pH is over 4.5. This pH is elevated because of a lack of the normal acid-producing lactobacillus predominance in the vagina. Vaginal fluid generally has a pH below 4.5 and is usually in the 3.8 to 4.2 range. Conversely, mucus from the cervix generally has a pH that is in the 7.0 range and care must be taken not to sample cervical mucus when testing vaginal fluid for vaginitis. Make a wet mount of a very small smear of vaginal fluid. Take the fluid with a cotton swab and apply it to a glass slide. Mix it with a drop of 10% KOH and cover it with a coverslip. The fluid may have a fishy, amine smell (the “whiff” test). When examined microscopically (40 to 100 × power), the slide may reveal clue cells (vaginal epithelial cells studded with adherent coccobacilli that look somewhat like sugar cookies covered with poppy seeds).⁵

The vaginal discharge of moniliasis (candidiasis) is “cheesy” and is associated with severe itching and burning of the

perineum. A mixture of vaginal fluid with KOH should lyse many bacteria allowing the examiner to identify budding yeast cells, thereby helping with the diagnosis of monilial vaginitis (candidiasis).

Trichomoniasis. A wet mount of a tiny drop of vaginal fluid and a drop of normal saline, covered with a coverslip and examined microscopically, can aid in the diagnosis of trichomoniasis but such examination has poor sensitivity (51% to 65%).⁶ Trichomonads are about the size of white blood cells but are characterized by a rapid, flagella-caused movement.

The use of NAATs are highly sensitive and detect three to five times more *T. vaginalis* infections than wet-mount microscopy.⁵ There is also an antigen-detection test using immunochromatographic capillary flow dipstick technology (OSOM Trichomonas Rapid Test [Sekisui Diagnostics, Lexington, MA]) that can be performed at the point of care. The OSOM Trichomonas test is rapidly available and has a sensitivity of 82% to 95% with a specificity of 97% to 100%.⁷

Cervicitis and PID. For women with a purulent cervical discharge, the diagnosis of cervicitis or PID should be considered. The cervix should be visualized during the speculum exam, assessing for mucopurulent discharge from the os. Appropriate transport culture medium should be available and a cervical swab should be obtained, placed in the medium, and sent to a bacteriologic laboratory.

Chlamydia and Gonorrhea. NAATs are the diagnostic tests of choice, when available, for both chlamydia and gonorrhea.⁴ The difference between urine, cervical, and vaginal specimen tests is not statistically significant.⁸ The sensitivity of a Gram stain of endocervical discharge for the diagnosis of chlamydia or gonorrhea is low compared to culture or NAATs and is not recommended.

CULDOCENTESIS

Culdocentesis is a procedure in which peritoneal fluid is aspirated from the retrouterine pouch by the insertion of a hollow needle through the posterior fornix of the vagina. Historically, this technique was used to diagnose ruptured ectopic pregnancies and ruptured ovarian cysts, and, rarely, to obtain cultures for diagnosis and treatment of PID. Widespread utilization of transvaginal US and β -hCG have largely replaced the use of culdocentesis. Nevertheless, culdocentesis has clinical utility to diagnose ruptured ectopic pregnancy in a patient for whom sonography is not readily available.⁹

Anatomy for Performing a Culdocentesis

Before attempting culdocentesis, the clinician must be familiar with the anatomy of the vagina and the rectouterine pouch (pouch of Douglas) (see Fig. 57.1). In adult women, the vagina is approximately 9 cm long. From its inferior to its superior aspect, the posterior wall of the vagina is related to the anal canal by way of the perineal body, the rectum, and the peritoneum of the rectouterine pouch.¹⁰ The uterus lies at nearly a right angle to the vagina. The rectouterine pouch and the posterior wall of the vagina are adjacent only at the upper quarter (\approx 2 cm) of the posterior vaginal wall. The vaginal wall in this area is less than 5 mm thick.

The blood supply to the upper part of the vagina comes from the uterine and vaginal arteries, which are branches of the internal iliac artery. This area is drained by a vaginal venous plexus that communicates with the uterine plexuses. The vagina has its greatest sensation near the introitus and little sensation in the area adjacent to the rectouterine pouch.

The rectouterine pouch is formed by reflections of the peritoneum, and it is the most dependent intraperitoneal space in both the upright and the supine positions. Blood, pus, and other free fluids in the peritoneal cavity pool in the pouch because of its dependent location. This pouch separates the upper portion of the rectum from the uterus and the upper part of the vagina. The pouch often contains small intestine and, normally, a small amount of peritoneal fluid.

Indications

Culdocentesis is indicated in any adult woman in whom aspiration of fluid from the rectouterine pouch will help confirm the clinical diagnosis. If US examination is not readily available in the ED or if the patient is too hemodynamically unstable to be transported to an off-site location for US, culdocentesis may be the fastest and most accurate diagnostic technique available to the emergency clinician.¹¹ Analysis of peritoneal fluid is also an acceptable method of differentiating inflammatory from hemorrhagic pelvic pathologic conditions. Conditions in which culdocentesis may be of diagnostic value include a

ruptured viscus (particularly an ectopic pregnancy or a corpus luteum cyst), PID and other intraabdominal infections (particularly appendicitis with rupture or diverticulitis with perforation), intraabdominal injuries to the liver or spleen, and ruptured aortic aneurysms.¹²

Ectopic Pregnancy

Ectopic pregnancy is often one of the most difficult gynecologic lesions to diagnose.¹³ The incidence of ectopic pregnancy is estimated to be 0.64% to 2.0%, although surveillance data is imprecise and limited for a variety of reasons.¹⁴ Ectopic pregnancy is the most common obstetric cause of maternal death in the first trimester.¹³ In a series of 300 consecutive cases of ectopic pregnancy, 50% of patients received medical evaluation at least twice before the correct diagnosis was made.

The clinical picture of ectopic pregnancy may include vascular collapse, pelvic pain, isolated rectal or back pain, amenorrhea, abnormal menses, shoulder pain, syncope, cervical or adnexal tenderness, adnexal mass, anemia, and leukocytosis. It is important to note that blood in the peritoneal cavity does not consistently correlate with peritoneal irritation, blood pressure, or pulse rate.¹⁵ In fact, bradycardia in the presence of significant intraperitoneal bleeding from a ruptured ectopic pregnancy is not unusual (Tables 57.1 and 57.2).

Risk factors for an ectopic pregnancy include a history of salpingitis, use of an intrauterine contraceptive device, or tubal ligation; however, no combination of these signs, symptoms,

TABLE 57.1 Correlation Between the Results of Culdocentesis Performed on 77 Patients With Ectopic Gestation and Various Clinical Parameters

	Classic Triad			PERITONEAL SIGNS	PULSE ≥100 BEATS/MIN	BLOOD PRESSURE < 90/40 MM HG	MEAN HEMATOCRIT (%)	HEMOPERITONEUM ≥100 ML	RUPTURED TUBE	TOTAL
	BLEEDING	PAIN	ADNEXAL MASS							
Positive	37	54	10	26	19	9	35	52	30	54
Negative	8	8	3	1	1	0	39	0	0	8
Inadequate	13	15	6	5	4	1	38	13	7	15
Total patients	58	77	19	32	24	10	65	37	77	

Note: There is a lack of correlation between positive culdocentesis and peritoneal signs and changes in vital signs. Patients are grouped by the result of culdocentesis (i.e., positive, negative, or inadequate). Note that only 10 patients were hypotensive and only 24 experienced tachycardia. From Cartwright PS, Vaughn B, Tuttle D: Culdocentesis and ectopic pregnancy, *J Reprod Med* 29:88, 1984.

TABLE 57.2 Correlation Between Tubal Status and Hypotension, Tachycardia, Hematocrit, Signs of Peritoneal Irritation, and Hemoperitoneum in 77 Patients With Ectopic Gestation

CULDOCENTESIS	CULDOCENTESIS POSITIVE	PERITONEAL SIGNS	BLOOD PRESSURE <90/40 mm Hg	PULSE ≥ 100 BEATS/MIN	HEMOPERITONEUM ≥100 mL	AVERAGE HEMATOCRIT (%)
Ruptured (n = 37)	30	25	8	19	37	33.6
Intact (n = 40)	24	7	2	5	28	37.3
Total patients	54	32	10	24	65	

Note: Culdocentesis is frequently positive in the absence of rupture. Patients are grouped by the presence (i.e., “ruptured”) or absence (i.e., “intact”) of hemoperitoneum. Note that only about half the patients with “ruptured” status had tachycardia.

From Cartwright PS, Vaughn B, Tuttle D: Culdocentesis and ectopic pregnancy, *J Reprod Med* 29:88, 1984.

or historical data is diagnostic of an ectopic pregnancy. To confuse the diagnosis further, a normal menstrual history is reported in approximately 50% of patients with an ectopic pregnancy. A urine pregnancy test may occasionally be negative.¹⁶ Though rarely seen, the combination of a uterine decidual cast (Fig. 57.7) and a positive pregnancy test is virtually pathognomonic of an ectopic pregnancy. A uterine cast is decidua that has been hormonally stimulated by the ectopic pregnancy but is passed vaginally when the tissue can no longer be supported. The cast is an outline of the uterine cavity, but it can be mistaken for products of conception if not inspected carefully. Therefore all tissue passed vaginally should be carefully inspected before being sent to the laboratory for analysis for products of conception. An ectopic pregnancy can occasionally occur in conjunction with an intrauterine pregnancy. Patients who have undergone a therapeutic abortion may actually have had an unrecognized ectopic pregnancy, hence the need for pathologic evaluation of any tissue obtained by uterine evacuation procedures.

The greater sensitivity of the serum and urine β -hCG assay, coupled with the increased availability of emergency medicine physicians trained to perform pelvic US, has greatly increased the chance of early diagnosis of unruptured and ruptured ectopic pregnancy.¹⁷ Urinary β -hCG tests are sensitive at 20 mIU/mL

or greater and are positive 98% of the time in the first few weeks of pregnancy. However, ectopic pregnancy is often associated with very low production of this hormone.

Quantification of the serum test adds additional information as it is sensitive to 5 mIU/mL. Therefore a negative *urine* β -hCG test rules out pregnancy in greater than 98% of cases, and pregnancy in any site can be ruled out in virtually all patients with a negative *serum* β -hCG test.¹⁸ A single quantitative β -hCG level is a poor predictor of the size of the pregnancy or the risk for ectopic pregnancy, but serial testing is quite helpful. It is expected that the quantitative serum β -hCG level should double approximately every 2 days in the first trimester.

To increase the accuracy of diagnosis, it is helpful to combine quantitative β -hCG testing with US examination (Fig. 57.8). An empty uterus by transvaginal or abdominal US combined with positive quantitative serum β -hCG results are strongly suggestive of ectopic pregnancy. The quantitative range in which the ultrasonographer should detect an intrauterine pregnancy varies, but an intrauterine pregnancy should be detected if the serum β -hCG level is in the range of 1200 to 1500 mIU/mL when using a *transvaginal probe* and greater

Figure 57.7 This decidual cast, a perfect outline of the uterine cavity, was initially thought to be a product of conception when found in the vaginal vault of a pregnant woman treated for abdominal pain and vaginal bleeding. The initial diagnosis was a spontaneous abortion, but this cast is *virtually diagnostic of an ectopic pregnancy*. Hypotension developed later and the woman was found to have a ruptured tubal pregnancy.

Figure 57.8 **A**, Pelvic ultrasound showing an empty uterus. The endometrial stripe (*arrow*) is clearly visible, and there is no evidence of a gestational sac. If the β human chorionic gonadotropin (β -hCG) level is below the discriminatory zone (see text), this could represent an early viable intrauterine pregnancy, a nonviable intrauterine pregnancy, completed abortion, or an ectopic pregnancy. If β -hCG exceeds the discriminatory zone, the chance of an ectopic pregnancy exceeds 85%. **B**, Pelvic ultrasound showing the presence of a yolk sac (*arrow*) within a gestational sac in the uterus. This patient was 5 weeks pregnant by dates.

than 6000 mIU/mL when using a *transabdominal probe*. Endovaginal US scanning consistently identifies a 4-week gestational sac if the β -hCG level is 2000 mIU/mL or greater. The presence of a fetal pole and cardiac activity are detectable with endovaginal US scanning at approximately 6 and 7 weeks, respectively.¹⁹ Note that a heartbeat can occasionally be detected in an ectopic pregnancy or in an extrauterine pregnancy and may be mistakenly deemed intrauterine. It is important to note that the absence of an intrauterine pregnancy by US, when the β -hCG level is below the discriminatory zone (defined as the hCG level at which a normal intrauterine pregnancy can be detected by US), is *nondiagnostic* and could represent an early viable normal pregnancy, a nonviable intrauterine pregnancy, a completed abortion, or an ectopic pregnancy. When no intrauterine pregnancy is detected by US and the serum β -hCG level *exceeds the discriminatory zone*, the chance of an ectopic pregnancy ranges from 86% to 100%.²⁰

Culdocentesis may play an important role in some patients in the diagnosis of ectopic pregnancy. The test has an accuracy rate of 85% to 95%.^{11,21,22} Romero and coworkers²³ reported that an ectopic pregnancy was found in 99% of patients with a positive pregnancy test and positive results on culdocentesis. Although culdocentesis is most often positive in the presence of a frankly ruptured ectopic pregnancy, it may be diagnostic even in a nonruptured case when bleeding has been slow or intermittent. Note that many ectopic pregnancies leak varying amounts of blood for days or weeks before rupture. Hemoperitoneum has been found in 45% to 60% of cases of *unruptured* ectopic pregnancy, as proved at surgery.^{14,23}

Hence, culdocentesis may be helpful in a stable patient whose US examination does not demonstrate an intrauterine pregnancy despite a quantitative serum β -hCG level in the appropriate range. Although some clinicians opt for outpatient monitoring of serial β -hCG levels in this setting, patients in whom the clinician has high suspicion for an ectopic pregnancy (e.g., a patient who has or has had significant discomfort) or in whom close follow-up cannot be ensured may be candidates for culdocentesis.¹¹ Even though a negative finding on culdocentesis does not rule out an early ectopic pregnancy, patients with a nondiagnostic US and a negative culdocentesis generally represent those at lower risk for “rupture” of an ectopic pregnancy during outpatient serum β -hCG monitoring. Patients with a nondiagnostic US examination and a serum β -hCG level below the threshold at which an intrauterine pregnancy should be visible on the US examination may need further evaluation. These patients, especially those with significant pain, an unexplained low hematocrit, or postural changes in vital signs (or near syncope), might be candidates for culdocentesis.

Blunt Abdominal Trauma

Historically, diagnostic peritoneal lavage (DPL) and computed tomography (CT) have been used to identify hemoperitoneum in blunt trauma patients. The use of culdocentesis has also been advocated to aid in this diagnosis.^{12,24} In the ED, two factors have largely obviated the need to perform invasive procedures for diagnosis of hemoperitoneum: (1) the increasing availability of high-resolution CT and (2) emergency clinicians trained to perform the bedside US focused assessment with sonography for trauma (FAST) examination. However, because small amounts of blood tend to collect in the rectouterine pouch, aspiration of clear peritoneal fluid is of great potential value in excluding a diagnosis of hemoperitoneum. This is

especially helpful in situations in which US is unavailable or the patient is too unstable to leave the ED for a CT scan. In fact, culdocentesis may be more advantageous than DPL in some instances because there is less risk for urinary bladder perforation or bowel injury. In addition, previous abdominal surgery is not a relative contraindication to culdocentesis, as it is with DPL.²⁵

Contraindications

Contraindications to culdocentesis are relatively few and include an uncooperative patient, a pelvic mass detected on bimanual pelvic examination, a nonmobile retroverted uterus, and coagulopathies. Pelvic masses may include TOAs, appendiceal abscesses, ovarian masses, and pelvic kidneys. It has been suggested that the only major risk with the procedure is rupture of an unsuspected TOA into the peritoneal cavity. This can be avoided by careful bimanual pelvic examination to exclude patients with large masses in the cul-de-sac.²⁶ Although no data are available to guide the age at which culdocentesis may be performed safely, the procedure is generally limited to patients beyond puberty. This limitation is suggested on the basis of anatomy and with the consideration that the procedure is difficult to perform through a small prepubertal vagina.

Equipment

The equipment required for culdocentesis is depicted in [Review Box 57.1](#). Either an 18-gauge spinal needle or a 19-gauge butterfly needle held by ring forceps is acceptable. It may be helpful to anesthetize the posterior vaginal wall at the site of the puncture with 1% to 2% lidocaine with epinephrine administered through a 27- or 25-gauge needle. Some physicians use a topical anesthetic (eutectic mixture of local anesthetics [EMLA], benzocaine), viscous lidocaine, or a cocaine-soaked cotton ball to anesthetize the mucosa before infiltration with a local anesthetic. Although puncture of the posterior vaginal wall at the upper fourth of the vagina is generally no more painful than a venipuncture, there is some advantage to using a local anesthetic if multiple attempts at culdocentesis are required, as is sometimes the case. In addition, the epinephrine may produce vasoconstriction and reduce bleeding associated with the needle puncture. Culdocentesis is often stressful to the patient, and all attempts should be made to render the procedure as painless as possible. Parenteral analgesia and/or sedation should be administered when the patient is uncomfortable or anxious.

Technique

Preparation

Culdocentesis is an invasive procedure that requires a written, witnessed, and signed consent form from the patient, parent, or guardian when the patient's condition permits. If verbal consent is obtained, this action should be witnessed and a notation made in the medical record documenting that the procedure was described, complications were discussed, and any alternatives (e.g., CT, sonography, or immediate laparoscopy) were offered when appropriate.

Once written or verbal consent is obtained, place the patient in a lithotomy position with the head of the table slightly elevated (reverse Trendelenburg position) so that intraperitoneal fluid gravitates toward the rectouterine pouch. Place the patient's

feet in stirrups. Premedicate with intravenous opioids or sedatives if appropriate. Administration of nitrous oxide analgesia is also an accepted practice. Procedural sedation with propofol, etomidate, or benzodiazepines can be considered. Although the pain associated with passage of the culdocentesis needle is generally minor, judicious use of analgesia and sedation makes the procedure easier for both the clinician and patient.

If radiographs are indicated, take them before culdocentesis to avoid confusion with procedure-induced pneumoperitoneum.

Exposure

Perform a bimanual pelvic examination before culdocentesis to rule out a fixed pelvic mass and to assess the position of the uterus. It is possible to palpate an adnexal mass if the mass exceeds 3 cm in diameter. Insert a bivalve vaginal speculum and open it widely by adjusting both the height and the angle thumbscrews (Fig. 57.9, step 1). Grasp the posterior lip of the cervix with the toothed uterine cervical tenaculum and elevate the cervix. Warn the patient in advance that she may feel a sharp pain when the cervix is grasped with the tenaculum. Inform the patient also that bleeding from the tenaculum puncture site or culdocentesis site, or both, may produce postprocedural spotting.

Use the tenaculum to elevate a retroverted uterus from the pouch, to expose the puncture site, and to stabilize the posterior wall during puncture with the needle. Some clinicians prefer to use longitudinal traction on the cervix to produce the same result. The vaginal wall adjacent to the rectouterine pouch will be tightened somewhat between the inferior blade of the bivalve speculum and the elevated posterior lip of the cervix. Such tightening of the vaginal wall exposes the puncture site and keeps it from moving away from the needle when the wall is punctured.

After the tenaculum is applied and the posterior lip of the cervix is elevated or traction is applied, swab the vaginal wall in the area of the rectouterine pouch with an antiseptic, followed by a small amount of sterile water. Administer a local anesthetic (1% lidocaine with epinephrine) at this point. Anesthetic may be injected through a separate 27- or 25-gauge needle or with the spinal needle that will be used for the culdocentesis. Use a cotton ball soaked in 4% cocaine or 20% benzocaine solution or apply viscous lidocaine to the area for topical anesthesia of the posterior vaginal wall approximately 15 minutes before infiltration with a local anesthetic. This combination will make the needle puncture nearly painless. Attach the needle to a 20-mL syringe. A smaller syringe might not be long enough to allow adequate control of the needle, and the clinician's hand may block the view of the puncture site if a smaller syringe is used.

Aspiration

Following local anesthesia, advance the syringe and the spinal needle parallel to the lower blade of the speculum (see Fig. 57.9, step 2). Fill the syringe with 2 to 3 mL of saline (nonbacteriostatic) before puncture. After needle puncture, the free flow of fluid from the syringe will expel tissue that may have clogged the needle and will confirm that the tip of the needle is in the proper position and not lodged in the uterine wall or the intestinal wall. Use saline rather than air because if air is used, it may be difficult to interpret the presence of free peritoneal air on subsequent radiographs. To avoid the need to change the syringe during the procedure, use 1% lidocaine for both anesthesia and confirmation of proper needle place-

ment; however, the bacteriostatic property of this agent precludes its use if the procedure is performed to obtain fluid for culture.

Penetrate the vaginal wall in the midline 1 to 1.5 cm posterior (inferior) to the point at which the vaginal wall joins the cervix (see Fig. 57.9, step 2).²⁷ Pass the needle a total of 2 to 2.5 cm.^{27,28} Apply gentle suction with the syringe while slowly withdrawing the needle. Avoid aspirating any blood that has accumulated in the vagina from previous needle punctures or from cervical bleeding because this may give the false impression of a positive tap. Bleeding from the puncture site in the vaginal wall can be minimized by adding epinephrine to the local anesthetic.

Blood or fluid may be obtained immediately but may also be obtained when the needle is withdrawn from the peritoneal cavity. Therefore it is important to aspirate continuously while *gradually* withdrawing the needle. If no fluid is aspirated, reintroduce the needle and direct it only slightly to the left or right of the midline. Directing the needle too far laterally may result in puncture of the mesenteric or pelvic vessels. If no fluid is obtained on the first attempt, repeat the procedure.

Some physicians prefer the use of a 19-gauge butterfly needle held with ring forceps (see Fig. 57.9, step 3, and Fig. 57.10).²⁷ This technique offers a built-in guide to needle depth and allows good control of the needle during puncture. An assistant must aspirate the tubing while the physician controls positioning and withdrawal of the needle.

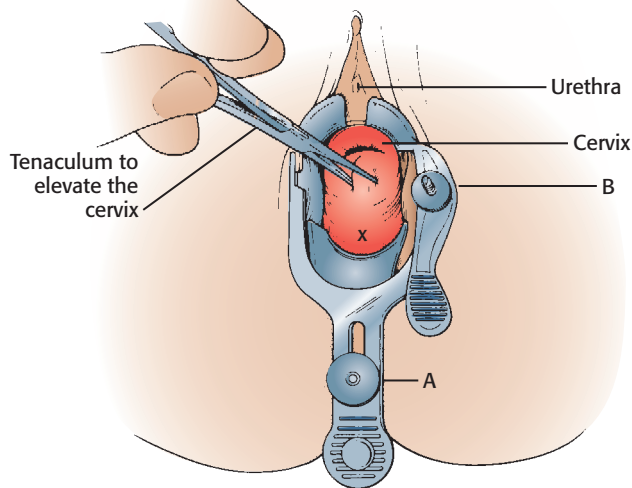

Fluid that is aspirated may be old nonclotting blood, bright red blood, pus, exudate, or a straw-colored serous liquid. Any fluid that is not blood should be submitted for Gram stain, aerobic and anaerobic culture, and cell count. Blood should be observed for clotting. Blood should also be sent for determination of the hematocrit.

Interpretation of Results

Interpretation of the results of culdocentesis depends primarily on whether any fluid was obtained. It should be noted that in the absence of a pathologic condition, 2 to 3 mL of clear yellowish peritoneal fluid can be aspirated. When there is no return of fluid of any type (a so-called dry tap), the procedure has *no diagnostic value*. Because a dry tap is nondiagnostic, it should not be equated with normal peritoneal fluid. In addition, when less than 2 mL of clotting blood is obtained, this is also considered to be a nondiagnostic tap because the source of this small amount of blood may be the puncture site on the vaginal wall. Such blood will usually clot. More than 2 mL of *nonclotting blood* is certainly suggestive of hemoperitoneum. However, some researchers interpret as little as 0.3 mL of *nonclotting blood* as a positive tap.¹⁵ There is no particular significance of larger amounts of blood because absolute volume may be related to the position of the needle or the rate of bleeding. Brenner and colleagues¹⁴ reported no blood from culdocentesis in 5% of patients with proven ectopic pregnancies even when rupture had occurred. In the series of 61 patients with surgically proven ectopic pregnancy reported by Cartwright and associates,¹⁵ culdocentesis performed within 4 hours of surgery was positive in 70%, negative in 10%, and inadequate in 20%. "Positive" in their series was defined as obtaining at least 0.3 mL of nonclotting blood with a hematocrit of greater than 3%. "Negative" was defined as obtaining 0.3 mL of fluid with a hematocrit of less than 3%. An "inadequate" tap was one in which no fluid was obtained. In the 252 patients reported by Vermesh and coworkers²⁹ who had surgically proven ectopic

Culdocentesis

1

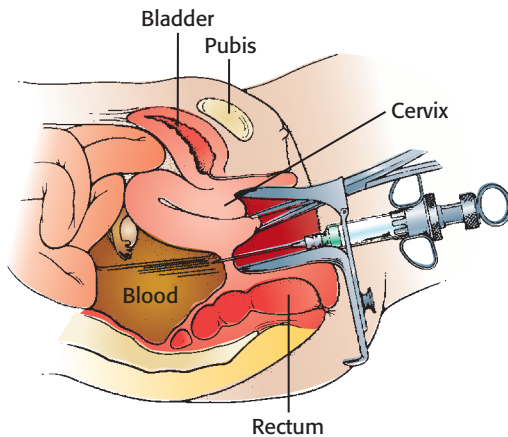

Place the patient in the lithotomy position with the head of the bed slightly elevated so that intraperitoneal fluid gravitates toward the rectouterine pouch. Premedicate with sedatives or intravenous opiates as clinically indicated. Perform a bimanual pelvic examination to exclude the presence of a pelvic mass.

Insert a bivalve pelvic speculum and open it widely by using both the height (A) and angle (B) thumbscrews. Grasp the posterior lip of the cervix with a tenaculum and elevate the cervix.

Swab the vaginal wall in the area of the rectouterine pouch with antiseptic followed by a small amount of sterile water.

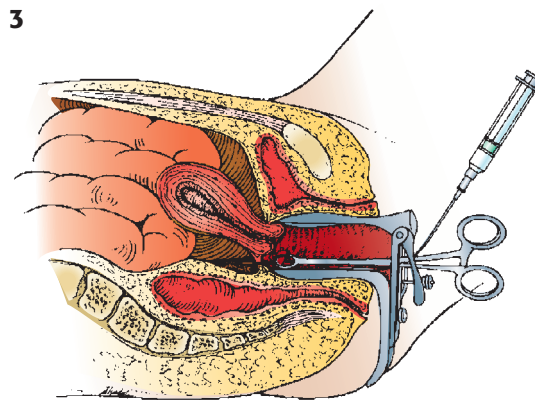

Administer a local anesthetic with a separate 25- or 27-gauge needle or with the needle that will be used for culdocentesis. The site of needle entry is 1 cm posterior to the point at which the vaginal wall joins the cervix (X). (Optional: before injecting the local anesthetic, place a cocaine [4%]- or benzocaine [20%]-soaked cotton ball on the area to be punctured for 15 minutes.)

2

Fill the syringe with 2 to 3 mL of saline prior to puncture. Advance the spinal needle parallel to the lower blade of the speculum. Gently depress the plunger during advancement of the needle. Free flow of fluid will confirm proper needle placement in the rectouterine pouch. Pass the needle 2 to 2.5 cm. Apply gentle suction while slowly withdrawing the syringe.

3

Alternatively, use a 19-gauge butterfly needle held with ring forceps. This technique offers a built-in guide to needle depth and allows good control of the needle during puncture. Use the help of an assistant to aspirate while you control needle position and withdrawal.

Figure 57.9 Culdocentesis. (1 and 2, from Vander Salm TJ, Cutler BS, Wheeler HB: *Atlas of bedside procedures*. Boston, 1979, Little, Brown; 3, from Webb MJ: Culdocentesis, *JACEP* 7:452, 1978.)

pregnancies and underwent culdocentesis, 83% had a positive tap. They defined a positive tap as nonclotting blood with a hematocrit of greater than 15%.

When culdocentesis is used to diagnose a ruptured ectopic pregnancy, a “negative tap” is one that yields pus or clear, straw-colored peritoneal or cystic fluid. A large amount of clear fluid (>10 mL) indicates a probable ruptured ovarian cyst, aspiration of an intact corpus luteal cyst, ascites, or possibly carcinoma. The significance of this fluid and interpretation of the results are outlined in [Table 57.3](#) and [Box 57.1](#). Elliot and colleagues³⁰ cautioned that obtaining greater than 10 mL of clear fluid should not automatically rule out an ectopic pregnancy because the latter may coexist with other pathologic conditions.

A “positive tap” is one in which nonclotting blood is obtained, although the presence of nonclotted blood does not confirm a tubal pregnancy. Intraperitoneal blood from any source (ectopic pregnancy, ovarian cyst, ruptured spleen) may remain unclotted after aspiration for days in the syringe as a result of the defibrination activity of the peritoneum. Return of serosanguineous fluid also suggests a ruptured ovarian cyst. The hematocrit of blood from active intraperitoneal bleeding is greater than 10%. In one series, the hematocrit of blood from a ruptured ectopic pregnancy was 15% or greater in 97% of cases.¹⁴

It should be emphasized that a positive finding on culdocentesis in the presence of a positive pregnancy test does not always prove an ectopic pregnancy.²⁹ A ruptured corpus

Figure 57.10 Variations in culdocentesis technique. **A**, An 18-gauge spinal needle attached to a syringe. The operator applies continuous suction during withdrawal of the needle. **B**, A 19-gauge butterfly needle attached to a syringe and held with ring forceps. An assistant is required to aspirate the syringe while the operator controls the needle with the forceps

BOX 57.1 Interpretation of Culdocentesis

POSITIVE

- >0.5 mL nonclotting, bloody fluid (hematocrit >12%)
- Indicates hemoperitoneum
 - When β -hCG is also positive, ectopic pregnancy is found in greater than 95%
 - Nonspecific—can occur in intrauterine pregnancies and nonpregnant women (e.g., ruptured cyst, retrograde bleeding)
- Does not necessarily indicate tubal rupture
 - 50% to 62% of ectopic pregnancies with peritoneal blood may be unruptured

NEGATIVE

- Serous fluid
 - Excludes hemoperitoneum and tubal rupture
 - Falsely negative in 10% to 15% of ectopic pregnancies (generally unruptured)

NONDIAGNOSTIC

- Dry tap or clotting blood
 - Excludes neither ectopic pregnancy nor hemoperitoneum
 - 15% of procedures are nondiagnostic
 - 16% of ectopic pregnancies have nondiagnostic study results

TABLE 57.3 Interpretation of Culdocentesis Fluid

ASPIRATED FLUID	CONDITION AND SUGGESTED DIFFERENTIAL DIAGNOSIS
Clear, serous, straw colored (usually only a few milliliters)	Normal peritoneal fluid
Large amount of clear fluid	Ruptured or large ovarian cyst (fluid may be serosanguineous); pregnancy may be coexistent Ascites Carcinoma
Exudate with polymorphonuclear leukocytes	Pelvic inflammatory disease Gonococcal salpingitis Chronic salpingitis
Purulent fluid	Bacterial infection Tuboovarian abscess with rupture Appendicitis with rupture Diverticulitis with perforation
Bright red blood ^a	Ruptured viscus or vascular injury Recently bleeding ectopic pregnancy ^a (ruptured or unruptured) Bleeding corpus luteum Intraabdominal injury Liver Spleen Other organs Ruptured aortic aneurysm
Old, brown, nonclotting blood	Ruptured viscus Ectopic pregnancy with intraperitoneal bleeding over a few days or weeks Old (days) intraabdominal injury (e.g., delayed splenic rupture)

^aNote: The hematocrit of blood from a ruptured ectopic pregnancy is usually 15% or greater (97.5% of cases), but some authors use greater than 3% as positive.

luteum cyst in the presence of an intrauterine pregnancy test is probably the most common cause of a false-positive scenario. Whenever possible, US can help corroborate the findings on culdocentesis.

Complications

Culdocentesis is one of the safest procedures performed in the emergency setting, and there are probably fewer complications with this technique than with peripheral venous cannulation. Complications have been reported, however, the most serious being rupture of an unsuspected TOA.²⁷ Other complications include perforation of the bowel, perforation of a pelvic

kidney, and bleeding from the puncture site in patients with clotting disorders. Because the most common complications result from puncture of a pelvic mass, careful bimanual examination of the patient should help prevent this problem. Puncture of the bowel and the uterine wall occurs relatively frequently but does not generally result in serious morbidity. Obviously,

penetration of a gravid uterus has greater potential for harm. Occasionally, one will aspirate air or fecal matter, thereby confirming inadvertent puncture of the rectum.

Examination of the Sexual Assault Victim

Carolyn Joy Sachs and Malinda Wheeler

The majority of sexually assaulted individuals do not share the experience with anyone, suffering in silence. An estimated one-third of all sexual assaults are reported to law enforcement. In many cases, after contact with law enforcement, patients are taken to the emergency department (ED) for evaluation, examination, and treatment. Sexual assault patients may also present to the ED *de novo*, without prior law enforcement contact. In 2013, according to the Centers for Disease Control and Prevention (CDC) statistics, sexually assaulted patients accounted for slightly more than one-tenth of all assault-related visits to the ED by female patients.¹

Some sexual assault victims agree to police interviews and investigations, and others do not. Federal legislation guarantees all victims the right to a forensic examination and treatment of sexual assault regardless of their cooperation with legal investigation or their desire to initially pursue prosecution.² Some states require medical personnel treating sexual assault patients to report the assault to local law enforcement, whereas others forbid such reporting without patient consent. Clinicians must know their own state laws regarding such reports.

DEFINITIONS

Sexual assault refers to any sexual contact between one person and another without appropriate legal consent.³ Physical force may be used to overcome the victim's lack of consent, but this is not mandatory to prove assault. Coercion into sexual contact by intimidation, threats, or fear also defines sexual assault. State laws differ slightly on the definition of exact acts that constitute sexual contact and on which populations are unable to give legal consent. In general, persons under the influence of drugs or alcohol, minors, and those who are mentally incapacitated are considered unable to give consent for sexual contact.

Clinicians who treat sexual assault patients have a professional, ethical, and moral responsibility to provide the best medical and psychological care possible. At the same time, they must collect and preserve the proper medicolegal evidence that is unique to the evaluation of sexual assault cases.

Often hospitals and jurisdictions affiliate with designated sexual assault examination teams to provide specialized evaluation and treatment of patients. These sexual assault response teams (SARTs) provide clear advantages outlined near the end of the chapter. However, patients may be brought to an ED that does not routinely provide specialized care for sexual assault. This chapter is designed to aid clinicians in such a general care location. Prepared emergency personnel can help attenuate the psychological and physical impact of sexual assault. Through proper care of the patient and careful acquisition of

evidence, ED staff can help the patient recover from the assault and aid society in improving the prosecution and conviction rates of sexual predators.

EVALUATION AND TREATMENT OF PATIENTS SUFFERING FROM SEXUAL ASSAULT

Preparation

Most often, local jurisdictions or hospitals provide clinicians with detailed forms and instructions for examination and documentation of sexual assault. This chapter is meant to supplement such instructions and forms. Clinicians should be familiar with local documents before performing a sexual assault examination. Careful step-by-step planning and the use of written protocols ensure the best care for victims and aids in the prosecution of assailants and the exoneration of wrongly accused subjects.

ED personnel must secure patient privacy and designate a separate area for the care of sexually assaulted patients. If medically and logistically possible, interviews should be conducted in a private room separate from the examination room. EDs often have such an area, frequently called the “grieving room” or the “family room.” Law enforcement or other governmental agencies may provide examination kits for the collection of forensic evidence from victims (Fig. 58.1). These kits should be available in the ED and the staff should be familiar with them. If such kits are not provided by local sources, hospital staff may need to assemble their own kits from material found in most EDs. Alternatively, private companies assemble and sell such kits (e.g., The Lynn Peavey Company, <https://www.lynnpeavey.com>). Prepared kits can save a tremendous amount of nursing and clinician time. A checklist of local requirements for sexual assault examination should be included in the kits and serves as a reminder for all the necessary medicolegal procedures to be completed.

Although this chapter is devoted primarily to the evaluation of adult female sexual assault patients, guidelines for the evaluation of adult male sexual assault patients, female child patients, male child patients, and accused assailants are provided in separate sections of this chapter. The same examiners designated to perform adult female examinations may easily perform male victim and assailant examinations; however, examination of a child sexual assault patient often requires considerable expertise and training. When possible, medical staff with specialized training in the examination of child sexual assault patients should perform these examinations. If this is not possible, the section on [Child Sexual Assault Examinations should provide emergency medical personnel with a basic framework to perform an initial examination.](#)

Consent

Consent for the evaluation and treatment of a sexual assault patient is mandatory. The patient has undergone an experience in which her/his right to grant or deny consent was taken from her/him, and obtaining consent for medical treatment and gathering evidence has important psychological and legal implications. The patient has the right to decline medicolegal examination and even medical treatment. Before beginning evaluation and treatment, obtain witnessed, written, informed consent. If no local forensic examination forms are available,

use the standard ED “consent to treat” forms, but ensure that the patient is well informed and gives verbal consent to each step of the examination. Although a few states mandate that medical personnel report sexual assaults to law enforcement, patients may choose to not discuss the event with police. If the patient cannot give consent for a forensic examination because of a reversible process (e.g., intoxication, an acute psychological reaction), wait several hours for the patient’s mental status to improve to a reasonable level before consent is obtained. When patients cannot give consent because of minor status or a developmental disability, the person authorized to give medical consent for the patient may give consent for the examination unless that person is a suspect in the assault. Many states allow an adolescent patient of a certain age (e.g., > 12 to 14 years old) to consent to an examination for conditions related to sexually transmitted diseases (STDs), sexual assault, and pregnancy. State laws also differ in examiners’ requirements to make an attempt to contact the legal guardian (unless the guardian is a suspected perpetrator). Clearly, emergency personnel must be informed regarding their local laws concerning these requirements. In the rare case that a patient cannot give consent as a result of a potentially irreversible medical condition, such as severe head trauma and coma, seek the advice of institutional legal counsel before proceeding with a forensic examination. In some cases, the next of kin may provide the needed consent, whereas in other cases, it may be necessary to obtain a court order to proceed.

History

The history of the event should include only the elements necessary to complete the required forms, to perform a focused

TABLE 58.1 Maximal Reported Time Intervals for Sperm Recovery

BODY CAVITY	MOTILE SPERM	NONMOTILE SPERM
Vagina	6–28 hr	14 hr–10 days
Cervix	3–7 days	7.5–19 days
Mouth	—	2–31 hr
Rectum	—	4–113 hr
Anus	—	2–44 hr

From Marx J, ed: *Rosen’s emergency medicine: concepts and clinical practice*, ed 6, Philadelphia, 2006, Elsevier.

physical examination, and to collect evidence. Questions beyond this, such as the details leading up to the assault, should be left to police investigators. Avoid the urge to “help” the alleged victim by unduly embellishing or detailing uncorroborated or nonmedical information supplied during the examination. Limiting the history not only shortens the evaluation in the ED but also helps prevent discrepancies between the ED history and the official police investigation report, which could weaken the victim’s case in court. Document the pertinent medical history, including the last menstrual period, current contraception, recent anal-genital injuries or surgeries, and preexisting injuries.

The history of the event required by legal documentation or protocol usually includes the time, date, and place of the alleged assault and a description of the use of force, threats of force, and the type of assault. Elements of force may include the type of violence used (e.g., grabbing, hitting, kicking, strangling, weapon use), threats of violence, the use of restraints, the number of assailants, the use of alcohol or drugs (forcibly or willingly) by the patient, and any loss of consciousness experienced by the patient. Sexually assaultive acts may include manual or oral fondling (of breasts, genitalia, or both); vaginal, oral, or anal penetration or attempted penetration (with fingers, penis, or other objects); ejaculation on or in the body; and the use of a condom. Use of physical force or violence is partly a police matter, but from a medical standpoint it is desirable to correlate positive findings on the physical examination (e.g., abrasions, ecchymosis, and scratches) with a description of any force, restraint, or violence.

Clearly indicate the patient’s post-assault activity, which is commonly requested on the necessary documentation, including douching, bathing, urinating, defecating, gargling, and brushing teeth. These activities can alter the recovery of seminal specimens and other sexual assault evidence. However, hygiene activities should not deter the clinician from the collection of evidence because perpetrator DNA has been recovered from the patient’s skin even after multiple showers. In addition, obtain a good history from the patient about potential injuries and any body trauma that may have occurred before the assault.

Elements of the victim’s history should help in deciding which potential samples to collect. For example, sperm may be recovered from the cervix for up to 19 days after intercourse and from the vagina for up to 10 days (Table 58.1).⁴ Cervical samples are now recommended in all cases that will involve speculum examination because of greater forensic yield.

Obtain a gynecologic history in preparation for documentation of injuries and treatment plans. From a medicolegal standpoint, inquire about any recent gynecologic surgical procedures or unintentional genital trauma that might alter the expected normal genital appearance. The history should also include the use of any method of birth control before the attack (with information regarding any missed birth control pills), last normal menstrual period, last voluntary intercourse, gravidity and parity, and recent STDs. As with all assaulted patients, the medical history should include current medications, tetanus immunization status, and allergies.

While taking the history, observe the patient's ability to understand and respond appropriately to questions. Victims of sexual assault may not possess the capacity to consent to intercourse because of a developmental disability, young age, or intoxication with drugs or alcohol. Consider obtaining blood, urine, or both and testing for drugs or alcohol when the history suggests impaired consciousness. Patients who lack consenting capacity because of a developmental disability may have sufficient prior documentation of the condition. In the rare instance in which an examiner suspects a previously undocumented developmental disability, formal examination of the patient's mental capacity can be performed at a later time by request of the district attorney.

Physical Examination

Physical examination of a sexual assault patient differs from most other ED examinations in that examiners are not only caring for a patient's physical and mental well-being but also investigating a crime scene and collecting specific evidence. As always, patiently explain every step of the examination process to the patient. Remind the patient to communicate any discomfort or questions during the examination and to ask for a break from the examination if needed. In addition, remind the patient of her right to decline any portion of the examination and the ability to stop at any point. Each patient should have the opportunity to have a family member, friend, victim advocate, or any combination of such individuals in the room during all parts of the examination, if they so desire.

Collection of Clothing

If not already collected by law enforcement, collect the clothes that the victim wore during the assault for potential evidence. Ask the patient to disrobe by dropping her clothes onto a large piece of paper or blue disposable underpad that is protected from the floor by a sheet. Using gloved hands, place each item of clothing in a separate paper bag. Label all collected material meticulously and describe it in the chart. Labels should include date, time, contents, and name of person who collected clothing. Bundle the paper or underpad and any material that might have fallen during the patient's disrobing and place it in a separate paper bag. Minute amounts of blood, semen, and/or saliva can produce a DNA profile. When properly dried and free of moisture DNA can persist in swabs and on clothing for years at room temperature. Therefore, be sure that clothing is dried (but not by using heat) before packaging. The DNA profile obtained by the laboratory can be uploaded into the FBI's CODIS (Combined DNA Index System) database and identify an unknown assailant. When a victim's clothing must be collected, be sure to provide suitable clothing for the patient to wear home after release from the ED.

General Body Examination

After the patient disrobes and is placed in a gown, examine her body for signs of trauma and foreign material. Uncover only one part of the body at a time to examine and then carefully re-cover it. This allows the patient to retain some modesty during the examination. Important areas for evaluation are the back, thighs, breasts, wrists, and ankles (particularly if restraints were used). Even in the absence of ecchymosis, note tender areas during the examination. Evidence from the physical surroundings of the assault can occasionally be found in the hair or on the skin. Retain such material as evidence. Document areas of trauma and evaluate further (e.g., with radiographs) as indicated by the type and extent of injury. Approximately 10% to 67% of sexual assault victims display bodily injuries.⁴ Document these injuries because they correlate significantly with successful prosecution of perpetrators.⁵ Bodily evidence may range from abrasions to major blunt force and penetrating trauma. If the victim has not bathed, bodily evidence in the form of dried semen stains may be visible on the hair or the skin of the victim. In a darkened room, dried semen (and, unfortunately, many other substances) on skin may fluoresce under examination with shortwave light, such as that produced by a Woods lamp or an alternate light source, but may also be noticed equally well by its reflective appearance under regular room lighting.⁶⁻⁸ Use moistened swabs to collect potential dried secretions; then air-dry them thoroughly and preserve as evidence. Dried secretions may be semen or saliva stains. If the history indicates oral contact or ejaculation in specific areas, these areas should be sampled using moistened swabs even if no dried secretions are visible. Fragments of the assailant's skin, blood, facial hair, or other foreign material from the assault site may be trapped beneath a victim's fingernails. Obtain fingernail scrapings by cleaning under a victim's nails with a toothpick or small swab or by cutting the nails closely over a clean piece of paper. Fingernail samples should be collected in such a way as to maximize the detection of foreign DNA and minimize the amount of the patient's cells present, using only light pressure to avoid any injury or bleeding to the patient. Fold the toothpick and debris into the paper, place it in an envelope, and package it with the other specimens.

Imaging

Photographs can be a valuable addition to the documentation of bodily injury. Medical institutions may employ professional-quality photographic teams; others must rely on law enforcement for photo documentation. Most institutions require patient consent for photographs taken by hospital personnel. Optimally, institutions should have a prearranged plan to handle film or digital media according to a written "chain of custody." Alternatively, self-developing film (Polaroid) or instant digital prints that can be permanently labeled (e.g., subject, date, details of the pictured injury) may be used but will provide inferior resolution in most cases. The photographs should be labeled immediately and may be added to the legal evidence. In some jurisdictions, photographs of physical injuries will be taken and retained by an accompanying law officer. These photographs may serve as evidence or may simply refresh the examiner's memory at the time of the trial.

Oral Evaluation

If indicated by the history, inspect the oral cavity closely for signs of trauma and collect evidence if indicated. Mouth injuries from forced oral copulation include lacerations of the labial

Figure 58.2 Oral injuries incurred as a result of sexual assault. **A**, Mucosal labial injury after forced oral copulation. **B**, Petechial hemorrhage seen on the soft palate after a similar assault.

or lingual frenulum, mucosal lacerations, and abrasions (Fig. 58.2A). Injury to the lips is often produced by the patient's own teeth as her lips are forced inward by forced oral penetration with the perpetrator's penis. Potential injuries to the posterior pharyngeal wall and soft palate include contusions, submucosal hemorrhage, and lacerations (see Fig. 58.2B). Document these injuries at the initial examination because mucosal injuries heal quickly and may not be present hours or days later. Collect potential evidence with swabs rubbed between the teeth and the buccal mucosa on both the upper and lower gingival surfaces bilaterally. Spermatozoa have been identified in oral smears for hours after the attack despite brushing the teeth, using mouthwash, or drinking various fluids and may provide valuable evidence up to 12 hours after examination.⁹ Collect any foreign material (e.g., hair) to include as potential evidence. During the oral inspection, local law enforcement may request that examiners collect buccal cell swabs to provide the crime laboratory with a sample for victim DNA reference.

Genital Examination

Once the patient is in the lithotomy position, inspect the thighs and perineum for signs of trauma and for foreign material such as seminal stains. Use an ultraviolet light again to look at suspicious dried secretions. Many jurisdictions recommend routine collection of swabs from the external genital area because of the high likelihood of evidence being present after drainage from the vaginal vault and the inconsistent fluorescence of seminal fluid with a Wood's lamp.

Pubic Hair Samples

If local crime laboratories request pubic hair samples, proceed with the following protocol. Before the pelvic examination, comb the patient's pubic hair for foreign material (particularly pubic hair belonging to the assailant). Place clean paper below the victim's buttocks with the patient in the lithotomy position and comb the pubic hair onto the paper. Fold these hairs and the comb into the paper and place them directly in a large paper envelope to be given to law enforcement. Foreign pubic hairs can often provide enough cellular DNA material from the root to enable the crime laboratory to perform DNA analysis. In addition, specialized laboratories possess the

capability of performing mitochondrial DNA analysis from the hair shaft in many cases.

Significant hair transfer occurs in less than 5% of assaults.¹⁰ For the small minority of cases in which crime labs desire to compare foreign suspect hairs with the victim's hair, a sample pulled from the patient may be requested. Although pulling the patient's hair from the roots may provide the best sample, this collection method is painful, considered insensitive, and not recommended by these authors during the initial evaluation. Additionally, many agencies perform DNA testing on any hair recovered initially, rendering microscopic comparison with victim hairs superfluous. In the very rare case when it is requested, a patient can provide the hairs at a later time.

Genital examination of a sexual assault patient differs considerably from most ED pelvic examinations. First, carefully explain what you are doing to the patient. Perform a careful visual evaluation of the vulva and vaginal introitus for signs of trauma. The following techniques of separation and traction move the tissues that are most likely to suffer injury into view. In performing separation, use both hands to gently separate the labia laterally in each direction and inspect the posterior fourchette and vaginal introitus. Similarly, in performing traction, use both hands to hold each labium majus and apply gentle inferior labial traction (i.e., toward the examiner); this gives a much-improved view of the hymen, especially in prepubertal females (Fig. 58.3). If these maneuvers are not performed, traumatic genital injuries may be missed.

Familiarity with female (Fig. 58.4) and male (Fig. 58.5) genital anatomy, including all terms, is important for accurate descriptions. Although most novice examiners concern themselves with detecting injuries to the hymen, the majority of sexual assault-related vaginal injuries occur to the posterior fourchette (Fig. 58.6).¹¹ In fact, hymenal injuries are rare in sexually active adult women and are more commonly observed in sexually inexperienced adolescents (Fig. 58.7).^{12,13} More uncommon injuries to the vaginal walls and cervix may be discovered during the speculum examination.

Reported rates of genital injury in forensically examined patients range from 6% to 20% without colposcopy to 53% to 87% with colposcopy.^{11,12,14} Most importantly, examiners must be cognizant of the fact that even completely normal findings on genital examination remain consistent with forced

Figure 58.3 The normal hymen in a prepubertal female as seen with inferior labial traction.

sexual assault. In fact, a study of more than 1000 sexual assault patients found that almost half of all victims with forensic evidence positive for sperm had no genital injury.¹³

Colposcopy

Teixeira first described the use of colposcopy for documentation of sexual assault in 1981.¹⁵ Although it is not readily available, nor a standard of care in most EDs, the use of colposcopy has revolutionized the documentation of injury. The colposcope provides magnification, a bright light source, and usually permanent documentation of injuries in the form of still images or video (mainly in digital format but occasionally traditional film). In one small study the colposcope increased the rate of detection of genital injury from 6% to 53%.¹⁶ Colposcopes with photo or video attachments provide excellent photographic documentation for the court and allow review by expert practitioners for court testimony without subjecting the victim to reexamination (Fig. 58.8 A and B). Experienced sexual assault examiner programs are increasingly using high-quality digital single-lens reflex cameras mounted on a tripod to obtain excellent images that are indistinguishable from those obtained with colposcopy (see Fig. 58.8C). ED practitioners may have access to such equipment. Colposcopically visible injuries have also been described in adolescent women after the first consensual intercourse; hence, genital injury does not always translate to nonconsensual vaginal penetration.¹⁷ Conversely, totally normal findings on genital examination by colposcopy are often found after sexual assault. Even in sexually inexperienced adolescents, forced penetration can occur without leaving discernible genital injury.¹⁷ Although previous sexual experience by the victim decreases the likelihood of finding genital injury, experts cannot fully explain the reasons why some rape victims sustain measurable genital injury whereas others do not.

Forensic Evidence Collection

Protocols for collection of evidence vary by legal jurisdiction. The following discussion draws from the model protocol suggested by the state of California and the American College of Emergency Physicians manual.³

BOX 58.1 Potential Evidence Collected

- Clothing (list and describe all clothing collected on the chart and checklist form)
- Debris
- Dried secretions, swabs, and slides
- External genital swabs and slides
- Pubic hair combings
- Oral mucosal swabs and slides
- Anal swabs and slides
- Vaginal pool swabs and slides
- Vaginal lavage fluid in a test tube or urine container
- Cervical swabs and slides
- Tampon or condom present in the vagina (dried or frozen)
- Urine or blood toxicology sample (timed collection)
- Reference blood, buccal mucosa, and/or hair sample
- Collect all evidence with gloved hands to avoid DNA contamination
- Change gloves when necessary to avoid interlocation contamination

Obtain standard specimens during inspection of the external genitalia, rectum, vagina, and cervix. Lubricate the speculum as usual. Lubricant use is no longer considered a potential threat to evidence recovery and should be used for patient comfort per examiner protocol. Generally, the specimens collected will be determined by the patient's history and local protocol, but they may include any of the items listed in Box 58.1 and shown in Fig. 58.9. Some protocols recommend that examiners make a wet mount of one swab from the vaginal pool and look at it under the microscope for the presence of motile sperm. Because of rapid cell death, studies have shown a negligible chance of finding motile sperm from a vaginal wet mount more than 8 hours after intercourse.¹⁸ Furthermore, in complying with the Clinical Laboratory Improvement Amendments of 1988, ED practitioners in the United States rarely have sufficient access or experience with microscopy to make this step a routine recommendation. Several swabs from the vaginal pool (including the one used to make the wet mount, if done) and the external genitalia should be obtained and then applied over clean slides for a dry mount. In addition, collect cervical swabs. The crime laboratory may recover sperm from cervical specimens up to 12 days or more after coitus.⁴ Label all slides and then allow them to air-dry. Package swabs and slides in paper envelopes for the local crime laboratory. Some EDs maintain specific equipment (i.e., a dry box) to aid in the drying of specimens; in others, the swabs and slides must be left out until completely dried.

Crime laboratories may also request collection of a vaginal washing, although this specimen is becoming obsolete with advances in DNA technology. For this procedure, insert 5 mL of sterile (but not bacteriostatic) water or saline into the vagina and then remove it. Place the washing in a sealed container (such as those used for urine collection or a red-topped blood tube). Label each sample separately and record in the chart the area from which the specimen was collected.

Due to the extreme sensitivity of new DNA tests, exercise caution to prevent contamination of samples. Wear gloves at all times during specimen collection and packaging. Take care not to inadvertently sneeze, spit, or cough on or near samples.

Figure 58.8 A, Colposcope, and B, method of examination. This technique is not a standard intervention by an emergency physician. C, High-quality digital cameras mounted on tripods can also obtain excellent images.

Genital Testing for STDs

Guidelines from the CDC no longer recommend routine testing but suggest tests be ordered on an individual basis using standard methods currently employed in most EDs. The majority of

SART programs in the United States do not routinely perform STD testing on adults and adolescents.¹⁸ STD testing during sexual assault examination can detect only infection before the assault and provides no meaningful information for the crime laboratory. In addition, routine prophylactic treatment with

Figure 58.9 Sample contents of a sexual assault evidence kit. Note that an instruction booklet is provided, along with labels, swabs, glass slides, blood tubes, collection envelopes, and other necessary equipment.

antibiotics effective against *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and incubating syphilis makes detection of these preexisting infections superfluous; however, clinicians might want to consider obtaining samples for culture or nucleic acid amplification test from child victims, in whom the presence of an STD would be indicative of previous sexual contact.

Perineal Toluidine Blue Dye Staining

Toluidine blue dye is a nuclear stain, also used for cancer detection and mast cell staining, that highlights areas of injury. It adheres to areas denuded by abrasions and lacerations where the epidermal layer of nonnucleated cells has been removed (Fig. 58.10). The underlying nucleated cells take up the dye. Although it is not a uniform standard of care and is unavailable in many EDs, the dye can enhance the examiner’s ability to visualize and photographically document more subtle genital injuries (Fig. 58.11; also see Fig. 58.6B). Genital lacerations may provide corroborating evidence of nonconsensual intercourse, or at least sexual activity. To outline injuries, apply a 1% aqueous solution of toluidine blue dye to the perineum and wipe the excess dye off with a cotton ball moistened with lubricating jelly. A swab containing the dye is commercially

available from several distributors (<http://nfni.org/products.html>). After the excess dye is removed, any areas that retain the stain signify a disruption in the epidermis, most likely injury. Separate any folds of the area and carefully examine them to avoid missing injuries. Ideally, apply the dye before speculum examination to eliminate the possibility of iatrogenic injury. The procedure is described in Fig. 58.10 and Box 58.2. In one study, the use of toluidine blue dye increased the injury detection rate from 16% to 40% in women, without the use of colposcopy¹⁹; however, injuries detected with the aid of toluidine blue dye are not 100% specific for sexual assault because such injuries have also been found after consensual intercourse, especially in adolescents.²⁰

Collect external genital samples before the application of toluidine blue to avoid washing away potential DNA evidence. The use of toluidine blue dye itself does not interfere with DNA evidence from vaginal specimens, and it has proved safe for mucosal application.^{21,22}

Anal Evaluation

The anal examination follows the genital examination in most cases (Fig. 58.12). Documentation of anal penetration holds

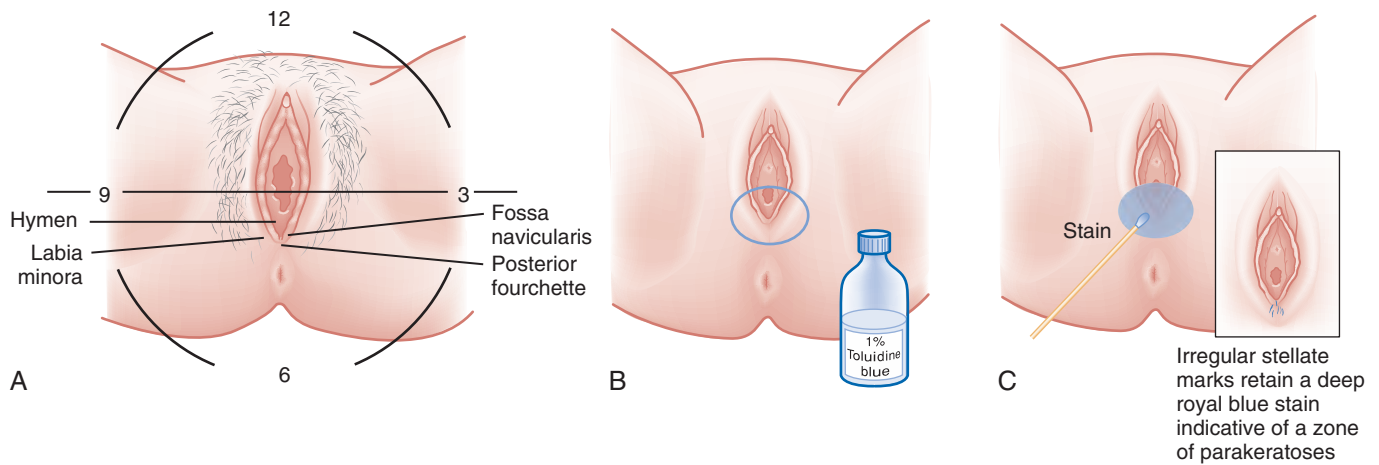

Figure 58.10 A, During a sexual assault, injuries are often multiple and typically occur between the 3-, 6-, and 9-o'clock positions. B and C, Traumatic skin injuries can be highlighted by applying toluidine blue to the perineum and vaginal area and then wiping it off to show the lesions. (A, From Marx J: *Rosen's emergency medicine: concepts and clinical practice*. ed 6, Philadelphia, 2006, Elsevier.)

Figure 58.11 Posterior fourchette injury A, before and B, after application of toluidine blue dye. Toluidine dye highlights an injury that would likely go unnoticed without dye application.

significant value because it is a separate crime in addition to vaginal penetration and may increase criminal penalties against convicted sexual predators. First, gently separate the anal folds to look for lacerations and abrasions, and collect two external anal swabs. If desired, apply toluidine blue as outlined in the genital section. Clean the dye off thoroughly. If anoscopy is not indicated or planned, collect the internal rectal sample as

BOX 58.2 Toluidine Blue Staining of the Perineum to Detect Microabrasion

1. Collect all external genital specimens as indicated by examination before application of the dye.^c
2. Before speculum examination or anoscopy, apply 1% toluidine blue to the entire vulva (labia majora, labia minora, posterior fourchette, perineal body, and perianal area). The anus may also be stained. Do not use dye in the vaginal vault or mucous membranes.
3. Allow it to dry for approximately 1 minute.
4. Remove excess dye with water-soluble lubricant by gently blotting the area until the excess dye is removed.
5. DO NOT rub the area.
6. Photograph the area if indicated.
7. The dye will fade in 1 to 2 days.

^aA prefilled swab (F-Blue Swab/TBS, Tri-Tech, Inc.) is available through the National Forensic Nursing Institute.

^bSee Fig. 58.10.

^cThis does not interfere with DNA or semen testing.

Modified from The National Forensic Nursing Institute [<http://nfnri.org/forensicblueswabs.html>]. This testing is not usually performed in the emergency department without a special assault team.

follows: separate the anal folds as much as possible by applying gentle lateral or vertical traction, clean the external anal skin with water and gauze, and then insert swabs approximately 2 cm into the anus. Gently move them in a circular motion and then remove them. Use the swabs to make slides, air-dry them, and then include them in the evidence sent to the crime laboratory. Anoscopy is indicated to document potential internal mucosal injuries in victims who report anal penetration or who describe loss of consciousness during the assault. Perform this procedure in the same manner as diagnostic anoscopy to evaluate other anal or rectal emergencies in the ED. It is best to collect the internal rectal specimens at the end of the anoscope to prevent contamination from any external sample being dragged internally. In one retrospective observational study of male patients, the use of anoscopy and colposcopy

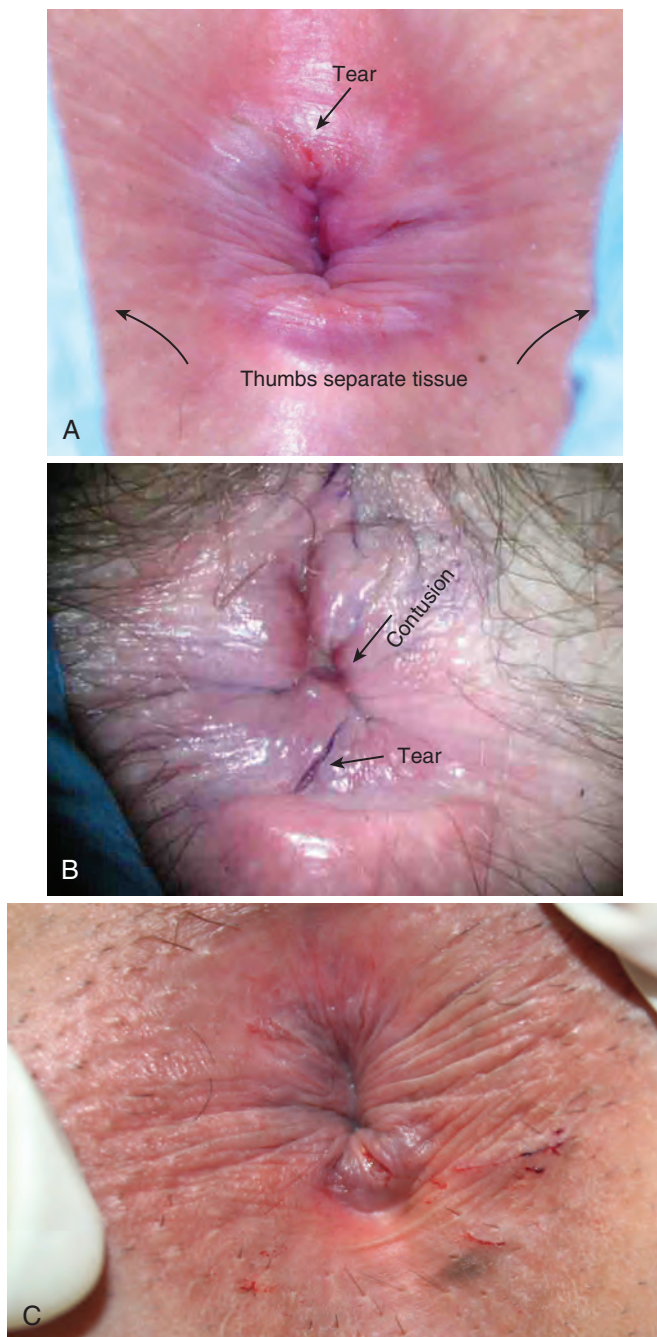

Figure 58.12 Anal injury is best seen with separation of perianal tissues. **A**, Anal tear in a 13-year-old boy after forced penile-anal penetration. **B**, Anal contusion and tear (*arrows*) in an adult male after forced penile-anal penetration. **C**, Multiple superficial tears to the anus and perianal region.

provided superior documentation of injuries over colposcopy alone.²³ The location of anoscopically detected injuries may be recorded geographically on an imaginary clock face as with vaginal injuries.

Reference Samples

Crime laboratories may request reference samples from various locations on the patient's body to use in comparison testing with potential evidence from the perpetrator. These reference

samples may include two buccal swabs collecting mucosal epithelial cells, a blood sample in a designated tube or filter paper card, or even two nasal swabs, especially useful in pediatric cases. The need for such samples will be determined by local protocol.

Blood Tests

Some crime laboratories request blood samples for DNA reference, toxicology analysis, or both. Include these samples with the material sent to law enforcement. When collecting blood for toxicology testing, record the exact date and time of collection on the specimen so that the criminalist may estimate the dose and timing of substances used by perpetrators to facilitate the assault.

Urine Tests

Perform bedside urine β -human chorionic gonadotropin (β -hCG) testing in all female patients of childbearing age to exclude preexisting pregnancy before administering pregnancy and STD prophylaxis. Collect the patient's first available voided urine as requested by local crime laboratories to optimize recovery of potential toxicology evidence.

Spermatozoa, Semen, and DNA Testing

Motile and immotile sperm may be found microscopically in wet mounts of vaginal aspirates and in vaginal, oral, and rectal swabs. If formally trained, evaluate the slide microscopically immediately after the physical examination. Examiners may find sperm in vaginal wet mount specimens.¹ Early discovery of sperm may be helpful to law enforcement investigations. However, most ED examiners lack formal training in this process and crime laboratories possess much higher sensitivity for detection of sperm, thus making a negative initial wet mount unhelpful. For these reasons, most examiners do not routinely perform the wet mount examination. After consensual intercourse with a normal ejaculate, laboratory testing of vaginal secretions detects sperm in 50% of specimens 4 days after coitus.²⁴ However, despite penile penetration during sexual assault, crime laboratories may fail to detect sperm. Reasons for failure include inadequate specimen collection, degradation of the ejaculate, azoospermia, failure of the perpetrator to ejaculate, vasectomy in the perpetrator, washing by the victim, or use of a condom. Collection of relevant clothing may prove most important for DNA recovery as laboratories have recovered spermatozoa DNA from laundered clothing as long as 8 months after deposit.²⁵

A crime laboratory analyst initially looks for semen in a given sample by searching microscopically for sperm on a concentrated specimen and by testing for other components found in semen. The presence of spermatozoa is the only confirmatory test for semen. Seminal plasma components include p30 and acid phosphatase. p30 is a glycoprotein found in the prostate and other body fluids and is no longer regarded as conclusive evidence of semen (i.e., ejaculation within 48 hours). The presence of high levels of p30 is suggestive of a vasectomized or azoospermic male. Both p30 and acid phosphatase are presumptive evidence only because they can occur in other body fluids, such as vaginal secretions, male urine, etc.^{26,27} Despite negative testing for seminal plasma components, laboratories may be able to detect male-specific "Y" DNA

evidence from persistent sperm cells or the perpetrator's epithelial cells.^{28,29} As DNA testing technology rapidly changes, the ability of crime laboratories to perform a specific forensic test varies by location and over time. Most crime laboratories look for unique short tandem repeats in perpetrator DNA with polymerase chain reaction amplification testing, which requires minimal material.

Chain of Custody

Samples and other evidence need to be carefully and formally transferred to the police, a crime laboratory, or a forensic pathologist. Label each sample with the patient's name, hospital number, date, time of collection, area from which the specimen was collected, and collector's name. Package these specimens according to local crime laboratory specifications and transfer them to the next appropriate official (police officer, pathologist, or other individual) along with a written confirmation of chain of custody, including a list of the specimens, the signature of each person who collected them, and the signature of each person who received them. If this documentation is inadequate or the documentation chain is broken, important evidence may be deemed inadmissible in court.

TREATMENT

STD Prophylaxis

The approach to prophylaxis for potential diseases transmitted by sexual assault varies by region, disease prevalence, and local practice and is often influenced by the emotional state of the victim and personal and religious viewpoints. We present an overview that may serve as a general guideline, with the understanding that many issues are vague, unsettled, and not totally adopted by all clinicians (Box 58.3).

It is advisable to address the issues of STD, pregnancy, psychological distress, and follow-up in the treatment of a patient with a history of recent sexual assault. Because infection rates before the assault are not known, the risk of contracting an STD as a consequence of a sexual assault has been difficult to determine, and estimates vary widely (Table 58.2).³⁰ Jenny and colleagues found the post-assault incidence of STDs to be 2% for chlamydia and 4% for gonorrhea.³¹ The reported rates of 12% for *Trichomonas* and 19% for bacterial vaginosis seem high and may reflect a preexposure infection because

male transmission of these infections, especially bacterial vaginosis, is uncommon. There is a lack of specific data on risk for the development of herpes, hepatitis B, or human immunodeficiency virus (HIV) infection from sexual assault. However, HIV transmission has been noted.³²

Because some patients tend to have relatively low compliance with keeping follow-up visits, most examiners offer, at the least, treatment of gonorrhea and chlamydia at the time of the initial examination.¹⁸ Though most often termed prophylaxis, technically this antibiotic administration is considered "treatment" given so early that the disease is subclinical. The need for routine administration of medication to combat *Trichomonas* is unclear, and many clinicians do not recommend it as a routine intervention. Prophylaxis for bacterial vaginosis is rarely suggested.

With the increasing prevalence of antibiotic-resistant *N. gonorrhoeae*, ceftriaxone in an intramuscular 250-mg dose is the CDC's most current recommended treatment of choice in targeting gonorrhea after sexual assault. Ceftriaxone also treats incubating syphilis. No single-dose regimen for gonorrhea

BOX 58.3 Recommended Empirical Emergency Department Testing and Pharmacologic Treatment After Sexual Assault

- NO routine STD cultures of the victim unless symptomatic for an STD or the victim is a child (a positive test in a child is indicative of abuse).
- Treat empirically for GC,^b *Chlamydia*, *Trichomonas* (optional), and bacterial vaginosis (optional) (see Box 58.4).
- Administer a tetanus booster vaccine if indicated.
- If not immunized for hepatitis B or unsure of the victim's vaccination status, give first dose of vaccine empirically and follow with subsequent vaccination at 1 to 2 and 4 to 6 months. If previously vaccinated, offer hepatitis surface antibody testing with follow-up vaccination if the test result is negative. In addition to vaccination, consider HBIG in nonimmune patients after high-risk exposure to a known hepatitis B–positive perpetrator, followed by a full vaccination schedule.
- If the suspect is known or suspected to be HIV positive, treat with medications recommended by local ID experts or provided in occupational exposure kits or consider either of the following: Combivir (GlaxoSmithKline, Research Triangle Park, NC) (twice a day) or Truvada (Gilead Sciences, Inc., Foster City, CA) (once a day) for 28 days.
- If the suspect is not known to be HIV positive, there is no consensus on recommendations for treatment, and clinicians must consider each patient individually.^c This is an area of uncertainty. HIV prophylaxis may be given after a discussion of the risks and benefits with the patient.
- Obtain a pregnancy test and administer pregnancy prevention if not already pregnant and physically able to conceive (see Table 58.3).

^aTreatment regimens are subject to change based on sensitivities and local patterns.

^bTreatment of GC will treat incubating syphilis. Prophylaxis for herpes is not recommended.

^cThere are no published data on the effectiveness of HIV postexposure prophylaxis after sexual assault.

GC, *Gonococci*; HBIG, hepatitis B immune globulin; HIV, human immunodeficiency virus; ID, infectious disease; STD, sexually transmitted disease.

TABLE 58.2 Risk for Sexually Transmitted Diseases After Sexual Assault^a

DISEASE	RISK (%)
Gonorrhea	6–18
<i>Chlamydia</i>	4–17
Syphilis	0.5–3
Human immunodeficiency virus	< 1

^aAssistance with postexposure prophylaxis–related decisions can be obtained by calling the National Clinician's Post Exposure Prophylaxis Hotline (PEP Line) (telephone: 888-448-4911).

From Marx J, ed: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, Philadelphia, 2006, Elsevier.

BOX 58.4 CDC Recommended Regimens for Prevention of STDs After Sexual Assault

Ceftriaxone, 250 mg intramuscularly in a single dose (for prevention of *Neisseria gonorrhoeae* infection)

Or

(if ceftriaxone unavailable) cefixime, 400 mg orally in a single dose^b

Plus

Metronidazole, 2 g orally in a single dose (optional for prevention of *Trichomonas* infection and bacterial vaginosis)

Plus

Azithromycin, 1 g orally in a single dose (for prevention of *Chlamydia* infection)

Or

(If azithromycin unavailable) doxycycline, 100 mg orally twice a day for 7 days

^aBecause of widespread resistance, fluoroquinolones are no longer recommended. Prophylaxis for hepatitis B (vaccination without hepatitis B immune globulin) is also suggested.

^bCurrent recommendation for the treatment of uncomplicated infection that may intuitively substitute for prophylaxis.

CDC, Centers for Disease Control and Prevention; STDs, sexually transmitted diseases.

is effective against coexisting *C. trachomatis* infection. Therefore give patients either a single dose of azithromycin (1 g orally) or a 7-day course of doxycycline (100 mg orally twice a day) or tetracycline (500 mg orally four times a day). A negative pregnancy test is a prerequisite for using either of the latter two antibiotics. Erythromycin may be used as a second alternative for *Chlamydia* prophylaxis in a pregnant patient. Some examiners administer prophylaxis for *Trichomonas* with a single 2-g oral dose of metronidazole or tinidazole; although effective and recommended by the CDC,³³ these medications may cause significant nausea, vomiting, and diarrhea, which can interfere with the efficacy of pregnancy prophylaxis. One option to circumvent metronidazole-induced emesis interfering with efficacy of concomitantly administered medications is to delay administration by several hours. Box 58.4 provides several options for STD prophylaxis.

Prevention of Hepatitis B

Most sexual assaults involve perpetrators whose hepatitis B status is unknown. In these cases, the CDC recommends hepatitis B vaccination at the time of examination, followed by two more vaccines at the age-appropriate vaccine dose and schedule for previously unvaccinated victims.³³ Give the vaccine to victims as soon as possible after the assault. The CDC recommends that it be given within 24 hours, but this may not be possible in all cases. When a perpetrator is known to be hepatitis B antigen–positive and the victim is known to be hepatitis B antigen–negative and has not been adequately vaccinated, the CDC recommends the administration of hepatitis B immune globulin (HBIG) in addition to vaccination. If the patient is first seen by medical providers 14 days or more after the sexual exposure, HBIG is not recommended. Hepatitis B vaccine should be administered simultaneously with HBIG at a separate injection site, and the vaccine series should be

completed at subsequent visits. Complete CDC recommendations for treatment of hepatitis B and other sexually transmitted infections in sexual assault victims can be found at <http://www.cdc.gov/std/tg2015/sexual-assault.htm>.

Prevention of HIV Infection

In a non–assault-related scenario, the risk for transmission of HIV from one episode of unprotected consensual receptive vaginal intercourse with an infected individual is approximately 1 in 1000. The incidence with unprotected receptive anal intercourse is significantly higher at 8 to 32 per 1000.³⁴ However, sexual assault victims often sustain tissue injury because of the violent nature of the act, which may increase the rate of transmission of the virus. Although postexposure prophylaxis (PEP) for parenteral occupational exposure to infected body fluids (i.e., needlestick) is believed to be effective based on case-control studies, there is no proof that PEP for human sexual exposure prevents transmission of the virus.³⁵ Furthermore, victims of sexual assault frequently arrive for treatment much later than those who have occupational exposures.

However, 40% of sexual assault victims fear contracting HIV after assault and should, at a minimum, receive counseling and, many argue, the option of taking anti-HIV medications because they may be effective.^{36,37} Unfortunately, immediate testing of the perpetrator remains a remote option. The majority of cases lack a perpetrator in custody for testing, and few state laws provide for mandated legal preconviction HIV testing of alleged perpetrators.³⁸ The CDC recommends administering PEP to sexual assault victims only in cases in which the perpetrator is known to be HIV positive.³³ This recommendation specifies a 28-day medication course for patients with a history of sexual assault, who arrive for care less than 72 hours after the event, with an HIV-positive perpetrator, and when that exposure represents a substantial risk for transmission (i.e., mucosal contact with genital secretions). As with occupational exposure, antiretroviral medications should be initiated as soon as possible after exposure. HIV seroconversion due to failures of PEP following sexual exposure have been reported³⁹ (<http://cid.oxfordjournals.org/content/41/10/1507.long>). For sexual assault exposure with a perpetrator of unknown HIV status, the CDC states PEP must be addressed by practitioners on an individual case-by-case basis.⁴⁰ Given the extreme negative outcome, the relative safety of treatment, and the lack of conclusive scientific evidence, at least two states have written policies legislating examiners to offer HIV PEP to all sexual assault victims, and practitioners must be aware of local mandates. The CDC guidelines provide a useful framework to approach individual decisions in prescribing HIV PEP (<http://www.cdc.gov/std/tg2015/sexual-assault.htm>).

Pregnancy Prophylaxis

Pregnancy occurs in up to 4.7% of sexual assault victims.⁴¹ An estimated 22,000 annual rape-related pregnancies could be avoided if all victims received pregnancy prophylaxis.⁴² As an initial step, perform a urine pregnancy test before administering postcoital contraception (PcC). Modern urine pregnancy tests possess a β -hCG detection threshold approaching 20 mIU/mL to 25 mIU/mL and will usually be positive 1 to 2 weeks after conception, often before a menstrual period is missed.

Offer pregnancy prevention with available oral PcC to all patients with a history of sexual assault. Several methods can

TABLE 58.3 Emergency Contraception^{a,b}

BRAND	MANUFACTURER	PILLS ^c
Progestin-Only Emergency Contraception Oral Therapy: Recommended		
Plan B One-Step	WCC	1 pill (levonorgestrel, 1.5 mg) immediately
<i>Or</i>		
Progesterone Receptor Agonist/Antagonist		
Ulipristal (Ella)	Watson Pharma, Inc. Morristown, NJ	One 30-mg pill immediately

^aFor the most up-to-date and alternative recommendations and general information, call 1-800-not-2-late or view <http://www.not-2-late.com>.

^bSome regimens cause nausea and an antiemetic may be used. If vomiting occurs, repeat the dose of antiemetic.

^cAlternatively, the older Yuzpe method may be used with any combination oral contraceptive containing levonorgestrel, ethinylloestradiol 0.03 mg/0.3 mg dosed as two pills immediately and two pills after 12 hours.

be used to prevent pregnancy after forced, nonconsenting intercourse (Table 58.3). The drug of choice for PcC is levonorgestrel, which is available without a prescription in the United States in commercial kits called Plan B (Teva Women's Health, Inc., Frazer, PA), Plan B One-Step (Teva Women's Health, Inc.), Next Choice One-Dose (Watson Pharma, Inc., Parsippany, NJ), Take Action (Teva Pharmaceuticals, Israel), My Way (GAVIS Pharmaceuticals, Somerset, NJ), or other generics. In 2013, the US Food and Drug Administration (FDA) extended the approved sale of Plan B without a prescription to all women of childbearing status, from a more restrictive policy which limited its sale to individuals 17 years or older.⁴³ Although the original Plan B kit included two pills containing 0.75 mg of levonorgestrel, each approved for administration 12 hours apart, a large World Health Organization (WHO) trial demonstrated that both pills may be taken at once with the same efficacy as the divided dose, with the potential for increased compliance.⁴⁴ The newer Plan B One-Step is a single 1.5-mg pill to be taken as outlined in the WHO study. In the rare instance in which levonorgestrel is unavailable, there are several combined oral contraceptive pills, known as the *Yuzpe regimen*, that may be used for PcC (see Table 58.3).⁴⁴ The Yuzpe method is somewhat less effective but prevents approximately 75% of pregnancies that would otherwise have occurred.⁴⁴ Levonorgestrel prevents 89% of pregnancies that would otherwise have occurred and causes fewer side effects. Potential adverse side effects of both methods include nausea, vomiting, and breast tenderness. If the patient vomits within 1 hour of taking a dose, repeat the dose. Some practitioners routinely offer prophylactic antiemetic therapy, and such a strategy seems appropriate. Others reserve such treatment for patients who vomit. In 2010, the FDA approved a third option for pharmacologic emergency contraception, ulipristal acetate (brand name Ella [Afaxys, Inc, Charleston, SC]). This selective progesterone receptor modulator has been demonstrated to be as effective as levonorgestrel for prevention of pregnancy 72 hours after intercourse and more effective for longer postcoital use. Ulipristal requires a prescription and is approved for use up to 120 hours after intercourse.⁴⁵ Despite taking

PcC, patients who meet criteria for obesity may be two to four times more likely to become pregnant than those who do not meet obesity criteria, though this failure is somewhat less with ulipristal.^{46,47}

All available evidence demonstrates no untoward effects on the fetus should pregnancy occur despite oral PcC.⁴⁸ The common practice of obtaining written patient consent for these medications seems unwarranted. Insertion of a copper intra-uterine device is another form of PcC and remains the most effective emergency contraception available, preventing more than 99% of pregnancies, but is generally outside the purview of the emergency physician.⁴⁹

Unfortunately, religious preferences may deter some hospital EDs from providing PcC.⁵⁰ In these instances, the website and number listed at the end of this paragraph provide practitioners information to give referral for easy access to PcC for patients who lack funds to pay for the medication. In addition, given the ever-increasing availability of new methods and drugs for PcC, examiners may want to obtain up-to-date information from this site (<http://www.not-2-late.com>; telephone: 1-800-not-2-late). The site also provides links for patients to order levonorgestrel and ulipristal via courier, including methods for concomitantly obtaining a prescription for ulipristal.

Psychological Support

Sexual assault precipitates a psychological crisis for the patient, and psychological care should begin as soon as possible, ideally initiated when the patient first arrives in the ED.^{45,51,52} Reassure the victim that she will be in control of the examination, that she may ask questions at any point, and that she should notify the examiner if anything hurts or if she needs a break. Ensure that the patient has a complete understanding that in the ED she has full control over her body and the examination is the first step toward psychological support and healing. Unfortunately, if this is not made a priority, full recovery may be impaired. Posttraumatic stress disorder (PTSD), manifested as numbed responsiveness to the external world, disturbances in sleep, feelings of guilt, memory impairment, avoidance of activities, and other symptoms, often develops in sexual assault victims. *Rape trauma syndrome* is the specific label for PTSD in this population.⁵¹ Rape trauma syndrome stems from the following characteristics of sexual assault: (1) it is sudden and the victim is unable to develop adequate defenses, (2) it involves intentional cruelty or inhumanity, (3) it makes the victim feel trapped and unable to fight back, and (4) it often involves physical injury. Attention to the initial psychological care of a rape victim in the ED is fundamental and can reduce distress during forensic examination.⁵²

Many areas have a local sexual assault crisis agency that can dispatch an advocate that will accompany patients with a history of sexual assault during the interview and examination. This same agency may help to provide the follow-up psychological support that must be offered to all victims. It is critical that all examiners maintain current contact information with these agencies and use their services. The importance of this contact is emphasized in some areas by the fact that state law dictates that medical personnel contact a local sexual assault crisis agency when a victim arrives for examination (California penal code 264.2, Notification of a Counseling Center [*Amended by Stats. 2014, Ch. 136, Sec. 1. Effective January 1, 2015*]). In the absence of immediate local crisis services, a hospital social worker may fill this role.

Postexamination Follow-Up

Medical and psychological follow-up of sexual assault victims is essential. Unfortunately, less than one-third of victims complete follow-up medical care.⁵³ Many protocols recommend a 2-week follow-up to reexamine any injuries and to repeat testing for STDs and pregnancy. The timing of this follow-up seems less important given the widespread use of prophylactic medication to prevent STDs and pregnancy. However, because of the measurable failure rate of PcC, repeated pregnancy testing is critical for a victim who does not experience an expected menses. Further follow-up evaluations may be performed at 4 or 6 weeks and 3 and 6 months to repeat serologic tests for HIV, hepatitis B, hepatitis C, and syphilis. In addition, local volunteer support groups can be of immense assistance to a sexual assault victim; contact with such a group should be offered to each victim.

SPECIFIC POPULATIONS

Male Evidentiary Examinations

Male evidentiary examinations include all the same forensic evidence collection as for female victims except vaginal and cervical specimens. As with all patients who have been sexually assaulted, the forensic examination is guided by the history of events related by the patient. Most male victims suffer from anal penetration, or sodomy, by a perpetrator. In addition, male victims may also suffer from rape trauma syndrome but may be less likely to get the psychological support they require. The increased risk for transmission of HIV with anal intercourse has been noted (see earlier section on [Prevention of HIV Infection](#)). Because of the extreme emotional reaction that men often feel after a sexual assault, they report the crime even more sporadically than female victims do.^{53,54} Male patients with a history of sexual assault deserve the same unhurried, nonjudgmental, compassionate care that female victims do. Penile samples from the shaft, glans, corona, and scrotum may be obtained if there is oral or anal contact with the perpetrator.

Child Sexual Assault Examinations

In general, the care and treatment of a pediatric sexual assault patient requires expert knowledge and experience. Frequently, ED practitioners are the first professionals to examine a child victim, and based on the history provided, the presence of obvious genital injury and trauma should be an adequate prompt to manage the forensic process. However, in less obvious cases, the subtle variations in developmental changes and congenital anomalies may leave many clinicians ill equipped to render an opinion concerning findings indicative of sexual assault. The lives of children and families may be disrupted or severely affected, depending on the practitioner's opinion of the presence of genital penetration-type findings. The history in these cases can be challenging to obtain given the age of the patient, their developmental stage, and psychological state. Emergency providers must remain vigilant for any clues, no matter how insignificant they may appear initially.

A well-known study by Adams and associates demonstrated that the majority of children reporting sexual abuse have normal or nonspecific genital findings.⁵⁵ As these authors succinctly

stated regarding child sexual assault, it is “normal to be normal.” Despite expert physical examination, the vast majority of sexually abused children cannot be differentiated from nonabused children.⁵⁶ Discovery of one of the rare examination markers of injury should be confirmed by experts, and a discussion of these findings, though beyond the scope of this chapter, is covered extensively in other resources.⁵⁷ The potential sexual assault history provided by the child or caretaker should therefore remain the primary indicator that inappropriate genital contact has occurred. Any concerning elements of the history warrant an investigation of the possibility of sexual abuse.

It cannot be emphasized enough that the examiner's responsibility in the care of a child victim of sexual abuse remains within the realm of experts. However, in EDs lacking timely availability of local experts, inspect the genitalia carefully in an unhurried, child-friendly manner, and if indicated, collect forensic specimens. For a very young child with small genital orifices, the aid of a magnification source may be extremely helpful. Ask a parent (unless a suspect) to assist in the calming, reassurance, and positioning of the child for careful inspection. Whereas the basic lithotomy position may be used for an older, more mature child or an adolescent patient, use of alternative positioning of a pediatric female patient is essential for inspection. The frog leg position (the feet together and the knees spread widely apart) with the use of labial or gluteal (or both) separation and traction is often beneficial in children ([Fig. 58.13](#)). Take care to gently separate the labia to avoid superficial examiner-induced injuries. In addition, to get a better look at the hymenal perimeter in prepubertal girls and the anus in girls and boys, ask them to turn over into the knee-chest position ([Fig. 58.14](#)). Genital findings that are deemed definitive of

Figure 58.13 “Frog leg” position to examine children.

Figure 58.14 Child in the knee-chest position to facilitate examination of the hymen.

BOX 58.5 Acute Findings on Examination Diagnostic of Sexual Contact in Children**ACUTE TRAUMA TO EXTERNAL GENITAL/ANAL TISSUES, WHICH COULD BE ACCIDENTAL OR INFLICTED**

- Acute laceration(s) or bruising of labia, penis, scrotum, perianal tissues, or perineum.
- Acute laceration of the posterior fourchette or vestibule, not involving the hymen.
- Residual (healing) injuries to external genital/anal tissues. (These rare findings are difficult to diagnose unless an acute injury was previously documented at the same location.)
- Perianal scar.
- Scar of posterior fourchette or fossa.

INJURIES INDICATIVE OF ACUTE OR HEALED TRAUMA TO THE GENITAL/ANAL TISSUES

- Bruising, petechiae, or abrasions on the hymen.
- Acute laceration of the hymen, of any depth; partial or complete.
- Vaginal laceration.
- Perianal laceration with exposure of tissues below the dermis.
- Healed hymenal transection/complete hymen cleft (a defect in the hymen between 4 o'clock and 8 o'clock that extends to the base of the hymen, with no hymenal tissue discernible at that location.)
- A defect in the posterior (inferior) half of the hymen, wider than a transection, with an absence of hymenal tissue extending to the base of the hymen.

INFECTIONS TRANSMITTED BY SEXUAL CONTACT, UNLESS THERE IS EVIDENCE OF PERINATAL TRANSMISSION OR CLEARLY, REASONABLY, AND INDEPENDENTLY DOCUMENTED BUT RARE NONSEXUAL TRANSMISSION

- Genital, rectal, or pharyngeal *Neisseria gonorrhoea* infection.
- Syphilis.
- Genital or rectal *Chlamydia trachomatis* infection.
- *Trichomonas vaginalis* infection.
- HIV, if transmission by blood transfusion has been ruled out.

DIAGNOSTIC OF SEXUAL CONTACT

- Pregnancy.
- Semen identified in forensic specimens taken directly from a child's body.

"These findings support a disclosure of sexual abuse and are highly suggestive of abuse even in the absence of a disclosure, unless a timely and plausible description of accidental injury is provided by the child and/or caretaker. Physical findings should be confirmed using additional examination positions and/or techniques. Diagnoses of sexually transmitted infections must be confirmed by additional testing to avoid assigning significance to possible false positive screening test results. Photographs or video recordings of these findings should be evaluated and confirmed by an expert in sexual abuse evaluation to ensure accurate interpretation.

From Adams JA, Kellogg ND, Farst KJ, et al: Updated guidelines for the medical assessment and care of children who may have been sexually abused, J Pediatr Adolesc Gynecol 2:81–87, 2015, doi: 10.1016/j.jpap.2015.01.007.

sexual abuse or penetration or are nonspecific are included in Box 58.5.⁵⁸ However, many normal hymenal differences exist from one child to the next, and the definitive diagnosis of "abnormal" is often difficult even for experts. When any doubt exists in the ED, completely describe the findings and refer the child for later examination by experts. The availability of a colposcope or alternative photographic equipment with magnification clearly aids in the documentation of any injuries that may heal before examination by an expert can be performed.

When disclosure or genital injuries confirm possible penetration of the child, collect specimens for potential evidence. On all conscious prepubertal children, collect the specimens without inserting a pediatric speculum. If there is no bleeding or significant trauma, procedural sedation is rarely indicated. If a child proves to be too uncooperative for an ED examination, refer the patient to a child sexual assault expert for examination in a controlled setting or make the appropriate referral to a specialist. For the rare cases involving severe vaginal trauma or suspected internal genital injury (active bleeding) that will possibly require surgical repair, conduct the examination under deep procedural sedation or refer for examination by a consulting gynecologist under general anesthesia. External anal and vulvar swabs are usually collected quite easily; however, lack of estrogen in prepubertal children may increase hymenal sensitivity making vaginal samples difficult to obtain. Therefore many local protocols do not require collection of internal samples. For extraordinary circumstances, internal samples should remain the very last evidence collected. Make every effort possible to avoid swab contact with hymenal tissue during

collection. Vaginal aspirates can be obtained with a feeding tube or plastic angiocatheter and may provide an alternative to vaginal swabs.

Collecting genital specimens to screen for STDs remains a controversial issue in the realm of child abuse experts. For *N. gonorrhoeae*, at least, the literature supports the notion that all infected children will display an abnormal discharge.⁵⁹ With very young children, the practitioner may have only one opportunity to collect vaginal specimens without causing agitation and prohibiting further examination. Forcing specimen collection under physical restraint is considered a second assault on the child. Because the child is being evaluated for possible sexual abuse, the primary specimens collected should be for forensic DNA analysis. STD detection and treatment can be performed at a later time. Clinicians should consult local child abuse centers and state agencies for protocols regarding immediate STD specimen collection, referral, and follow-up services.

Suspect Examinations

As forensic evidence collection in the form of DNA retrieval continues to evolve, EDs may see more requests from local law enforcement for collection of evidence from suspects. EDs should be familiar with local and state protocols, especially regarding consent. Some jurisdictions permit examination of suspects without consent, given the imminent degradation of potential biologic evidence. Other jurisdictions require that suspects give consent or, at the very least, that police obtain a search warrant from the court. The sooner that a suspect is

apprehended and brought in for a medical-forensic examination, the better the quality of forensic biologic evidence.

Performing a medical-forensic examination on a suspect can give important corroborating information for the investigation of a crime. It can also help exonerate the innocent. Law enforcement should be in attendance during the examination of any suspect to ensure the safety of the examiner, the witness, and the cooperation of the suspect. Be sure that the suspect and victim do not encounter one another in the hospital setting during the examination period. Examine the victim and suspect in separate locations within the ED or clinical setting. It is extremely beneficial to conduct the examination and history of the victim before the suspect's examination, to search for physical findings on the suspect that were indicated by the victim's history. For example, if during the victim's history she relates that she scratched the suspect's left shoulder in defense, the examiner should examine, document, and preferably photograph the presence (or absence) of an injury on the suspect's left shoulder.

The physical and evidentiary examination of the suspect is similar to that of the victim. The primary differences lie in history taking, reference samples, and more "blind" samples. During the examination of a suspect, law enforcement officers, rather than the suspect, provide the history of the event. Collect reference samples of blood and buccal swabs if possible. Previously recommended, head and pubic hair reference samples are no longer required in most areas and practitioners should refer to local protocols for guidance on this. Apply special attention not only to nail scrapings but also to swabbing all the fingers for possible vaginal epithelial cells from digital penetration. Female DNA persists in the male fingernail scrapings for up to 6 hours or more.⁶⁰ The shaft and corona of the glans penis should be swabbed along with separate swabs of the scrotum for vaginal secretions. Criminalists often recover a female victim's DNA from the scrotal swab even if the perpetrator wore a condom. With an unwashed penis, swabs almost uniformly show evidence of female cells up to 24 hours after coitus.²⁸

Examining suspects requires the same amount of professional sensitivity and respect that any patient receives within the ED. It is not within the realm of the clinician's expertise to determine whether the suspect is guilty or innocent.

The Unconscious Victim and "Drug-Facilitated Sexual Assault"

Alcohol and other drugs play an important role in many sexual assaults. Half of all sexual assaults involve drug or alcohol ingestion.⁶¹ In many cases it is unclear whether a drug was taken voluntarily or whether it was surreptitiously given to the assaulted victim.

Popular media has raised public awareness of drugs used to facilitate sexual assault under the term *date-rape drugs* (Box 58.6).⁶² Although date-rape drugs are of significant concern, extensive forensic testing in the United States shows that only a minority of sexual assault cases involve the suspect covertly spiking a victim's drink with a tablet, capsule, powder, or liquid mind-altering drug.⁶³ A routine hospital urine drug screen is inadequate to evaluate a sexual assault victim. Forensic laboratories usually offer an evaluation for multiple drugs in a specific test designed for the sexual assault victim. However, testing may not be adequately sensitive to test for all substances used during drug-facilitated sexual assault. The drugs most

BOX 58.6 Possible Date Rape Drugs^a

Alprazolam	Ketamine ^b
Amphetamines	Lorazepam
Barbiturates	Meprobamate ^b
1,4-Butanediol (BD) ^b	Methamphetamine
γ-Butyrolactone (GBL) ^b	Midazolam (Versed) ^b
Cannabis	Oxazepam
Cocaine	Phencyclidine (PCP)
Chloral hydrate ^b	Propoxyphene ^b
Clonazepam ^b	Scopolamine ^b
Clonidine ^b	Secobarbital
Diazepam	Temazepam
Ethanol	Triazolam
Flunitrazepam (Rohypnol) ^b	Zolpidem ^b
γ-Hydroxybutyrate (GHB) ^b	

^aFrequently, more than one drug is found. Most common are alcohol, marijuana, cocaine, and benzodiazepines; others account for less than 5% of positive tests.

^bWill not be detected on a routine immunoassay drug screen. A more detailed analysis will be required.

Data from Slaughter L: Involvement of drugs in sexual assault, *J Reprod Med* 45:425, 2000; Schwartz RH, Milteer R, LeBeau M: Drug-facilitated sexual assault ("date rape"), *South Med J* 93:558, 2000; and Negrusz A, Juhascik M, Gaenslen RE: Estimate of the incidence of drug-facilitated sexual assault in the US, Document 212000. Federal Grant 2000-RB-CX-K003. U.S. Department of Justice, 2005.

commonly associated with drug-facilitated sexual assault are ethanol, marijuana, cocaine, and benzodiazepines. Zolpidem, a common sleeping medication, has been used, but it is difficult to detect and only transiently positive in urine samples. Frequently, more than one drug is found. Although any type of sedative or hypnotic drug, or a combination of both, may be used to facilitate sexual assault, the most publicized drugs include flunitrazepam (Rohypnol), γ-hydroxybutyrate (GHB), and most recently, beverages containing high amounts of alcohol and caffeine (e.g., Four Loko [2017 Phusion Projects, Chicago IL]).^{63,64} In previous decades, laboratory testing implicated flunitrazepam and GHB in drug-facilitated sexual assault in approximately 3% to 5% of cases.⁶⁵ Flunitrazepam is a benzodiazepine unavailable in the United States but available in Mexico. It can be detected in urine up to 3 weeks after ingestion.⁶⁵ In the United States, GHB is a schedule 1, federally banned central nervous system depressant. Legally, it is available only by prescription as the drug Xyrem (Jazz Pharmaceuticals plc, Dublin, Ireland) for narcolepsy with a schedule 3 exception, but it can easily be manufactured illegally by users. It can be detected in drinking material residue by crime laboratories, as well as in the victim's urine, up to 4 hours after a sufficiently large ingestion. Drugs similar to GHB are 1,4 butanediol and γ-butyrolactone.

Often, the victim's last memory is of using drugs or alcohol and then passing out. A common scenario is for the victim to have one glass of wine (or another usual drink), suddenly feel nauseated, and then wake up hours later in a different location and lacking intervening memory. Some remember short segments of activity that may indicate some type of sexual acts. Victims may lack any memory at all but desire to be "checked" for intercourse. A comprehensive medical-forensic examination should be conducted on these individuals. Without

a history from the victim, examiners should collect samples from every potential oral or genital contact, including the neck, breasts, vulva, and from all orifices (oral, vaginal, and anal). Obtain samples of both blood and urine, if possible, for toxicology (including ethanol), with exact times of collection documented. Remember to collect the first voided urine to optimize potential recovery. Many of the drugs used to facilitate sexual assault are not found on routine hospital laboratory testing. Some forensic laboratories offer a “date-rape panel” that tests for a variety of commonly used substances. Obviously, a positive drug test does not prove date rape, and it may be impossible to distinguish self-administration from clandestine ingestion.

Extreme sensitivity must be used when discussing positive genital findings with a victim who has no memory of any sexual activity. Many times, the imagined sexual acts can create just as severe a traumatic response as an actual remembered sexual assault. For the unconscious victim, there is no memory of events to fill in the blanks, only his or her terrifying imagination of what could have happened.

LEGAL ISSUES

When the local government decides to proceed with a sex crime case against an alleged perpetrator, the district attorney will commonly contact the examiner to give legal testimony. A concise and complete well-documented chart often negates the need for a clinician to appear in court. When required for this task, it is best for the examiner to work with the prosecuting attorney to prepare testimony. As is the case for all ED patients, chart notes should be written objectively and carefully in the expectation that the ED evaluation and evidence collection may be presented in court. In some jurisdictions it is possible to minimize the time spent away from work by arranging to be called to the courtroom just before the time of testimony or by giving a deposition before the court date. Once on the witness stand, the examining clinician is most often considered a percipient witness and not necessarily an expert in the area of sexual assault. The law requires that one testify only to one’s best recollection and to what is indicated in the chart. Factual information in answer to questions should be given only if one knows the facts; assumptions should be avoided. One should not be afraid to acknowledge the limits of one’s knowledge or expertise. Statements such as “there were marks on the body that were consistent with bite marks” are preferable to statements such as “there were bite marks.” The court decides if a person was sexually assaulted, and the clinician is there to give information about the patient’s findings and statements, what was found, and what was done for treatment.

SARTS

Before the 1990s, sexual assault examinations were mostly the responsibility of emergency clinicians. However, since the early 1990s, nurses or nurse clinicians have been performing an increasing number of sexual assault examinations. Called sexual assault nurse examiners (SANEs), these nurses are the core members of SARTs. Other members of SARTs include law enforcement individuals, victim advocates, prosecutors, and forensic laboratory personnel.

Most examinations still take place in the ED but may be done in a space near the ED or an affiliated clinic. To establish SARTs, extra funding by government or a charitable organization is often needed because many local police jurisdictions often do not have the necessary funding to adequately reimburse for the evidentiary examination to support a program. However, law enforcement is increasingly willing to pay more for a SANE-performed forensic examination because they believe that it provides superior documentation for legal proceedings. Nurse examiners have formed the International Association of Forensic Nurses. This group has drafted standards of practice for sexual assault examiners’ education and the examinations themselves. Advantages of SARTs using SANEs include the following:

1. The practitioner performing the examination is specifically dedicated to treating the patient with a history of sexual assault, not tending to multiple patients in a busy ED.
2. The clinician has usually completed more extensive training on sexual assault examination (mean of 80 hours) and evidence collection and, accordingly, may perform a more comprehensive examination with better collection of evidence.^{18,66}
3. Many involved feel that designated clinicians understand and consider the emotional needs of the victim more fully because of their extra specialty training.

Useful guidelines and resources for establishing SANE programs are currently available.^{3,66,67}

ACKNOWLEDGMENT

The editors and author wish to acknowledge the contributions of G. Richard Braen to this chapter in previous editions; Beverly Kerr, Supervising Criminalist at Los Angeles County Sheriff’s Department; Mary Hong, Sr. Forensic Scientist-DNA Supervisor at Orange County Crime Laboratory; and Patricia A. Huck, Criminalist II of the LAPD Crime Laboratory for their technical forensic advice.

Neurologic Procedures

CHAPTER 59

Management of Increased Intracranial Pressure and Intracranial Shunts

Alessandra Conforto and Jonathan G. Wagner

Headache and head injury are encountered commonly in the emergency department (ED). If either is accompanied by vomiting, decreased level of consciousness, or abnormal vital signs, the possibility of increased intracranial pressure (ICP) should be considered. Acutely increased ICP is a neurologic emergency that must be managed rapidly to prevent further brain damage and death. In some cases the accompanying clinical symptoms may be vague or subtle and make diagnosis difficult. Familiarity with the pathophysiology of increased ICP facilitates its diagnosis and management.

PATHOPHYSIOLOGY OF ICP

Alexander Monro, an anatomist in the 18th century, described the intracranial contents as containing a fixed volume. The fixed-volume theory was supported by George Kellie a few years later and became known as the Monro-Kellie doctrine. This doctrine has since guided our understanding of intracranial dynamics and the principles of autoregulation.

The components of the calvaria are the brain parenchyma, cerebrospinal fluid (CSF), the venous blood supply, and the arterial blood supply (Fig. 59.1). CSF and the venous blood supply have the greatest ability to change their volume to compensate for increases in pressure. These dynamic changes in the relative proportion of the cranial content may not affect the patient if ICP is not excessive. However, if a pathologic process overwhelms the compensatory mechanisms, the result will be a nearly exponential increase in ICP (Fig. 59.2).

Normal supine ICP ranges from 5 to 15 mm Hg. Transient increases in ICP as high as 80 to 100 mm Hg occur with coughing or straining. Other factors that can transiently increase ICP are movement, pain, and fever. A space-occupying lesion such as a tumor, hematoma, abscess, or foreign body can also raise ICP. Fig. 59.3 demonstrates that the area and cause of

the increased ICP will determine where shifts occur to result in brain herniation.

Brain

Brain volume can be increased by edema, idiopathic intracranial hypertension (IIH), tumor, or bleeding. The three types of edema are vasogenic, cytotoxic, and interstitial. Vasogenic edema results from increased permeability of the capillaries, which leads to passage of excess fluid into the extracellular space. Cytotoxic edema is due to accumulation of intracellular fluid in brain tissue (neurons and glia) secondary to dysfunction of the adenosine triphosphatase pump. Interstitial edema occurs when fluid accumulates as a result of blockage of CSF absorption.

IIH, formerly known as pseudotumor cerebri or benign intracranial hypertension, is a chronic condition characterized by increased CSF pressure not caused by a tumor, edema, hydrocephalus, or change in CSF composition. It occurs most frequently in obese women. Symptoms may include headache, nausea, and blurry vision. The headache is typically worse on waking or with exertion. In general, patients with IIH have normal findings on neurologic examination except for the frequent presence of papilledema. The precise pathophysiology behind IIH remains unclear, with several proposed etiologies, including: cerebral venous outflow abnormalities (e.g., venous stenosis); increased CSF outflow resistance at either the level of the arachnoid granulations or CSF lymphatic drainage sites; obesity-related increased abdominal and intracranial venous pressure and obesity-related chronic inflammation; altered sodium and water retention mechanisms; abnormalities of vitamin A metabolism; and sex hormone dysfunction.¹⁻³ Severe and untreated cases of IIH can lead to permanent vision loss. There appears to be some crossover with the more serious and life-threatening diagnosis of cerebral venous thrombosis (CVT), and therefore magnetic resonance (MR) (ideally with venography) or computed tomography (CT) venography of the cerebral venous system is recommended in patients with presumed IIH to rule out CVT.^{4,5} Other commonly associated conditions are listed in Box 59.1.

Brain tumors encompass neoplasms that originate in the brain itself (*primary brain tumors*) or involve the brain as a metastatic site (*secondary brain tumors*). Primary brain tumors include tumors of the brain parenchyma, meninges, cranial nerves, and other intracranial structures (the pituitary and pineal glands) (Fig. 59.4). Primary central nervous system lymphoma refers to high-grade B-cell non-Hodgkin's lymphoma confined to the central nervous system. Secondary brain tumors, the most common type, originate elsewhere in the body and metastasize to the intracranial compartment.

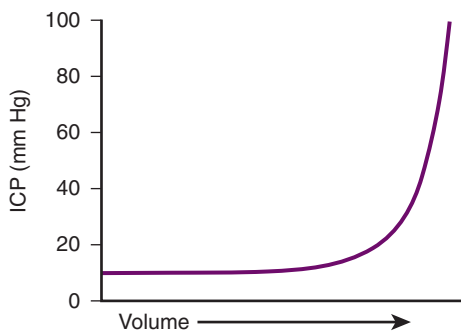

Figure 59.2 The intracranial volume-pressure relationship demonstrates the limits of compensatory mechanisms. Small changes in intracranial volume markedly increase intracranial pressure. ICP, Intracranial pressure.

Figure 59.3 Intracranial shifts as a result of supratentorial lesions. **A**, Relationships of the various supratentorial compartments as seen in a coronal section. **B**, Herniation of the cingulate gyrus under the falx (1); herniation of the temporal lobe into the tentorial notch (2); compression of the opposite cerebral peduncle against the unyielding tentorium, which produces Kernohan's notch (3); and downward displacement of the brain stem through the tentorial notch (4). (A and B, From Plum F, Posner JB: *The diagnosis of stupor and coma*, ed 2, Philadelphia, 1972, Davis. Reproduced by permission.)

Bleeding in the brain can occur spontaneously (as in the case of hemorrhagic stroke or spontaneous subarachnoid hemorrhage) or can be a result of trauma. In addition to the mass effect of the blood itself, the associated edema contributes to further increases in ICP. Diffuse axonal injury (DAI) may occur in isolation or in conjunction with intracerebral bleeding. With DAI, it is believed that the axons are not actually torn, but instead suffer significant injury that may lead to edema (shearing effect).⁶

BOX 59.1 Clinical Conditions and Factors Associated With Idiopathic or Benign Intracranial Hypertension (Pseudotumor Cerebri)

Hematologic Disorders

- Iron deficiency anemia
- Pernicious anemia
- Polycythemia vera
- Thrombocytopenia

Lupus

- Cushing's disease
- Hypoparathyroidism
- Hypothyroidism

Endocrine Conditions and Disorders

- Addison's disease
- Menstrual irregularities, menstrual cycle
- Pregnancy

Medical/Surgical Conditions with Impaired Cerebral Venous Drainage

- Otitis media, mastoiditis
- Idiopathic dural sinus thrombosis
- Radical neck surgery
- Chronic pulmonary disease with venous hypertension
- Heart failure with venous hypertension
- Congenital heart disease
- Renal failure
- High-flow arteriovenous malformation
- Chronic obstructive pulmonary disease
- Sleep apnea
- Growth hormone
- Cimetidine

Common Drugs

- Systemic steroid withdrawal
- Topical steroid withdrawal (infants)
- Oral contraceptives
- Tetracycline/minocycline
- Nitrofurantoin
- Sulfamethoxazole
- Vitamin A excess
- Glucocorticoids
- Nalidixic acid
- Levothyroxine
- Lithium
- Isotretinoin
- Nonsteroidal anti-inflammatory drugs
- Tamoxifen
- Cyclosporine

Dietary Considerations

- Hypervitaminosis A
- Hypovitaminosis A
- Obesity
- Malnutrition

CSF

CSF is produced by the choroid plexus at a daily rate of 400 to 600 mL (~ 20 mL per hour) with complete turnover of total volume occurring four to five times per day in young adults (Fig. 59.5).⁷ It flows from the ventricles into the cisternae of the subarachnoid space and is drained by the arachnoid villi of the

dural sinuses to maintain a constant volume of 100 to 150 mL. *Obstructive hydrocephalus* occurs when flow is blocked at any point in the ventricular system by clotted blood, tumor, colloid cyst, edema, or primary stenosis. *Communicating hydrocephalus* is due to impedance of flow beyond the ventricular system at the level of the basal cisternae or lack of absorption by the arachnoid villi. Communicating hydrocephalus can occur with both infection and subarachnoid hemorrhage (Fig. 59.6).

Figure 59.4 T2-magnetic resonance image of a patient with a left frontal mass (*right arrow*) and surrounding parenchymal edema, consistent with glioblastoma. The lesion has exerted a mass effect on the brain causing 7 mm of midline shift (*left arrow*) and subsequent subfalcine herniation.

Blood

Up to a certain range, cerebral blood flow (CBF) is maintained by an autoregulatory mechanism despite fluctuations in cerebral perfusion pressure (CPP) (Fig. 59.7). Constant CBF can typically be maintained at any CPP between 60 and 160 mm Hg. Once CPP is out of the autoregulatory zone, CBF is linearly related to CPP. CPP lower than 60 mm Hg can lead to ischemia, whereas CPP higher than 160 mm Hg can result in hypertensive encephalopathy.

SIGNS AND SYMPTOMS

Findings on neurologic examination can be normal in a patient with a mild increase in ICP because of the brain's compensatory mechanisms. Patients with a complaint of headache or head

Figure 59.5 Cerebrospinal fluid production and flow. (From Rengachary SS, Wilkins RH, editors: *Principles of neurosurgery*. Philadelphia, 1994, Mosby.)

Figure 59.6 Subarachnoid hemorrhage. **A**, Hyperdense blood from subarachnoid hemorrhage can be seen collecting in the basal cisternae (*arrow*). **B**, Image from the same patient, more superior in the cranium. Note the ventricular enlargement (*long arrow*) and effacement of the peripheral sulci (*short arrows*). These findings are indicative of hydrocephalus, and external ventricular drainage by a neurosurgeon should be considered.

Figure 59.7 Cerebral autoregulation. *CPP*, Cerebral perfusion pressure; *ICP*, intracranial pressure.

Figure 59.8 Acute subdural hematoma. The large hyperdense (*white*) collection on the right side of the brain is an acute subdural hematoma. The finding of hypodense areas (*black arrow*) within the subdural is referred to as the “swirl” sign, which suggests active bleeding. Also seen is approximately 3 cm of midline shift (*white arrow*), which indicates subfalcine herniation. Immediate reduction of intracranial pressure and surgical intervention are required.

injury may not initially manifest the more dramatic and worrisome symptoms of increased ICP such as vomiting, syncope, altered mentation, or Cushing’s reflex (bradycardia, increased blood pressure, and irregular respirations). ICP correlates poorly with clinical symptomatology. One of the earliest clinical signs is decreased venous pulsation on fundoscopic examination, but this may be difficult to appreciate in an acutely ill patient in a busy ED. Moreover, the initial findings on head CT might not reveal the true extent of injury, especially with early stroke or when DAI is involved. However, as compensatory mechanisms fail, CT findings, as well as clinical symptoms, will become more obvious.

Signs and symptoms of severely increased ICP include a decreasing level of consciousness, papilledema, cranial nerve palsies, and lateralizing neurologic deficits. When any of these are noted, particularly when CT confirms the presence of a mass effect, such as hydrocephalus or a midline shift, urgent intervention is necessary (Fig. 59.8). Neurosurgical consultation for possible invasive measures to reduce ICP is indicated. Medical management of increased ICP should also proceed without delay.

MEDICAL TREATMENT OF INCREASED ICP

Oxygenation

Management of the airway and breathing is paramount in patients with brain injury. If the patient is hypoxic, supplemental oxygen is critical in preventing further ischemia. Patients with a Glasgow Coma Scale (GCS) score of 8 or lower or with impending signs of inadequate respiratory status should undergo rapid-sequence intubation (RSI) to protect their airway and better control blood levels of oxygen and carbon dioxide (partial pressure of oxygen [PO_2] and partial pressure of carbon dioxide [PCO_2]). Apneic patients should receive bag-valve-mask ventilation while preparing for intubation, with specific avoidance of hyperventilation, and apneic oxygenation via a high-flow nasal cannula (rate of 15 L/min or higher) during airway securement.

Sedation and Paralytics

A rapid neurologic examination that assesses the patient’s pupillary reflexes, motor response to voice and painful stimuli, and the ability to interact with his/her surroundings should be performed before sedation and RSI. To blunt the hemodynamic response to intubation, fentanyl, at an intravenous (IV) dose of 2 to 5 $\mu\text{g}/\text{kg}$, can be given over 30 to 60 seconds while preoxygenating the patient.⁸ Fentanyl is an excellent drug for control of pain, which if untreated, can lead to increased ICP. Fentanyl can also be given during the pretreatment phase of RSI (3 minutes before administration of the paralytic agent) if time allows. Caution should be exercised, however, to avoid precipitous drops in blood pressure, which can threaten CBF and exacerbate brain injury. Therefore it should be avoided in hypotensive patients and hypovolemic patients. We also recommend caution in brain-injured patients with concomitant trauma, who may have exaggerated episodes of hypotension with narcotics and sedatives. Pretreatment lidocaine, which was traditionally believed to decrease the sympathomimetic response to intubation, is no longer recommended as multiple studies have shown conflicting and insufficient evidence to support its use.^{8,9} A defasciculating dose (typically 1/10 the intubating dose) of a nondepolarizing neuromuscular blocking agent given prior to intubation has also fallen out of favor as no sufficient evidence has supported its use.^{8,10}

In patients who are normotensive or hypotensive, etomidate (0.3 mg/kg IV) is the induction agent of choice due to its minimal effect on systemic blood pressure and its lowering of ICP.^{11,12} Ketamine, at a dose of 1 to 2 mg/kg IV, can also be used as it does not appear to increase ICP, as previously believed, and should be strongly considered in severely hypotensive patients due to its ability to increase blood pressure and its analgesic effects that minimize the adverse sympathetic stimulation of laryngoscopy.¹³ In hypertensive patients, thiopental (50 to 100 mg IV or 3 to 5 mg/kg IV) or propofol (1 mg/kg IV) can be used for induction.^{11,12,14} Propofol has gained acceptance as a sedative in patients with increased ICP because of its short duration of action and depression of cerebral metabolism and oxygen consumption. This may have a neuroprotective effect. However, with higher doses propofol can cause profound decreases in systemic blood pressure and extended periods of use can be associated with significant morbidity.¹⁴

Succinylcholine (1.5 mg/kg in adults and up to 2.5 mg/kg in pediatric patients) is the ideal paralytic agent in patients with increased ICP due to its rapid onset, short duration of

action, and consistent and reliable effects.¹⁵ Nondepolarizing agents (e.g., rocuronium) are appropriate when contraindications to succinylcholine exist (see [Chapter 5](#)). Sedatives and paralytics should be short-acting to facilitate close monitoring of the patient's neurologic status.

Oxygenation and Hyperventilation

As the airway is secured, adequate supplemental oxygen should be provided, with titration down rapidly from the initial fraction of inspired oxygen of 1.0 used for RSI to ensure oxygen saturation greater than 90%.⁶

In general, avoid hyperventilation in patients with brain injury as low PCO₂ levels cause cerebral vasoconstriction, resulting in decreased CBF in the critical hours following injury.^{6,16} Hyperventilation is also associated with poor survival and neurologic outcomes.^{16,17} For the majority of brain-injured patients, the target is thus eucapnia with a PCO₂ of 35 to 40 mm Hg.¹⁶ Nevertheless, if a patient displays evolving signs of brain herniation (e.g., anisocoria, hemiparesis, asymmetric posturing, Cushing's reflex, or rapid deterioration in GCS score), hyperventilation may be necessary to arrest the process. Current recommendations target a PCO₂ of 28 to 35 mm Hg in these scenarios as a temporizing measure until surgical or other interventions to lower ICP can occur.¹⁶

Head Position

If not in shock, routinely elevate the patient's head to decrease ICP, risk of aspiration, and in those who are intubated, rates of ventilator-associated pneumonia. This position allows drainage of cerebral veins. Feldman,¹⁸ Ng,¹⁹ and their colleagues demonstrated that elevation of the head to 30 degrees significantly reduces ICP in most patients without impairing CBF, CPP, or cerebral metabolism. Raising the head of a patient with hypotension, however, exacerbates any decrease in the patient's mean arterial pressure (MAP) and hence lowers CPP. If head elevation is to be used, MAP must be maintained above 90 mm Hg to facilitate a CPP of approximately 60 mm Hg.²⁰ It is also important to avoid neck rotation and flexion or any other intervention that could result in compression of the jugular vein. If the jugular veins are compressed, venous outflow from the head can be further compromised, increasing ICP. Therefore the head and neck should be kept in a neutral position.

Fluid Management

The goal in fluid management is to maintain euolemia; head-injured patients with hypotension have double the mortality of normotensive patients. Patients with increased ICP may be hypovolemic from profuse vomiting, decreased fluid intake, or hemorrhage. Distributive shock may also be present and occurs as a result of loss of vasomotor sympathetic tone, especially in patients with concomitant cervical spine injury. Only isotonic or hypertonic fluids should be used (normal or hypertonic saline), as hypotonic fluids may lead to worsening brain edema. Vasopressors may also be necessary. A target CPP of 60 mm Hg and MAP of greater than 90 mm Hg are recommended.²¹

Hyperosmolar Therapy

Mannitol effectively and rapidly reduces ICP. Mannitol can be given at doses of 0.25 to 1 g/kg (with the highest dose used

in emergency situations) infused every 2 to 4 or more hours.²² Current recommendations favor bolus therapy over continuous infusion. Mannitol can cause a precipitous drop in blood pressure (and hence CPP) in patients who are hypovolemic. Thus, mannitol is contraindicated in those with preexisting hypotension (typically defined as systolic blood pressure lower than 90 mm Hg). The effect of mannitol on ICP is transient; repeated doses lose their ability to decrease ICP over time. It may also cause renal damage as serum osmolarity increases. Similar to hyperventilation, mannitol should be viewed as a bridge to definitive neurosurgical intervention and its use reserved for patients with signs of impending herniation.

Mannitol has two properties: it initially acts as a volume expander and then serves as an osmotic agent. On administration of mannitol, intravascular volume expands and blood viscosity decreases, resulting in augmentation of CBF. Once volume expansion has occurred, osmotic movement of fluid from the brain parenchyma to the intravascular compartment begins and results in a decrease in ICP. The osmotic effect usually occurs within 15 minutes. The half-life of mannitol ranges from 90 minutes to 6 hours.²¹ Its effect is most pronounced in patients with CPP lower than 70 mm Hg.²¹

Hypertonic saline is a good alternative to mannitol in patients who are found to be hypotensive. Hypertonic saline is an ideal resuscitation fluid for patients with concomitant head injury and hemorrhagic shock as it effectively expands intravascular volume while causing osmotic diuresis of the brain. Hypertonic saline is typically used as a 3% solution in 150-mL boluses, as a 7.5% solution in 75-mL boluses, or as a 23.4% solution in 30-mL boluses. There is no consensus on the preferred concentration or volume of administration.²¹⁻²³ Hypertonic saline can be redosed if needed and its onset of action occurs rapidly.

Although the use of mannitol and hypertonic saline have both been endorsed by the Brain Trauma Foundation and a large consortium of pediatric societies, no clear evidence favors the use of one or the other in normotensive or hypertensive patients.^{21,22,24} However, in patients with hypotension, hypertonic saline is clearly preferred. A serum osmolarity of 320 mmol/L has previously been stated to be the upper limit of safety with both mannitol and hypertonic saline; however, this has been safely exceeded in practice without deleterious effects.^{22,25}

Seizure Prophylaxis

Controlling seizure activity is paramount in the early stages of traumatic brain injury to avoid hypoxia and aspiration, as well as elevation of ICP and possible herniation. In the absence of a seizure, it is currently controversial whether prophylactic anticonvulsant medication should be routinely administered after spontaneous intracranial hemorrhage. If a seizure occurs, anticonvulsant therapy is warranted. Following traumatic brain injury, there is low-quality evidence supporting the use of prophylactic phenytoin during the first week following injury to prevent early posttraumatic seizures, with the recognition that this has no effect on the occurrence of late seizures or mortality.²⁶ Rapidly acting benzodiazepines such as lorazepam and diazepam are first-line therapy for actively seizing patients, followed by anticonvulsant agents such as pentobarbital or phenytoin. Fosphenytoin can be given more rapidly (up to 150 mg/min IV by infusion) than phenytoin, which can be administered no faster than 50 mg/min IV. Phenytoin can induce hypotension and lower CPP, even at rates below 50 mg/

min. The use of levetiracetam in cases of severe head injury and stroke has been increasing.²⁷ Although beneficial effects of prophylactic anticonvulsants on outcomes have not been established, the risks associated with administration of anticonvulsants are small in comparison to the potentially devastating secondary injury that results from uncontrolled seizure activity.

Patients who are paralyzed, either chemically or by their neurologic disease, are difficult to monitor for seizure activity without the use of electroencephalography (EEG). These patients may manifest seizures by subtle rhythmic movements of the extremities, tonic gaze deviation, an elevation in heart rate or blood pressure, or spikes on an ICP monitor (if one is placed by the neurosurgeon). Whenever possible, avoid giving paralytic agents so that seizure activity can be monitored. If seizures are not controlled despite upward titration of benzodiazepines, phenytoin, or other agents, endotracheal intubation and induction of a barbiturate or propofol coma may be necessary. Pentobarbital has been used to treat uncontrolled elevations in ICP when other medical and surgical treatments have failed. It decreases CBF, metabolism, oxygen consumption, and cerebral edema. It also scavenges free radicals.²⁸ Pentobarbital is given at a loading dose of 10 mg/kg over a 30-minute period followed by infusion at 1 to 3 mg/kg per hour with an EEG monitor available for burst suppression. Intensive monitoring of the patient's hemodynamic status is necessary because of pentobarbital's hypotensive effect.

Steroids

Steroids have been shown to be beneficial in patients with vasogenic edema, that is, edema associated with brain tumors. Steroids decrease CSF production, stabilize membranes, and restore normal membrane permeability.²⁹⁻³¹ Dexamethasone is usually administered at 10 to 20 mg IV as a loading dose, followed by 4 to 10 mg every 6 hours. No studies support the use of steroids in head-injured patients; in fact, steroid use in this population has been found to increase mortality.^{32,33} In addition, glucocorticoids are not believed to be useful in the management of intracranial hemorrhage or cerebral infarction.

Glucose Control

Head-injured patients tend to be hyperglycemic in response to stress or steroid administration. Optimization of blood glucose levels is currently undertaken in the management of these patients to avoid cellular edema in brain tissue. Hypoglycemic states can exacerbate brain injury and therefore should be scrupulously avoided. However, the long-term value of tight glycemic control in the management of acute brain injury with increased ICP is unclear.

Hypothermia

Lower body temperatures have been associated with a decrease in CBF, ICP, and metabolism. The previous method of keeping core temperatures lower than 30°C has been abandoned due to increased incidence of cardiac arrhythmias, severe coagulopathy, and the difficulty of maintaining such profound hypothermia. More recently, mild therapeutic hypothermia (32°C to 34°C) has become popular in the management of post-cardiac arrest victims who do not regain consciousness. Although one study has shown a benefit in survival and

decreased ICP with mild hypothermia (32°C to 34°C),³⁴ in the setting of traumatic brain injury and stroke it is not currently recommended and should only be considered if all other treatment modalities have been ineffective in lowering ICP.³⁵ Hyperthermia increases ICP and should be aggressively treated with antipyretics and cooling measures.

Skull Trephination

Skull trephination, also known as trepanning, trepanation, or bur hole placement, is a technique that has been traced back to the Neolithic age.³⁶ Though rarely performed by non-surgeons, it can be a lifesaving procedure for severely head-injured patients. In a patient with an acute epidural hematoma and deteriorating findings on neurologic examination (decreasing level of consciousness, anisocoria, or hemiparesis), skull trephination has been shown to improve both short- and long-term neurologic outcomes.^{37,38} Trephination is an appropriate treatment of acute subdural hematoma as well, but this requires incision through the dura mater and is less realistic for non-neurosurgeons (Figs. 59.9 and 59.10). Trephination may be lifesaving if performed before transport in selected patients from remote-practice environments without neurosurgical capability. This heroic procedure is not standard nor is it an expected skill for most emergency clinicians; nonetheless, it may be attempted when the situation is dire.

Trephination in the ED should be performed only in the temporal regions. Trephination in the parietal and occipital regions is associated with a much higher risk for hemorrhage and air embolism because of their proximity to the dural venous sinuses. These approaches should generally be performed only after the results of CT are available for guidance.³⁷

In practice environments without access to CT, it is not unreasonable to attempt this procedure before transport of the patient when all other measures to lower ICP have failed and signs of evolving brain herniation are present. The blind approach for temporal trephination is depicted in Fig. 59.11

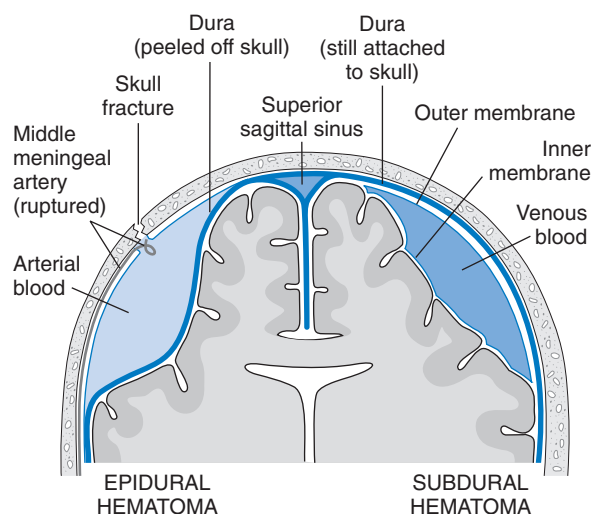

Figure 59.9 Epidural hematoma (left): rupture of a meningeal artery (usually associated with a skull fracture) leads to accumulation of arterial blood between the dura and skull. Subdural hematoma (right): damage to bridging veins between the brain and superior sagittal sinus leads to accumulation of blood between the dura and the arachnoid. (From Mitchell R, Kumar V, Fausto N, et al: *Pocket companion to Robbins & Cotran pathological basis of disease*, ed 8, Philadelphia, 2011, Saunders.)

Emergency Skull Trephination

Indications

Acute epidural hematoma and both of the following:

1. Deteriorating findings on neurologic examination (e.g., decreasing level of consciousness, anisocoria, hemiparesis)
2. Delay in obtaining definitive neurosurgical care (e.g., remote-practice environments)

Contraindications

Parietal or occipital epidural hematomas (high risk for hemorrhage and air embolism because of dural venous sinuses)
Subdural hematomas (requires an incision through the dura mater and is less realistic for the non-neurosurgeon)

Complications

Bleeding
Infection
Brain parenchymal injury

Equipment

- | | |

Review Box 59.1 Emergency skull trephination: indications, contraindications, complications, and equipment.

Figure 59.10 Epidural and subdural hematomas. **A**, Acute epidural hematoma. The hyperdense (*white*) appearance of this lesion indicates that it is acute. The inner margins of epidurals (*arrows*) have a convex appearance, which results in a lens-shaped hematoma. Note that the hematoma does not cross the suture lines (temporal-sphenoid anteriorly, temporal-parietal posteriorly.) **B**, Acute-on-chronic subdural hematoma. The heterogeneous density of this lesion (hypodense anteriorly [*double asterisk*], hyperdense posteriorly [*asterisk*]) suggests an acute-on-chronic hemorrhage. The inner margins of subdurals (*arrows*) are concave, which results in a crescent-shaped hematoma. Subdural hematomas may cross suture lines (note that this hematoma extends from the frontal to the parietal regions). Both these examples demonstrate effacement of the lateral ventricles and midline shift, which are indicators of increased intracranial pressure.

Emergency Skull Trephination

Shave, prepare, and drape the entry site. Use CT to guide the location of the burr hole placement. If CT is not available, choose a site 2 cm anterior and 2 cm superior to the tragus.

Make a 4-cm vertical incision extending down to the periosteum. Optionally apply Raney clips to the skin edges to control bleeding.

Insert a self-retaining scalp retractor to provide exposure. The exposed area should be about 2.5 cm in diameter.

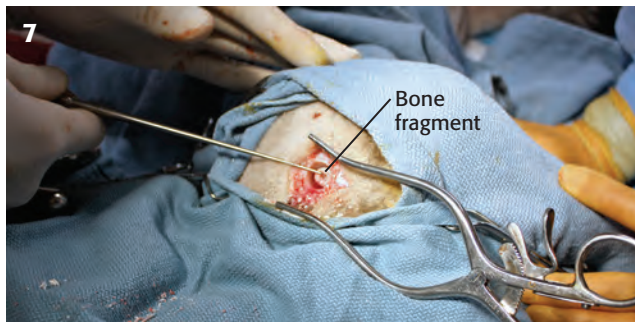

Use the periosteal elevator to elevate the periosteum off the skull.

Adjust the centering point of the trephine so that it protrudes 1/8 inch. With the trephine at a 90-degree angle to the skull, apply gentle pressure with a clockwise-counterclockwise rotating motion.

Stop sawing into the skull when you feel a slight give, which indicates that you have penetrated the full thickness of the skull. Remove the trephine.

If the bone fragment does not come out in the trephine, use toothed forceps or a hooked instrument to remove it. Preserve the bone fragment in sterile saline.

Allow the clot and blood to extrude from the burr hole. Apply gentle suction as needed to assist evacuation of the clot. A small suction catheter can be left in place during transport if needed.

Figure 59.11 Emergency skull trephination. This technique is for patients with epidural hematomas in the temporal region. It should not be used for parietal or occipital hematomas. If a subdural hematoma is present, the dura must be opened. If no blood is encountered on a blind procedure done on the same side as a blown pupil, repeat it on the opposite side. *CT*, Computed tomography.

and involves locating an area 2 cm anterior and 2 cm superior to the tragus on the side of the suspected hematoma.³⁷ In the majority of cases, the appropriate side for trephination is ipsilateral to pupillary dilation and contralateral to motor paresis.

The temporal area (between the ear and the orbit) should be shaved and prepared with chlorhexidine or povidone-iodine via sterile technique. Local anesthetic can be used to infiltrate the area of the planned incision; however, this is not necessary in an unconscious patient and adds time to the procedure.

Once the proper location is identified, either with a blind approach or by using the results of CT, make a 4-cm vertical incision through the skin and temporalis fascia. Divide the temporalis muscle. Once the periosteum is identified, incise it. Expose the skull by elevating the periosteum (with a periosteal elevator if available). Insert a trephine or hand drill into the area underneath the periosteum.³⁷ While holding the drill perpendicular to the skull, apply continuous gentle downward pressure and rotate the drill in an alternating clockwise-counterclockwise motion. As progress is made with the hand drill, gradually reduce pressure to avoid inadvertent “plunging” into the brain parenchyma. The operator will know when penetration through both the outer and inner tables of the skull has been accomplished once resistance against the drill is no longer felt. After skull penetration has been accomplished, remove the round piece of bone that has been cored out (with the diameter of the drill) and place it in saline.

In many cases, epidural blood and clots under pressure will extrude from the site on full penetration of the skull. However, insertion of a suction catheter into the trephined space may be necessary for full evacuation of clotted material. If easily identified, the bleeding artery (usually the middle meningeal artery) may be clamped.³⁷ After successful trephination, the patient's status should immediately be reassessed for signs of improvement. In a significant minority of patients, false localizing signs may lead the clinician to suspect a hematoma on the wrong side. Thus, if no improvement is noted with trephination on the side of the suspected hematoma, the procedure may be repeated on the opposite side. However, in all cases the delay in definitive neurosurgical care caused by attempts at trephination must be weighed against the possible benefits of the procedure. Moreover, trephination should ideally be performed after consultation with the accepting neurosurgeon.³⁸

Complications of the procedure include bleeding, infection, and injury to the brain parenchyma.

Operative Management

Operative management is the definitive treatment of increased ICP secondary to a space-occupying lesion. This entails either craniotomy or ventriculostomy with drainage of blood and CSF.

INTRACRANIAL SHUNTS

Intracranial shunts are used for the long-term management of increased ICP. An estimated 30,000 intracranial shunts are placed in the United States every year. Intracranial shunts have a high rate of failure and represent a disproportionately high number of hospital readmissions.³⁹ Approximately 80% of patients will require at least one revision in 20 years and more

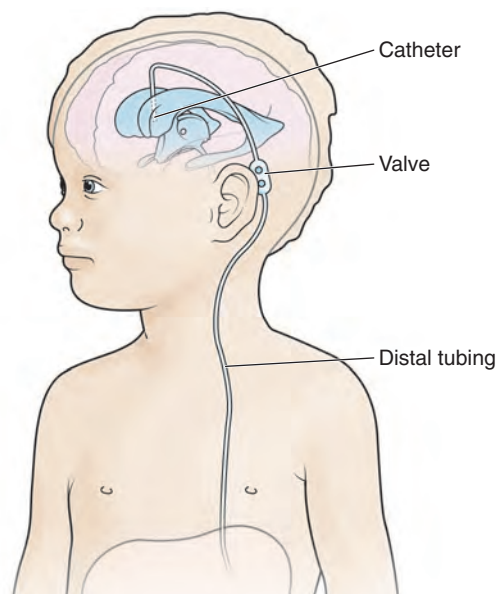

Figure 59.12 The basic tripartite ventricular shunt system is composed of a ventricular catheter, valve mechanism, and distal tubing. A slit valve may be used in the far end of the distal tubing instead of a more proximally placed valve, as shown.

than half of these occur within the first 2 years after shunt placement.⁴⁰ Shunt failure tends to be more common in the pediatric population.^{41,42} A recurrent elevation in ICP because of shunt malfunction can occur days to years after shunt placement.

The basic principle behind an intracranial shunt is to divert CSF into a body cavity from which it can readily be eliminated and drained. The essential elements of the shunt system include a proximal and a distal catheter, a valve, and a reservoir. The valve allows unidirectional flow, incorporates a pumping chamber, and regulates the pressure at which flow will occur across it. The reservoir is usually located between two valves. The proximal valve allows flow from the ventricles to the reservoir, whereas the distal valve allows flow from the reservoir to the distal catheter (Fig. 59.12). Many different types of shunt systems, incorporating a variety of designs, are available (Fig. 59.13). Some have unique characteristics, such as a double dome, whereas in others, valves are absent altogether.

In most cases the reservoir allows for measurement of pressure, testing for patency, fluid sampling, and injection of medication or contrast material. In rare cases, other equipment is incorporated into the shunt system for specific purposes, including an on-off switch, a telemetric pressure sensor, and an anti-siphon device.

Ventriculoperitoneal (VP) shunts are at present the mainstay for treatment of hydrocephalus in infants and children because of the ease of insertion of the catheter and the capacity of the peritoneal cavity to absorb CSF. Other types of shunts include ventriculovenous, ventriculoatrial, ventriculopleural, and lumboperitoneal. These are usually reserved for circumstances in which VP shunting has failed or when the patient has a history of multiple abdominal surgeries or peritoneal infections.

In the VP shunt system, a ventricular catheter is placed in the right frontal horn of the lateral ventricle (nondominant hemisphere) and connected to a subcutaneous valve traversing the temporal aspect (Fig. 59.14). This valve is then connected

to a distal catheter threaded subcutaneously into the neck and finally into the peritoneum (Fig. 59.15). Ventricular catheters can be either straight or angled, with the latter having the option of a reservoir component attachment. Valves come in four different types (ball, diaphragm, miter, slit), each with unique flow characteristics. The distal catheter has either an open or closed end. Identifying the type of shunt in place

is often difficult unless the patient or caretaker has the information available. Moreover, the skin overlying the subcutaneous component of the shunt in the temporal regions can scar, thus rendering palpation of the shunt type impossible.

Programmable VP shunts have recently become more popular and several different brands are now available. Unlike a traditional shunt, which has a fixed pressure threshold for

CSF drainage, the opening pressure of the valve in a programmable shunt can be adjusted transcutaneously using a magnetic coding device.

Shunt Failure

Shunt failure can occur because of mechanical obstruction, fracture or migration of the shunt, excessive CSF drainage or infection.⁴³

Mechanical Obstruction

The most common cause of shunt malfunction is catheter obstruction. This usually occurs at the ventricular catheter tip or at the valve.⁴⁴ The proximal blockage may be due to tissue debris or choroid plexus within the ventricular catheter, whereas the distal obstruction of venous shunts may result from thrombus or venous occlusion (such as in a ventriculovenous shunt). Peritoneal shunts may be associated with infection (peritonitis) or mechanical obstruction (e.g., omental blockage). Some evidence suggests that delayed hypersensitivity to the shunt material is also an occasional cause of obstruction.

Postoperatively, following shunt placement, the ventricles usually begin to diminish in size within a week in patients with high-pressure hydrocephalus, so continued enlargement suggests (but does not confirm) shunt malfunction. With normal-pressure hydrocephalus, however, the ventricles may remain large despite adequate drainage of the CSF.

Fracture and migration of the catheter usually present with subtle signs of elevated ICP and clinically are similar to shunt obstruction.⁴⁴

Excessive CSF Drainage

Extra-axial fluid collection may occur in response to rapid decompression of enlarged ventricles. This is a relatively rare cause of shunt failure and is estimated to occur in approximately 3.4% of cases. Although most commonly due to a benign collection of CSF, at times a subdural hematoma may form in response to the sudden decompression of the ventricles, which leads to tearing of the bridging veins as the brain pulls away from the dura. Slit ventricle syndrome (SVS) can also occur in response to chronic overdrainage in children and is characterized by small ventricles demonstrated on CT scan with symptoms suggestive of shunt malfunction. In contrast to shunt obstruction, symptoms of SVS are typically influenced by postural changes and improve after resting supine.⁴⁵

Shunt Infection: Treatment and Prevention

Of all the potential complications associated with shunting procedures, infection is the most notorious and occurs in 2% to 10% of cases.⁴⁶ Two studies have shown that approximately 8% of neurosurgical patients with implanted shunts acquire infections.^{47,48} Infection can be due to skin organisms overlying the valve that may ulcerate the skin and colonize the shunt⁴⁹; however, the most common cause of shunt infection is colonization at the time of shunt placement.⁵⁰ Typical organisms include *Staphylococcus epidermidis* and *Staphylococcus aureus*, as well as gram-negative bacilli, which are thought to be introduced into the system during manipulation of the site.⁵¹ Approximately 70% of these infections are seen within 2 months of shunt placement. Other risk factors associated with shunt infection include perioperative infection and dental or urologic instrumentation.

Most shunt infections are caused by otherwise nonvirulent bacteria such as *S. epidermidis*. In the presence of the shunt, these organisms exhibit unusual virulence. This reflects a variety of factors, including the ability to adhere to shunt surfaces, as well as production of mucoid substances that protect the bacteria from host defenses. The Silastic shunt material itself has an adverse effect on the immune system. Specifically, leukocytes cannot adhere to such surfaces as well as bacteria can.

The diagnosis may be obvious in patients with variable systematic signs, wound infection, meningitis, peritonitis, or septicemia. However, the shunt may harbor an indolent infection without symptoms or signs. Culture of CSF obtained from a shunt tap may be negative even when the shunt is ultimately shown to be infected.^{52,53}

A 2014 systematic review recommends removal of the shunt “with a moderate degree of clinical certainty” in the presence of shunt infection; however, controversy still exists over the need for complete or partial shunt removal.⁵⁴ Nevertheless, many neurosurgeons still recommend replacement of the entire shunt after the infection is eradicated.

If a shunt infection is suspected, empiric systemic antibiotics should be given as soon as possible in the ED. Consultation with a neurosurgeon and infectious disease specialist is recommended before administering antibiotics directly into the CSF, as the available evidence is insufficient to support intrathecal administration of antibiotics in addition to those administered systemically.⁵⁴

Clinical Presentation

Patients with intracranial shunt malfunctions frequently present to the ED. In many cases the patient’s significant other or caretaker provides the subtle clues that lead to the diagnosis. Depending on the age of the patient, symptoms of increased ICP may include changes in behavior and level of consciousness. Headache, nausea, vomiting, and visual disturbances are also common. In children, lethargy, poor feeding, vomiting, ataxia, decreased or increased activity level, fussiness, fever and diaphoresis, as well as bulging fontanelles can all be indications of shunt malfunction. Bradycardia not associated with hypertension is also suggestive of increased ICP and shunt malfunction. Fever, particularly within the first 6 months after surgery, is strongly associated with shunt infection.⁴³ In children, lethargy and shunt site swelling are the most predictive signs of shunt malfunction.⁵⁵ Failure of upward gaze is another sign (“sunset eyes” or Parinaud’s syndrome).⁵⁶ Cranial nerve, visual field, and fundoscopic examination should be routine in the assessment of older, cooperative patients with intracranial shunts.

Symptoms of shunt malfunction may be difficult to interpret, particularly if the symptoms are atypical or nonspecific or if they occur in young children. Likewise, asymptomatic shunt obstruction can occur in children in whom shunt independence has developed. Clinical evaluation of a child may not always be diagnostic of a shunt malfunction.

Shunt Assessment

The characteristics of the valve reservoir on compression or “pumping” the shunt may be useful in diagnosing shunt malfunction in some cases, although the utility of this technique has been challenged by some experts.^{46,57} Partial shunt valve compression should be done because full depression and release may lead to suction of the choroid plexus. If the CT scan

shows narrow (slit) ventricles, indicative of overdrainage, further valve compression may similarly cause blockage of the shunt. When compressing the shunt, a normal refill time of 15 to 30 seconds should be observed. If the valve fills more slowly than this but can be compressed easily, the obstruction is proximal to the valve. If the valve is not compressible, the blockage is either at the valve or distal to it. Proximal obstruction is more common than distal obstruction. Other sources of proximal blockage include blood clots or debris related to the surgical procedure. Sources of distal occlusion include malposition, infection, shunt disconnection, and pseudocyst formation. The entire shunt tract and all surgical incisions should be examined for signs of wound infection, disruption of the tubing, or CSF leakage around the tract. Definitive treatment usually requires shunt revision.

Radiographic imaging is the cornerstone of shunt evaluation when dysfunction is suspected in the ED. A non-contrast-enhanced head CT is the initial imaging modality of choice. Radiographic findings indicative of hydrocephalus include enlarged ventricles and evidence of transependymal flow of CSF. It should be noted, however, that the finding of enlarged ventricles on CT reveals little about shunt function unless comparison with previous images or serial scans show progressive ventricular expansion. Head CT has a sensitivity of 83% in detecting shunt obstruction and a negative predictive value of 93%.

Although shunt series radiographs have long been a mainstay in the evaluation of VP shunts, evidence challenges the role

of these radiographs as a routine part of the diagnostic workup for shunt malfunction in the setting of a normal CT or radionuclide imaging. Findings of an abnormal shunt series alone changed management only in 0.3% of cases in a recently published (2011) ED retrospective review.⁴¹

Patients with intracranial shunts are subjected to repeat radiological evaluation over the course of their lifetime and excessive exposure to ionizing radiation is a very real concern. Therefore sparing additional unnecessary exposure to radiation has been advocated by certain experts.⁴¹ Other techniques, such as low-dose CT scan obtained with decreased tube current and a lower number of CT slices (as low as three), have significantly decreased radiation exposure (up to 87%) while still accurately diagnosing shunt malfunction.⁵⁸ Modified magnetic resonance imaging (MRI) protocols have also decreased the use of ionizing radiation in the evaluation of shunt function. One note of caution: MRI studies may interfere with the settings of programmable VP shunts; consultation with the patient's neurosurgeon is advised before proceeding with MRI in these patients.⁵⁹

Shunt series radiographs consist of anteroposterior (AP) and lateral skull, AP chest, and AP abdominal radiographs (Figs. 59.16 and 59.17). They still have an essential role in the setting of an abnormal CT as these films may reveal kinking, breakage, or disconnection of the catheter (Fig. 59.18) and help localize the site of shunt malfunction. Shunt series radiographs have a sensitivity of 20% and a negative predictive value of 22%.

Figure 59.16 Computed tomography (CT) evaluation of a ventriculoperitoneal shunt. Axial (*top row*) and coronal (*middle row*) CT images reveal the intracranial portion of the shunt. Mild ventriculomegaly is noted; however, this reveals little about shunt function without comparison to previous scans. The shunt (*arrows*) can also be visualized on the CT scout images (*bottom row, left and middle*). A companion chest radiograph (*bottom row, right*) demonstrates continuity of the shunt (*arrows*) through to the peritoneal cavity.

Figure 59.17 Conventional radiography standard shunt series. A standard shunt series includes skull, chest, and abdominal radiographs. **A**, This anteroposterior (AP) skull radiograph reveals the proximal intracranial portion of the shunt and a Rickham reservoir (*arrow*) over the bur hole. A companion non-contrast-enhanced head CT scan (see Fig. 59.16) is usually performed to further evaluate shunt function. **B**, The lateral skull radiograph better reveals a cylindrical Holter valve (*long arrow*) several centimeters distal to the Rickham reservoir (*short arrow*). **C**, This AP chest and abdominal radiograph reveals the distal portion of the shunt (*arrow*). Note the length of the catheter to allow patient growth. **D**, The lateral chest and abdominal view demonstrates the course of the shunt.

If the distal catheter is in the peritoneum and a distal obstruction is suspected or if the patient complains of abdominal pain, abdominal ultrasound should be obtained. Ultrasound may reveal a pseudocyst at the distal portion of the catheter or an abnormal fluid collection. Ultrasound has also been used to rapidly identify the cause of catheter malfunction at the bedside, in the case of catheter discontinuity, and it is likely that its use in this role will continue to increase, particularly if radiographic studies are not readily available.⁶⁰

Tapping the reservoir proximal to the distal valve allows percutaneous testing of proximal shunt patency. Although this is useful in most instances, it can be difficult to assess the rate of inflow or runoff adequately with a small-bore needle, particularly if the patient is a child or is unable to cooperate. CSF should be sent for analysis, including cell count, glucose, protein, Gram stain and culture, when infection is suspected. The potential for introducing infection is a concern when

accessing the VP shunt and strict sterile technique should be maintained throughout the procedure.

Other invasive techniques include injection of either radio-nuclide or contrast material into the shunt as a marker of flow. If ventricular fluid pressure is low, there may be little evidence of flow, thus giving a false indication of shunt malfunction.

Various noninvasive techniques have been devised for assessing shunt function. Changes in visual evoked potentials associated with elevated ICP have been suggested as a means of determining function. Thermographic and Doppler detection of shunt flow is also possible. MRI techniques can likewise assess CSF flow and shunt patency.

Shunt Tapping

Percutaneous access of the VP shunt is generally performed by a neurosurgeon; however, if neurosurgical consultation is

Figure 59.18 Before and after series of a shunt malfunction. The left column (A–C) demonstrates a malfunctioning shunt. The right column (D–F) is the same patient after shunt revision. **A**, The shunt has become disconnected at the valve; no efferent catheter tubing is seen coming from the inferior portion of the valve (*arrow*). **B**, The catheter has migrated inferiorly and has coiled in the pelvis (*arrow*). **C**, Head computed tomography (CT) scan showing ventriculomegaly (*arrow*), a direct result of the shunt malfunction. **D**, After shunt revision, the lateral skull radiograph shows that a catheter is now connected to the valve (*arrows*, difficult to appreciate on this film). **E**, The catheter is seen coursing through the abdomen (*arrows*). **F**, Repeated head CT shows resolution of the ventriculomegaly.

not available, the emergency physician may need to perform the procedure as described.

Clip the scalp hair over and around the reservoir, prepare the skin with a surgical scrub brush for 10 minutes, followed by the application of a povidone-iodine solution, and then

allow it to fully dry. After appropriate draping, infiltrate the skin with 1% plain lidocaine to a level of adequate local anesthesia. Use a 25-gauge butterfly needle with tubing and enter the reservoir percutaneously at a 20- to 30-degree angle (Fig. 59.19). Lack of CSF flow from the reservoir indicates a

Figure 59.19 Tapping a ventriculoperitoneal shunt. Use a 25-gauge butterfly needle to puncture the reservoir. To avoid damage to the reservoir, the angle should be approximately 20 to 30 degrees. Note that the dome reservoir is under the skin. Before passing the butterfly needle, the skin is anesthetized, sterilized with povidone-iodine, and nicked with a No. 11 scalpel blade or a larger needle. Fluid is not aspirated but is allowed to drain passively. *CSF*, Cerebrospinal fluid.

proximal obstruction unless the ventricles are completely deflated (SVS). Even so, a small amount of CSF should be obtained within the tubing, thus ensuring that entry into the lumen of the reservoir has been accomplished. If the ventricles are deflated and only a small amount of CSF is aspirated, hold the end of the tubing 5 to 10 cm below the level of the reservoir to see whether CSF will fill the tubing and eventually begin to drip at the rate of 2 to 3 drops/min. If CSF is readily aspirated from the reservoir, hold the tubing vertically to obtain an indication of intraventricular pressure. This pressure reading, as well as the ease with which CSF is aspirated, will give some indication of proximal obstruction. To assess runoff or patency of the distal end, apply pressure to the tubing proximal to the reservoir and then deflate the reservoir without any resistance. If any resistance is encountered when deflating the reservoir, suspect a distal obstruction.

It is essential to send any aspirated CSF for laboratory analysis, including a cell count, protein, glucose, and most importantly, Gram stain and culture to evaluate the system for infection.

Future Directions

The diagnosis of shunt malfunction remains challenging and delays in diagnosis can cause permanent neurologic sequelae and death. Proposed solutions include developing new techniques to drain CSF that are not reliant on intracranial shunts with their high failure rates and frequent need for revision. Endoscopic third ventriculostomy (ETV) has been considered a valuable alternative to VP shunt placement in selected cases. Although there are no trials directly comparing the two techniques, a 2014 systematic review of the evidence has found that ETV is a viable treatment option for pediatric hydrocephalus, with equivalent outcomes in determined clinical scenarios.⁶¹

Another possible solution would rely on improved evaluation of the implanted shunts. An indwelling device that monitors ICP would obviate the need for repeated exposure to ionizing radiation and the risk of infection of repeated shunt taps. One such device, currently still in the experimental phase, shows clinical promises. The *baric probe* is an implantable, long-term ICP monitor based on a compressible gas design that can be interrogated by handheld ultrasound and provide continuous data on the status of the shunt.⁶²

Spinal Puncture and Cerebrospinal Fluid Examination

Brian D. Euerle

Cerebrospinal fluid (CSF) examination is performed in the emergency department (ED) to obtain information relevant to the diagnosis and treatment of specific disease entities. Many urgent and life-threatening conditions require immediate and accurate knowledge of the nature of the CSF. However, on rare occasions, certain harmful consequences may result from a spinal puncture. Perform a careful neurologic examination before the procedure, and give special thought to the risks and merits of the procedure in each situation.

HISTORICAL PERSPECTIVE

In 1885, Corning punctured the subarachnoid space of a living patient to induce cocaine anesthesia.¹ In 1891, Quincke first removed CSF in a diagnostic study and introduced the use of a syringe.² He studied the cellular contents and measured protein and glucose levels. Quincke was also the first to record CSF

pressure with a manometer. Subsequently, increasingly sophisticated bacteriologic, biochemical, cytologic, and serologic techniques were introduced. In 1919, Dandy reported on replacing CSF with air to determine normal brain anatomy and to identify pathologic changes.³ Water-soluble contrast media have since been used to delineate the spinal subarachnoid space and cerebral cisterns. Other uses of spinal dural puncture include drainage of fluids and injection of anesthetic agents, chemotherapeutic agents, and antibiotics.

ANATOMY AND PHYSIOLOGY

In adults, CSF occupies approximately 140 mL of the spinal and cranial cavities, with approximately 30 mL in the spinal canal. This volume is the result of a balance between continuous secretion (primarily by the ventricular choroid plexus) and absorption into the venous system (mainly by way of the arachnoid villi). After formation, the fluid passes out of the ventricles via the midline dorsal foramen of Luschka and the lateral ventral foramina of Magendie. The fluid then flows into the spinal subarachnoid space, the basilar cisterns, and the cerebral subarachnoid space. The rate of production is approximately 0.35 mL/min, and ventricular production of CSF is such that there is a net flow out of the ventricles of 50 to 100 mL/day. The usual volume of CSF (15 to 20 mL) removed at lumbar puncture is commonly regenerated in approximately 1 hour.

CSF may have an embryologic nutritive function; at maturity, CSF most likely acts as a mechanical barrier between the soft brain and the rigid fibro-osseous dura, skull, and vertebral column. It also appears to support the weight of the brain.⁴ When buoyed by CSF, the functional weight of the brain is

Spinal Puncture

Indications

- Suspected central nervous system infection (meningitis)
- Suspected spontaneous subarachnoid hemorrhage
- Suspected central nervous system syphilis
- Suspected idiopathic intracranial hypertension

Contraindications

Absolute:

- Presence of infection near the puncture site

Relative:

- Coagulopathy
- Presence of increased intracranial pressure caused by a space-occupying lesion
- Severe thrombocytopenia

Complications

Brain herniation	Meningitis
Cauda equina syndrome	Minor backache
Cranial nerve VI palsy	Postdural puncture headache
Epidermoid tumor	Retroperitoneal abscess
Epidural cerebrospinal fluid collection	Subarachnoid hemorrhage
Epidural hematoma	Subdural hematoma
Intrathecal pump catheter	

Equipment

The equipment for spinal puncture is most commonly found in a prepackaged kit.

Review Box 60.1 Spinal puncture: indications, contraindications, complications, and equipment.

reduced from 1400 g to 50 g. Contraction and expansion of CSF accommodate changes in brain volume.

INDICATIONS FOR SPINAL PUNCTURE

General Indications

The indications for spinal puncture have been reduced with the introduction of noninvasive diagnostic procedures, that is, magnetic resonance imaging (MRI) and computed tomography (CT). A few clinical situations require early or even emergency spinal puncture. The primary indication for an emergency spinal tap is the possibility of central nervous system (CNS) infection (meningitis), with the exception of a suspected brain abscess or a parameningeal process. The need for early detection of meningitis results in the performance of many more lumbar punctures than ultimate diagnoses of infection.⁵ No other method can be used to completely exclude meningitis.

The mere presence of a fever does not mandate lumbar puncture. However, CSF should generally be examined for evidence of infection in patients with a fever of unknown origin, especially if consciousness is altered or the immune system is impaired, even in the absence of meningeal irritation. Meningeal signs may not be present in patients who are old, debilitated, or immunosuppressed; are receiving antiinflammatory drugs; or have had partial treatment with antibiotics.^{6,7} In a newborn, even a fever is not a dependable sign because temperatures may be normal or even subnormal. For infants younger than 1 year, a high index of suspicion is required to make the diagnosis of meningitis.

Approximately 25% of infants with meningitis will not have nuchal rigidity, but many appear toxic or moribund. A tense and bulging fontanelle is somewhat more reliable, although this sign may be absent in a dehydrated child. Neonatal meningitis occurs in 25% of sepsis cases. In addition, 15% to 20% of infants with meningitis have negative blood cultures.^{8,9} In a child between the ages of 1 month and 3 years, fever, irritability, and vomiting are the most common signs of meningitis. Typically, handling is painful for the child, and the child cannot be comforted. In addition, an older child may complain of a headache. At all ages, patients generally appear ill and drowsy with a dulled sensorium. Physical signs become more useful in diagnosing meningitis in children older than 3 years¹⁰ and include nuchal rigidity, Kernig's sign (effort to extend the knee is resisted), and Brudzinski's sign (passive flexion of one hip causes the other leg to rise, and effort to flex the neck makes the knees come up). The jolt accentuation test is a more sensitive sign of meningeal irritation.¹¹ This test is considered positive when the patient's pain is exacerbated by lateral rotation of the head to either side. A petechial rash in a febrile patient should also raise suspicion for *Neisseria meningitidis*.¹² Previous use of antimicrobial agents may modify the clinical and CSF findings; partially treated children are less likely to be febrile or exhibit an altered mental status. In addition, patients in the early stages of meningitis may lack the classic features associated with advanced disease.

The second indication for emergency spinal puncture is suspected spontaneous subarachnoid hemorrhage (SAH). The diagnosis is usually made by imaging (head CT) or by the direct finding of blood in CSF obtained by spinal puncture.^{13,14} Before a major hemorrhage, 20% to 60% of patients with aneurysmal SAH have had a "sentinel thunderclap" or "warning

leak" headache (i.e., an unusual sudden headache caused by a "minor" leak of blood from the aneurysm). The headache may precede a major rupture by hours to months. The goal of early clinical recognition is surgical or other interventional therapy before a recurrent major hemorrhage. After a warning leak, head CT is more likely to be falsely negative, thus giving added importance to the performance of a lumbar puncture.

The usual clinical picture of SAH is an instantaneous excruciating headache. Patients generally recall the exact moment that the headache occurred. The location of the headache is variable and does not necessarily indicate the site of hemorrhage. Nausea, vomiting, and a decreased level of consciousness are common symptoms, with approximately one third of patients becoming unconscious at the onset. Examination usually reveals an acutely ill patient with irritability or overtly altered mental status. Meningeal signs are commonly present at the time of initial examination and usually develop within 2 to 3 days. The meningeal signs may become more severe during the first week after hemorrhage and correspond to the breakdown of blood in CSF. During the first week, many patients are febrile, a reflection of chemical hemic (blood-related) meningitis.¹⁵ Failure to detect blood radiographically in an awake patient may indicate a small hemorrhage or a predominant basal accumulation of blood. If a patient is initially seen several days after the hemorrhage, the blood may have become isodense with brain tissue and may no longer be visible on CT. The proper diagnosis would then require spinal puncture.

Modern CT scanners detect recent SAH quite accurately.¹⁶ However, because acute SAH is not detected by the initial CT scan in all patients, lumbar puncture has been used to rule out the diagnosis with certainty.¹⁷⁻¹⁹ A 2011 study conducted at academic medical centers found that a non-contrast head CT done with a third-generation scanner within 6 hours after onset of the headache and read by a qualified radiologist was 100% sensitive for the detection of SAH.²⁰ Another study performed at non-academic hospitals determined the negative predictive value for the detection of SAH of a head CT done within 6 hours after the onset of headache to be 99.9%.²¹ If the neurologic picture demonstrates localizing findings, the presence of a large intracranial hematoma should be suspected, and spinal puncture is contraindicated until imaging studies delineate the nature of the lesion.

Other non-emergent reasons for examination of CSF include evaluation for CNS syphilis, unexplained seizures, instillation of chemotherapy and contrast agents, assessment for a suspected demyelinating or inflammatory CNS process, and treatment of headache from SAH. Carcinomatous meningitis and suspected spinal cord compression from metastatic disease may require spinal puncture for myelography and cytologic examination. MRI is a suitable alternative for identifying compressive myelopathy and has largely replaced contrast-enhanced myelography in developed countries.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Idiopathic intracranial hypertension (IIH) is a rare condition of unclear etiology. Patients with IIH have a marked elevation in intracranial pressure (ICP; usually to 250 to 450 cm H₂O) without hydrocephalus or mass lesions in the setting of normal CSF composition. Findings on neuroimaging studies are typically normal, and most cases are idiopathic. Because

of the nonspecific signs and symptoms, many cases initially escape detection by clinicians. IIH has been associated with hypervitaminosis A, tetracycline, estrogen therapy, and a plethora of other conditions such as sarcoidosis, tuberculosis, and carcinomatosis. IIH is most common in obese adolescent girls and young women, but it can also occur in children and men. Patients suffer from chronic headaches, typically worse with maneuvers that increase ICP (e.g., Valsalva maneuver, squatting, bending, coughing). Papilledema is frequently present. Cranial nerve palsies, particularly of the sixth cranial nerve, are caused by increased ICP alone and may be falsely localizing.²²

IIH may regress spontaneously after a few months. The major concern is visual loss, which may be permanent. The diagnosis can be made only by lumbar puncture performed after neuroimaging. This condition underscores the need to measure opening pressure during lumbar puncture whenever possible. Many cases can be controlled with medication, but occasionally, lumbar puncture is required to lower ICP. One way to lower ICP in the ED is to drain CSF via lumbar puncture by removing 5- to 10-mL aliquots of CSF and checking ICP after each removal until a pressure lower than 200 mm H₂O is achieved. Herniation does not occur despite the elevated pressure in IIH, probably because ICP is uniform in all CNS compartments. As spinal fluid is regenerated rapidly, the procedure may need to be repeated every few days to keep CSF pressure at this level. Analysis of CSF should demonstrate all parameters to be normal. Drug therapy, in the form of acetazolamide, glycerol, diuretics, or corticosteroids, has been advocated and may negate the need for repeated lumbar puncture. Resistant cases may require shunting procedures.

CONTRAINDICATIONS TO SPINAL PUNCTURE

Spinal puncture is absolutely contraindicated in patients with infection in the tissues near the puncture site.^{4,23} Spinal puncture is relatively contraindicated in the presence of increased ICP caused by a space-occupying lesion. Caution is particularly advised when lateralizing signs (hemiparesis) or signs of uncal herniation (unilateral third-nerve palsy with an altered level of consciousness) are present. In such cases, a tentorial or cerebellar pressure cone may be precipitated or aggravated by the spinal puncture. Cardiorespiratory collapse, stupor, seizures, and sudden death may occur when pressure is reduced in the spinal canal.²⁴

The risk for herniation seems to be particularly pronounced in patients with brain abscesses.^{25,26} Brain abscesses are frequently manifested as expanding intracranial lesions that induce headache, mental disturbances, and focal neurologic signs rather than as an infectious process with signs of meningeal irritation. Fever is often absent. In 75% of cases, a primary source of chronic suppuration is present. Common predisposing factors for brain abscess include craniofacial trauma, craniocerebral trauma, penetrating injuries that push bone fragments into the brain, large animal bites of infants' skulls, neurosurgical procedures, cardiovascular disorders treated with right-to-left shunts, bacterial endocarditis, gram-negative sepsis in neonates, dental infections, chronic sinusitis, otitis, mastoiditis, chronic abdominal, pulmonary, or pelvic infection, bacterial meningitis, and immunosuppression. Abscesses may also develop in infarcted brain tissue in septic patients if the blood-brain barrier is compromised.²⁷ Although the CSF is usually abnormal (elevated pressure, elevated white blood cell [WBC] count, and elevated

Figure 60.1 This computed tomography scan demonstrates a low-density mass lesion with an enhancing rim and surrounding edema in an immunosuppressed patient with an *Aspergillus* abscess. Lumbar puncture in such a patient would be contraindicated. (From Zitelli BJ and Davis HW: *Atlas of pediatric physical diagnosis*, ed 5, Philadelphia, 2007, Saunders.)

protein concentration), spinal puncture in patients with a known or suspected abscess is contraindicated. Brain herniation markedly reduces the patient's likelihood of survival. If the history suggests abscess, CT can rapidly diagnose and localize the lesion (Fig. 60.1).²⁸ Because the appearance of brain abscesses on CT is similar to that of neoplastic and vascular lesions, false-positive reports of brain abscess are possible.²⁸

Spinal epidural hematomas are very rare but may occur in certain subpopulations of patients undergoing lumbar puncture. Those most at risk are individuals with a bleeding diathesis, including those treated with anticoagulants either before or immediately after lumbar puncture and those with abnormal clotting mechanisms, especially thrombocytopenia. The condition occurs, but rarely, even with an atraumatic tap and in the absence of a coagulation defect.²⁹ Spinal subdural hematomas after lumbar puncture are even rarer.^{30,31} Lumbar puncture can injure the dural or arachnoid vessels, which may result in minor hemorrhage into the CSF. This is generally of little consequence. However, the number of patients with hemophilia and human immunodeficiency virus (HIV) infection who require lumbar puncture has increased since the late 1990s. In a coagulopathic patient, attempt to correct the clotting deficiency if clinically feasible and time permits. The procedure should be performed by experienced clinicians, who are less likely to traumatize the dura. After the procedure, monitor the patient carefully for progressive back pain, lower extremity motor and sensory deficits, and sphincter impairment. Thoroughly investigate any complaints of motor weakness, sensory loss, or incontinence after lumbar puncture. Lumbar puncture may be performed in patients with a coagulation defect if the procedure is expected to provide essential information, such as in the diagnosis of meningitis and the pathogen responsible. Correct warfarin-induced coagulopathy with fresh frozen plasma (FFP) or prothrombin complex concentrate together with

vitamin K. The vitamin K–FFP protocol might need 12 to 24 hours to totally reverse the effect of warfarin. Correct the coagulopathy before a puncture if the clinical situation permits such delay. Butler has described the off-label use of low-dose prothrombin complex concentrate for the correction of warfarin-induced coagulopathy prior to lumbar puncture.³² Lumbar puncture can be performed safely in patients with hemophilia A or B whose deficient clotting factor is replenished before the procedure.³³ Additional replacement of the clotting factor after the procedure is of unknown value.

Performance of lumbar puncture in patients with leukemia and low platelet counts has also been studied. Howard and coworkers reported on 5223 lumbar punctures performed on 958 children with newly diagnosed acute lymphoblastic leukemia.³⁴ The platelet count was $10 \times 10^9/L$ or lower in 29 children, 11 to $20 \times 10^9/L$ in 170 children, and 21 to $50 \times 10^9/L$ in 742 children. No serious complications were reported in any group. The overall rate of traumatic taps was 10.5%, but such taps were not associated with adverse sequelae. The authors concluded that in children with acute lymphoblastic leukemia, prophylactic platelet transfusion for lumbar puncture is not required if the platelet count is higher than $10 \times 10^9/L$. The number of patients with platelet counts lower than $10 \times 10^9/L$ was too small to allow any conclusion about this group. A more recent review (2010) concluded that in the absence of additional risk factors, a platelet count of $40 \times 10^9/L$ is “safe” for lumbar puncture. Lower counts are probably safe as well, but there was insufficient evidence to make recommendations.³⁵ The 2015 clinical guidelines from the AABB (formerly the American Association of Blood Banks) include a weak recommendation for prophylactic platelet transfusion for patients having elective diagnostic lumbar puncture with a platelet count less than $50 \times 10^9/L$, acknowledging that the position was based on very-low-quality evidence.³⁶

Aspirin and nonsteroidal antiinflammatory agents have not been shown to increase the risk for bleeding following lumbar puncture. Subcutaneous heparin administration is not believed to pose a substantial risk for bleeding after lumbar puncture if the total daily dose is less than 10,000 units. The risk for bleeding in patients taking clopidogrel, ticlopidine, or a glycoprotein (GP) IIb/IIIa receptor antagonist is not known but is probably small; however, use of these agents should cause the clinician to proceed with caution. One scenario is the need to diagnose meningitis because of an unusual or difficult-to-treat pathogen. It is necessary to withhold clopidogrel and ticlopidine 1 to 2 weeks before their anticoagulant effect has fully dissipated, making the decision for emergency lumbar puncture in such patients a risk-benefit scenario, with no firm guidelines. Pharmacologic data suggest that cessation of the GP IIb/IIIa receptor antagonist tirofiban may allow lumbar puncture after 8 hours and cessation of abciximab after 24 to 48 hours. Spinal hematoma may develop in 1% to 2% of patients who receive full anticoagulant therapy *after* undergoing lumbar puncture.

Proceed with caution in a patient with prior lumbar fusion or laminectomy. It is technically difficult to enter the subarachnoid space in the presence of significant postoperative changes. It would be acceptable to perform the puncture in an applicable space above or below the surgical scar; otherwise, opting for fluoroscopic guidance is prudent.

Attempts have been made to link bacterial meningitis to a lumbar puncture procedure in a bacteremic patient. Presumably, the procedure introduces bacteria into the CSF. This

phenomenon is rare, difficult to substantiate, and not supported by clinical data. Though of theoretical concern, bacteremia should not be used as a criterion to forego lumbar puncture if meningitis is suspected.

If the history and physical examination suggest a treatable illness such as meningitis or SAH, the clinician may perform a spinal puncture after careful consideration of the entire clinical picture. In all cases, undertake the study after careful thought regarding how the results will contribute to the evaluation and treatment of the patient. It is unlikely that spinal puncture will beneficially alter management in patients with neoplastic disease, intracranial hematoma, abscess, a completed nonembolic infarction, or cranial trauma. Moreover, even when acute life-threatening emergencies such as SAH or meningitis are suspected, delaying CSF examination temporarily while empirical treatment proceeds is an important management option when there are concerns about the safety of the procedure.

EQUIPMENT

Assemble the standard equipment for a spinal puncture before starting the procedure. Place it where the operator can easily access it. A standard-point Quincke cutting needle is most often used and supplied with the kit. Some operators prefer to use a Sprotte needle (Havel's, Inc., Cincinnati, OH) or a Whitacre needle (Becton Dickinson and Company, Rutherford, NJ) to minimize any dural injury associated with passage of the needle (Fig. 60.2). These styletted needles have a side port for withdrawal of fluid and, theoretically, are more likely to separate than cut the dural tissue. Although commercial kits provide most of the items needed for lumbar puncture, the operator should bring additional supplies, including supplemental spinal needles, specimen tubes, gauze, antiseptic solution, additional local anesthetic, needles and syringes, and extra sterile gloves of the appropriate size (see Review Box 60.1).

PROCEDURE

Lumbar puncture (Videos 60.1 and 60.2) is commonly carried out with the patient in the lateral recumbent position (Fig. 60.3). A line connecting the posterior superior iliac crests intersects the midline at approximately the L4 spinous process (Fig. 60.4). Spinal needles entering the subarachnoid space at this point are well below the termination of the spinal cord, and the only important neurologic structure is the cauda equina. Generally, the needle pushes isolated nerves to the side during advancement. The adjacent interspace above or below may be used, depending on which area appears to be most accessible to palpation. The space between the lumbar vertebrae is relatively wide. In the thoracic region, the spinous processes overlap and are directed caudally; therefore there is no midline area free of overlying bone. In adults, the spinal cord extends to the lower level of L1 or the body of L2 in 31% of persons, thus eliminating higher levels as sites for puncture. Puncture in adults and older children may be performed from the L2–L3 interspace to the L5–S1 interspace.

Developmentally, the spinal canal and the spinal cord are of equal length in the fetus. Growth of the cord does not keep pace with the longitudinal growth of the spinal canal. At birth, the cord ends at the level of the L3 vertebra. Consequently, in infants the needle should be placed at the L4–L5 or L5–S1

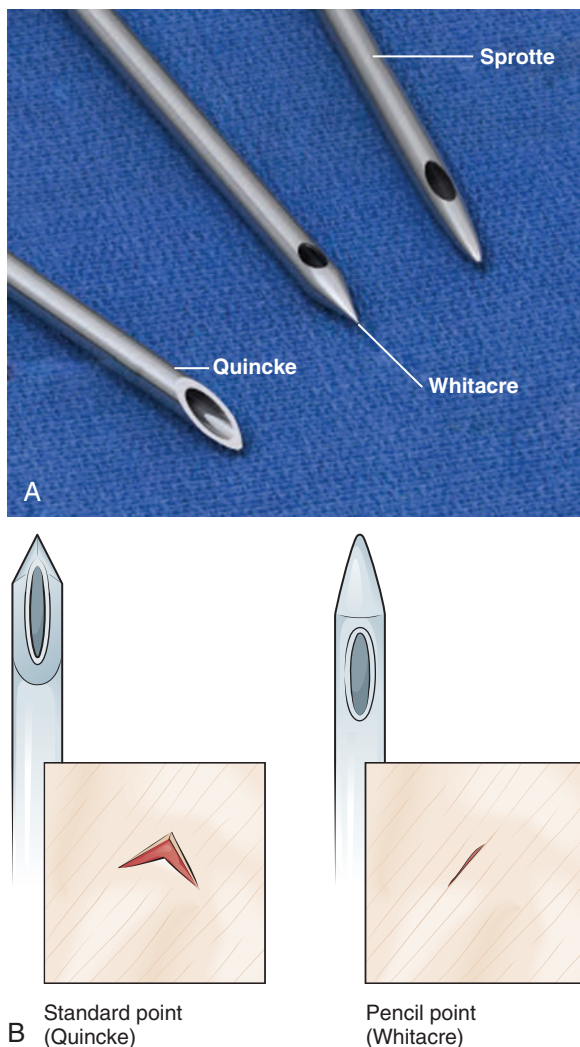

Figure 60.2 A, Various spinal needles. B, Penetration of the dura by Whitacre (pencil-point) and Quincke (cutting) needles. The Whitacre needle separates the fibers of the dura without cutting them, whereas the Quincke needle cuts the fibers. The Quincke needle leaves a hole in the dura through which cerebrospinal fluid can leak until the hole heals several days or weeks later. Use of the Whitacre needle has been associated with a lower incidence of post-lumbar puncture headache. (A, From Thomsen T, Setnik G, editors: *Procedures consult—emergency medicine module*. Philadelphia, 2008, Elsevier Inc. All rights reserved.)

interspace. The subarachnoid space extends to the S2 vertebral level; however, the overlying bony mass prevents entry into this lowermost portion of the subarachnoid space.

When performed with parenteral sedation and proper local anesthesia, a spinal tap is neither overly distressing nor very painful to most patients. Almost all patients are likely to have some anxiety about a spinal puncture for several reasons, including the stories commonly told of severe complications. Explain the procedure in advance and discuss each step during the course of the test to reduce the patient's anxiety. Inquire about any history of allergies to local anesthetic agents and topical antiseptics. Obtain written informed consent whenever possible. In all cases, include a detailed procedural note that documents the process of patient or guardian education regarding the indications, procedural techniques, risks and benefits, alternatives to the procedure, and the patient's or guardian's consent for the procedure. Abridge this step when the patient

is critically ill or eliminate it when the patient is mentally incapacitated and no guardian is present. Many patients greatly fear lumbar puncture, and hence some clinicians provide routine preprocedure sedation or analgesia if not clinically contraindicated. Intravenous midazolam and fentanyl are useful adjuncts, but practices vary and there is no consensus on standards with regard to the use or nonuse of preprocedure medications. If the patient is anxious, it is reasonable to give a benzodiazepine agent parenterally (e.g., midazolam, 0.1 to 2.5 mg intravenously for a healthy adult younger than 60 years of age) to facilitate the procedure. Fentanyl at a dose of 0.5 to 1.5 $\mu\text{g}/\text{kg}$ (adults) is a reasonable alternative.

The next important step is positioning the patient. Generally, place older children and adults in the lateral decubitus position for the procedure. Give the patient a pillow to keep the head in line with the vertebral axis. Position the shoulders and hips perpendicular to the stretcher or table. Use a firm table or bed when available. Because flexion of the neck does not facilitate the procedure to any great extent and severe flexion may add to the patient's discomfort, this step may be omitted. Severe flexion of the neck in an infant may cause airway compromise. Arch the lower part of the patient's back toward the clinician by having the patient's knees drawn toward the chest.

Some clinicians place the patient in an upright sitting position because the midline is more easily identified. This position can be used in both adults and infants (Fig. 60.5). The higher CSF hydrostatic pressure while sitting may aid flow of CSF in a dehydrated patient. Observe caution regarding orthostatic changes in blood pressure and airway maintenance. Generally, allow a sitting patient to lean onto a bedside stand and use a pillow to rest the head and arms. Have an assistant support the patient during the procedure. Radiographic studies by Fisher and colleagues have demonstrated the advantages of hip flexion when the sitting position is used.³⁷ To accomplish hip flexion, use a stool to support the patient's feet, which pulls the knees up toward the chest. This increases lumbar interspinous width, which may increase the success and ease of needle passage.

Iatrogenic infection after lumbar puncture is extremely rare. Use sterile gloves during the procedure; the need for face masks is debatable.^{38–40} Some authors have suggested applying the same guidelines for control of central line infection (caps, gowns, gloves, and masks) to lumbar puncture.⁴¹ Wash the patient's back with an antiseptic solution applied in a circular motion and increase the circumference of the cleansed area with each motion. Place a sterile towel or drape between the patient's hip and the bed. Commercial trays have a second sterile drape with a hole that may be centered over the site selected for the procedure.

Infiltrate the skin and deeper subcutaneous tissue generously with local anesthetic. Buffered or warmed 1% lidocaine is preferred. Warn the patient about transient discomfort from the anesthetic. Anesthetizing the deeper subcutaneous tissue significantly reduces procedural discomfort. Merely raising a skin wheal is insufficient anesthesia. Some operators not only anesthetize the interspinous ligament but also apply local anesthetic in a vertically fanning distribution on both sides of the spinous processes near the lamina. Such a field block on each side of the spinous processes anesthetizes the recurrent spinal nerves that innervate the interspinous ligaments and muscles.

While waiting for the anesthetic to take effect, connect the stopcock and manometer and ensure that the valve is working. Commonly, a 3.5-inch, 20-gauge needle is used in adults, and a 2.5-inch, 22-gauge needle is used in children (a 1.5-inch,

Spinal Puncture

1 Position the patient in the bed. Generally, the lateral decubitus position is preferred. Arch the patient's back towards you.

Consider mild sedation or analgesia when clinically appropriate.

2 Identify and mark anatomic landmarks. The L4 spinous process is at the level of the posterior-superior iliac crests.

3 Prepare the skin with antiseptic solution. Apply in a circular motion with a gradually increasing circumference.

4 Apply a sterile drape.

5 Create a wheal with anesthetic in the skin overlying the entry site. Then, infiltrate and anesthetize the deeper tissues.

6 Insert the needle in the midline. Hold the needle parallel to the bed, and advance it toward the umbilicus. Remove the stylet periodically to check for CSF.

7 CSF will flow from the needle hub when the subarachnoid space has been penetrated.

8 Attach the manometer and measure the opening pressure.

9 Collect the CSF sample in sequential, numbered vials.

10 Replace the stylet before removing the needle.

Figure 60.3 Spinal puncture. CSF, Cerebrospinal fluid.

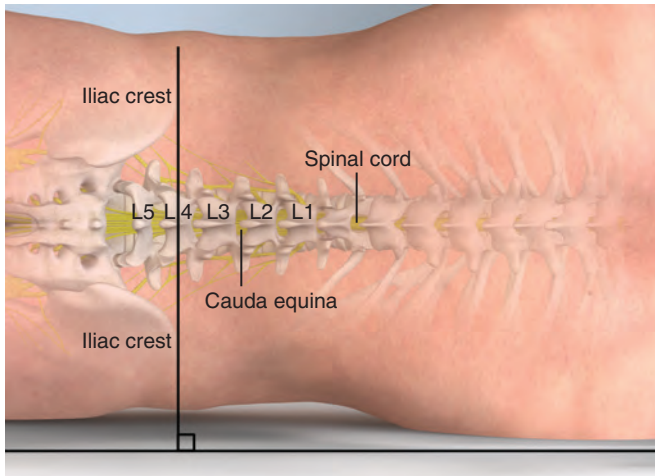

Figure 60.4 The L4 spinous process is at the level of the posterior superior iliac crest. The spinal cord ends approximately at the level of L1 or L2 in adults; fibers of the cauda equina extend inferiorly from there. When the patient is positioned correctly for lumbar puncture, an imaginary line connecting the iliac crests will be exactly perpendicular to the bed, and the spine will be parallel to the bed.

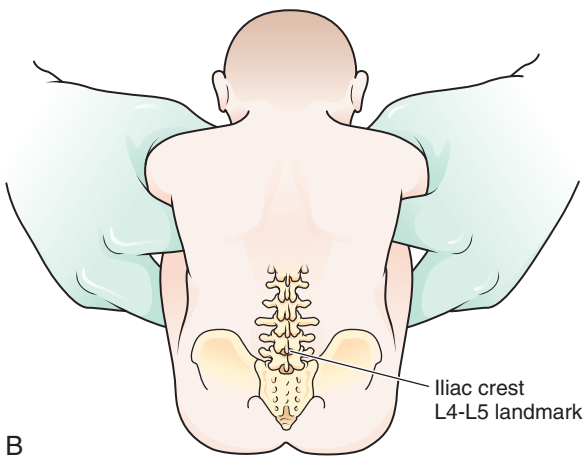

Figure 60.5 **A**, Many clinicians prefer the sitting position for lumbar puncture because of the ease of entering the dural space. However, the opening pressure obtained in this position is not accurate. If possible, place the patient in the lateral decubitus position for measurement of pressure, usually after fluid has been collected. **B**, Upright positioning in an infant. (**A**, From Thomsen T, Setnik G, editors: *Procedures Consult—Emergency Medicine Module*. Philadelphia, 2008, Elsevier Inc. All rights reserved. **B**, from Dieckmann R, Selbst S, editors: *Pediatric emergency and critical care procedures*. St. Louis, 1997, Mosby.)

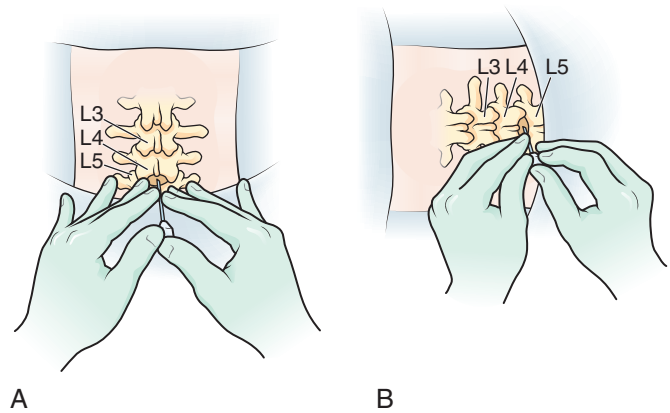

Figure 60.6 Various ways to hold the spinal needle.

22-gauge needle is available for infants). Needles of these sizes have enough rigidity to allow the procedure to be accomplished easily but make less of a dural tear than larger needles do. Patients should be told to report any pain and should be informed that they will feel some pressure.

With the patient in the lateral decubitus position, place the needle into the skin in the midline, parallel to the bed. Hold the needle between both thumbs and index fingers (Fig. 60.6). After the subcutaneous tissue has been penetrated, angle the needle toward the umbilicus. The bevel of the needle should be facing straight up toward the ceiling. The supraspinal ligament connects the spinous processes, and the interspinal ligaments join the inferior and superior borders of adjacent spinous processes. The ligamentum flavum is a strong, elastic membrane that may reach a thickness of 1 cm in the lumbar region. The ligamentum flavum covers the interlaminar space between the vertebrae and assists the paraspinal muscles in maintaining an upright posture (Fig. 60.7). The ligaments are stretched in a flexed position and are more easily crossed by the needle. The ligaments offer resistance to the needle, and a “pop” is often felt as they are penetrated. Some clinicians choose to advance the needle in small increments, removing the stylet to check for CSF flow. If no fluid flows, the stylet is replaced and the needle is advanced. Hold the stylet in place during advancement, until the subarachnoid space has been reached. The pop may not be felt with the very sharp needles contained in disposable trays.

If bone is encountered, partially withdraw the needle to subcutaneous tissue. Repalpate the back and ascertain that the needle is in the midline. Directing the tip of the needle toward the navel often enhances navigation of the interspinal space. If bone is encountered again, slightly withdraw and reangle the needle so that the point is placed at a more sharply cephalad angle (Fig. 60.8). This approach should avoid the inferior spinous process.

Normal CSF is a clear fluid and will flow from the needle when the subarachnoid space has been penetrated and the stylet is removed. In normal patients, the dura will be penetrated when the needle is advanced approximately one-half to three-fourths of its length. In obese patients, the entire length of the needle may be required to reach the subdural space (Fig. 60.9).

If feasible, attach the manometer and record the opening pressure (Fig. 60.10). This step is commonly omitted in critically ill patients. Pressure readings from a struggling patient may be inaccurate. Readings are valid only if taken with the patient relaxed and in the lateral decubitus position (not the

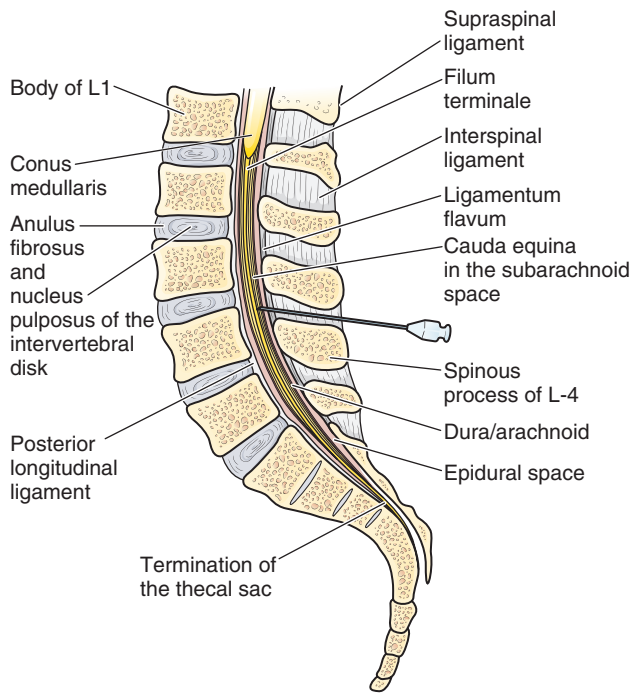

Figure 60.7 Midsagittal section through the lumbar spinal column with a spinal puncture needle in place between the spinous processes of L3 and L4. Note the slightly ascending direction of the needle. The needle has pierced three ligaments and the dura/arachnoid and is in the subarachnoid space. (From Lachman E: *Anatomy as applied to clinical medicine*, *New Physician* 17:145, 1968.)

sitting position). A three-way stopcock, supplied in disposable trays, allows both collection of CSF and measurement of opening pressure with a single needle. Positioning of the manometer is often more convenient if an extension tube (provided with most disposable trays) connects the needle hub to the stopcock, which in turn is attached to the manometer. Position the manometer so that the “zero” mark is at the level of the spinal needle. Then ask the patient to relax. Changing position from a straight to a fully extended position increases CSF pressure minimally, by 2 to 8 cm of water. Extending the legs after needle placement does not meaningfully decrease opening CSF pressure.⁴² CSF flow is enhanced if the patient straightens or extends the legs following confirmation of proper needle position. The observation of phasic changes in the fluid column with respirations and arterial pulsations confirms needle placement in the subarachnoid space. If the needle is against a nerve root or is only partially within the dura, the pressure may be falsely low, and respiratory excursions will not be reflected in the manometer. Minor rotation of the needle may solve these problems. Hyperventilation will reduce the pressure readings because of hypocapnia and the resultant cerebral vasoconstriction.

After measuring the pressure, turn the stopcock and collect enough fluid to perform all the studies desired. It is generally advised that CSF should be collected by a free flow from the needle, and not by aspiration. The first sample of fluid exits from the manometer if pressure has been measured, and then additional fluid flows from the spinal canal. Even if the pressure is elevated, remove sufficient fluid for performance of all indicated studies because the risk associated with the procedure involves the dural rent, not only the amount of fluid initially

Figure 60.8 **A**, This 22-gauge spinal needle has struck bone during advancement (notice the bend in the needle) and needs to be repositioned. **B**, If bone is encountered, it is usually the inferior spinous process (*red spinal needle*). The needle must be partially withdrawn into subcutaneous tissue and then readvanced in a more cephalad direction (*green needle*).

Figure 60.9 The spinal needle is usually advanced one-half to three-fourths of its length before the spinal canal is reached. In this obese patient, the needle was advanced all the way to the hub of the needle before spinal fluid was returned.

removed. Presumably, more fluid will subsequently be lost through the hole in the dura. Replace the stylet into the needle before withdrawing it.

Commercial trays generally supply four specimen tubes. One tube is commonly used for determining protein and glucose levels and for electrophoretic studies, another is used for microbiologic and cytologic studies, and a third is used for serologic tests. Cell counts should be performed in the first

Figure 60.10 To measure the opening pressure, attach the manometer to the needle hub with a 3-way stopcock. The “zero” mark of the manometer should be level with the site of needle entry.

and third tubes to help differentiate traumatic taps from true SAH. Depending on the clinical scenario, additional tests may be indicated. Use special stains, such as India ink for suspected *Cryptococcus* infection in patients with acquired immunodeficiency syndrome (AIDS), acid-fast stain in patients with possible tuberculous meningitis, and viral studies in patients with suspected encephalitis. The fourth tube can be stored under refrigeration in the laboratory for any additional studies that may be required after the initial assessment.

Traumatic taps are common and usually clinically inconsequential. Nevertheless, they can be minimized by proper patient and needle positioning. A traumatic tap most commonly occurs when the subarachnoid space is transfixed at the entrance of the ventral epidural space, where the venous plexus is heavier. A plexus of veins forms a ring around the cord, and these veins may be entered if the needle is advanced too far ventrally or is directed laterally (Fig. 60.11). If blood is encountered and the fluid does not clear, repeat the procedure at a higher interspace with a fresh needle. A traumatic tap, per se, is not a particularly dangerous problem in a patient with normal coagulation, and no specific precautions are needed if blood-tinged fluid is obtained. However, observe for signs of cord or spinal nerve compression from a hematoma developing within the first several hours in patients with a coagulopathy.

Lateral Approach for Lumbar Puncture

The supraspinal ligament might be calcified in older persons, making a midline perforation difficult. A calcified ligament may deflect the needle. In this case, use a slightly lateral approach. Because the lower lamina rises upward from the midline, direct the needle slightly cephalad to miss the lamina and slightly medially to compensate for the lateral approach. The needle passes through the skin, superficial fascia, fat, the dense posterior layer of the thoracolumbar fascia, and the erector spinae muscles. The needle then penetrates the ligamentum flavum (bypassing the supraspinal and interspinal ligaments), the epidural space, and the dura before CSF is obtained (Fig. 60.12). Lateral cervical puncture is an alternative approach that can be performed utilizing an insertion site 1 cm inferior and 1 cm dorsal to the mastoid process.⁴³

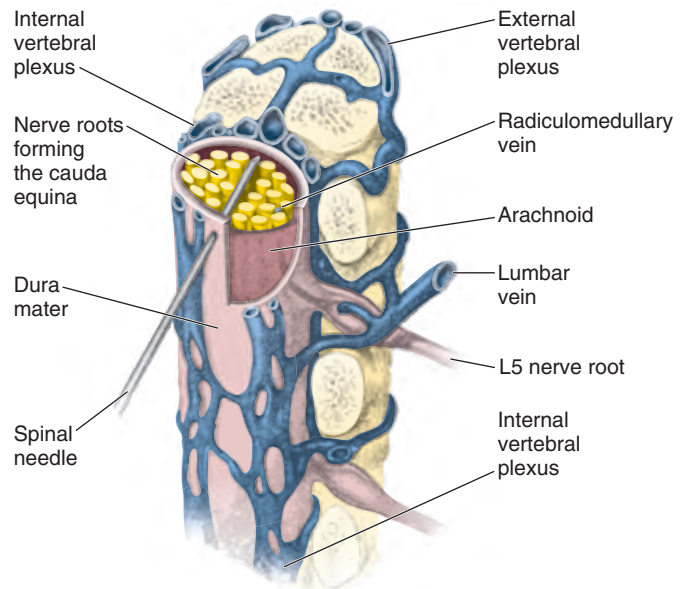

Figure 60.11 The spinal contents at L4 and L5 show the relationship of a lumbar puncture needle to the major vessels at this level. The major radiculomedullary vein, shown accompanying the L5 nerve root, is situated far lateral to a needle correctly positioned in the midline of the dural sac. Note the avascular subdural space. (From Edelson RN, Chernik IVL, Rosner JB: Spinal subdural hematomas, *Arch Neurol* 31:134, 1974. Illustration by Lynn McDowell. Reproduced by permission. Copyright 1974, American Medical Association.)

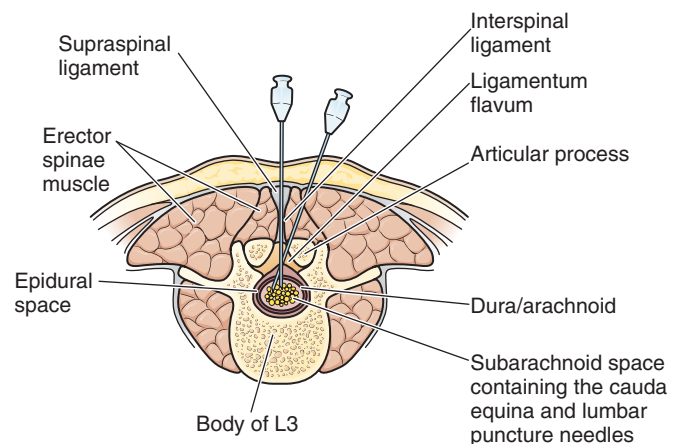

Figure 60.12 Horizontal section through the body of L3. Note the two puncture needles in the subarachnoid space. The medial needle is in the midline. The lateral needle exemplifies the lateral approach, which avoids the occasionally calcified supraspinal ligament. Note the lateral needle piercing the intrinsic musculature of the back and only one ligament, the ligamentum flavum. (From Lachman E: Anatomy as applied to clinical medicine, *New Physician* 17:745, 1968.)

Lumbar Puncture in Infants

Lumbar puncture in infants is usually performed to exclude meningitis or encephalitis. The sitting position may allow the midline to be identified more easily. Use of a needle without a stylet has been suggested for small infants because this device allows the pressure to be estimated as the needle punctures the dura.⁴⁴ However, failure to use a stylet may cause the subsequent development of an intraspinal epidermoid tumor.⁴⁵

Use of a butterfly infusion set needle simplifies the procedure, which is helpful when managing a squirming or hyperactive patient.⁴⁴ In general, a stylet is recommended primarily at the time of skin penetration and on needle withdrawal, although many operators use the stylet during any advancement of the needle.

If the child's neck is very tightly flexed, CSF might not be obtained. However, if the head is held in midflexion, CSF usually flows briskly. If CSF fails to flow, gently suction with a 1.0-mL syringe to exclude a low-pressure syndrome. Because pressure readings are inaccurate in a struggling child, measurement of pressure is not commonly attempted in infants and young children.⁴⁶

Avoid prolonged severe flexion of the neck in an infant because it may produce dangerous airway obstruction. If the infant suddenly stops crying, check the airway immediately.⁴⁷ Proper positioning is best accomplished by an assistant, who maintains the spine maximally flexed by partially overlying the child and using the chest and body weight to immobilize the thorax and hips while holding the child behind the shoulders and knees.⁴⁸ Infants have poor neck control; therefore the assistant must also ensure that the child maintains an open airway. Pay particular attention to avoiding marked neck and trunk flexion. Incorrect positioning usually results in multiple punctures and a bloody tap.

Newborn and preterm infants may experience significant hypoxia and clinical deterioration during lumbar puncture; a sitting position appears to be preferable.⁴⁹ Lumbar puncture in infants with respiratory distress syndrome may pose greater risk than benefit.⁵⁰ This is a problem primarily in neonates but may also apply to younger infants with sepsis. Closely monitor all infants with serious cardiopulmonary disease during the procedure. Preoxygenation with or without monitoring oxygen saturation may be used as a precaution.

Although local anesthesia or sedation has not been a routine practice during lumbar puncture in an infant or child, it is being reconsidered.^{51,52} Neonates perceive pain, and local anesthesia neither produces physiologic instability nor makes the procedure more difficult.^{53,54} The use of topically applied eutectic mixture of local anesthetics (EMLA) (AstraZeneca, Cambridge, United Kingdom) reduces the pain associated with needle insertion in newborns.⁵⁵ Sedation of an anxious child may be considered, but sedatives are relatively contraindicated in an obtunded patient without a protected airway and in the setting of hemodynamic instability.

The Difficult Lumbar Puncture

The traditional approach to lumbar puncture depends on palpation of bony landmarks to determine the correct location

ULTRASOUND BOX 60.1: Lumbar Puncture

by Christine Butts, MD

When ultrasound is used to guide lumbar puncture, it is generally done in a static manner: the ultrasound probe is used to determine the site of skin entry, the skin is marked, and the probe is then set aside.

Equipment

A linear probe is preferred, although for patients with an extremely high body mass index, a curvilinear probe may be required because of the distance between the skin and the spine.

Figure 60.US1 Transverse image of the lumbar spine. The crescent-shaped hyperechoic structure (*arrow*) is a spinous process. Note the presence of posterior acoustic shadowing. Align the probe so that the spinous process is directly centered in the image. The general symmetry of the image provides additional assurance that the probe is centered correctly.

Image Interpretation

The bony spinous process will appear as a hyperechoic crescent-shaped structure with posterior acoustic shadowing. In the transverse view, acquisition of a perfectly symmetric image will provide assurance that the probe is in the anatomic midline (*Fig. 60.US1*). In the longitudinal view, multiple spinous processes can be visualized, along with the interspaces between them (*Fig. 60.US2*).

Figure 60.US2 Longitudinal image of the lumbar spine. The spinous processes (*small arrows*), are visible again, and appear as crescent-shaped hyperechoic structures with acoustic shadowing. In between each spinous process is the interspinous space (*large arrow*). Note how this space is bordered on either side by the acoustic shadow of the spinous process. Note also how the probe is centered directly over the interspace.

Continued

ULTRASOUND BOX 60.1: Lumbar Puncture—cont'd

Figure 60.US3 First use the ultrasound (US) probe in the transverse orientation at the level of the iliac crests, and obtain an image with the shadow of the spinous process centered on the screen (as in Fig. 60.US1). Mark the skin at the exact midpoint of the transducer. This represents the anatomic midline.

Figure 60.US4 Rotate the ultrasound (US) probe 90 degrees and obtain a midline longitudinal view. Position the probe so that the interspace is centered on the screen (as in Fig. 60.US2). Mark the skin at the midpoint of the transducer. This represents the level of needle entry.

Procedure and Technique

To perform ultrasound-guided lumbar puncture, position the patient in the usual manner. Place the ultrasound probe over the spine in a transverse orientation at the level of the iliac crests such that the shadow caused by the spinous process is centered on the screen. Use a pen to mark the skin on each side of the transducer, exactly at the midpoints (Fig. 60.US3). These two marks can then be connected to mark the midline of the spine. Next, rotate the transducer 90 degrees to obtain a midline longitudinal view and position it until the gap between two spinal processes is in the center of the screen. Mark the skin at the midpoint of each side of the transducer and then connect the marks to form a single line (Fig. 60.US4). The intersection of the two lines is the site for entry of the needle (Fig. 60.US5). Cleanse the skin with antiseptic solution and perform the remainder of the procedure in the usual fashion.

Figure 60.US5 The intersection of the anatomic midline and the level of the interspinous space is the site of needle entry.

for insertion of the needle. However, landmarks are difficult to palpate in overweight and obese patients.⁵⁶ When lumbar puncture fails, the usual alternative has been fluoroscopic guidance, which necessitates movement of the patient out of the ED, as well as the availability of an appropriately trained radiologist.⁵⁶ Brook found CT guidance to be comparable to fluoroscopy in the facilitation of lumbar puncture in obese patients with a previously unsuccessful attempt.⁵⁷ Bedside ultrasound is being used increasingly in emergency and critical care medicine, and its scope of practice has expanded to include guidance for a number of procedures, including lumbar puncture (see **Ultrasound Box**).⁵⁷⁻⁶¹ Ultrasound can be used in adults as well as neonates and infants.⁶²

COMPLICATIONS

Headache After Lumbar Puncture

A number of complications from lumbar puncture have been reported.⁶³ One of the most common is headache, which occurs after 1% to 70% of spinal taps.⁶⁴⁻⁷² In general, the development of post-puncture headache can be neither prognosticated nor prevented. The syndrome most commonly starts within the first 48 hours after the procedure (although a case occurring 12 days after the procedure has been reported⁷³) and usually lasts for 1 to 2 days (occasionally as long as 14 days). Cases lasting months have been described. The headache usually

begins within minutes after the patient arises and characteristically ceases as soon as the patient lies down. The pain is mild to incapacitating and is generally cervical and suboccipital in location but might involve the shoulders and the entire cranium. Exceptional cases include nausea, vomiting, vertigo, blurred vision, ear pressure, tinnitus, and stiff neck. The headache may change to a positional backache or neck ache.

The technique of spinal puncture probably has little to do with the development of a postprocedure headache. The syndrome is widely thought to be caused by leakage of fluid through the dural puncture site. This results in a reduction in CSF volume below the cisterna magna and downward movement of brain tissue, along with displacement and stretching of pain-sensitive structures such as the meninges and vessels, and causes a traction headache. The recumbent position brings relief because the weight of the brain is shifted cephalad. Another proposed mechanism is cerebral vasodilation. Another hypothesis suggests that the headache is caused by an altered distribution of craniospinal elasticity and acute intracranial venous dilation.⁷⁴ Some authors have commented on the incidence and severity of post-dural puncture headache as being related to the orientation of the spinal needle bevel and its type and size.^{75–85} It is clear that the incidence of post-dural puncture headache is lower when the bevel of the needle is oriented parallel to the longitudinal axis of the spine. The traditional explanation for this was that the parallel bevel would separate rather than cut the longitudinal dural fibers and thus produce a smaller dural hole and less CSF leakage. However, the dural fibers are oriented randomly, not longitudinally.⁸⁶ Even with random fiber orientation, back flexion is more likely to close a dural hole in the longitudinal plane than a hole in the horizontal plane.

The two basic types of spinal needles are cutting (Quincke) and noncutting or pencil point (Sprotte and Whitacre) (see Fig. 60.2). Noncutting needles cause a lower incidence of headache after dural puncture, perhaps because the tip of the needle tends to separate rather than cut the dural fibers. It has traditionally been thought that the dural hole resulting from puncture with a noncutting needle is smaller than that created by puncture with a cutting needle; however, this may not be true. The important difference may be that the cutting needle causes a clean-cut opening in the dura whereas the noncutting needle produces a jagged opening with rough edges.⁸⁷ The jagged opening may produce a more intense inflammatory response that results in edema and more complete closure of the hole. The use of atraumatic spinal needles is not routine.⁸⁸ As more spinal kit manufacturers include them in kits, their use might increase.⁸⁹ A single-institution study suggested that routine use of noncutting needles yields a potential cost saving.⁹⁰ However, in thick-skinned individuals, passage of a thin, noncutting needle may be technically difficult. Making the initial pass with a thicker cutting needle to the level of the interspinal ligament, followed by removal and advancement of a noncutting needle in the same soft tissue tract, can be helpful.

Use of a smaller-diameter needle is one intervention that will probably cause a lower incidence of post-puncture headache because it creates a smaller dural hole. If diameter were the only consideration, as small a needle as possible would be used. However, a needle must provide adequate CSF flow rates to allow timely CSF collection and pressure measurement. With a very small needle, a syringe may be needed to withdraw fluid, and pressure cannot be recorded easily. In addition,

technically, a small needle such as a 26-gauge is difficult to place and manipulate into a position in which it does not become intermittently obstructed by nerve roots. A 2014 randomized crossover trial compared the use of 22-gauge and 25-gauge needles in children and found no difference in the incidence of post-puncture headache, but the 25-gauge needles were found to be flimsy and difficult to use, with fluid collection taking much longer.⁹¹ When these characteristics are considered, a 20- to 22-gauge atraumatic needle seems to be the best overall choice for diagnostic lumbar puncture.⁷⁸

Despite common beliefs about techniques and post-procedure interventions, lumbar puncture headaches may not be completely preventable. Studies of the influence of directives such as strict bed rest on post-puncture headache have yielded contradictory results, with no consensus on any specific preventive intervention forthcoming concerning the worsening of, improvement in, or effect on the incidence. Brocker reported a reduction in the incidence of headache from 36.5% to 0.5% when patients lie prone instead of supine for 3 hours after puncture with an 18-gauge needle.⁹² He postulated that the prone position caused hyperextension of the spine and disrupted alignment of the holes in the dura and the arachnoid, making leakage less likely. Theonissen and coworkers concluded that there was no evidence that longer bed rest after lumbar puncture was better than immediate mobilization or short bed rest in reducing the incidence of headache.⁹³ There appears to be no reason to enforce bed rest following lumbar puncture.⁹⁴

Other factors that might influence the incidence of a post-spinal puncture headache were reviewed by Fishman and by Lin and Giederman.^{23,95} The incidence is higher in young patients than in older patients and is also increased in females and individuals with a history of headache. Many medications have been advocated for the treatment of headache after lumbar puncture: barbiturates, codeine, neostigmine, ergots, diphenhydramine (Benadryl [Johnson & Johnson, New Brunswick, NJ]), dimenhydrinate (Dramamine [APP Pharmaceuticals, Schaumburg, IL]), caffeine, amphetamine sulfate (Benzedrine [GlaxoSmithKline plc, London, United Kingdom]), ephedrine, intravenous fluids (normal saline, lactated Ringer's solution), magnesium sulfate, and vitamins.^{23,96–98} Niraj and colleagues tested the use of greater occipital nerve block in patients with post-procedural headache, a less invasive alternative to epidural blood patch, and achieved modest success in a small trial.⁹⁹

Traditionally, caffeine has often been used as the initial intervention for post-puncture headache, and it appears to be of benefit.⁹⁸ Although caffeine may decrease post lumbar puncture headache, there is a high recurrence rate. Caffeine can be administered in the ED, bringing pain relief within a few hours. It is thought to result from caffeine's vasoconstrictive effect on the cerebral vasculature. One suggested regimen is 500 mg of caffeine (sodium benzoate) diluted in 1000 mL of normal saline infused over a 1- to 2-hour period. A second dose can be given if the headache is not relieved. If successful, consumption of caffeinated beverages may be continued as an outpatient. A cup of coffee contains 50 to 100 mg of caffeine.

Most post-puncture headaches can be managed by bed rest with the head in the horizontal position. Avoid dehydration because it lowers CSF pressure and might aggravate the headache. Although dehydration should be avoided, the role of fluid supplementation in the prevention of post-dural puncture headache remains uncertain.

Simple analgesics are commonly prescribed, but they have no apparent advantage over bed rest and fluid intake. A patient with a prolonged headache after spinal puncture should be reassessed to rule out structural causes. Because a spinal headache has classic signs and symptoms, if the headache is not postural, consider other causes.

In summary, because most post-lumbar puncture headaches are mild and self-limited, conservative therapy for the first 24 to 48 hours is recommended. Bed rest and oral analgesics, including opioids, are usually effective, as well as, perhaps, oral caffeine drinks, but for those refractory to conservative measures, an epidural blood patch is recommended. For patients with a prolonged low-pressure headache, placement of an epidural blood patch by experienced operators is highly successful and often provides dramatic relief.^{100–104} Consider a blood patch for all patients with seriously symptomatic spinal headaches. Perform an epidural tap at the level of the previous lumbar puncture. Use the loss-of-resistance technique with sterile saline to locate the epidural space.¹⁰⁵ Draw 10 to 20 mL of autologous blood into a syringe aseptically and slowly inject it (1 to 2 mL every 10 seconds) into the epidural space at the site of the dural puncture.¹⁰⁶ Slow or discontinue the injection if back pain or paresthesia develops. Keep the patient supine for 1 hour while hydration is administered intravenously. Relief usually occurs within 20 to 30 minutes after the procedure. Epidural patches are less likely to be effective if symptoms have been present for more than 2 weeks. Pain is relieved when the blood patch forms a gelatinous tamponade that stops the CSF leak and immediately elevates CSF pressure. Patch failures (15% to 20%) are believed to be caused by improper needle placement, injection of an inadequate quantity of blood (after which a second patch is usually successful), or an incorrect diagnosis.

Complications reported after placement of an epidural patch include back stiffness, paresthesia, radicular pain, subdural hematoma, adhesive arachnoiditis, and bacterial meningitis.¹⁰⁷ The procedure should be used in patients with refractory headaches that do not respond to conservative therapy, and it should be performed by clinicians trained in its use.

Infection

Spinal puncture is contraindicated in the presence of local infection at the puncture site (cellulitis, suspected epidural abscess, or furunculosis) because of the danger of inducing meningitis. A large concentration of bacteria in the bloodstream at the time of CSF examination is associated with meningitis. The meningitis could be coincidental (“spontaneous”) or could result from leakage of blood containing bacteria into the subarachnoid space after lumbar puncture (“induced”). It is likely that many cases of puncture-induced meningitis emerge after a cautious clinician performs a lumbar puncture early in the course of meningitis, before the infection has had time to be reflected in CSF. A 2006 review concluded that the majority of cases of post-puncture meningitis are probably caused by contamination of the site with aerosolized bacteria from medical personnel, contamination from skin flora, or least commonly, direct or hematogenous spread from an endogenous infectious site.⁴¹ Suspected bacteremia is not a contraindication to lumbar puncture. Delay in diagnosis because of concern regarding the risks associated with lumbar puncture is probably more serious than the risk of causing meningitis with the procedure.^{108,109}

Herniation Syndromes After Lumbar Puncture

Lumbar puncture is of value in confirming a diagnosis of meningitis, encephalitis, or SAH. Generally, when the patient has symptoms consistent with bacterial meningitis but not increased ICP, it is safe to perform lumbar puncture before a head CT scan. Lumbar puncture may also be the best initial procedure to diagnose SAH, thus reducing the need for routine CT scanning in certain low-risk patients with acute sudden headache.¹¹⁰ However, in patients with severely altered mentation, focal neurologic findings, papilledema, or a suspected intracranial mass lesion, one should perform a CT scan before lumbar puncture to rule out increased ICP or mass effect. Others have considered a recent seizure an indication for CT scan prior to LP. When meningitis remains in the differential diagnosis, antibiotics are best administered after blood is obtained for culture and before the CT scan. In patients with suspected elevated ICP based on clinical features, head elevation, hyperventilation, and intravenous mannitol have been recommended.

Particularly in patients with supratentorial masses, there may be a large pressure gradient between the cranial and lumbar compartments. When brain volume is increased because of a mass or edema, rostrocaudal displacement may occur after lumbar puncture if the skull is intact.

The question of whether lumbar puncture precipitates brain herniation in cases in which herniation would not have occurred spontaneously cannot be answered with certainty. Controversy still exists regarding the risk for brain herniation from lumbar puncture in patients with acute bacterial meningitis, and data continue to be sparse.¹¹¹ Herniation may occur in the absence of lumbar puncture in the setting of acute bacterial meningitis and has been temporally related to the procedure. Brain herniation is usually fatal, and occurs in approximately 5% of patients with acute bacterial meningitis and accounts for approximately 30% of the deaths associated with the disease.¹¹¹ Although CT imaging may reveal contraindications to lumbar puncture, normal findings on CT do not eliminate the risk for herniation and do not necessarily mean that a lumbar puncture is safe.

Lowering pressure in the lumbar spinal canal by removing CSF can increase the gradient between the cranial and lumbar compartments and thereby theoretically promote both transtentorial and foramen magnum (cerebellar) herniation. The frequency with which lumbar puncture causes or accelerates transtentorial herniation is unknown because herniation might have developed spontaneously in a seriously ill patient without the procedure. With the current use of small-caliber spinal needles, herniation appears to be extremely rare; nonetheless, it is not fully predictable by CT or the opening CSF pressure readings.

A careful neurologic examination should precede all spinal punctures. When the patient has a history of headache and fever with progressive deterioration in mental status and localizing neurologic signs, spinal puncture should not be performed as the initial diagnostic procedure. Gopal and colleagues identified three statistically significant predictors of new intracranial masses: papilledema, focal abnormalities on neurologic examination, and altered mental status.¹¹² Greig and Goroszeniuk made similar recommendations.¹¹³ Hasbun and associates demonstrated that in adults with suspected meningitis, the presence of any of 13 clinical features is predictive of abnormal findings on CT (Box 60.1).¹¹⁴ Theoretically,

BOX 60.1 Clinical Characteristics Associated With Abnormal Findings on Head CT in Adults With Suspected Meningitis

Age 60 years or older
 Immunocompromised state^a
 History of central nervous system disease^b
 Seizure within 1 week before initial evaluation
 Abnormal level of consciousness
 Inability to answer two questions correctly
 Inability to follow two commands correctly
 Gaze palsy
 Abnormal visual fields
 Facial palsy
 Arm drift
 Leg drift
 Abnormal language^c

^aIncludes patients with human immunodeficiency virus infection or acquired immunodeficiency syndrome, those receiving immunosuppressive therapy, and those who have undergone transplantation.

^bMass, stroke, or focal infection.

^cAphasia, dysarthria, or extinction.

CT, Computed tomography.

From Hasbun R, Abrabams J, Jekel J, et al: *Computed tomography of the head before lumbar puncture in adults with suspected meningitis*, *N Engl J Med* 345:1727, 2001.

the presence of abnormal findings on CT portends potential herniation, with or without lumbar puncture. The absence of abnormal findings suggests the patient is a good candidate for immediate lumbar puncture because the risk for brain herniation as a result of the procedure is low (see Box 60.1). Joffe argues that clinical signs of impending herniation are the most appropriate criteria on which to base decisions regarding the timing of lumbar puncture in patients with acute bacterial meningitis.¹¹¹ Such signs include a significantly decreased level of consciousness (Glasgow Coma Scale score ≤ 11), brain stem findings (pupillary changes, posturing, irregular respirations), and a very recent seizure.¹¹¹ It is recommended that these patients undergo neuroimaging (CT or MRI) and receive antibiotics empirically while awaiting the results of imaging, which will help in assessment of the safety of a subsequent lumbar puncture. Measures to lower ICP before spinal puncture may also be considered. Appropriate cultures of blood and more easily accessible body fluids should be obtained before the administration of antibiotics. Blood cultures are positive in 80% of infants with meningitis.

Critically ill patients with acute bacterial meningitis often deteriorate rapidly and experience fatal brain herniation, both shortly after lumbar puncture and in the absence of the procedure. A direct cause-and-effect relationship between lumbar puncture and brain herniation in the setting of suspected meningitis is obscure and probably cannot be defined prospectively in the ED when clinical decisions must be made. A 2007 review identified 22 case reports of rapid deterioration and herniation after lumbar puncture in adults and children with acute bacterial meningitis.¹¹¹ The general consensus is that less ill patients (clearly a subjective clinical judgment) with a clinical scenario that includes meningitis as a possibility can be evaluated safely with lumbar puncture. In critically ill patients, especially those with localizing neurologic signs,

severely depressed level of consciousness, or papilledema, diagnostic lumbar puncture may be delayed until the risk for herniation is lower, and aggressive and empirical treatment with meningitis doses of antibiotics should proceed.

Head CT can identify hemorrhagic lesions and most neoplasms. Its results should contribute to the decision regarding the need for and the risk involved with spinal puncture. Head CT can identify patients with unequal pressure between intracranial compartments, who are at greater risk for cerebral herniation. Findings that suggest unequal pressure include (1) lateral shift of midline structures, (2) loss of the suprachiasmatic and perimesencephalic cisterns, (3) shift or obliteration of the fourth ventricle, and (4) failure to visualize the superior cerebellar and quadrigeminal plate cisterns with sparing of the ambient cisterns.¹¹⁵ The presence of a mass in the posterior fossa is a strong contraindication to lumbar puncture. Unfortunately, because of bone and motion artifact, the posterior fossa may be a difficult area to visualize on CT.

Although there is no clear standard with respect to the use of CT before lumbar puncture, a reasonable and logical approach is to avoid initial lumbar puncture and first perform head CT when a mass lesion is suspected or if the patient has signs and symptoms of increased ICP (see Box 60.1). This approach correlates with the clinical policy promulgated by the American College of Emergency Physicians in 2002.¹¹⁶

Epidermoid Tumor

An epidermoid tumor or cyst is a mass of desquamated cells containing keratin within a capsule of well-differentiated stratified squamous epithelium. Congenital lesions arise from epithelial tissue that becomes sequestered at the time of closure of the neural groove between the third and the fifth weeks of embryonic life, but such lesions are rare. Acquired intraspinal epidermoid tumors result from the implantation of epidermoid tissue into the spinal canal at the time of lumbar puncture performed with needles without stylets or with ill-fitting stylets. The clinical syndrome consists of pain in the back and lower extremities developing years after spinal puncture. Failure to use a stylet on needle withdrawal might also result in aspiration of a nerve root into the epidural space.

Backache and Radicular Symptoms

Minor backache from the trauma of the spinal needle occurs in 90% of patients. Frank disk herniation has been reported from passage of the needle beyond the subarachnoid space into the annulus fibrosus. Transient sensory symptoms from irritation of the cauda equina are also common.

Other reported complications include transient unilateral or bilateral sixth-nerve palsies caused by stretching or displacement of the abducens nerve as it crosses the petrous ridge of the temporal bone, SAH, subdural and epidural hematoma, epidural CSF collection, cauda equina syndrome, anaphylactoid reactions to local anesthetics, settling of cord tumors, and retroperitoneal abscess produced by laceration of the dura in patients with meningitis.¹¹⁷⁻¹²³ Most of these complications are rare and seldom encountered; however, they should be considered if a patient returns after a lumbar puncture with worsening back pain or abnormal findings on neurologic examination.

The complications associated with lateral cervical and cisternal puncture are similar to those encountered with lumbar

puncture. Perforation of a large vessel with resultant cisterna magna hematoma or obstruction of vertebral artery flow has been described. Puncture of the medulla oblongata may cause vomiting or apnea, and puncture of the cord may be associated with pain. Long-lasting side effects of cord puncture seem to be rare. A traumatic tap and post-puncture headache may occur.

Spinal Epidural Hemorrhage

Rarely, serious bleeding leading to spinal hematoma after lumbar puncture can produce spinal cord compromise and permanent significant neurologic deficits, such as cauda equina syndrome.²⁹ This may occur more frequently in coagulopathic patients but can also arise in those with a normal coagulation profile and a seemingly atraumatic tap. Aspirin and nonsteroidal medications are not associated with an increased bleeding risk after lumbar puncture. The bleeding is concealed and might be suspected only by persistent severe backache or neurologic findings. Weakness, numbness, and incontinence after spinal puncture must be investigated, usually with MRI, for a possible spinal hematoma. Surgical intervention, including laminectomy and evacuation of blood, may be required and must occur in a timely manner to avoid permanent loss of neurologic function. Those with mild symptoms and progressive recovery may be managed conservatively with close monitoring.

INTERPRETATION

Pressure

CSF pressure is clinically important.¹²⁴ Measure it accurately whenever feasible. Unfortunately, in some cases it will be logistically impossible to obtain. If the lumbar puncture is being performed with the patient in a seated position, place the patient in the lateral decubitus position before a measurement is obtained. This may be done initially, before fluid is collected, or after fluid collection, in which case a closing pressure is obtained. By repositioning the patient and measuring the pressure after fluid is collected, the likelihood of the needle being displaced as a result of the repositioning is minimized.^{13,17} Accurate measurement depends on cooperation of the patient. Measurements from struggling or agitated patients will probably be inaccurate; in such cases, sedation may allow more accurate readings to be obtained.

Normal CSF pressure is between 7 and 20 cm H₂O. Obese patients may have a CSF pressure of up to 25 cm H₂O. Elevated pressure is abnormal. Opening pressure is taken promptly, thereby avoiding falsely low values caused by leakage through and around the needle. Herniating cerebellar tonsils may occlude the foramen magnum and prevent increased ICP from being reflected in the lumbar pressure reading. Increased ICP can result from expansion of the brain (edema, hemorrhage, or neoplasm), overproduction of CSF (choroid plexus papilloma), a defect in absorption, or obstruction of flow of CSF through the ventricles. Cerebral edema may be associated with meningitis, CO₂ retention, SAH, anoxia, congestive heart failure, or superior vena cava obstruction. Pressure may be falsely elevated in a tense patient when the head is elevated above the plane of the needle and, possibly, in markedly obese patients and those experiencing muscle contraction.²³ Pressure is not usually measured in neonates because a struggling or crying child will have a falsely elevated pressure. Avery and colleagues

concluded that for most children (1 to 18 years of age), an opening pressure above 28 cm H₂O should be considered elevated.¹²⁵

Low pressure suggests obstruction of the needle by the meninges. Low pressure can also be seen with a spinal block. Rarely, a primary low-pressure syndrome occurs in a setting of trauma, after neurosurgical procedures, secondary to subdural hematoma in elderly patients, with barbiturate intoxication, and in cases of CSF leakage through holes in the arachnoid.^{126,127}

The Queckenstedt test is useful for demonstrating obstruction in the spinal subarachnoid space,^{4,23} but it is seldom performed today because myelographic techniques have been refined and the availability of MRI has reduced the number of myelograms and associated lumbar puncture studies. However, because situations might arise when this simple and reliable test is important diagnostically, the technique is described here.

With the patient in the lateral recumbent position, compression of the jugular vein causes decreased venous return to the heart. This distends the cerebral veins and causes a rise in ICP, which is transmitted throughout the system and measured in the manometer. After 10 seconds of bilateral compression, CSF pressure usually rises to 15 cm H₂O over the initial reading and returns to baseline 10 to 20 seconds after release. If there is no change in lumbar pressure or if the rise and fall are delayed, one may conclude that the spinal subarachnoid space does not communicate with the cranial subarachnoid space. In this situation, to facilitate subsequent myelography, consider injecting Pantopaque before removing the needle. This is necessary because the lumbar dural sac may collapse, making it impossible to reenter the canal. If cervical cord disease is suspected, repeat the test with the neck in the neutral position, hyperextended, and flexed. When lateral sinus obstruction is suspected, use unilateral jugular venous compression (Tobey-Ayer test).

Appearance

If the CSF is not crystal clear and colorless, a pathologic condition of the CNS should be suspected. The examiner should compare the fluid with water and view down the long axis of the tube or by holding both tubes against a white background. A glass tube is preferred because plastic tubes are frequently not clear. CSF will appear grossly bloody if more than 6000 red blood cells (RBCs)/ μ L are present. Note that the fluid may appear clear with as many as 400 RBCs/ μ L and 200 WBCs/ μ L.²³ Xanthochromia, a yellow-orange discoloration of the supernate of centrifuged CSF, is generally considered to be the result of SAH of at least a few hours' duration and has been used to differentiate prior bleeding from a traumatic tap. A traumatic tap does not usually exhibit xanthochromia (see the later section on [The Traumatic Tap](#)). Xanthochromia is produced by red cell lysis and is caused by one or more of the following pigments: oxyhemoglobin, bilirubin, or methemoglobin.

Traditionally, CSF samples have been assessed for xanthochromia by visual inspection by a laboratory technician after centrifugation of a sample of CSF. Most hospitals still use this method.¹²⁸ Recently, spectrophotometry, designed to demonstrate both oxyhemoglobin and bilirubin, has been advocated as a more precise way of determining xanthochromia. Oxyhemoglobin alone without bilirubin in a CSF sample is thought

to be artifactual (traumatic). Visually, bilirubin and oxyhemoglobin cannot be differentiated. Therefore detection of bilirubin by spectrophotometry should define xanthochromia and prompt additional investigation for SAH. Relying on spectrophotometry to identify xanthochromia without pigment differentiation will cause a high false-positive interpretation. The absence of both oxyhemoglobin and bilirubin by spectrophotometry does not support the diagnosis of SAH. Oxyhemoglobin causes red coloration; bilirubin, yellow; and methemoglobin, brown. Oxyhemoglobin is seen within 2 hours after subarachnoid bleeding and red cell lysis, but it may be detected immediately if the bleeding is profuse. Formation of oxyhemoglobin peaks 24 to 48 hours after hemorrhage, and the discoloration disappears in 3 to 30 days.⁴

Blood must be present in CSF (in vivo) for a number of hours for bilirubin to appear; it will not appear spontaneously once CSF is in the collection tube. The appearance of bilirubin in CSF involves the conversion of oxyhemoglobin by the enzyme heme oxygenase. The enzyme is found in the choroid plexus, the arachnoid, and the meninges. Enzyme activity appears approximately 12 hours after the hemorrhage.⁴ Bilirubin may persist in CSF for 2 to 4 weeks. Moreover, bilirubin in CSF caused by hepatic or hemolytic disease does not appear until a serum level of 10 to 15 mg of total bilirubin per 100 mL is reached, unless underlying disease associated with high CSF protein levels is present. Xanthochromia may also be seen with CSF protein values above 150 mg/dL. CSF may clot in patients with a complete spinal block and very high CSF protein.

Graves and Sidman noted that an RBC concentration of 5000/ μ L, created by adding RBCs to acellular CSF, will produce xanthochromia evident on spectrophotometry by 2 hours.¹²⁹ The addition of RBCs to achieve RBC concentrations of 20,000/ μ L and 30,000/ μ L will produce xanthochromia by 1 hour or immediately, respectively. Therefore xanthochromia may occur with a traumatic tap and does not always indicate SAH.

Methemoglobin is a reduction product of oxyhemoglobin that is characteristically found in encapsulated subdural hematomas and in old intracerebral hematomas.

Cells

In adults, WBC counts higher than 5 cells/ μ L indicate the presence of a pathologic condition. A large study by Kestenbaum and colleagues in 2010 determined 95th percentile WBC reference values in normal infants: 19 cells/ μ L for infants 28 days of age or younger and 9 cells/ μ L for those between the ages of 29 and 56 days.¹³⁰ A median CSF WBC count of 271 WBCs/ μ L has been reported in infants with group B *Streptococcus* in the era of intrapartum antibiotic prophylaxis. The CSF WBC count in infants is higher with gram-negative meningitis than with gram-positive CNS infections. In general, polymorphonuclear leukocytes are never seen in normal adults. However, with use of the cytocentrifuge, an occasional specimen from an otherwise normal individual may show one to two neutrophils.¹³¹ More than three neutrophils is always abnormal in an adult. Moreover, as many as 30% of patients exhibit CSF pleocytosis after a generalized or focal seizure. Nonetheless, such a finding should prompt culture of CSF because the presence of neutrophilic pleocytosis is commonly associated with bacterial meningitis or the early stages of viral or tuberculous meningitis. Small lymphocytes may be seen in normal individuals. Small and large immunocompetent cells are found

with a variety of bacterial, fungal, viral, granulomatous, and spirochetal diseases.

Eosinophils always indicate an abnormal condition, most commonly a parasitic infestation of the CNS. They may also be seen after myelography and pneumoencephalography and, to a minor degree, with other inflammatory diseases, including tuberculous meningitis and neurosyphilis. Normal CSF RBC counts are lower than 10 cells/ μ L. Herpes simplex virus (HSV) encephalitis may elevate the RBC count. Finally, myeloid and RBC precursors may contaminate CSF with bone marrow cells from an adjacent vertebral body.¹³²

Glucose

Glucose enters CSF by way of the choroid plexus, as well as by transcapillary movement into the extracellular space of the brain and the cord via carrier-mediated transport. It then equilibrates freely within the CSF subarachnoid space. Once in the CSF, glucose undergoes glycolysis and there is an invariable rise in CSF lactate levels. Glucose levels remain subnormal for 1 to 2 weeks after effective treatment of bacterial meningitis.

The normal range of CSF glucose is 50 to 80 mg/dL, which is 60% to 70% of the glucose concentration in blood. Ventricular fluid glucose levels are 6 to 8 mg/dL higher than in lumbar fluid. A ratio of CSF glucose to blood glucose of less than 0.5 or a CSF glucose level below 40 mg/dL is invariably abnormal. The ratio is higher in infants, in whom a ratio of less than 0.6 is considered abnormal. Hyperglycemia may mask a depressed CSF glucose level; when present, the ratio of CSF glucose to blood glucose should be measured routinely. With extreme hyperglycemia, a ratio of less than 0.3 is abnormal.¹³³ Between 90 and 120 minutes is required before CSF glucose reaches a steady state with changes in blood glucose (e.g., after an intravenous injection of glucose). When CSF glucose is of diagnostic importance, obtain CSF and blood samples, ideally after a 4-hour fast.

Low CSF glucose levels may be associated with several diseases of the nervous system (Box 60.2). Only low concentrations of glucose are of diagnostic value; elevated CSF glucose levels generally have little significance and usually reflect hyperglycemia. A rapid estimate of the CSF glucose level can be obtained by using bedside reagent strip testing with a

commercial autoanalyzer. Formal laboratory testing is recommended for confirmation of the bedside levels.

Protein

The normal range of lumbar CSF protein is 15 to 45 mg/dL. Infants normally have a lower level than adults, and protein levels may drop after lumbar puncture. The concentration is lower in the ventricles (5 to 15 mg/dL) and the basilar cisterns (10 to 25 mg/dL) as a result of a gradient in the permeability of capillary endothelial cells to proteins in blood. Levels of CSF protein in premature infants and full-term neonates are higher than in adults, with a mean of 90 mg/dL; protein levels decline by the age of 8 weeks because of maturation of the blood–brain barrier.

Most of the proteins in CSF come from blood, which normally has a protein concentration of up to 8000 mg/dL. Protein entry is determined by its molecular size and the relative impermeability of the blood–CSF barrier. A full range of serum proteins is found in CSF at a several hundred-fold dilution.

An increase in the total CSF protein level is a nonspecific abnormality associated with many disease states. Levels higher than 500 mg/dL are uncommon and seen mainly with meningitis, SAH, and spinal tumors. The high levels that occur with cord tumors result from an increase in local capillary permeability. With high levels (generally 1000 mg/dL), CSF may clot (Froin's syndrome).

Hemorrhage into CSF or the introduction of blood by a traumatic tap increases CSF protein levels. If the serum protein concentration is normal, the CSF protein level should theoretically rise by 1 mg/dL for every 1000 RBCs, but this relationship varies. The inflammatory effect of hemolyzed RBCs may also significantly increase CSF protein.

Selective measurement of immunoglobulin fractions in CSF has proved to be of diagnostic value in suspected cases of multiple sclerosis. Elevated CSF immunoglobulin levels may reflect disruption of the blood–brain barrier or a local antibody response to a CNS immune response.¹³⁴ Stimuli may be infectious or antigenic and produce an inflammatory response. Elevated immunoglobulin levels have been found in many conditions, including syphilis, viral encephalitis, subacute sclerosing panencephalitis, progressive rubella encephalitis, tuberculous meningitis, sarcoidosis, cysticercosis, and acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome).

The Traumatic Tap

The incidence of a traumatic tap is 10% to 30%, depending on the criteria used to define the condition.^{135–137} Currently, there is no consensus on what constitutes a traumatic tap. Traditionally, the number of RBCs in CSF, the rate of clearance of RBCs from tube 1 to tube 3 or 4, and the presence or absence of xanthochromia have guided clinicians in attempts to define the need for further investigation for SAH when blood is detected during lumbar puncture.

Absolute Number of RBCs

The current literature makes no firm recommendations regarding the absolute CSF RBC count that can be used as a cutoff to differentiate SAH from a traumatic tap. However, SAH consistently produces more RBCs in CSF than a traumatic tap does. In tube 3 or 4, an absolute RBC value of 400 to

500 RBCs/ μ L or less is very suggestive of a traumatic tap, and this value has been traditionally used by clinicians.¹³ In a retrospective study of 300 patients, Gorchynski and coworkers reported a 100% negative predictive value for SAH with an RBC count in tube 4 of 500 RBCs/ μ L or less, with a sensitivity of 100% for SAH.¹³⁸ No radiographically normal subject had an RBC count higher than 10,000 RBCs/ μ L, suggesting that results above this number are suspicious for radiographically detectable SAH. When the RBC count in tube 4 ranged between 500 and 10,000 RBCs/ μ L, SAH could not be ruled out without further study. Perry and colleagues concluded that the combination an RBC count of fewer than 2000×10^6 in the final tube and no xanthochromia reasonably excluded the diagnosis of aneurysmal SAH with a sensitivity of 100% and 95% confidence interval of 74.7% to 100%.¹³⁹ They added that patients with a high pretest probability might need further investigation.

Any attempt to define precisely how low an RBC count must be to eliminate the possibility of SAH would result in an arbitrary threshold. As the foregoing discussion suggests, SAH is exceedingly unlikely with RBC counts lower than 500 RBCs/ μ L and becomes progressively less likely as this number decreases.

RBC Clearance From First to Last Tubes

In traumatic punctures, the fluid generally clears of RBCs between tubes 1 and tubes 3 or 4 as the needle is washed by CSF. In fact, a decrease in the RBC count between the first and last tubes of at least 25% to 30% has traditionally been considered strong evidence of a traumatic tap.^{2,140} However, it must be remembered that a traumatic tap may also occur in a patient with true SAH. Thus, regardless of the change in RBC count from the first to last tubes, SAH cannot be excluded unless the RBC count approaches zero in either tube. If this is not the case and xanthochromia is not present (see later), it may be most prudent to repeat the puncture at a different interspace or site. To help avoid this situation, when a clinician encounters what is suspected to be a traumatic tap (e.g., a streak of blood flowing into an otherwise clear-appearing stream of CSF), wasting the first 2 or 3 mL of CSF while positioning the needle to obtain the clearest possible sample will increase the odds of an RBC count approaching zero.

Xanthochromia

RBCs undergo hemolysis in CSF after a few hours and xanthochromia is produced. Xanthochromia persists for up to 4 weeks, depending on the number of RBCs originally present. Xanthochromia is suggestive of but not pathognomonic for SAH.¹⁴¹ An early CSF examination may show clear fluid before the development of hemolysis, even after spontaneous subarachnoid bleeding. However, xanthochromia may be detected immediately after a traumatic tap if the RBC count exceeds 30,000/ μ L.¹³⁸ The presence of a clot in one of the tubes strongly favors a traumatic tap. With SAH, clotting does not occur because blood is defibrinated at the site of the hemorrhage. Lumbar puncture performed several days after a traumatic tap may also yield stained fluid. Collection of clear CSF from an immediately repeated puncture at a higher interspace also indicates a traumatic tap. The fluid from a traumatic tap should contain approximately 1 WBC per 700 RBCs if the complete blood cell count is normal, but this ratio is highly variable. All blood-contaminated CSF should be cultured, especially samples from uncooperative infants and children being evaluated for sepsis.

A D-dimer test on CSF can be used to determine SAH by identifying local fibrinolysis.¹⁴² Other conditions such as disseminated intravascular coagulation, a previous traumatic tap, or prior thrombolytic therapy may produce false-positive results.

Fluoroscopically guided lumbar puncture in patients with suspected SAH and negative findings on CT is another option that may reduce the frequency of traumatic punctures, but it requires specific expertise and is frequently performed in the radiology suite.¹⁴³

CSF Analysis With Infections

Bacterial Infections

The CSF findings are essential to establish a provisional diagnosis of acute bacterial meningitis.¹⁴⁴ CSF analysis establishes not only the diagnosis but also the causative organism and therefore the choice of antibiotics (Table 60.1). CSF must be transported to the laboratory immediately and examined at once. CSF cells begin to lyse within 1 hour after collection; this process can be slowed by refrigeration. In cases of meningococcal infection, a delay in processing may cause the diagnosis to be missed because the organism tends to autolyze rapidly. For other organisms, speed is somewhat less important but still warranted.

Gram stain is of great importance because the results direct antibiotic therapy. Gram-negative intracellular or extracellular diplococci are indicative of *Neisseria meningitidis*. Small gram-negative bacilli may indicate *Haemophilus influenzae*, especially in children. The presence of gram-positive cocci indicates *Streptococcus pneumoniae*, other *Streptococcus* species, or *Staphylococcus*. Twenty percent of Gram stains are falsely negative because too few organisms are present. The Gram stain smear is more likely to be positive in patients who have not received prior antibiotic therapy. Acridine orange stain may improve the yield with gram-negative organisms.¹⁴⁵

For culture, blood and chocolate agar are required. *N. meningitidis* and *H. influenzae* grow best on chocolate agar. The plates are incubated under 10% CO₂. Thioglycolate medium is used for possible anaerobic organisms. Cultures are examined at 24 and 48 hours, but the plates should be kept for at least 7 days. Large volumes of CSF may improve yields.

While the culture results are pending, bacterial infection should be suspected in patients with an elevated opening pressure and marked pleocytosis ranging between 500 and 20,000 WBCs/ μ L. The differential count with bacterial infections is usually neutrophil predominant. A count higher than

1000 cells/ μ L seldom occurs with viral infections. Occasionally, acellular fluid may be collected from a severely immunosuppressed patient. Moreover, repeated lumbar puncture may be required in febrile patients whose clinical features remain compatible with meningitis.^{133,146,147} In such scenarios, broad-spectrum empirical antibiotics should be continued until the results of repeated testing or bacterial culture are available.

CSF glucose levels of 40 mg/dL or lower, or less than 50% of a simultaneous blood glucose level, should raise the question of bacterial meningitis, even in the presence of a negative Gram stain and a low cell count. Glucose levels with bacterial meningitis are occasionally below 10 mg/dL but are normal in a small percentage of patients.¹³³ The CSF protein content with bacterial meningitis ranges from 500 to 1500 mg/dL and usually returns to normal by the end of therapy. Of note, previous antibiotic therapy may adversely affect the sensitivity of cultures and Gram stain for bacterial meningitis but does not significantly affect WBC counts, the ratio of CSF glucose to blood glucose, or CSF protein values.¹⁴⁸ Spanos and colleagues developed a useful nomogram to help distinguish bacterial from viral infections¹⁴⁹; however, no technique is perfect in this regard, and in general the clinician should err on the side of diagnosing bacterial meningitis until the results of culture are available.

Microbial Antigens and PCR

In 50% to 80% of cases of bacterial meningitis, blood cultures are positive for the etiologic agent.¹⁵⁰ In addition to Gram stain and cultures, several tests are available to establish a bacterial cause of meningitis, including CSF counterimmunoelectrophoresis (CIE), CSF latex agglutination, and coagglutination CIE.⁶ In general, these ancillary tests have low sensitivity for bacterial meningitis, limiting their use.

CIE uses wells in two rows of agarose gel. A different antiserum is placed in each well. A current is passed through the gel, which causes the reactants to move toward each other by electrophoretic mobilization of the antigen. The appearance of a line of precipitation in 1 to 4 hours represents a positive reaction between antiserum and antigen.¹⁵¹ Commercial kits are available to detect *S. pneumoniae*; *Listeria monocytogenes*; *H. influenzae*; *N. meningitidis* A, B, C, and W135; group B streptococci; K1 strains of *Escherichia coli*; *Klebsiella*; and *Pseudomonas* species.¹⁵²

Particle agglutination involves staphylococcal coagglutination and latex agglutination. Antibodies on the surface of a colloid combine with antigen-binding sites to cross-link the

TABLE 60.1 CSF Analysis in Bacterial and Viral Meningitis^a

	BACTERIAL MENINGITIS	VIRAL MENINGITIS
Opening pressure	Usually elevated	Usually normal
White blood cell count (per mm ³)	Elevated, 500–10,000+	Elevated, 6–1000
Differential count	Polymorphonuclear predominance	Lymphocytic predominance
Glucose level	Decreased, 0–40 mg/dL	Usually normal
Protein level	Elevated, > 50 mg/dL	Normal or slightly elevated

^aThis is only a guide. Care must be taken when interpreting these parameters, especially early in the clinical course.

CSF, Cerebrospinal fluid.

colloid-forming antigen bridges. A matrix forms and appears as a macroscopic agglutination. Agglutination tests can detect levels of antigen that are approximately 10 times lower than CIE is capable of detecting. False-positive results can occur in the presence of rheumatoid factor, serum complement components, and possibly other serum proteins. The technique may be used for infections with *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and group B streptococci.

Another technique that has some potential use for identification of bacterial meningitis is the enzyme-linked immunosorbent assay. This technique may detect levels of antigen 100 to 1000 times lower than agglutination tests can but is technically more difficult and requires 4 hours to perform.

A positive CSF antigen test may be expected in 70% to 90% of patients with *Neisseria meningitidis*. This compares with a positive Gram stain in approximately 70% of patients. Positive latex antigen tests have been reported in approximately 60% of *S. pneumoniae* meningitis cases, with a positive Gram stain in 80%. A positive latex test and Gram stain are reported in approximately 85% of *H. influenzae* meningitis cases.^{150,151} Group B streptococci can be detected with 60% to 90% sensitivity.

Bacterial antigens may persist in CSF for several days after antibiotic therapy. With appropriate antimicrobial therapy, 25% to 33% of positive tests convert to negative per day. A negative test, however, does not rule out bacterial meningitis.¹⁵² In addition, blood and urine can be examined for antigen. Frequently, antigen is found only in urine. Urine needs to be concentrated and may have the disadvantage of reflecting urinary tract infections. Moreover, the particle agglutination test for *H. influenzae* type B may be positive up to 10 days after children have received *H. influenzae* polysaccharide vaccine. Antigen tests are not useful in diagnosing gram-negative bacillary, staphylococcal, and *Listeria meningitidis*. In addition, although antigen tests may identify the bacterial pathogen, they do not provide information about the antibiotic susceptibility of the organism.

Polymerase chain reaction (PCR) may aid in the rapid diagnosis of CNS infection when results of the aforementioned common techniques are suboptimal. PCR amplifies target nucleic acid in CSF by the use of repeated cycles of DNA synthesis. PCR requires the use of flanking DNA sequences at the opposite ends of the target DNA. Synthetic primers anneal to their respective recognition sequences at the opposite end of the target sequence; they serve as primers for new DNA synthesis. PCR allows detection and quantification of organisms whose genetic material is DNA or messenger RNA. PCR permits the diagnosis of infectious disease with a high degree of sensitivity and specificity and allows rapid reliable detection of microbes present in small numbers. Nonetheless, false-negative and false-positive laboratory results may occur.

Empirical Antibiotic Use Before Lumbar Puncture

Many patients are transported within a facility or to a referral center for a CT to rule out an intracranial mass after clinical concern for meningitis is raised. In such instances, CSF examination might not be performed before transport because of technical problems (an uncooperative or a large patient) or concerns regarding the safety of lumbar puncture in an obtunded patient with possible increased ICP.^{133,153} The initial clinician may have to decide whether to initiate empirical antibiotic therapy. Antibiotic administration could obscure the bacterial source, whereas a delay in initiating therapy increases morbidity and mortality. It may be difficult to identify individuals at risk

for a fulminant course, and bacterial meningitis cannot always be diagnosed with confidence; some cases might be misdiagnosed as SAH or metabolic encephalopathy.

After administration of parenteral antibiotics, CSF cultures are not adversely affected for 2 to 3 hours. Twenty-four hours after treatment, as many as 38% of patients with meningitis could still have positive CSF cultures. Kanegaye and associates demonstrated that CSF sterilization may depend on the infecting organism.¹⁵⁴ They reported CSF sterilization after antibiotic administration within the following time frames: meningococcal, less than 2 hours; pneumococcal, less than 4.3 hours; and group B streptococcal, longer than 8 hours.

Whenever possible, blood should be obtained for culture immediately before the administration of antibiotics. When CSF is cultured more than a few hours after parenteral antibiotics are administered, antigen tests may be helpful. Occasionally, lymphocytic pleocytosis may develop in response to antibiotic therapy, but in most cases, the cell count, differential, glucose and protein concentrations are unchanged in the first 2 to 3 days of antibiotic therapy.¹³³ It is thus reasonable to initiate therapy on the premise that a delay might be deleterious. If a lumbar puncture cannot be performed, consultation with clinicians at a referral center seems appropriate. If a lumbar puncture is performed before transfer, a portion of the CSF (chilled on ice) should be sent with the patient or held in the referring hospital laboratory.

Bacterial meningitis in children younger than 10 years has historically been caused by *H. influenzae*. Fortunately, this organism is easy to grow in early postantibiotic cultures and is likely to be associated with positive blood cultures and antigen tests. In the pediatric population, a single dose of an antibiotic before transport is unlikely to prevent identification of bacteria. In neonates, adults, and immunosuppressed patients, the sensitivity of blood cultures and immunologic tests is less reliable. CSF examination as early as possible in the course of treatment is preferred.

For suspected or confirmed cases of acute bacterial meningitis, antimicrobial therapy can be started and based on the most likely causative organism with respect to the age of the subject, associated diseases, and renal function. [Tables 60.2 through 60.4](#) offer guidelines for emergency antibiotic therapy. For immunocompromised patients and after neurosurgery, a third-generation cephalosporin (cefotaxime, ceftizoxime, ceftazidime, or ceftriaxone) plus ampicillin and vancomycin should be used for coverage against staphylococci, *L. monocytogenes*, and gram-negative organisms.⁶ The third-generation cephalosporins are efficacious in many empirical regimens or situations in which the organism is known. Reliance on third-generation cephalosporins alone for all cases of bacterial meningitis would result in treatment failure for all *Listeria* species and increasing numbers of *Enterobacter*, *Serratia*, and *Pseudomonas* groups.

Dexamethasone Therapy for Bacterial Meningitis

In acute bacterial meningitis, bacterial cell wall components, including lipopolysaccharides and teichoic acid, initiate and exacerbate the host response. These substances stimulate the production of cytokines, including interleukin-1 and tumor necrosis factor, from macrophages and monocytes. Cytokines may injure vessels, diminish cerebral perfusion, and stimulate cerebral swelling.¹⁵³ The outcome of acute bacterial meningitis has been related to the severity of the inflammatory process in the subarachnoid space.

TABLE 60.2 Empirical Therapy for Purulent Meningitis^a

PREDISPOSING FACTOR	ANTIMICROBIAL THERAPY ^b
Age	
0–4 wk	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside
4–12 wk	Ampicillin plus a third-generation cephalosporin ^c
3 mo–50 yr	Vancomycin plus a third-generation cephalosporin ^{c,d}
>50 yr	Vancomycin plus ampicillin plus a third-generation cephalosporin ^c
Immunocompromised state	Vancomycin plus ampicillin plus ceftazidime
Basilar skull fracture	Vancomycin plus a third-generation cephalosporin ^c
Head trauma; post neurosurgery	Vancomycin plus ceftazidime
Cerebrospinal fluid shunt	Vancomycin plus ceftazidime

^aConsider corticosteroids before administration of antibiotics (see text).

^bVancomycin should be added to all empirical therapeutic regimens when strains of *Streptococcus pneumoniae* that are highly resistant to penicillin or cephalosporin are suspected.

^cCefotaxime or ceftriaxone.

^dAdd ampicillin if meningitis caused by *Listeria monocytogenes* is suspected.

TABLE 60.3 Recommended Total Daily Dose (With Divided Dosing Intervals in Hours) of Antimicrobial Agents for Meningitis in Adults With Normal Renal and Hepatic Function^a

ANTIMICROBIAL AGENT	TOTAL DAILY DOSE (INTRAVENOUS)	DOSING INTERVAL (hr)
Ampicillin	8–12 g/day	4
Cefotaxime	8–12 g/day	4–6
Ceftazidime	6 g/day	8
Ceftriaxone	4 g/day	12
Chloramphenicol ^b	4 g/day	6
Gentamicin ^c	2 mg/kg IV load, then 1.7 mg/kg q 8 hr	8

^aConsider corticosteroids before the administration of antibiotics (see text).

^bSmaller dosages and longer intervals of administration may be advisable for very-low-birth-weight neonates (< 2000 g).

^cPeak and trough serum concentrations must be monitored.

Studies have suggested benefit from adjunctive dexamethasone therapy in reducing neurologic sequelae, especially hearing loss, in children with *H. influenzae* meningitis and in lowering the mortality rate and providing a better overall outcome in adults with community-acquired acute bacterial meningitis caused by *S. pneumoniae*.¹⁵⁵ There appear to be few adverse sequelae from steroid therapy. The adjunctive benefit of corticosteroids during treatment of meningitis caused by other viral, fungal, or parasitic organisms is unknown. A Cochrane review concluded that “the corticosteroid dexamethasone leads to a major reduction in hearing loss and death in both children and adults with bacterial meningitis, without major adverse effects.”¹⁵⁶ Interestingly, in children in low-income countries, the use of corticosteroids was associated with neither benefit nor harmful effects.

The dosage of dexamethasone is 0.15 mg/kg (10 mg intravenously in adults) every 6 hours for 4 days. It is recommended that the corticosteroid be given before or simultaneously with antibiotic use, but the exact timing and specific benefits are unclear. It has been suggested that caution be exercised when administering corticosteroids to immunocompromised and leukopenic patients with bacterial meningitis, but no specific recommendations have been published.

A moderate inflammatory response in the meninges is required for penetration of the CNS by many antibiotics. Reducing meningeal inflammation reduces the concentration of antibiotics in CSF. Corticosteroids should be discontinued after approximately 4 days of treatment, at which time the meningeal inflammation should be reduced.^{157,158}

Neurosyphilis

The true incidence of neurosyphilis is unknown. Approximately 5000 new cases of this disease occur in the United States each year.¹⁵⁹ Its natural history and clinical manifestations have been modified in the antibiotic era. The widespread use of oral antibiotics has changed neurosyphilis into chronic, partially treated meningitis. Partial therapy might clear peripheral infection and attenuate the immune response. Therapy may be sufficient to minimize symptoms but insufficient to eradicate organisms in the CNS and eye, which could then multiply.

CSF findings suggestive of neurosyphilis include more than 5 WBCs/ μ L, an elevated protein concentration, an elevated γ -globulin concentration, and a positive serologic test for syphilis. The glucose concentration is usually normal. Cell and protein values are higher in early neurosyphilis than in late neurosyphilis.

Diagnostic certainty remains difficult. The diagnostic criterion standard is darkfield microscopy to identify the morphology and flexing “corkscrew” motility of spirochetes. Serologic tests for syphilis are either treponemal or nontreponemal. Nontreponemal tests detect a nonspecific globulin complex called reagin. Reagin tests, such as the Venereal Disease Research Laboratory (VDRL) flocculation test, lack sensitivity and should not be used to exclude the diagnosis of neurosyphilis. One third to one half of patients with neurosyphilis have a negative VDRL test on serum, and more than one-third have a negative VDRL test on CSF.¹⁵⁹ CSF VDRL is quite specific, with false-positive results seen primarily after traumatic taps.

Treponemal tests provide evidence of a specific immune response to *Treponema pallidum*. These tests include serum fluorescent treponemal antibody absorption (FTA-ABS), microhemagglutination tests for *T. pallidum*, and the *T. pallidum* hemagglutination assay. A positive serum treponemal

test indicates past infection with syphilis and may be reactive indefinitely, even after treatment. Therefore CSF is used as a guide to the presence and activity of neurosyphilis. The VDRL test is commonly used on CSF and, when positive, is strong evidence of neurosyphilis. False-positive CSF VDRL tests are rare. The FTA-ABS test can be used on CSF; the false-positive rate is between 4% and 6% and is believed to represent antibodies that have entered passively from serum.¹⁶⁰ The FTA-ABS test measures immunoglobulin G (IgG) antibody and cannot differentiate active from past infection. The CSF VDRL may be reactive as a result of contamination with seropositive blood (traumatic tap, SAH) or because of entry of serum reagin into CSF during meningitis. In summary, CSF VDRL and CSF FTA-ABS are complementary tests in the diagnosis of neurosyphilis: CSF VDRL is highly specific but not sensitive, whereas CSF FTA-ABS is less specific but more sensitive.

There is some concern that many patients with parenchymal neurosyphilis have normal CSF. This finding has led to the recommendation that a patient with signs of progressive neurosyphilis and a positive treponemal serologic test be treated with antibiotics regardless of the CSF findings. CSF pleocytosis may be provoked after 1 week of therapy and may provide supportive evidence for a diagnosis of neurosyphilis. PCR may have future applications for the diagnosis of neurosyphilis (see later section on [Neurosyphilis in Patients Infected with HIV](#)).

Viral Meningitis

The organisms most commonly isolated in viral meningitis are the enteroviruses (coxsackieviruses, echoviruses) and mumps virus. Enteroviruses are most commonly seen in the summer and fall, and mumps appears most frequently in the winter and spring. Viral cultures in most hospitals are not available and play little role in acute decisions regarding diagnosis and treatment. A serial rise in CSF antibody titers may be helpful but are difficult to obtain in patients who have recovered clinically. Intrathecal production of organ-specific antibodies (IgM, IgG, and IgA isotopes) may be diagnostic of neurologic infection if there is no history of infection. Serum and CSF antibody titers must be measured in a specialized laboratory. Viral meningitis is diagnosed when bacterial culture and Gram stain are negative. A tentative diagnosis may be based on analysis of CSF.

The WBC count in viral meningitis and encephalitis is characteristically 10 to 1000 cells/ μ L. The differential cell count is predominantly lymphocytic and mononuclear in type. In the early stages of meningoencephalitis, however, polymorphonuclear cells may predominate, making the distinction between viral and bacterial infection difficult. In such cases, a tap repeated in 12 to 24 hours will assist in clarifying the diagnosis. Protein levels are usually mildly elevated, but normal levels may be seen. Antibiotic coverage pending the results of culture may be reasonably initiated if the diagnosis of viral meningitis is in doubt.¹³³ The CSF glucose concentration is characteristically normal; notable exceptions include some cases of mumps meningoencephalitis and HSV encephalitis. CSF pleocytosis and elevated protein levels have also been found in asymptomatic HIV-seropositive individuals.¹⁶¹

If CSF cannot be delivered to the viral laboratory in 24 to 48 hours, it should be refrigerated at 4°C. Members of the enterovirus group are occasionally isolated from CSF. Herpesviruses and arboviruses are also found in CSF. PCR is the diagnostic test of choice for HSV meningoencephalitis and

will be used increasingly for the diagnosis of other CNS viral infections. Although the majority of cases of viral meningitis are self-limited and have a good outcome, HSV encephalitis is a rapidly progressive and life-threatening emergency that responds to treatment with intravenous acyclovir. Thus, in an acutely ill patient in whom the diagnosis of acute meningoencephalitis is being considered, a negative Gram stain and pleocytosis are sufficient grounds to initiate empirical acyclovir therapy until the results of more definitive diagnostic data from PCR are available.¹⁶²

CSF Analysis in Immunocompromised Patients

The number of immunocompromised individuals is increasing because of the HIV epidemic and the increased survival of patients with cancer and autoimmune disorders. The nervous system is a major target of the HIV virus: neurologic disease develops in 40% to 60% of infected individuals during their lifetime. One third of HIV-infected patients have neurologic complaints as the initial manifestations of AIDS, and an even higher incidence of nervous system involvement is found at autopsy.¹⁶³ The risk for CNS infection depends on the underlying disease, treatment, duration, and type of immune abnormality. Abnormalities include defects in T-lymphocyte and macrophage cellular immune function, defects in humoral immunity, defects in the number and function of neutrophils, and loss of splenic function with an inability to remove encapsulated bacteria.¹⁶⁴

Patients with defective cell-mediated immunity include those with lymphoma or organ transplants, those taking corticosteroids daily, and patients with AIDS. These individuals are vulnerable to infections with microorganisms that are intracellular parasites. A common source of acute bacterial meningitis in such patients is *L. monocytogenes*. Clinical findings include fever, headache, seizures, focal neurologic deficits, and brain stem encephalitis.

Patients with defective humoral immunity include those with chronic lymphocytic leukemia, multiple myeloma, and Hodgkin's disease after radiotherapy or chemotherapy. These patients have difficulty controlling infection by encapsulated bacteria. A fulminant meningitis caused by *S. pneumoniae*, *H. influenzae* type B, or *N. meningitidis* may develop. After splenectomy, patients are at risk for the development of meningitis for the same reason. Neutropenic patients are at risk for meningitis caused by *Pseudomonas aeruginosa* and the *Enterobacteriaceae*.

Establishing a specific diagnosis in HIV and organ transplant patients may be difficult or impossible because of overlapping clinical and radiographic findings, the presence of simultaneous infections with more than one organism, and changes in CSF that may be nonspecific. The immune response can be altered, with absence of the usual signs of meningeal irritation. Patients might have diffuse encephalopathy or focal neurologic deficits. CSF is abnormal in 60% of asymptomatic HIV-infected individuals, complicating correlation of the CSF and clinical findings.¹⁶³

Neurosyphilis in Patients Infected With HIV

Syphilis and HIV infection can both be transmitted sexually, and patients with syphilis are at increased risk for HIV infection. CNS invasion is probably no more common in patients with HIV than in those not infected with the virus.¹⁶⁵ Both diseases

may cause an elevation in CSF WBC counts, protein levels, and γ -globulin levels. The incidence of syphilitic meningitis, meningovascular syphilis, and ocular syphilis seems to be increasing. HIV-infected patients treated for syphilis may have viable organisms in CSF after therapy or have persistent CSF VDRL titers. Treatment failures are more likely to occur with single-dose benzathine penicillin therapy.

Neurosyphilis may be more difficult to diagnose in HIV-infected patients. A small number of patients with secondary or ocular syphilis have negative serum reagin tests. Positive treponemal tests may revert to nonreactivity after treatment, particularly in individuals with advanced symptomatic HIV disease and a low VDRL titer at the time of diagnosis. CSF pleocytosis and increased γ -globulin levels may not help distinguish between HIV infection and CNS syphilis.

HIV-infected patients should undergo serum treponemal and nontreponemal tests early in their illness to minimize the likelihood of false-negative results.¹⁶⁵ Infected patients should undergo a CSF examination. Previously treated patients who did not have a CSF examination at the time of initial syphilis treatment should undergo lumbar puncture because of a probable increased risk for neurosyphilis even with a decline in serum nontreponemal titers.

Cryptococcal Meningitis

The most common cause of CNS fungal infection is *Cryptococcus neoformans*. Infection with this fungus develops in approximately 5% of AIDS patients. Clinical findings in AIDS and non-AIDS patients include nonspecific symptoms of headache and altered mental status with or without meningeal signs. Most patients have increased ICP. Immunocompetent patients show a lymphocytic pleocytosis with CSF WBC counts lower than 500/ μ L. Glucose levels are depressed, with elevation of CSF protein. India ink preparations are positive in 50% of cases. CSF is less likely to have abnormal cell counts and chemistries in patients infected with HIV. However, CSF cultures and cryptococcal polysaccharide capsular antigens are almost always positive. False-positive antigen tests are rare but may be seen in the presence of rheumatoid factor. Blood cultures are frequently positive in AIDS patients. Cisternal puncture for fluid analysis may be helpful in undiagnosed cases of lymphocytic meningitis in which multiple lumbar punctures have not established a diagnosis.¹⁶³

Toxoplasmosis

Toxoplasma gondii, an intracellular protozoan, is associated with CNS infection in up to 30% of AIDS patients who have antibodies to this organism. Most adults have antibodies against this organism; infection is believed to represent reactivation of latent primary infection. *Toxoplasma* encephalitis usually develops within the first 2 years after the diagnosis of AIDS. Cerebral toxoplasmosis is usually accompanied by the acute or subacute development of focal disease, including seizures. MRI or CT scanning often reveals multiple abscesses that might represent multiple pathogens. Toxoplasmosis and lymphoma can be difficult to distinguish clinically. Less commonly, the manifestation is one of chronic meningitis with confusion, memory loss, and lethargy similar to the AIDS-dementia complex. CSF in these patients is nonspecific with increased protein, mononuclear pleocytosis (<100 cells/ μ L), and, rarely, a reduced glucose concentration. Serum and CSF serology may be either positive or negative and does not help make a diagnosis, although most patients with encephalitis

have detectable IgG antibodies. The diagnosis is usually based on clinical and imaging responses to antibiotics (pyrimethamine or sulfadiazine) or on brain biopsy. Treatment failures with relapse occur in 50% of AIDS patients and in 15% to 25% of non-AIDS patients and necessitate life-long treatment.

Mycobacterial Tuberculosis

CNS mycobacterial infection is almost always the result of infection with *Mycobacterium tuberculosis*. Infection typically occurs in the setting of disseminated tuberculosis. Atypical *Mycobacterium* infection in HIV-infected individuals uncommonly affects the CNS.

The clinical manifestation is meningitis (particularly meningitis involving the basal cisterns), encephalitis, or abscess formation. If tuberculosis is suspected, a large volume of CSF (10 mL) is required for adequate culture. The cell count varies from 100 to 400 cells/ μ L, with a lymphocytic predominance; 30% may show predominantly neutrophils early in the course of infection. Protein levels are elevated (100 to 500 mg/dL), and the CSF glucose level may be depressed. Acid-fast stains should be examined by experienced technicians. Fluid is inoculated onto Löwenstein-Jensen medium, and the absence of visible growth on the medium should not be considered negative until 8 weeks has elapsed. CSF cultures are more sensitive than stains.

Primary CNS Lymphoma

CNS lymphoma develops in 2% of AIDS patients. The signs and symptoms resemble those of diffuse encephalopathy, although focal neurologic deficits occur occasionally. Leptomeningeal spread of malignancy is reflected in a modest lymphocytic pleocytosis with slightly elevated protein and decreased glucose levels. Cytologic yield is improved by repeated

lumbar punctures and submitting large quantities of CSF or fluid obtained by cisternal puncture.¹⁶³

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy, an uncommon disorder in individuals with impaired cell-mediated immunity, is caused by reactivation of JC papovavirus in the kidney. Progressive demyelination is manifested as dementia, blindness, aphasia, hemiparesis, and seizures, which progress until death. MRI and CT demonstrate nonenhancing white matter lesions without a mass effect. Definitive diagnosis is made by brain biopsy, but CSF may show the presence of myelin basic protein, increased IgG, and an acellular or a mild CSF pleocytosis (<50 WBCs/ μ L). Average survival is 4 months.¹⁶⁴

Cytomegalovirus Infection

Cytomegalovirus is detected in the brains of 30% of HIV-infected persons at autopsy. A distinct CNS disorder has not been defined. CSF pleocytosis may be minimal. Retinitis and painful polyradiculopathies are recognized, with a prominent CSF pleocytosis found in the latter condition.¹⁶³

ACKNOWLEDGMENTS

The editors and author acknowledge the contributions of Jon Kooiker to this chapter in previous editions. The author would like to thank Linda J. Kesselring, MS, ELS, for copyediting the manuscript and incorporating revisions into the final document.

Special Neurologic Tests and Procedures

Mikaela L. Chilstrom

EVALUATION OF THE COMATOSE PATIENT

Coma is defined as a state of deeply reduced consciousness from which a patient cannot be aroused by verbal, tactile, or noxious external stimuli.¹ This subsection will review procedures that have important diagnostic and prognostic significance in the comatose patient: caloric testing and the evaluation of brain death.

Caloric Testing

Background

In a comatose individual with normal brain stem and cranial nerve function, stimulation of the vestibular labyrinth results in well-described and reproducible extraocular movements through the vestibulo-ocular reflex (VOR). Pathologic conditions involving the labyrinth, vestibulocochlear nerve, or the oculomotor reflex pathways in the brain stem will alter or abolish the VOR.

Physiology and Functional Anatomy

The anatomic pathways underlying the VOR begin in the lateral semicircular canal of the inner ear. Movement of endolymphatic fluid within the canal results in changes in polarization in the underlying hair cells, which in turn are relayed via cranial nerve VIII (vestibular) to the brain stem (Fig. 61.1).

There are two main pathways between the vestibular and oculomotor nuclei in the brain stem. The direct pathway travels from the vestibular complex to the nuclei of the ipsilateral third cranial nerve (oculomotor) and contralateral sixth cranial nerve (abducens), and ultimately to the ipsilateral medial rectus and contralateral lateral rectus muscles. The indirect pathway occurs over multisynaptic circuits in the tegmental reticular formation.²

Rotation of the head generates flow of endolymphatic fluid within the semicircular canals; the direction of flow increases or decreases stimulation of the vestibular neuron, which results in conjugate deviation of the eyes away from or towards the affected side, respectively. This principle forms the physiologic basis of caloric testing. When the lateral canal is in the vertical position (head elevated 30 degrees above horizontal) and ice water is infused into the ear, the endolymph nearest the canal cools and sinks, which results in decreased stimulation of the vestibular neuron, and the eyes deviate conjugately toward the side of irrigation. When warm water is used in the same position or when the canal is inverted 180 degrees, the opposite occurs.

Indications and Contraindications

Caloric testing is infrequently used in emergency department (ED) settings in the United States where advanced neuroimaging

is readily available. However, in resource-limited settings, caloric testing at the bedside may assist in the evaluation of comatose patients by differentiating structural, metabolic, and psychogenic causes of unresponsiveness.

Few contraindications exist to caloric testing of an unresponsive patient. An absolute contraindication is the presence of a basilar skull fracture, either documented radiologically or suspected by clinical signs, because of the risk of introducing infection into the central nervous system (CNS) through an associated dural tear. If active bleeding or cerebrospinal fluid otorrhea or rhinorrhea is present in a trauma patient, defer caloric testing and evaluate the patient for a potential basilar skull fracture. Tympanic rupture, hemotympanum, or step-off deformities of the auditory canal may indicate fracture of the temporal bone, which is a contraindication to caloric testing. Signs of active ear infection and perforation of the tympanic membrane are relative contraindications to caloric testing.

Equipment

A 30- or 50-mL plastic syringe is ideal for irrigation. The syringe may be used as is, or a short length of soft plastic tubing (e.g., a butterfly catheter with the needle cut off) may be attached. At least 100 mL of ice water should be available, although larger quantities of cool tap water (<25°C) can be used with similar results if ice is unavailable. Saline or tap water may be used. A small, curved plastic emesis basin is useful to collect water as it drains from the ear canal. Other equipment required includes an otoscope, ear specula, and equipment for removal of cerumen. Towels and a thermometer may be helpful.

Procedure

Inspect the ears before inserting the otoscope. Remove excess cerumen and foreign material. Clearly visualize the tympanic membrane. Leave the ear speculum in the canal as a guide for irrigation. Perform the test with the patient supine and the head and upper part of the body raised to 30 degrees, if possible. Drape the patient with a towel and position a small emesis basin below the ear to collect the outflow of water from the ear. Fill a container with ice water and place it near the bedside.

Fill a syringe and catheter system (without the needle) with 10 mL of ice water and direct the irrigation stream toward the tympanic membrane. Because the goal of qualitative caloric testing is to induce a maximum response, the amount and rate of infusion are not critical. As a general guide, infuse 5 to 10 mL of ice water initially over a period of 5 to 10 seconds. Amounts less than 5 mL may be advisable in suspected cases of light coma or psychogenic unresponsiveness. If no response is noted at first, infuse at least 100 mL before declaring that there is no response. Ask an assistant to hold the patient's eyelids open, which makes it easier to observe for eye deviation. Movement usually occurs after a latency of 10 to 40 seconds, with the response persisting for as long as 4 to 5 minutes. Focusing on a scleral vessel makes small deviations easier to detect. Wait at least 5 to 10 minutes after the eyes have returned to their original position before testing the contralateral ear.

Complications

Carefully selecting equipment can avoid the few complications that are possible with caloric testing. Using plastic syringes and soft catheter tubing instead of needles to irrigate the ear will reduce the risk of perforation of the tympanic membrane or canal wall injury if the patient moves unexpectedly.

As mentioned in the contraindications section, caloric testing should not be performed in patients with possible basilar skull fractures, due to the theoretical risk of meningitis. Other potential complications include otitis media and induction of vomiting with subsequent aspiration. Although ice water irrigation might produce nausea and emesis in awake patients, vomiting with aspiration has not been reported as a complication of caloric testing in comatose patients. Nevertheless, some may prefer to delay testing until the patient's airway is protected.

Interpretation

After irrigation, ocular movements should be observed for any response to the stimulus. Typically, there is a latency of response of 10 to 40 seconds. Reactions to ice water irrigation may be divided into four categories: (1) caloric nystagmus, (2) conjugate

deviation, (3) dysconjugate deviation, and (4) absent responses (Fig. 61.2).

The first reaction, caloric nystagmus, is seen in normal, alert individuals. Ice water infusion induces a rhythmic jerking of the eyes that includes a slow deviation toward the irrigated side followed by a quick compensatory saccade toward the midline. In an apparently comatose individual, caloric nystagmus usually signifies psychogenic unresponsiveness due to catatonia, conversion reactions, schizophrenia, or feigned coma, but can also be present in patients with very mild organic disturbances in consciousness. The response is present in more than 90% of children by 6 months of age and declines in magnitude only after the seventh decade of life.³

In the second type of response to cold caloric stimulation, conjugate deviation, the eyes deviate conjugately toward the

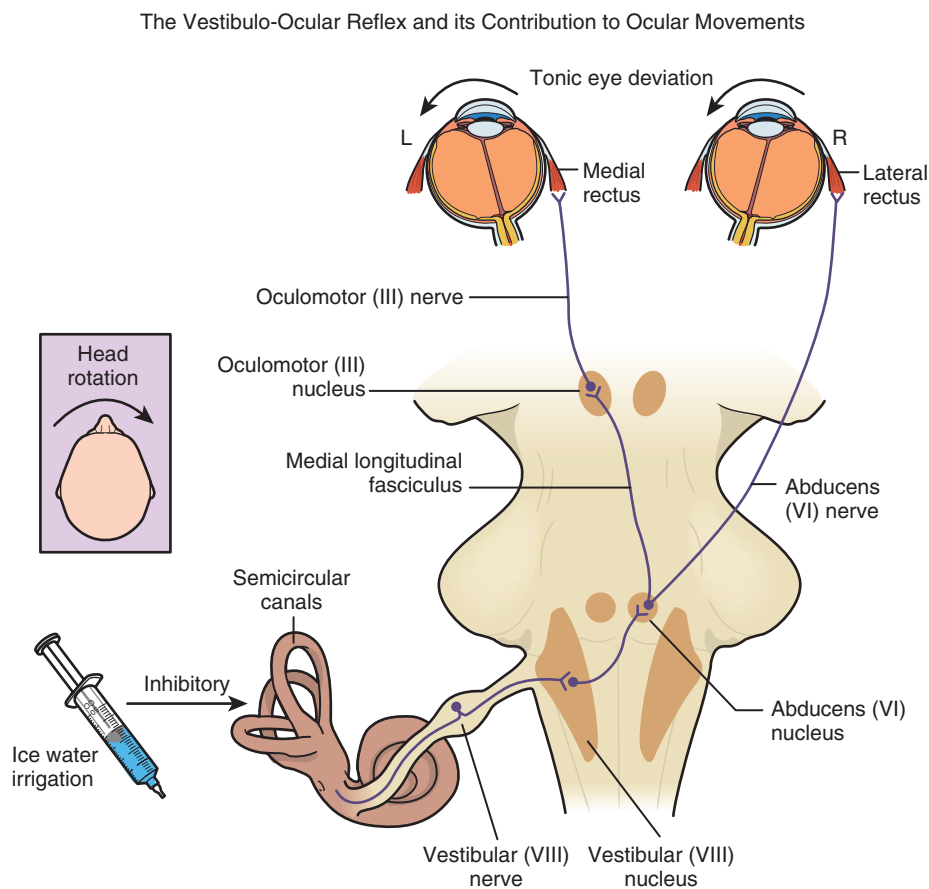

Figure 61.1 Brain stem pathways mediating the vestibulo-ocular reflex. Rotational acceleration of the head to the right results in excitatory projections that travel to the contralateral sixth cranial nerve and lateral rectus, as well as the ipsilateral third cranial nerve and medial rectus, resulting in eye deviation to the left. In a similar manner, inhibitory projections are sent to the antagonist ipsilateral lateral rectus and contralateral medial rectus. (From Simon RP, Aminoff MJ, Greenberg DA, editors: *Clinical neurology*, ed 4, Stamford, 1999, Appleton & Lange, p 313, Fig. 11.3)

side of ice water stimulation (they “look” toward the source of irritation). When present, this reaction indicates intact brain stem function, as well as intact afferent and efferent limbs of the VOR. This is seen during general anesthesia, in supratentorial lesions without brain stem compression, and with many metabolic and drug-induced comas.

Dysconjugate reactions constitute the third type of caloric response to ice water stimuli. The most common dysconjugate reaction is internuclear ophthalmoplegia, in which a lesion of the medial longitudinal fasciculus causes weakness or paralysis of the adducting eye after caloric irrigation. Internuclear ophthalmoplegia can be due to acute damage to the rostral pons or as a manifestation of multiple sclerosis or stroke. With acute supratentorial lesions, the development of dysconjugate caloric responses is a significant sign that may indicate compression of the brain stem and impending herniation. Caloric responses of this type are less common with metabolic and drug-induced coma. Reversible internuclear ophthalmoplegia has been reported in patients with hepatic coma and may occur during toxic responses to phenytoin, barbiturates, or amitriptyline.

Absent caloric response is the fourth category of reactions to ice water stimuli. Loss of caloric responses in comatose patients with structural lesions is usually a sign of brain stem damage. The VOR may also be transiently absent or decreased on the side opposite massive supratentorial damage during the first hours after injury.⁴ Whereas the initial absence of the VOR is generally a poor prognostic indicator, it does not uniformly predict a poor outcome when performed in the first 24 hours after presentation.⁵ This has particular relevance in cases of traumatic coma, where testing in the first 24 hours after injury may generate variable responses and is of less prognostic value.⁶ Absent caloric responses may occur with any subtentorial lesion that affects the vestibular reflex pathways, including pontine hemorrhage, basilar artery occlusion, cerebellar hemorrhage, or infarction with encroachment on the brain stem, and with any expanding mass lesion within the posterior fossa. Caloric responses may disappear in patients with deep coma resulting from subarachnoid hemorrhage, perhaps because of pressure on the brain stem.

The VOR is usually retained until the late stages of metabolic coma. Nevertheless, caloric responses may be transiently absent in certain types of drug-induced coma, with eventual complete recovery of the patient. The VOR seems to be particularly sensitive to the effects of sedative-hypnotic drugs, antidepressants (e.g., amitriptyline, doxepin), and anticonvulsants (e.g., phenytoin, carbamazepine).^{7,8} As one would expect, neuromuscular blocking agents (e.g., succinylcholine) will abolish caloric-induced ocular movements.

Finally, the caloric response may be absent for reasons other than the neurologic causes responsible for the coma. Inadequate irrigation because of excessive cerumen or poor technique and unilateral or bilateral dysfunction of the peripheral vestibular apparatus must be considered. Bilateral loss of the caloric response (*areflexia vestibularis*) is uncommon in conscious patients, constituting 1.7% and 0.2% in two large series of patients.^{9,10}

Summary

Caloric testing is a simple, easily performed bedside procedure that may enhance the neurologic assessment of comatose patients. In the ED this test should be reserved for stable patients undergoing secondary assessment. The examination requires minimal equipment and can be particularly useful in

settings where access to advanced neuroimaging is limited or delayed. Complications are few if patients are properly selected and correct technique is used.

Brain Death Testing

Background

Brain death is defined as irreversible and complete loss of cerebral and brain stem function with preserved cardiac function.¹¹ Prior to declaring brain death, the cause of the brain injury should be definitively identified, as some toxicologic syndromes may mimic brain death. The most common scenario where emergency clinicians may be asked to perform a brain death examination is to identify potential organ and tissue donors. It should also be noted that a determination of brain death is not necessary for withdrawal of life-supporting measures. If a cause of coma or severe neurologic injury is identified and a poor prognosis is shared with the family, withholding or withdrawing life-sustaining treatment may be appropriate and formal determination of brain death need not be performed.

Indications and Contraindications

Evaluation for brain death implies that severe CNS dysfunction has been identified, that the cause of the CNS dysfunction is known, and that reversible causes of coma have been confidently excluded.^{12,13} Complex medical issues that may confound the assessment should be considered and ruled out, including severe electrolyte disturbances, hypothermia (defined as a core temperature <32°C), hypotension, drug intoxication or poisoning, and pharmacologic neuromuscular blockade.¹³ Neuroimaging studies should be carefully reviewed.

Procedure

The clinical neurologic examination remains the standard for determination of brain death.¹³ It typically involves assessment for cerebral function, brain stem reflexes, and respiratory drive. The emergency clinician should be familiar with local practices and policies, which may also require an electroencephalogram, documentation of absent cerebral blood flow by angiography or radioisotope brain scan, or other techniques. The following components of the clinical examination are generally utilized to establish brain death.

Coma Assessment

While holding the patient's eyes open, give loud verbal commands such as “Look up!” and assess for voluntary eye movements; this assessment is particularly important to identify patients with locked-in syndrome. Additionally, deliver a strong painful stimulus by forcefully pressing on the brow, sternum, or nail bed. Any purposeful response to stimuli in any extremity indicates the patient is not brain-dead. The absence of responses documents the presence of coma.

Brain Stem Reflex Testing

Pupillary Response. The pupils in brain-dead patients are unreactive and midposition to dilated. Shine a bright light into the pupil and observe for a reaction; none will be seen in a brain-dead patient.

Auditory Reflex. Deliver a loud handclap into each ear. Observe for eye blink or other reaction. Any reaction establishes that some brain stem function remains and excludes brain death.

Oculocephalic Reflex. Hold eyelids open and rotate the head abruptly from side to side in the horizontal plane. If the eyes do not turn with the head and appear to maintain visual fixation on a point in space, the oculocephalic reflex is present and brain death is excluded.

Caloric Testing. Perform cold water irrigation of the external auditory canals with large volumes (≥ 100 mL) to elicit any eye movements through the VOR. In a brain-dead patient, there will be no movement of the eyes in response to irrigation.

Corneal Reflex. Stimulate the cornea with a cotton wisp or applicator. Any eye closure indicates an intact cranial nerve V to VII reflex and excludes the diagnosis of brain death.

Cough Reflex. Stimulate the trachea or main stem bronchi by deep suctioning and observe for coughing. A cough excludes brain death.

Apneic Oxygenation Test. If brain stem reflexes are absent, apnea is formally tested to evaluate the function of the medulla, where respiratory drive originates. As hypercapnia (and not hypoxia) triggers respiratory effort, simply disconnecting the ventilator to allow hypercapnia to develop may lead to hypoxia and should therefore be avoided.¹⁴ The most commonly described technique to avoid hypoxia while generating hypercapnia is to: (1) disconnect the patient from the ventilator, (2) deliver oxygen at 10 to 15 L/min through a catheter inserted into the trachea, and (3) observe for respiratory effort for 8 minutes. An alternative technique is to set the ventilator rate to zero while allowing continuous oxygen flow to continue and maintaining any necessary continuous positive pressure through the ventilator.¹⁵ Any observed excursion of the abdomen or chest sufficient to produce a tidal volume suggests that brain death is not present. If no respiratory excursions are observed, an arterial blood gas analysis should be obtained and artificial ventilation resumed pending results. An arterial partial carbon dioxide pressure (PCO₂) of 60 mm Hg or higher and the absence of respiratory excursions are the criteria for a positive apnea test (i.e., that the patient lacks spontaneous respirations).¹⁶

Declaration of Death

If the criteria for brain death are satisfied, the family and all clinicians involved in patient care should be informed to allow further management decisions. At some institutions, the patient is declared dead at the time that the criteria are met, and further care is assumed by the transplant services if that is the anticipated course. Some institutions require evaluation by two independent clinicians with specific specialty training, or repeated examinations several hours apart; however, the need for a second brain death determination has been questioned.^{17,18} Families are generally given the option of being present at the bedside when mechanical ventilation is discontinued, although some advise against this policy because spontaneous reflex movements may occur and disturb the family.¹⁹

Brain death in the pediatric population is more complex, with varying recommendations for repeated examinations and ancillary tests; such discussion is outside the scope of this chapter but is summarized in other resources.^{13,20,21} A model for direct family conversation in this sensitive interaction has been described and includes a sample script and procedure.²²

Complications

A substantial proportion of brain-dead patients (33% to 75%) may exhibit movements originating in the spinal cord or peripheral nerves.^{23,24} These movements can be spontaneous or provoked by tactile stimuli, and may falsely be interpreted as evidence of cerebral or brain stem function. Among the most frequently observed movements are finger jerks, the undulating toe flexion response (slow and repetitive flexion/extension of the toes), and the triple flexion reflex (flexion of thigh, leg, and foot); however, many other movements have been described.^{23,25–29}

Summary

The emergency clinician may become involved in the assessment of patients for brain death. The cause of irreversible coma should be definitely identified prior to initiating a systematic brain-death examination, which includes an assessment of cerebral function, brain stem reflexes, and apnea. The clinician should be familiar with local practices and policies in this sometimes complex medicolegal process.

PROCEDURES TO EVALUATE AND TREAT VERTIGO

Vertigo is the illusory sensation of movement, sometimes experienced by patients as self-motion, other times as motion of the environment. There are a wide variety of diseases that can cause vertigo, including damage to or dysfunction of the labyrinth, vestibular nerve, or central vestibular structures in the brain stem. In this subsection, we focus on two distinct disorders, each with characteristic clinical features that present with vertigo: benign paroxysmal positional vertigo (BPPV) and acute vestibular syndrome (AVS).

BPPV is a common mechanical disorder of the inner ear in which certain head movements precipitate vertigo; nystagmus, nausea, and vomiting commonly accompany the vertigo. Although patients may have quite dramatic findings with severe symptoms, the actual episodes of vertigo are extremely brief and typically last less than 1 minute. In contrast, AVS refers to a separate group of disorders characterized by an acute onset of vertigo, nausea, vomiting, and gait instability that lasts for days to weeks.

Dix-Hallpike Test

Background

In BPPV, it is thought that small crystals of calcium carbonate, or *canaliths*, are displaced into the endolymph of the posterior semicircular canal. Head movement shifts the canaliths, which induce bidirectional forces in the fluid that create the sensation of spinning and trigger the attack of BPPV.^{31–34} The posterior semicircular canal is most commonly affected,^{33–35} but at times the lateral canal is thought to be involved, thereby leading to variants of typical BPPV.^{36–38}

Indications and Contraindications

The Dix-Hallpike test may be used to confirm the diagnosis of BPPV by provoking a specific type of nystagmus. The maneuver should not be performed on patients with severe cervical spine disease, unstable spinal injury, high-grade carotid stenosis, or unstable heart disease.³⁵ Patient discomfort and physical infirmity are relative contraindications; some elderly

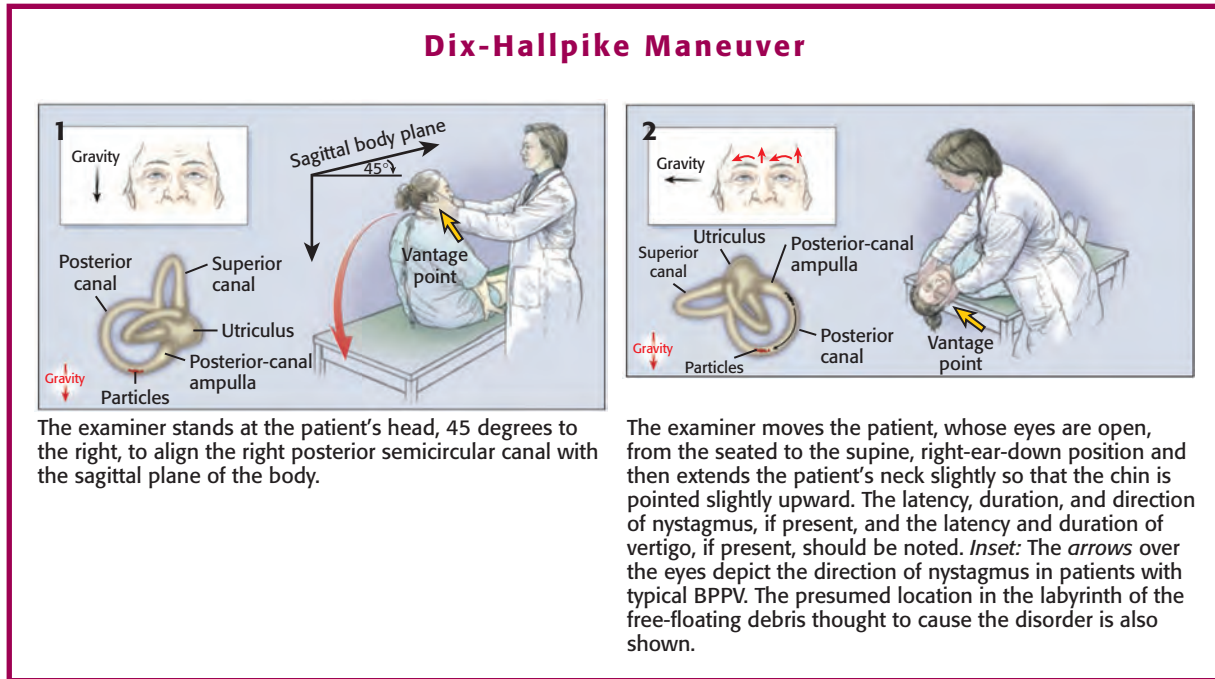

Figure 61.3 The Dix-Hallpike test for evaluating a patient complaining of dizziness from benign paroxysmal positional vertigo affecting the right ear. BPPV, Benign paroxysmal positional vertigo. (Adapted from Furman C: Benign paroxysmal positional vertigo, *N Engl J Med* 341:1590, 1999.)

patients or those with ongoing nausea or vertigo may not tolerate the changes in body position necessary for performance of the procedure. If nystagmus is present at rest without any provocation, the diagnosis of BPPV is unlikely and the maneuver should not be performed.

Procedure

The Dix-Hallpike maneuver is illustrated in Fig. 61.3 and Video 61.1. Place the patient initially in the upright seated position on the stretcher with the head turned 45 degrees to one side. Instruct the patient to keep the eyes open and focused on the examiner, then quickly lay the patient down flat so the head hangs over the edge of the bed and observe the eyes for nystagmus. Repeat the entire maneuver with the head turned 45 degrees toward the opposite side.³⁵

Interpretation

The typical positive response in patients with BPPV is vertigo that develops after a brief delay (1 to 10 seconds), lasting less than a minute, and with rotatory nystagmus (where the eyes rotate about the visual axis). Nausea or other systemic symptoms are often present.^{35,39} The eye movements are mixed rotatory and vertical nystagmus of both eyes with the upper pole of the eye beating toward the dependent ear and the vertical nystagmus beating toward the forehead. The side with the ear in the downward position during the Dix-Hallpike test that elicits greater nystagmus usually identifies the affected ear. If the positional nystagmus is atypical, or if the maneuver fails to elicit nystagmus in a patient with ongoing symptoms of vertigo, another diagnosis should be considered.³⁵

Complications

The maneuver may precipitate brief, intense vertigo and nausea in patients with BPPV.

Summary

The Dix-Hallpike test may be useful in confirming the diagnosis of BPPV and in localizing the affected ear. Accurate identification of BPPV is of interest because canalith-repositioning maneuvers may be offered as a therapeutic option.

Canalith-Repositioning Maneuvers

Background

If the clinical evaluation of a patient with vertigo is consistent with the diagnosis of BPPV, the patient may be a candidate for canalith-repositioning maneuvers. Based on the theory that stray material in the posterior semicircular canal causes the symptoms of BPPV, maneuvers were designed that involved sequential head movements to reposition the debris.^{34,35,40,41} Manipulation of head position theoretically allows the debris (canaliths) to sequentially fall from the problematic location in the semicircular canal into the vestibule where they can adhere. The most commonly recommended maneuvers are the Epley and Semont maneuvers.^{34,41} Several randomized studies have compared the Epley maneuver with a sham maneuver, reporting success rates of 50% to 90%.⁴²⁻⁴⁵ One large study of 965 patients with BPPV found a single canalith-repositioning maneuver improved symptoms in 85% of patients.⁴⁶ Both the Epley and Semont maneuver appear to have similar efficacy (reported in the range of 90% in one small study),⁴⁷ although the Semont is less well studied.⁴⁸

Indications and Contraindications

The indication for canalith-repositioning maneuvers is the clinical diagnosis of BPPV as confirmed by the history and physical examination, including the Dix-Hallpike maneuver. Careful patient selection is key to the success of these maneuvers, as well as correct identification of the impaired ear, which

will dictate the initial position and movement of the patient. Contraindications are the same as for the Dix-Hallpike maneuver, including severe cervical spine disease, unstable spinal injury, and high-grade carotid stenosis.

Procedure

Epley Maneuver

▶ The Epley procedure is illustrated in Fig. 61.4 and Video 61.2. Place the patient initially in the seated position on the stretcher with the head turned 45 degrees toward the affected side. Lay the patient down flat with the head hanging over the edge of the bed. After 20 seconds or after the symptoms subside, rotate the patient's head so that it faces the opposite shoulder while maintaining the head-hanging orientation. Wait another 20 seconds or for symptom resolution and then roll the patient

further onto the side and rotate the head further into a face-down position. Again, after 20 seconds or after any symptoms subside, return the patient to a seated position.³⁴

Some authors suggest keeping the patient's head in each position long enough for any provoked symptoms of nystagmus or vertigo to resolve.³⁵ Others suggest a period of 3 to 4 minutes in each position.^{31,47,49} The maneuver may be repeated a few times until some improvement in symptoms occurs.^{47,50} After a successful procedure, advise the patient to remain in a head-upright position for 24 hours.

Semont Maneuver

The Semont maneuver involves larger and more abrupt body movements (Fig. 61.5). With the patient seated on the side of an examination table or bed, turn the patient's head 45 degrees

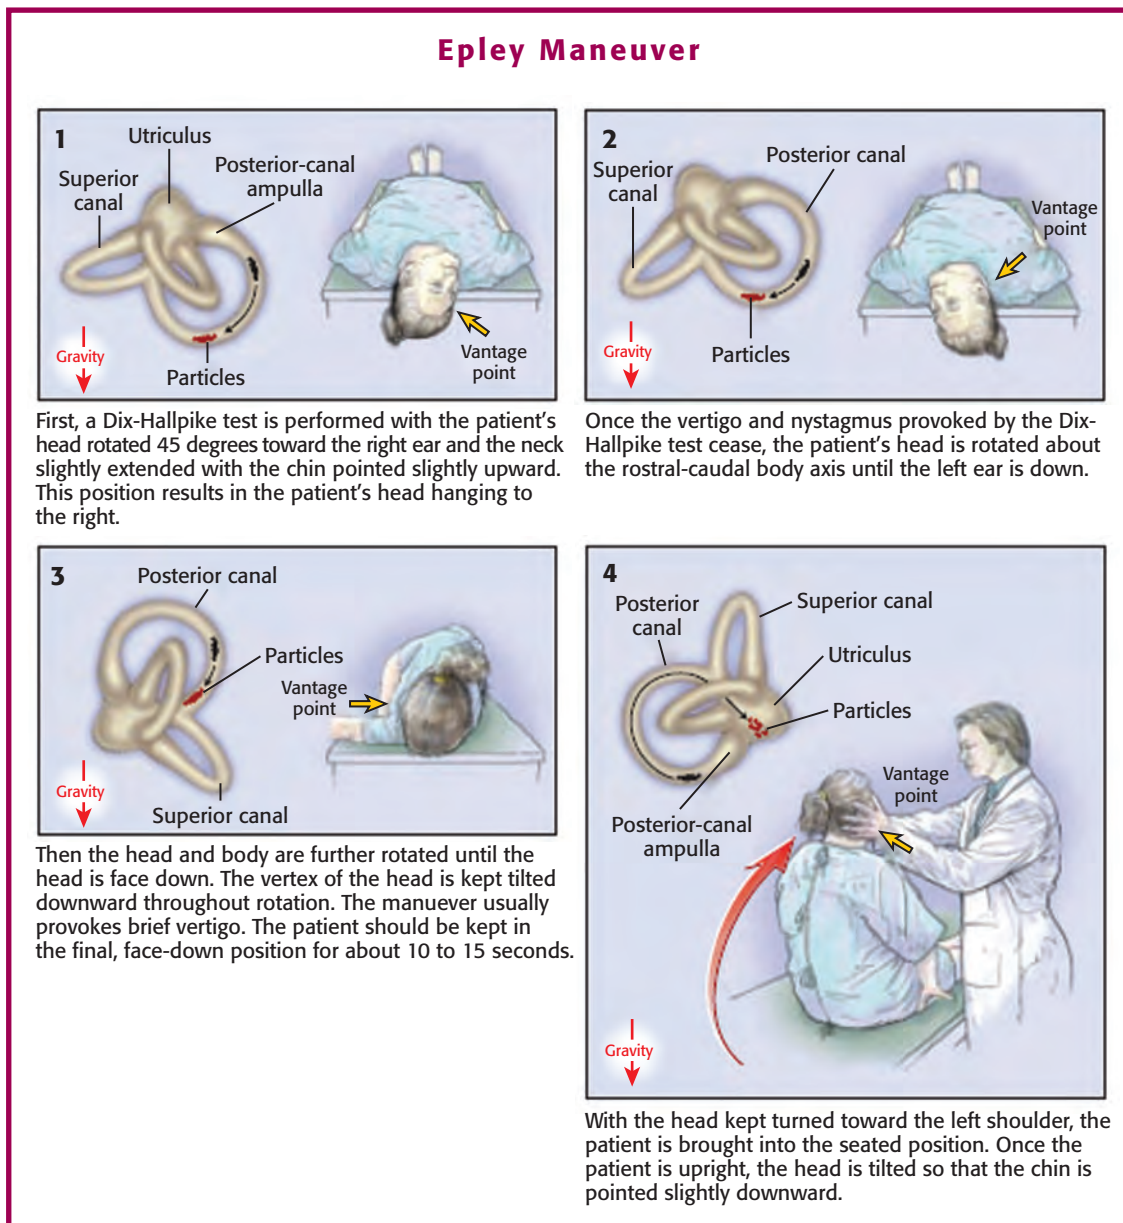

Figure 61.4 The Epley procedure, a bedside maneuver for the treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of debris within the labyrinth during the maneuver is shown in each panel. (Adapted from Furman C: Benign paroxysmal positional vertigo, *N Engl J Med* 341:1590, 1999.)

Semont Maneuver

1 Sit the patient on the side of the bed, with his head turned 45 degrees toward the unaffected side.

2 Quickly lay the patient down into a side-lying position onto the affected side; keep the head rotated 45 degrees, so he is looking at the ceiling.

3 Once vertigo symptoms subside, move the patient through the sitting position to the opposite side-lying position, head pointed towards the floor. After symptoms subside, return to the upright sitting position.

Figure 61.5 Semont maneuver.

toward the unaffected side; the head will maintain this position throughout the entire maneuver. Quickly lay the patient down into a side-lying position onto the affected side, keeping the head turned 45 degrees so the patient's head is directed partially towards the ceiling. Once the symptoms subside, move the patient abruptly through the sitting position to the opposite side-lying position, maintaining the head position so that now the head faces down partially towards the floor. Keep the patient there until the symptoms subside. Return the patient to the upright position.^{47,49} Advise the patient to remain in a head-upright position for 24 hours after a successful procedure.

Complications

Nausea is reported in 16% to 32% of patients during the Epley maneuver.⁴⁸ Exacerbation of vertigo occurs occasionally and is thought to result from displacement or dislodgment of canal debris. Repeating the procedure is recommended for relief. Symptoms of vertigo may recur in as many as 50% of patients, including 20% during the first 2 weeks.^{31,48}

Summary

In patients with correctly identified BPPV, canalith repositioning may bring immediate relief or improvement of symptoms. Evidence of success in the ED setting is limited but growing.⁵¹

HINTS Examination

Background

Whereas the majority of AVS conditions are the result of a peripheral neuropathy (such as acute labyrinthitis or vestibular neuritis), some AVS presentations (as many as 25% in some series) are due to a central pathology such as a brain stem or cerebellar stroke.⁵² It can be very difficult to distinguish a peripheral from a central process in patients with AVS using the standard neurologic examination. The “HINTS” examination was created for this very purpose and is intended to assist providers in distinguishing central from peripheral causes of AVS. The HINTS exam is composed of three separate tests: the horizontal Head Impulse test, a test of Nystagmus, and a Test of Skew (HINTS).⁵³

Indications and Contraindications

Each of the three components of the HINTS examination has separate contraindications. The horizontal head impulse test should not be performed in patients with severe cervical spine disease, unstable spinal injury, high-grade carotid stenosis, or unstable heart disease. Patient discomfort is also a relative contraindication. If vertical or bidirectional nystagmus is present at rest, or if vertical skew is present at baseline, a central cause of vertigo should be suspected and a full HINTS examination is not indicated.

Procedure

Horizontal Head Impulse Test (Video 61.3)

Have the patient seated in a comfortable position and stand in front of the patient. Ask the patient to gaze directly on the examiner's eyes at all times and relax the neck as much as possible. Place hands on either side of the patient's head and rapidly rotate the head by approximately 20 degrees to each side and back to midline several times while carefully observing the eyes for loss of fixation on the central target of the examiner's eyes. If the eyes fall off target when the head is rotated laterally to the affected side, a corrective saccade to resume

Horizontal Head Impulse Test (h-HIT)

Normal h-HIT Is Suggestive of a Central Lesion (e.g., Cerebellar Stroke)

1
Instruct the patient to fix his gaze directly on your eyes at all times.

A

2
Quickly rotate the head to each side while observing for nystagmus. If the vestibular apparatus is intact, the patient will be able to keep his eyes fixated on you throughout the motion.

3
Note that the patient's eyes remained fixed on the examiner. A normal test such as this is strongly suggestive of a central origin.

Abnormal h-HIT Is Suggestive of Peripheral Lesion (e.g., Vestibular Neuritis)

1
Patients with a peripheral vestibular lesion will not be able to keep their eyes fixated on you during the maneuver.

B

2
As the head is rapidly turned toward the abnormal side, their eyes cannot maintain fixation.

3
A corrective saccade (fast jerking movement) will be noted at the end of the maneuver as the patient tries to regain fixation on the examiner.

Figure 61.6 The horizontal head impulse test. In the setting of acute vestibular syndrome, a normal horizontal head impulse test result strongly suggests a central origin (e.g., brain stem or cerebellar stroke). **A**, The intact vestibular-ocular reflex causes the patient's eyes to smoothly track the examiner as the head is quickly turned to one side. **B**, A patient with a peripheral vestibular lesion does not track the examiner when the head is turned to the affected side, resulting in a quick, corrective saccade back to the examiner.

visual fixation on the central target occurs; this represents an abnormal horizontal head impulse test and is suggestive of a peripheral lesion. Randomly alter the speed and direction of rotation to generate an unpredictable sequence so the patient cannot anticipate the direction of rotation. A normal and abnormal horizontal head impulse test maneuver is simulated in [Fig. 61.6](#).

Test of Nystagmus

Ask the patient to fixate on the examiner's finger and slowly track the finger laterally in both directions. Observe for nystagmus at the extremes of gaze.

Test of Skew

Ask the patient to fixate on an object directly ahead. Alternately cover each eye in rapid succession. Look closely for subtle vertical refixation of the eyes (i.e., the eye moves up or down as it is uncovered to compensate for misalignment).

Interpretation

Horizontal Head Impulse Test

The terminology used to describe the results of the horizontal head impulse test can be confusing, as the test was initially designed to detect peripheral vestibular disease.⁵⁴ Therefore, a positive (abnormal) test is suggestive of a peripheral lesion, whereas a negative (normal) test is consistent with a more concerning central lesion. In the setting of AVS symptoms, the inability to maintain fixation during the horizontal head impulse test suggests a peripheral vestibular lesion. This is presumed to occur because there is no afferent input from the affected nerve when the head is rotated to the affected side. If a patient with AVS symptoms maintains fixation on the examiner during the horizontal head impulse test, it suggests a central pathology. In rare instances, patients with lateral pontine and cerebellar stroke syndromes can have a positive horizontal head impulse test that erroneously suggests a peripheral lesion.^{53,55}

Test of Nystagmus

The nystagmus that results from a peripheral lesion is unidirectional; its fast or corrective phase beats away from the affected side when looking away from the affected side. With gaze toward the affected side, the nystagmus may decrease in intensity or disappear, but the direction of the fast beats will not change. If the direction of the nystagmus differs with horizontal gaze to either side (e.g., left beating when looking left and right beating when looking right), a central cause should be suspected.⁵⁶

Test of Skew

Skew deviation refers to a vertical misalignment of the eyes (e.g., one eye is looking straight ahead, while the other eye is deviated downward or upward); it is usually associated with a central lesion. Although skew deviation can be subtle, it can be unmasked by alternately covering each eye in rapid succession while the patient fixes her gaze on the examiner.⁵⁷

HINTS Exam

If any one of the components of the HINTS examination suggests a central cause, the composite HINTS examination is suggestive of a central lesion. Several studies have examined the diagnostic accuracy of the HINTS exam for identifying central causes of AVS.^{53,58–60} In one study of 101 patients with chronic risk factors for cerebrovascular disease and new onset AVS, the HINTS examination was 100% sensitive (95% confidence interval [CI] 95%–100%) and 96% specific (95% CI 80%–99%) for a central cause. A subsequent study by the same group and two other smaller studies have reported sensitivities of 88% to 100% and specificities of 85% to 99%.^{58,59,61} Of note, the studies supporting the diagnostic accuracy of the HINTS examination have been conducted in patients with a moderate to high risk of stroke, where the examination was performed by experienced neuro-otologists^{53,58–60}; test performance in the ED setting by emergency clinicians is not known.

Complications

The horizontal head impulse test may exacerbate injury in improperly selected patients with unstable cervical spinal injury or, theoretically, with severe carotid atherosclerotic disease, although no reports of such complications have been reported.

Summary

The HINTS examination may be useful in identifying patients with a central cause of vertigo. Although early investigations appear to confirm its role in differentiating central from peripheral vertigo, it should be used with caution and in conjunction with other diagnostic data. Further studies are needed to confirm the reliability of these tests in the ED setting performed by emergency clinicians.

EVALUATION OF WEAKNESS

Background

Myasthenia gravis (MG) is the most common disease of neuromuscular transmission, with an annual incidence of seven to nine new cases per million.⁶² Patients with MG may be grouped into two major categories. The first group shows weakness in the proximal muscles that increases with activity and improves with rest. The second group has ocular complaints

Figure 61.7 Neuromuscular junctions. Acetylcholine is released from presynaptic vesicles and diffuses across the synaptic cleft to the postsynaptic receptors. Acetylcholinesterase, located deep within the synaptic folds, hydrolyzes acetylcholine. In myasthenia gravis there are a reduced number of postsynaptic acetylcholine receptors, which can lead to failed neuromuscular transmission and weakness.

of diplopia or ptosis. Patients in the ocular weakness group may or may not have generalized symptoms as well. Fatigue is the hallmark of the disease; the symptoms typically wax and wane.

Under normal circumstances, when the nerve terminal is stimulated, acetylcholine (ACh) is released and diffuses across the synaptic cleft in the neuromuscular junction to transiently interact with the ACh receptor (Fig. 61.7). This leads to an action potential that is propagated along the muscle membrane, followed by muscle fiber contraction. The ACh is rapidly hydrolyzed by acetylcholinesterase in the synaptic cleft. Of the millions of receptors at each neuromuscular junction, only a fraction must depolarize to stimulate muscle fiber contraction.

Any factor that decreases the interaction of ACh with ACh receptors decreases the probability of an action potential being generated and may lead to failure of neuromuscular transmission with resulting weakness. MG results from immune-mediated destruction of postsynaptic ACh receptors, with variable failure of neuromuscular transmission.^{63,64} Whereas immunotherapy and thymectomy are significant advances in the treatment of MG, acetylcholinesterase inhibitors remain the first-line therapy for symptomatic MG. Of note, excessive inhibition of acetylcholinesterase from these agents can also cause weakness, referred to as *cholinergic crisis*; persistence of ACh in the synaptic cleft leads to continuous depolarization of the receptor, which also manifests as weakness.

Several tests can be used for the assessment of a patient with suspected MG, but many are not available to the emergency clinician.^{65,66} Serologic testing for ACh receptor antibodies is positive in more than 80% of patients with MG, but has a turnaround time of several days.^{67,68} Repetitive nerve stimulation and single-fiber electromyography tests are available in the electrophysiology laboratory.⁶⁹ Multiple bedside tests have been used to aid in the diagnosis of suspected MG, including parenteral administration of edrophonium chloride, neostigmine, or curare, as well as the ice-pack test. The tests that appear to have the most ED relevance are the administration of edrophonium chloride (called the Tensilon test after a

proprietary preparation), due to the drug's rapid onset and short duration of action, and the ice-pack test, because it is safe and noninvasive.^{66,70,71}

Edrophonium (Tensilon) Test

Background

Edrophonium chloride is an acetylcholinesterase inhibitor that has been used for the diagnosis of MG since the 1960s. The short duration of action of edrophonium that made it unsatisfactory as a therapeutic agent for MG makes it useful as a diagnostic agent. The drug's onset of action is rapid (30–45 seconds), and the duration of maximal effect is short (usually less than 2 minutes). Any effect resolves within 5 to 10 minutes.⁷²

Indications and Contraindications

The bedside Tensilon test is indicated for the diagnosis of patients with suspected MG when there is a clinical need to make this diagnosis in the ED. If other bedside tests, such as the ice-pack test (discussed later), are conclusive, or if eyelid fatigue on prolonged upgaze can be demonstrated, there is no need to administer edrophonium.⁷³ If the patient will be admitted to an inpatient setting where timely electromyograms or serologic testing can be performed, it is reasonable to defer the Tensilon test. Although the Tensilon test was once touted as a way to distinguish myasthenic crisis from cholinergic crisis, it is not reliable and is not recommended.⁷⁴

A muscle that is clearly weak must be identified to monitor during Tensilon testing; some advocate only performing the test in patients with ptosis or ophthalmoparesis, as quantifying strength in other muscle groups independent of effort makes the test too unreliable.^{75,76}

Administration of edrophonium potentiates the muscarinic effects of ACh and is not entirely benign, particularly in patients with cardiac disease or asthma, which are relative contraindications to the test. Patients often have increased salivation and mild gastrointestinal cramping, but serious complications (e.g., symptomatic bradycardia and syncope) are rare.^{75,77,78} One study reported the complication rate in office settings by neuro-ophthalmologists to be 0.2%.⁷⁷ There is one report of transient asystole after the administration of edrophonium in a patient with suspected MG; however, the patient was critically ill and had been receiving intravenous labetalol, which may have exacerbated the effect of the edrophonium.⁷³ Hence, caution is advised in administering edrophonium to patients receiving

β -blocking agents, digoxin, or other drugs with atrioventricular-blocking properties.^{79–82}

Equipment

Intravenous access should be secured with a saline lock. Ten milligrams of edrophonium chloride (Tensilon, ICN Pharmaceuticals) should be drawn up in a tuberculin syringe. Edrophonium chloride is supplied in 1-mL and 10-mL vials at a concentration of 10 mg/mL. A second syringe of normal saline should be available to administer as a double-blind placebo, although some clinicians have recommended nicotine, calcium chloride, or atropine for this purpose.⁸³ Atropine and other cardiovascular drugs and resuscitative equipment should be readily available. It may be useful to prepare a syringe with 0.5 mg of atropine prior to the test should bradycardia or bronchospasm occur. Cardiac monitoring is recommended.⁷⁵ Photographic recording equipment may help objectively document any improvement in motor function.

Procedure (Video 61.4)

Identify a muscle that is clearly weak. Obvious ptosis or ophthalmoparesis allows direct observation of a single weak muscle becoming stronger in response to the drug. Ideally, one person is available to administer the edrophonium or placebo and a second person is free to observe the effect of medication on the patient. Neither the observer nor the patient should know which syringe contains edrophonium and which contains placebo, thus creating a double-blind testing situation.

Again, ptosis is a reliable sign to test and is generally used if present (Fig. 61.8). The principles involved in assessing the effect of edrophonium on ptosis may be extended to testing other muscles. Ask the patient to look upward for several moments to fatigue the levator muscles. Note the degree of ptosis and document it by measurements or photographs. After a moment's rest, ask the patient to look straight ahead. Inject 0.2 mL of the test substance in one syringe (2 mg of edrophonium or saline). If no response is seen within 1 minute, inject further increments of 2 mg up to a maximum of 10 mg. Note any increase in strength as reflected by an increase in size of the distance between the upper and lower lids (the *palpebral fissure*).

Incremental administration of edrophonium has several benefits. Many patients may respond to doses less than 10 mg and will be at less risk for muscarinic side effects at lower doses. Additionally, some patients may have improved strength

Figure 61.8 Tensilon test. **A**, Bilateral ptosis (right worse than left) and defective upgaze (right worse than left). **B**, Improvement of ptosis and left upgaze following the intravenous injection of edrophonium chloride (Tensilon). (From Kanski JJ: *Clinical diagnosis in ophthalmology*. St. Louis, 2006, Mosby.)

of extraocular muscles at lower doses that paradoxically worsens at higher doses.⁷⁵ Giving edrophonium in 2-mg aliquots will allow these patients to be properly identified as having a response. Repeat the procedure with the other test substance. Any improvement should occur within 30 seconds and disappear after 5 minutes.

Complications

A small percentage of individuals are hypersensitive to the initial small dose of edrophonium and exhibit the cholinergic side effects of salivation, lacrimation, and miosis. These effects are transient. Atropine, 0.5 mg, may be given intravenously, if necessary, to counteract these symptoms. A smaller number of patients may experience symptomatic bradycardia that responds to atropine. As described earlier, rare cardiac arrhythmias and death have been reported in patients taking digoxin or β -blockers.

Interpretation

Objective signs of improvement in the strength of an identified paretic muscle within 30 seconds of administration of edrophonium and fading of that improvement over the next 5 minutes are the criteria for a confirmatory test result. Subjective increases in general strength or relief of fatigue do not constitute a positive test. Normal individuals should have no change in muscle strength, but may transiently experience the side effects of salivation, lacrimation, and diaphoresis. Perioral, periorcular, or lingual fasciculations are almost always noted in normal patients after edrophonium administration.⁷² The Tensilon test may be repeated in 30 minutes if desired.

The sensitivity of the edrophonium test for MG is estimated to be approximately 80% to 90%.^{75,83–85} The specificity is difficult to estimate, but false-positive tests have been reported in patients with Eaton-Lambert syndrome, intracranial lesions, amyotrophic lateral sclerosis, botulism, and Guillain-Barré syndrome.^{75,86–88}

Ice-Pack Test

Background

It has been observed clinically that myasthenic patients have exacerbations of weakness with environmental heat and improvement in strength with cold temperatures, possibly because lower temperatures inhibit acetylcholinesterase function.⁷¹ A simple bedside test uses these observations to evaluate ptosis.^{66,70,71} An ice pack is placed lightly over the closed eyelid for 2 minutes. Ptosis has been noted to improve in 80% or more of patients with ocular MG and may be more sensitive than the edrophonium test.^{71,89} Although the reported number of patients evaluated by this method remains small, the test is included here because its safety, speed, and ease of administration make it an attractive ED application.

Indications

Unilateral or bilateral ptosis of uncertain etiology in patients being evaluated for MG is the sole indication for this test.

Procedure

Ice and a bag (or a surgical glove) is the only equipment required. A camera to record a response is optional. Measure or photograph the degree of the patient's ptosis prior to the test. Studies have used the vertical distance between the upper and lower lid, or palpebral fissure, as an objective measure of

the degree of ptosis.⁸⁹ If bilateral ptosis is present, test the more affected eye. Fill a bag (or surgical glove) with ice and place gently on the patient's closed eyelid for 2 minutes or until patient discomfort limits application. After removing the ice, immediately assess the width of the palpebral fissure and compare with the pretest width (Fig. 61.9).

Figure 61.9 The ice-pack test for myasthenia gravis. **A**, Before placement of an ice pack. **B**, Ice pack placed over the eyelid for approximately 2 minutes. **C**, After placement of an ice pack, improvement is noted in ptosis of the right eye. (For details, see Sethi and colleagues.⁷¹)

Complications

Patient discomfort from ice pack application may limit cold exposure time to less than 2 minutes, but may still allow a test to be successfully performed.

Interpretation

A clear improvement in ptosis in the cooled eye constitutes a positive test. Studies have defined 2 mm or more of improvement in the width of the palpebral fissure as a positive test.⁸⁹ The effect should be reproducible. In small clinical studies the ice-pack test was found to be at least as sensitive as administration of edrophonium in improving ptosis in patients with ocular MG. False-negative results do occur, more commonly in patients with complete ptosis, and probably at approximately the same frequency as with Tensilon testing. Normal individuals show no change in width of the palpebral fissure after cold exposure. False-positive results are rare.^{70,71,89}

Summary

MG is typically diagnosed by serologic testing for autoantibodies and electrodiagnostic studies in the ambulatory setting.^{67,69,73,90} However, when diagnosis in the ED is desired, the Tensilon test and ice-pack test may provide valuable information at the bedside. False-negative results do occur, and additional testing should be performed if clinical suspicion for MG persists.

Ophthalmologic, Otolaryngologic, and Dental Procedures

CHAPTER 62

Ophthalmologic Procedures

Kevin J. Knoop and William R. Dennis

The following discussion focuses on procedures performed by emergency clinicians during the evaluation and treatment of injuries and diseases of the eye. Emphasis is placed on practical application of the techniques; cautions to be heeded by the emergency clinician are included. Not all procedures are mandated to be performed by the emergency clinician, and if beyond the expertise available in the ED, they may be referred to a specialist.

ASSESSMENT OF VISUAL ACUITY

Evaluation of visual acuity may initially be deferred with simple, obvious, or straightforward cases, such as a stye, periorbital laceration, or minor eye irritation; however, assessment of visual acuity should be the first procedure performed in the majority of patients seen in the emergency department (ED) with an eye complaint (Videos 62.1 and 62.2). Even though it may initially be deferred in the triage or trauma room setting or under other relevant scenarios, the emergency clinician must ensure that visual acuity or function is assessed adequately as part of the initial evaluation.

Indications

Visual acuity should be assessed as soon as practicable and before the patient is examined with bright lights. In the event of blepharospasm from an injury (e.g., abrasion, chemical exposure), a topical anesthetic may facilitate the examination. Patients with eye complaints often say that they “can’t see.” In these instances, emergency visual acuity assessment should be performed first, beginning with evaluation of light perception, then hand motion, and finally counting fingers at 3 ft (Fig. 62.1). If the patient succeeds in performing these assessments, a near vision card may then be used or distant visual acuity assessed. In emergency circumstances, detailed formal vision testing is not essential; however, some form of visual acuity assessment is needed. In this situation, the ability to count fingers or read newsprint gives some indication of gross visual

function. Formal visual acuity testing should never delay critical therapeutic interventions such as eye irrigation in the case of eye exposures.¹

Distant Visual Acuity Procedure

For formal vision testing, ask the patient to face a well-lit standard Snellen or similar eye chart from a premeasured distance of 20 ft. Use a card or the palm of the hand to occlude one eye at a time. If possible, examine all patients while wearing their current lens correction to obtain the best corrected distant visual acuity. If not available, measure visual acuity first without correction and then with a pinhole device, and note any improvement in visual acuity. The pinhole device functions as a corrective lens by eliminating divergent light rays and allowing light only through the center of the lens, thus reducing corneal refractive error. In general, visual acuity is improved with the pinhole device. Decreased visual acuity that is not improved with this device suggests that corneal refractive error is not the cause. Construct a pinhole device by punching one to several holes in the center of a card (3 × 5 inch index card) with an 18-gauge needle. Devices with one or more pinholes drilled into an eye cover are available commercially (Fig. 62.2A and B) or can be constructed from readily available material in the ED, such as the index card with holes just mentioned (Fig. 62.3). Fig. 62.2C presents a chart for testing visual acuity while the patient is on a stretcher or in a chair. The chart can be used directly from this text if held 14 inches from the eye. Begin by testing the affected eye or the one presumed to have the worst visual acuity. First, instruct the patient to read the smallest letters on the chart that can easily be seen. Then ask the patient to read letters that can just barely be made out (i.e., they do not have to be clear). If the patient is unable to read the largest letter on the chart, move the patient to half the distance from the chart (10 ft), or if using the figure in this text, move it 7 inches closer to the eye and repeat the procedure. Record the results reflecting the change in distance (e.g., 10/200). The numerator in the vision ratio is the distance of the patient from the chart and the denominator is the distance at which a patient with normal vision can read the line of letters. For patients who still cannot read the letters on the chart, test vision progressively as follows: the ability to count fingers, detect hand motion, and perceive light (with or without projection; i.e., the ability to perceive the direction of light), and finally, the inability to perceive light.²

Near Visual Acuity Procedure

Perform near visual acuity assessment in the ED at the bedside or at triage. Hold a pocket near vision card (see Fig. 62.2C)

Figure 62.1 The “routine” progression for assessing visual acuity is reversed in the emergency situation. Assessment of an intact visual pathway begins with quickly discerning whether the patient has light perception (LP), can see hand motion (HM), and can count fingers at 3 ft (CF). Subsequent progression to assess vision at 10 and then 20 ft from a standard eye chart ensues.

or any printed material in good light at a distance of approximately 14 inches in front of the patient and occlude each eye alternately as described earlier. Alternately, an “app” may be used from a smart phone device, but directions vary and not all apps measure near distance.³ When using available printed material in lieu of a near vision card, measure the size of the letters that are discerned by the patient. At a later time compare these letters with the size of the letters on the near vision card to deduce the patient’s actual visual acuity. When near vision is decreased, it is usually caused by either loss of visual function or poor accommodation as a result of advancing age (presbyopia). Less commonly, it is caused by traumatic mydriasis. Thus, examine patients with presbyopia with their reading correction in place to obtain the best corrected near visual acuity.

For patients who cannot communicate or in whom factitious blindness or malingering is suspected, check for optokinetic nystagmus (OKN) to determine whether the visual pathway is intact. To test for OKN, pass a regularly sequenced pattern in front of the eyes. If an optokinetic drum is available, rotate the drum in front of the patient (Fig. 62.4). This is not available in many EDs, however multiple apps are available for use with an iPhone or smart phone which show a moving stripe which elicits nystagmus. Some apps have the ability to record the nystagmus in a video format (Optokinetic Drum Proversion 1.0, Bluestone Publishing, Inc, updated Sept 18, 2015). In place of the drum, substitute a printed piece of paper such as newsprint (without photographs or large areas with no print) or a standard tape measure. Pass it in front of the patient’s eyes at reading distance while instructing the patient to look at it as it moves rapidly by. Evaluate for tracking as demonstrated by involuntary nystagmus-like eye movements seen when the test object is moved from side to side in front of the patient. Such movement indicates an intact visual pathway. Finally, another effective method is to hold a mirror in front of the patient and slowly rotate the mirror to either side of the patient. Patients with an intact visual pathway will maintain eye contact with themselves as demonstrated by eye movement as the mirror is moved. A large mirror that reflects the patient’s entire face is most effective for this purpose.

All patients with decreased visual acuity from baseline require routine referral for further ophthalmologic follow-up; however, patients with moderately or severely decreased visual acuity not explained by refractive error require ophthalmologic consultation in the ED.

USE OF OPHTHALMIC ANESTHETIC AND ANALGESIC AGENTS

Topical anesthetic agents are widely used in the ED setting. Their use is essential in achieving adequate pain control and to evaluate and treat painful eye conditions. Two agents most commonly used are tetracaine and proparacaine. Comparative studies suggest that proparacaine is less painful on instillation, whereas tetracaine is longer lasting, and thus possibly more effective.^{4,5} Topical anesthetic agents have been used in the outpatient setting following ophthalmic surgery and are considered safe and effective for this condition. Although still controversial, there is a growing body of evidence that supports their use for brief outpatient treatment (a few days only) of corneal abrasions.^{6,7}

Ophthalmic nonsteroidal antiinflammatory drugs (NSAIDs) have been evaluated for their effectiveness and in the treatment of traumatic corneal abrasions. Examples include ketorolac tromethamine, diclofenac, and flurbiprofen. These agents are thought to be safe to use and effective for the relief of pain associated with corneal abrasions.^{8–11} Topical ophthalmic NSAIDs have also been shown to be safe and effective when used for the treatment of corneal abrasions in conjunction with bandage contact lenses.¹² Despite similar potential complications (delayed corneal healing) topical NSAIDs have gained widespread acceptance compared to topical anesthetic agents in their use for treatment of corneal abrasions.

Indications and Contraindications

Application of topical anesthetic agents can be both diagnostic and therapeutic. Relief of discomfort with a topical anesthetic strongly suggests, but does not ensure, a conjunctival or corneal injury. An ocular irritant may also be masked by the use of these agents. Classic teaching is that patients should not self-administer anesthetic preparations. It is thought that they delay wound healing by disrupting surface microvilli and causing a decrease in the tear film layer and tear break-up time.¹³ Although self-administered topical anesthetic agents are now routinely used after photorefractive keratectomy for the first 3 or 4 postoperative days, this likely safe technique has not yet become a common ED practice.¹⁴

As evident from Table 62.1, the anesthetic solutions commonly used have a duration of action of less than 20 minutes, though tetracaine may have a slightly longer clinical effect.⁴ Patients with a large corneal lesion may need a more extended period of pain relief and may require bed rest, opioid analgesics, and/or appropriate sedatives.

A final word of caution should be added regarding the use of ophthalmic solutions. Guaiac solutions are commonly supplied in dropper bottles similar in size and appearance to those containing ophthalmic solutions. Well-intentioned ED personnel may store the guaiac reagent bottles with the ophthalmic bottles. One should encourage both color coding of the bottles and examination of them and their labels before each use to avoid corneal injury from inadvertently instilling guaiac reagent into the eye.

Procedure

Instillation of anesthetic or analgesic agents is similar to the administration of other eye solutions as described later. Forewarn the patient that the medication will sting transiently

ROSENBAUM POCKET VISION SCREENER

The Card is held in good light 14 inches from eye. Record vision for each eye separately with and without glasses. Presbyopic patients should read through a bifocal segment. Check myopes with glasses only.

DESIGN COURTESY J.G. ROSENBAUM, M.D., CLEVELAND, OHIO

Figure 62.2 A commercial pinhole device reveals refractive error caused by corneal aberration (excessive tearing or nearsightedness). The pinhole device functions as a corrective lens by eliminating divergent light rays and allowing light only through the center of the lens, thus reducing corneal refractive error. In general, visual acuity is improved with the pinhole device. Decreased visual acuity that is not improved with this device suggests that corneal refractive error is not the cause. **A**, First measure visual acuity without the device. **B**, Measure again with the patient looking through the pinhole. Document the acuity with and without the pinhole device. **C**, If the patient cannot stand or a formal eye chart is not available, ask the patient to read this “distance equivalent” chart by holding the card 14 inches away from the patient.

on instillation but will quickly offer relief. Repeat instillation in one minute to ensure maximum effect. Instruct the patient not to rub the insensate eyes to avoid causing or worsening an abrasion. Provide the patient material to blot the eyes gently, if needed, as tearing occurs.

Complications

Open bottles can harbor bacteria and introduce infection. Out-of-date medication may not be effective and result in inadequate anesthesia. The absence of protective reflexes while the patient is under the effect of the medication may encourage use of the eye and result in further corneal injury from the foreign body (FB) or corneal infection.

A systemic review of the safety of topical anesthetics in the treatment of corneal abrasions found corneal erosions, edema, or iritis reported when agents were used for prolonged periods

Figure 62.3 A bedside pinhole device can be easily fashioned if commercial devices are not available. In this image, a single hole was crafted from a needle and an index card. Multiple holes work effectively as well. When assessing visual acuity with a handmade pinhole device, have the patient hold the device in front of the eye tested, while covering the other eye. (Courtesy Mary Jo Chandler, PA-C.)

of time (up to 10 weeks), too often (up to every 15 minutes), and with higher concentrations.¹⁵ Delayed corneal healing has been long taught as a significant complication of topical anesthetic and analgesic agents, but several well-designed randomized clinical trials in the ED-based and ophthalmology (PRK surgery) literature report no adverse events from topical anesthetic use and corneal re-epithelialization occurring by 72 hours, indicating that any delay in healing does not appear to be clinically significant.^{16–18} Thus, though not currently used for routine outpatient treatment, topical anesthetic drops can be considered for use safely for 2 to 3 days without documented adverse effects in selected patients.

DILATING THE EYE

Dilating the eye is useful for both diagnostic and therapeutic purposes. Be advised, however, that an attack of narrow-angle (angle-closure) glaucoma may be precipitated by dilating the pupil. The most common form of glaucoma, however, is open-angle glaucoma, and this type is not precipitated by dilating the pupil. Some patients may have a “mixed mechanism” glaucoma with both open-angle and narrow-angle components. Systemic reactions, such as bradycardia or even heart block from β -blocker eye drops, can be induced by mucosal absorption of dilating medications.

Figure 62.4 Optokinetic nystagmus (OKN) testing will determine whether the visual pathway is intact. It will be normal in the patient with factitious blindness or malingering. Induce OKN by passing a regularly sequenced pattern in front of the eye such as this commercially available drum. Hold the drum in front of the patient. Direct the patient to look at the drum as you rotate it slowly. Alternatively, draw a tape measure across the line of sight while asking the patient to look directly at it as it passes.

TABLE 62.1 Ophthalmic Anesthetic Agents

GENERIC NAME	TRADE NAME	CONCENTRATION (%)	ONSET OF ANESTHESIA	DURATION OF ANESTHESIA (min)	COMMENTS
Tetracaine	Pontocaine	0.5–1.0	< 1 min	15–20	Marked stinging; ointment and preservative free unit dose available
Proparacaine	Ophthaine, Ophthetic	0.5	< 20 sec	10–15	Least irritating; no cross-sensitization with other agents
Benoxinate	Dorsacaine	0.4	1–2 min	10–15	Contains fluorescein in solution

There are two types of dilators: sympathomimetic agents, which stimulate the dilator muscle of the iris, and cycloplegic agents, which block the parasympathetic stimulus that constricts the iris sphincter. Cycloplegic agents also block contraction of the ciliary muscles, which control focusing of the lens of the eye. This second effect of cycloplegic agents is beneficial in the therapeutic use of dilators for iritis.

Cycloplegic agents were used cosmetically as early as Galen's time. Beginning in the early 1800s, extracts from the plants *Hyoscyamus* and belladonna were used in ophthalmology. Atropine was first isolated in 1833. Epinephrine was used on eyes in 1900 as the first sympathomimetic agent.¹⁹

Indications and Contraindications

There are several diagnostic and therapeutic indications for dilating the pupil. Dilation is indicated for diagnosis when the fundus cannot be examined adequately through an undilated pupil. An elderly patient with miotic pupils and cataracts is an example of a patient in whom dilation may facilitate fundoscopic examination. Dilation is therapeutically useful for many ophthalmic conditions, including inflammation of the eye. In the emergency setting, corneal injury with secondary traumatic iritis is a common example. Dilation helps the inflamed eye in two ways. First, it may help to prevent adhesions (synechiae) from forming between the iris and other ocular structures. Such adhesions eventually limit movement of the pupil and may precipitate glaucoma. Second, cycloplegic dilating agents relax the ciliary muscle spasm that often accompanies an inflamed eye and thus may reduce the pain associated with inflammation. Though traditionally used for these purposes, both benefits are largely theoretical with little formal evidence to support or refute their use in the ED.

Dilation is discouraged in patients with head injury who are at risk for herniation when it is necessary to monitor pupil findings. Dilation is contraindicated in the presence of narrow anterior chamber angles. Patients predisposed to having narrow

angles may be unaware of this condition. Evaluate the depth of the anterior chamber before this procedure, and do not dilate the eye if there is any question of a narrow angle.

To estimate the depth of the anterior chamber, shine a penlight tangentially from the lateral side of the eye. When the depth of the anterior chamber is normal, uniform illumination of the iris is seen. However, when the iris has a forward convexity as in the case of a narrow anterior chamber, only a sector of iris is illuminated and there will be a shadow on the medial (nasal) side of the iris (Fig. 62.5). With a slit lamp, the depth of the anterior chamber angle can be assessed directly. The definitive test for assessing the anterior chamber angle is gonioscopy, in which the anterior chamber angle structures are viewed directly by means of a special mirrored contact lens and a slit lamp. Gonioscopy is not a technique normally performed by emergency clinicians.

Systemic effects can develop after the application of eye drops.^{20–26} Review the following sections on agents and complications before using these drugs in patients with compromised cardiovascular function.

Agents

Only two dilating agents are really needed in the ED. Phenylephrine (Neo-Synephrine, Hospira, Inc., Lake Forest, IL) 2.5%, a potent sympathomimetic, is used for diagnostic dilation of the pupil and visualization of the fundus. The drug is short acting, and because accommodation is not affected, the patient's vision is not altered. Phenylephrine 10% should *not* be used routinely because it can be absorbed systemically and, in rare cases, has caused hypertensive crisis, myocardial infarction, and death.^{24,25}

For therapeutic cycloplegia in patients with iritis, 5% homatropine works well. Even though Table 62.2 indicates a maximum duration of 3 days, 24 hours is more common. Therefore 5% homatropine is a useful therapeutic agent for traumatic iritis. Atropine itself should not be used for traumatic

TABLE 62.2 Mydriatic Agents^a

AGENT	MAXIMUM MYDRIASIS	DURATION OF MYDRIASIS ^b	COMMON TRADE NAME
Sympathomimetics			
Phenylephrine, ^c 2.5% ^d	20 min	3 hr	Neo-Synephrine, Hospira, Inc., Lake Forest, IL
Cocaine, 5% or 4%	20 min	2 hr	—
Parasympatholytics (Cycloplegics)			
Atropine, 1%	40 min	12 days	—
Scopolamine, 0.25%	30 min	7 days	—
Homatropine, 5% ^e	30 min	1–3 days	—
Cyclopentolate, 1%	30 min	6–24 hr	Cyclogyl, Alcon Laboratories, Inc., Fort Worth, TX
Tropicamide, 1%	30 min	4 hr	Mydracil, Alcon

^aBottle caps of all these agents except cocaine are usually red.

^bThe duration of effect shows considerable individual variation. These are general estimates.

^cPreferred for fundoscopic examination.

^dA 10% solution may produce cardiovascular reaction and hence should not be used.

^ePreferred for iritis or corneal abrasion therapy.

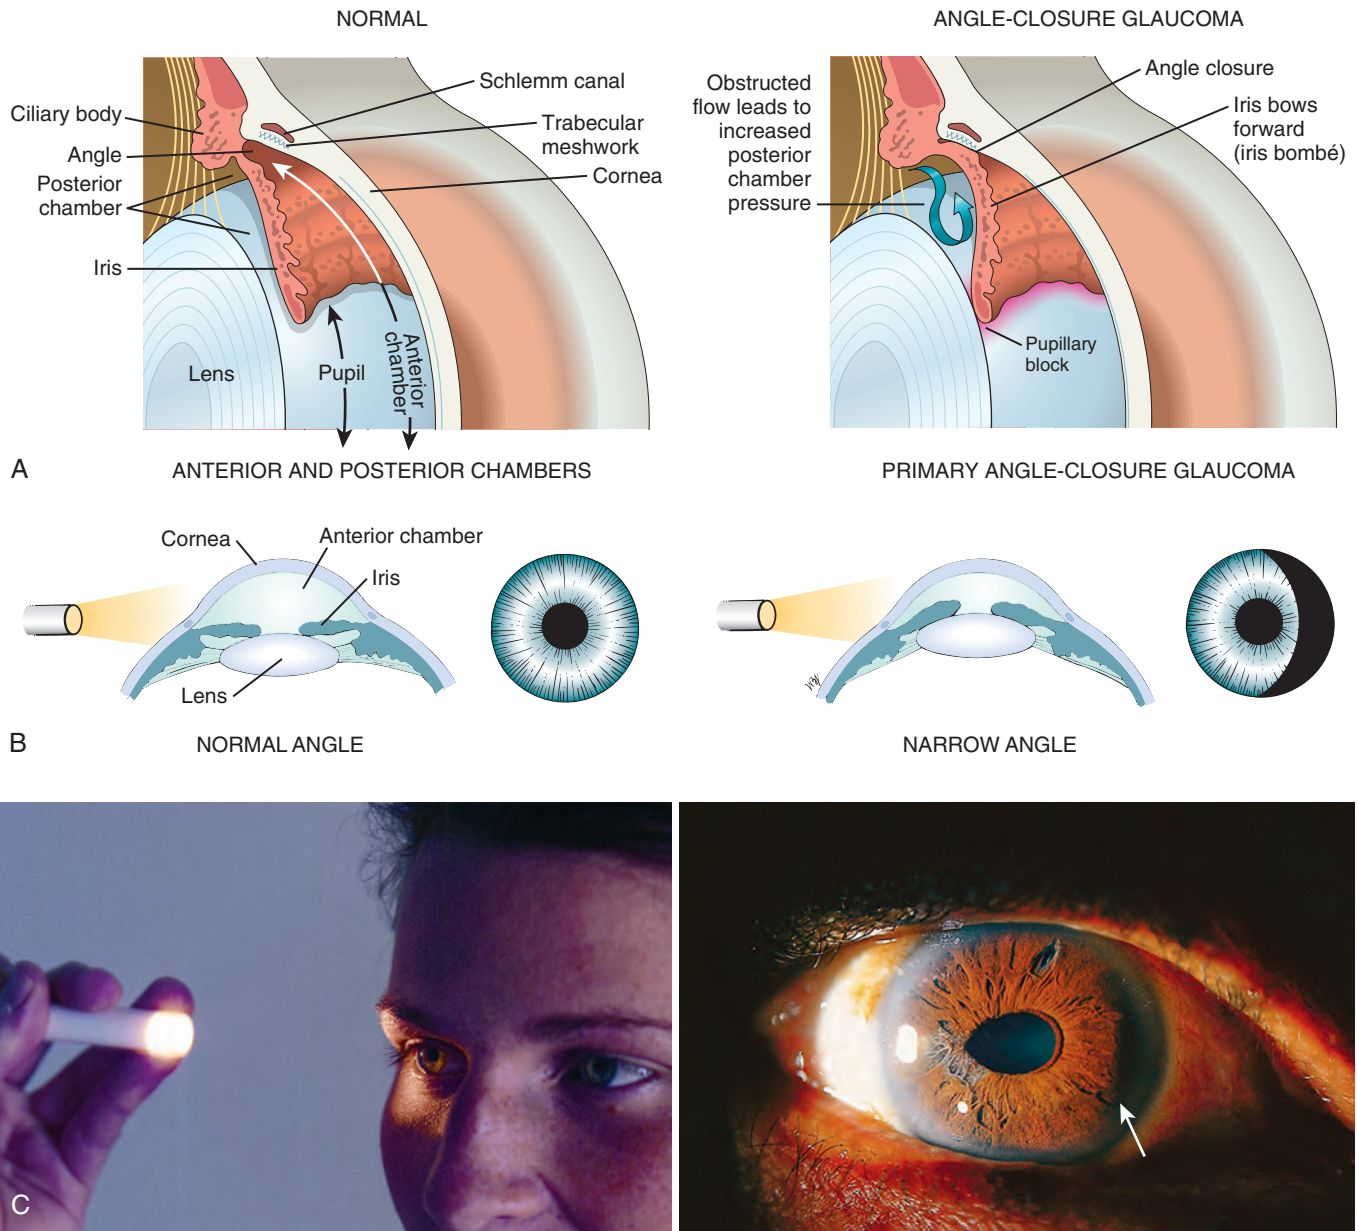

Figure 62.5 **A, Left:** The normal eye. Aqueous humor, produced in the posterior chamber, flows through the pupil into the anterior chamber. The major pathway for the egress of aqueous humor is through the trabecular meshwork into Schlemm's canal. **Right:** Primary angle-closure glaucoma. In anatomically predisposed eyes, transient apposition of the iris at the pupillary margin to the lens during pupil dilation blocks the passage of aqueous humor from the posterior chamber to the anterior chamber. Buildup of pressure in the posterior chamber bows the iris forward and occludes the trabecular meshwork. **B, Left:** Normal anterior chamber with a negative transillumination test. Note that the entire iris is illuminated. **Right:** Shallow anterior chamber with a positive transillumination test. Note the shadow on the outer half of the iris. **C, Left:** Clinical use of the penlight examination to assess the depth of the anterior chamber of the right eye. The examiner sits face to face with the patient to ensure that the light source is perfectly perpendicular to the line of vision. **Right:** The axial anterior chamber depth of the right eye is less than normal. This can be demonstrated by shining a light across the eye from the temporal side. Because of the convexity of the iris-lens diaphragm, the nasal iris manifests a crescentic shadow (eclipse sign). (A, From Kumar V, Abbas AK, Fausto N, et al, editors: *Robbins and Cotran pathologic basis of disease, professional edition*, ed 8, Philadelphia, 2009, Saunders; B, from Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2009, Saunders; C, from Kanski JJ: *Clinical diagnosis in ophthalmology*, St. Louis, 2006, Mosby.)

iritis because the undesirable effects of pupillary dilation and blurred vision persist for a week or longer after the associated corneal abrasions have healed. Atropine drops may be prescribed as part of the therapy for nontraumatic iritis after appropriate ophthalmologic consultation. Individuals with lightly pigmented irides tend to have greater sensitivity to cycloplegic agents than do individuals with greater pigmentation; the cycloplegic effect might therefore be more prolonged in people with light eyes. It might be difficult to dilate some patients with deeply pigmented irides, however, and numerous applications of drops might be required.

Malingers may use mydriatic agents to dilate a pupil unilaterally for the purpose of feigning neurologic disease. Normally, the pupillary dilation caused by intracranial compression of the third cranial nerve will constrict with 2% pilocarpine eye drops. A mydriatic-treated eye can be identified by full motor function of the third cranial nerve and absence of miosis after the instillation of pilocarpine. A fixed and dilated pupil in an awake and alert patient cannot be secondary to brain herniation. Although other neurologic problems may be present, in a normal-appearing patient with a fixed and dilated pupil, a pharmacologic cause is highly likely. It should be noted that legitimate patients may not recall the name of an eye medicine that they used but will usually recall whether the bottle had a red cap, as is found on all cycloplegic solutions marketed in the United States, though these agents are marketed in some countries (e.g., Greece, Turkey, India) with different colored caps. An unexpected mydriasis in a trusted patient may be the result of such an agent. Medications that constrict the pupil, such as pilocarpine, generally have a green cap. Pressure-lowering drops for glaucoma may be yellow or blue topped (β -blockers), purple topped (adrenergic agents), or orange topped (topical carbonic anhydrase inhibitors).

A fixed and dilated pupil from a pharmacologic cause may be encountered after both nasotracheal and orotracheal intubation (Fig. 62.6). In such ill or injured patients, cerebral herniation must be considered. When phenylephrine is used to constrict the nasal mucosa before nasal intubation (endotracheal tube, nasogastric tube), inadvertent spread to the eye can result in a fixed and dilated pupil. The same scenario may occur during resuscitation when endotracheal epinephrine has been instilled into the lungs and cardiopulmonary resuscitation has expelled epinephrine into the eye. In such scenarios, the affected pupil will not constrict after intraocular pilocarpine administration. Finally, a fixed and dilated pupil might occur as a result of inadvertent contamination of the eye with scopolamine after the application of a scopolamine patch.

Procedure

Instillation of mydriatic agents is similar to the administration of other eye solutions. For medicolegal purposes, note the patient's visual acuity before instillation of the medicine. This documents that any decreased vision is not the result of the mydriatic agent. Whenever dilation is performed, note on the patient's chart the dose and time that agents have been given to avoid confusion during subsequent neurologic evaluation.

Place the patient in a supine or a comfortable semirecumbent position. Instruct the patient to gaze at an object in the upper visual field, such as a fixture on the ceiling. Gently depress the lower lid with a finger on the epidermis. Instill a single drop of the solution into the lower lid fornix, and ask the

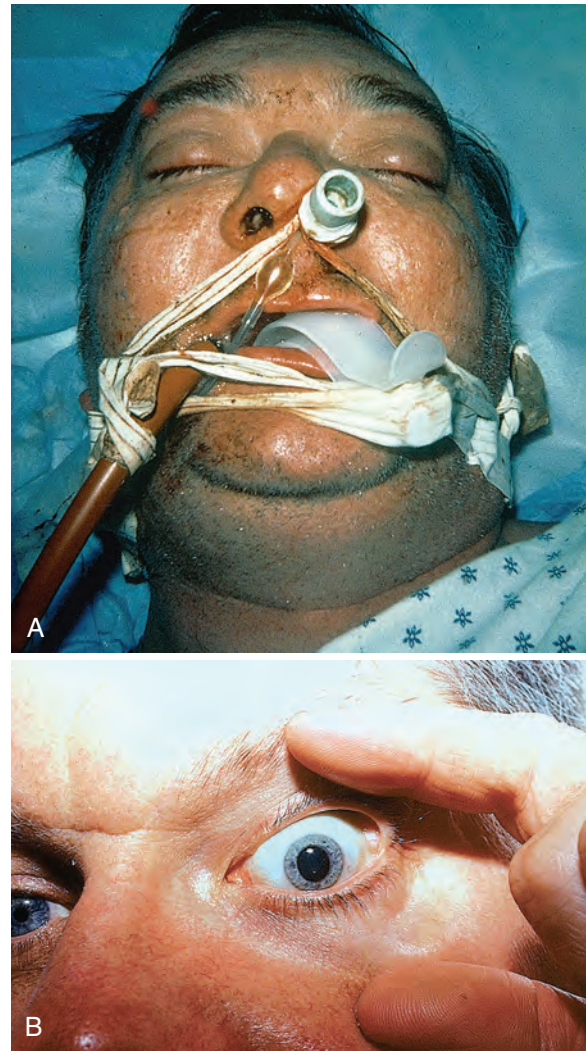

Figure 62.6 **A**, After phenylephrine (Neo-Synephrine, Hospira, Inc., Lake Forest, IL) drops were instilled in the nose to facilitate passage of a tube, this comatose patient was nasotracheally intubated for his drug overdose. **B**, On a subsequent examination a unilateral fixed and dilated pupil was noted. Cerebral herniation was suspected. The pupil dilation resulted from Neo-Synephrine nose drops that were snorted from the nose into the eye during intubation and simulated cerebral herniation. Other unusual causes of a fixed and dilated pupil are endotracheal epinephrine expelled from the lungs and splashed onto the eye during cardiopulmonary resuscitation and inadvertent contamination of the eye after the application of a scopolamine patch behind the ear.

patient to blink to spread the medication. Do not use more than a single drop because it produces reflex tearing and reduces the concentration in contact with the conjunctiva. Forewarn the patient that the medication is uncomfortable when it goes into the eyes. After the medication has been instilled, the patient may blot the eye when it is closed but should not rub it with a tissue. If the desired effect is not noted in 15 to 20 minutes, repeat the dose, but this is seldom required.

Complications

Any dilator can precipitate an attack of angle-closure glaucoma in susceptible patients.²⁶ In the case of angle-closure glaucoma,

BOX 62.1 Treatment Options for Acute Angle-Closure Glaucoma

Place patient supine; administer analgesics (such as IV morphine titrated to effect) and antiemetics (such as ondansetron 8 mg IV):

1. β -Blocker^b: Timolol 0.5% (Timoptic, Aton Pharma, Lawrenceville, NJ), 1 drop to the affected eye, wait 1 minute, and then
2. α -Agonist: Apraclonidine 1% (Iopidine, Alcon Laboratories, Inc., Fort Worth, TX), 1 drop to the affected eye, wait 1 minute, and then
3. Miotic agent: Pilocarpine 2% (Isopto Carpine, Alcon), 1 drop to the affected eye every 15 minutes for 2 total doses, wait 1 minute after first dose, and then
4. Prednisolone acetate 1%, 1 drop to the affected eye every 15 minutes for 4 total doses
5. Acetazolamide 500 mg IV (may give by mouth, two 250-mg tablets, if IV medication not available)

^aEmpiric therapy, no controlled trials, based on clinical experience.

^bRelative contraindications: severe bronchospasm, second- to third-degree heart block, uncompensated congestive heart failure.

Modified from Shields SR: *Managing eye disease in primary care. Part 3. When to refer for ophthalmologic care*, Postgrad Med 108(5):99–106, 2000.

it may take several hours before symptoms become evident. The patient often complains of smoky vision with “halos” around lights, as well as an aching pain that at times can be quite severe. Nausea and vomiting may occur. If the affected eye becomes infixed in association with a hazy cornea, elevated pressure on tonometry, and an oval, fixed pupil, consult an ophthalmologist immediately. Place the patient supine and administer analgesics and antiemetics. Treatment usually includes the agents suggested in Box 62.1, and later, definitive laser or surgical procedures.

Be aware that if contaminated, an eye medication can introduce infection. Most solutions contain bactericidal ingredients, but contamination of the tips of droppers can still occur (Fig. 62.7A).²⁷ Use only newly opened bottles of eye medication or single-use vials, particularly if the patient has a deep corneal injury or has recently undergone eye surgery. Promptly discard out-of-date drops and those in which crust or other material is found around the nozzle.

Forewarn the patient that any cycloplegic (in contrast to a sympathomimetic) will blur a patient’s near vision. Vision will be less blurred in adults older than 45 years, who generally have a reduced ability to focus for near vision. Although most adults will be able to drive safely, even with both eyes affected, it is advisable to have someone else drive whenever feasible. Light sensitivity caused by pupillary dilation may also be bothersome; sunglasses are sufficient for this problem.

Systemic reactions may rarely be induced by sympathomimetic and cycloplegic eye drops.^{20–26} In one report of 33 cases of adverse reactions associated with 10% phenylephrine, there were 15 myocardial infarctions (11 deaths), 7 cases of precipitation of angle-closure glaucoma, and a variety of systemic cardiovascular or neurologic reactions.²⁵

After instillation of eye drops into the conjunctival sac, systemic absorption can occur through the conjunctival capillaries, as well as by way of the nasal mucosa, the oral pharynx, and the gastrointestinal tract after passage through the lacrimal

Figure 62.7 A, Administration of eye drops. Position the patient with the head tilted back. Direct the patient’s gaze upward. Pull the lower lid downward and instill a single drop of medicine in the lower conjunctival fornix. Ensure that the tip of the dropper does not touch the lid or lashes. Instruct the patient to close the eyelids for 1 minute to increase contact of the medicine with the globe and to decrease outflow of medication down the tear duct and over the lid margin. B, If administering large amounts of eye drops that have systemic effects, such as β -blocker drops, place the operator’s index finger under the inferior eyelid along the nasal borders of the eye and firmly compress the nasolacrimal duct against the globe for a few minutes, thereby preventing migration of the drops into the nose and reducing systemic absorption.

drainage system. Mucosal hyperemia enhances absorption. Symptoms can often be avoided by maintaining digital pressure on the nasal canthus to occlude the puncta for several minutes after administration (see Fig. 62.7B).²⁰

THE FLUORESCEIN EXAMINATION

Perform fluorescein staining of the eye as part of the evaluation of patients with eye trauma and infection. It is a quick and easy technique that is crucial for the proper diagnosis and management of common eye emergencies. View the fluorescein-stained cornea and conjunctiva under a “blue” light and ideally in conjunction with slit lamp magnification (see later section on [Slit Lamp Examination](#)).

Sodium fluorescein is a water-soluble chemical that fluoresces. It absorbs light in the blue wavelengths and emits the energy in the longer green wavelengths. It fluoresces in an

alkaline environment (such as in Bowman's membrane, which is located below the corneal epithelium) but not in an acidic environment (such as in the tear film over intact corneal epithelium).²⁸ Thus it is useful in revealing even minute abrasions on the cornea.

Fluorescein was initially used in ophthalmology in the 1880s.²⁹ It was first used as a drop, but when the danger of contamination by bacteria (especially *Pseudomonas*) was recognized in the 1950s,³⁰ paper strips impregnated with fluorescein were developed. These strips are now supplied in individual sterile wrappers and should be used instead of the premixed solution.

Indications and Contraindications

Fluorescein staining is indicated for the evaluation of suspected abrasions, FBs, and infections of the eye,³¹ including "simple" cases of conjunctivitis, which may actually be herpetic keratitis. Exposure of the face to pepper spray has been associated with corneal abrasions, and such patients should undergo fluorescein staining and be evaluated with a slit lamp or Wood's lamp.³² Corneal defects may be seen after even a few seconds of unprotected viewing of a welder's arc flame.

Fluorescein permanently stains soft contact lenses. Therefore when fluorescein is used, remove soft contact lenses before instilling the fluorescein and caution the patient to not put the lenses back into the eye for several hours. Topically administered fluorescein is considered nontoxic, although reactions to a fluorescein-containing solution (not impregnated strips) have been described.³³ These reports, which consist of vagal reactions³⁴ and generalized convulsions,³⁵ are rare, not rigorously supported, and believed to be caused by agents other than fluorescein in the solution. If using one of these fluorescein-containing solutions rather than the fluorescein-impregnated strips, be aware of these potential, yet scientifically suspect idiosyncratic reactions.

In addition, be aware that fluorescein dye may enter the anterior chamber of the eye in patients with deep corneal defects. This form of intraocular fluorescein accumulation is nontoxic. When the anterior chamber is viewed under the blue filter of the slit lamp, a fluorescein "flare" is visible and should not be confused with the flare reaction noted with iritis.

Procedure

Theoretically, one should not use topical anesthetics before fluorescein staining because a superficial punctate keratitis may develop in some patients from the anesthetic,²⁸ which can confuse the diagnosis. However, in patients who are tearing profusely and squeezing their eyes shut from an abrasion or an FB, the examination is often impossible if a topical anesthetic is not first used. Thus, it is practical to apply a local anesthetic before instilling fluorescein.

Grasp the fluorescein strip by the non-orange end and wet the orange end with 1 drop of saline. Several convenient forms are available, including a small bottle of artificial tears or a 5-mL "bullet" or "fish" of normal saline commonly used for nebulizer treatments. Alternatively, wet the strip with tap water or the recently used local anesthetic drops. Once the strip is moistened, place it gently on the inside of the patient's lower lid (Fig. 62.8, step 1). Withdraw the strip and ask the patient to blink, which spreads the fluorescein over the surface of the eye. The key to a good examination is to have a thin layer of

fluorescein over the corneal and conjunctival surfaces. If the strip is too heavily moistened before placing it in the lower fornix, the eye may become flooded with the solution, which makes evaluation difficult. If too much dye accumulates, the patient can remove the excess dye by blotting the closed eye with a tissue. Conversely, placing a dry strip in an unanesthetized eye may be irritating. Next, use a Wood's lamp (4× magnification), the blue filter of a slit lamp, or simply a penlight with a blue filter to examine the eye in a darkened room (see Fig. 62.8, step 2). Check for areas of bright green fluorescence on the corneal and conjunctival surfaces. The naked eye may not be able to see small defects. Ideally, use a slit lamp with 10× or 25× magnification to examine the stained cornea before ruling out a pathologic process. A new handheld magnification device, the Eidolon Bluminator ophthalmic illuminator (Eidolon Optical, LLC of Natick, MA), produces an intense blue light from a light-emitting diode with 7× magnification (see Fig. 62.8, step 3). After completion of the fluorescein examination, irrigate excess dye from the eye to minimize damage to the patient's clothing from dye-stained tears.

The Seidel test uses fluorescein to detect perforation of the eye.³⁶ To perform this test, instill a large amount of fluorescein onto the eye by profusely wetting the strip. Examine the eye for a small stream of fluid leaking from the globe (see Fig. 62.8, plate 4). This stream will fluoresce blue or green, in contrast to the orange appearance of the rest of the globe flooded with fluorescein.²⁸

Interpretation

Fluorescein is used mainly for evaluation of corneal injuries. Although conjunctival abrasions pick up the stain, most of the staining on the conjunctiva represents patches of mucus rather than a real pathologic condition. Corneal staining is more specific for injury, and the pattern of injury often reflects the original insult.

Corneal staining patterns are illustrated in Figs. 62.8 and 62.9. Abrasions usually occur in the central part of the cornea because of the limited protection of closure of the patient's eyelids. The margins of the abrasions are usually sharp and linear if seen in the first 24 hours (see Fig. 62.8, plate 6). Circular defects are seen about embedded FBs and may persist for up to 48 hours after removal of a superficial foreign object. Deeply embedded objects may be associated with defects persisting for longer than 48 hours. Objects under the upper lid (including some chalazia) often produce vertical linear lesions on the upper surface of the cornea (see Fig. 62.8, plate 7). When vertical lesions are noted, search diligently for a retained FB under the upper lid. Overuse of hard contact lenses diminishes the nutrient supply to the cornea. The central part of the cornea sustains the most injury and thus fluoresces brightly when stained. Excessive exposure to ultraviolet light as a result of sunlamp abuse, snow blindness, or welding flashes produces a superficial punctate keratitis, which in its mildest form may not be visible without a slit lamp (see Fig. 62.8, plate 8). The central part of the cornea is the least protected by the lids, and a central, horizontal band-like keratitis can result. Herpetic lesions may develop anywhere on the cornea. Classically, these lesions are dendritic, although ulcers may also be punctate or stellate (see Fig. 62.8, plate 9).^{37,38}

Any area of corneal staining with an infiltrate or opacification beneath or around the lesion should alert the practitioner to the possibility of a viral,^{37,38} bacterial,³⁹ or fungal⁴⁰ keratitis.

The Fluorescein Examination

1 Moisten the fluorescein strip with 1 drop of saline or topical anesthetic. Depress the lower lid and gently place a wetted strip onto the inside of the patient's lower lid so that only the smallest amount is instilled.

2 Examine the eye with a Wood's lamp or a slit lamp with a cobalt blue filter (shown). Check for areas of bright green fluorescence on the corneal and conjunctival surfaces. Because the naked eyes may not be able to appreciate small defects, magnification should be used.

3 The Eidolon Bluminator ophthalmic illuminator provides an intense blue LED light with 7× magnification.

4 **Positive Seidel test.** Fluorescein seen streaming down the cornea indicates an open-globe injury. (From Krachmer JH, Mannis M, Holland E, editors: *Cornea*, ed 3, St. Louis, 2010, Mosby.)

5 **Large corneal abrasion seen with the naked eye.** Smaller abrasions or corneal injuries produced by keratitis or a welder's arc flash require slit lamp evaluation to identify minor corneal defects.

6 **Corneal abrasion as seen via a slit lamp.** A moderate-sized abrasion (arrow) is revealed by fluorescein staining and blue light. (From Friedman NJ, Raiser PK, Pineda R: *Massachusetts Ear & Eye Infirmary Illustrated Manual of Ophthalmology*, ed 3, Philadelphia, 2009, Saunders.)

7 **Vertical linear abrasions.** These types of abrasions are typically caused by a foreign body trapped under the upper eyelid. (From Kliegman R, Stanton B, Behrman R, et al, editors: *Nelson Textbook of Pediatrics*, ed 19, Philadelphia, 2011, Saunders.)

8 **Superficial punctate keratitis.** These diffuse, shallow corneal irregularities are caused by chemical irritation, viral illnesses, exposure to bright light, and many other conditions.

9 **Herpes simplex keratitis.** A classic herpetic epithelial dendritic lesion is seen on this fluorescein examination. (From Palay DA, Krachmer JH, editors: *Primary Care Ophthalmology: Concepts and Clinical Practice*, ed 2, St. Louis, 2005, Mosby.)

Figure 62.8 The fluorescein examination. Excessive fluorescein may obscure subtle findings and thus should be avoided. Fluorescein will permanently stain contact lenses if they are not removed. LED, Light-emitting diode.

Obtain urgent ophthalmologic consultation so that cultures of the possible etiologic agents can be procured and appropriate treatment initiated.

Many *Pseudomonas* organisms fluoresce when exposed to ultraviolet light⁴¹; therefore the presence of fluorescence before the instillation of fluorescein in a red eye should suggest the possibility of infection with this organism.

Summary

Fluorescein staining is a quick and easy diagnostic procedure that should be part of every eye evaluation. The extra time that the examination takes provides a wealth of diagnostic information on patients with eye trauma or infection. No complications are associated with the procedure with the

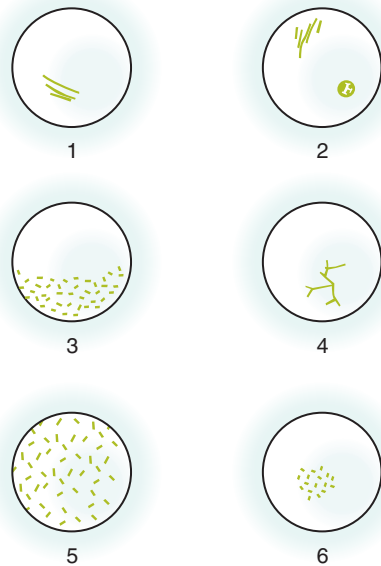

Figure 62.9 Patterns of acute corneal injury. 1, Traumatic abrasion, usually with linear features and sharp borders when seen early (< 24 hours), occurs more in the central part of the cornea. 2, Abrasion from a foreign body (FB). Vertical abrasions on the upper part of the cornea are seen when an FB is embedded in the upper lid. Also shown is a rust ring with a metallic FB. 3, Exposure pattern seen with prolonged exposure to ultraviolet light (e.g., welding flash, sunlamp exposure). A bandlike keratitis is produced over the lower half of the cornea. Squinting in the setting of the bright light protected the upper corneal surface. 4, Herpes simplex keratitis, classic dendritic pattern. 5, Adenovirus keratitis. Diffuse minute corneal staining is seen in patients with epidemic keratoconjunctivitis approximately 7 days after the onset of symptoms. 6, Contact lens overuse, central punctate staining. (From Knoop K, Trott A: Ophthalmologic procedures in the emergency department—part III: slit lamp use and foreign bodies, *Acad Emerg Med* 2:227, 1995. Reproduced by permission.)

exception of the reactions noted with the fluorescein solution, possible discoloration of soft contact lenses, and the potential for infection when premixed solutions rather than fluorescein-impregnated paper strips are used.

EYE IRRIGATION

The crucial first step in the treatment of chemical injuries to the eye is irrigation. Irrigate as clinically appropriate for the severity, length of exposure, and causative agent. Serious chemical injury to the eye requires irrigation as soon as possible, even at the site where the exposure occurred, before the patient is brought to the ED.³¹ Corneal injury can occur within seconds of contact, especially with an alkaline substance. Continue eye irrigation in the ED.

This section discusses methods of irrigation. Although it is best to irrigate liberally, copious irrigation is not needed when the patient has just a small amount of a noncaustic, nonalkaline compound in the eye.

Indications and Contraindications

Irrigation is indicated for all acute chemical injuries involving the eyes. Irrigation may also be therapeutic in patients with

an FB sensation but no visible FB. Small, unseen foreign material in the conjunctival tissues may be flushed out with irrigation. There is no contraindication to eye irrigation, but in patients with a possible perforating injury, perform the irrigation especially gently and carefully.

Equipment

The following equipment is necessary for eye irrigation:

- Topical anesthetic, such as 0.5% proparacaine
- Sterile irrigating solution (warmed intravenous saline or lactated Ringer's [LR] solution in a bag with tubing)*
- A basin to catch the fluid
- Cotton-tipped applicators
- Gauze pads to help hold the patient's lids open
- Lid retractors
- Irrigating device (e.g., Morgan Therapeutic Lens [MorTan Inc., Missoula, MT], modified central venous catheter, or Eye Irrigator) for prolonged irrigation
- Optimal: 10 mL of 1% lidocaine added to a liter of irrigating fluid

Procedure

Basic Technique

First, instill a topical anesthetic into the eye (Fig. 62.10, step 1). Evert the eyelid and sweep out any particulate matter in the conjunctival fornices with a moistened, cotton-tipped applicator³¹ (see later section on **Ocular FB Removal** and Fig. 62.10, step 2). Hold the eyelids open during irrigation (see Fig. 62.10, step 3). The easiest method is to use gauze pads to grasp the wet, slippery lids and hold them open. If the patient has severe blepharospasm, consider using lid retractors (Desmarres [Sklar Surgical Instruments, West Chester, PA] or paper clip retractors; Fig. 62.11). When lid retractors are used, be certain that the eye is well anesthetized, that the retractors do not injure the globe or the lids, and that chemicals are not harbored under the retractors. Be aware that simple retractors fashioned from metal paper clips (especially those that are nickel plated and shiny) may have surface chipping, which can create an ocular FB.⁴² Exercise caution to avoid ocular injury when using such a makeshift retractor.

Deutsch and Feller³¹ recommended an ipsilateral facial nerve block for severe blepharospasm (Fig. 62.12). To avoid swelling of periorbital tissue, block the facial nerve just anterior to the condyloid process of the ipsilateral mandible. Place a subcutaneous line of anesthetic (2% lidocaine) to temporarily paralyze the orbicularis muscle.

Irrigate with normal saline or LR solution directed over the globe and into the upper and lower fornices (see Fig. 62.10, step 4). The choice of fluid initially is less important than initiating irrigation as rapidly as possible. If tap water is available at the scene of the injury, begin irrigation immediately with copious amounts of fluid before transporting the patient to the hospital. Teach out-of-hospital care providers to irrigate all acid injuries of the eye for at least 5 minutes at the scene and to irrigate all alkali injuries for at least 15 minutes.^{43,44} LR or normal saline solution is preferred over tap water or 5%

*A balanced salt solution designed for eye irrigation is preferred by some (when available) and may produce less corneal edema with chemical injuries. Readily available normal saline and lactated Ringer's solution are equally well tolerated.

Irrigation Of The Eye

1 Instill a topical anesthetic such as tetracaine HCl 0.5%.

2 Evert the eyelid and use a moistened cotton-tipped applicator to sweep out any particulate matter in the fornices.

3 Hold the eyelids open during irrigation. Consider the use of lid retractors if the patient has severe blepharospasm (see Fig. 62.10).

4 Irrigate with normal saline or lactated Ringer's solution directed over the globe and into the upper and lower fornices.

5 Be careful to direct the fluid onto the conjunctiva and then across the cornea (without letting the stream directly hit the cornea) because the solution may cause mechanical corneal injury.

6 In the case of acid/alkali exposure, measure the pH of the conjunctival fornices with litmus paper to check the effectiveness of the irrigation. Normal tear film pH is 7.4.

Figure 62.10 Irrigation of the eye. Intravenous tubing is connected to a liter bag of saline or Ringer's solution, and irrigation occurs at a wide-open rate.

dextrose in water for eye irrigation because these solutions are isotonic and do not contain dextrose. Dextrose can be quite sticky if spilled and might serve as a nutrient for an opportunistic bacterial infection. Although one clinical trial found a balanced salt solution less painful in patients with a chemical eye injury,⁴⁵ another volunteer study on uninjured eyes found that LR solution is better tolerated than normal saline and balanced saline solution when used with a Morgan lens.⁴⁶ Warmed fluids are also better tolerated than fluids at room temperature.⁴⁷ Warmed LR solution should be considered when both it and normal saline are available for eye irrigation.

Be careful to direct the irrigating stream onto the conjunctiva and then across the cornea without letting the stream splash directly onto the cornea because striking the eye with the solution can in itself be harmful and cause mechanical injury (see Fig. 62.10, step 5). Direct irrigation of the cornea can

result in the development of a superficial punctate epithelial keratopathy.

Before irrigation, instill anesthetic eye drops, such as 0.5% tetracaine. Adding 10 mL of 1% lidocaine to a liter of irrigating fluid can decrease the patient's discomfort during prolonged irrigation.

Duration of Irrigation

Although Deutsch and Feller³¹ recommended that a full liter of irrigating solution be used in every case of caustic injury, the duration of irrigation is best determined by the extent of the exposure and the causative agent. Acids are quickly neutralized by proteins in the surface tissues of the eye and, once irrigated out, cause no further damage. The only exceptions are hydrofluoric and heavy metal acids, which can penetrate through the cornea. Alkalis can penetrate rapidly and, if not

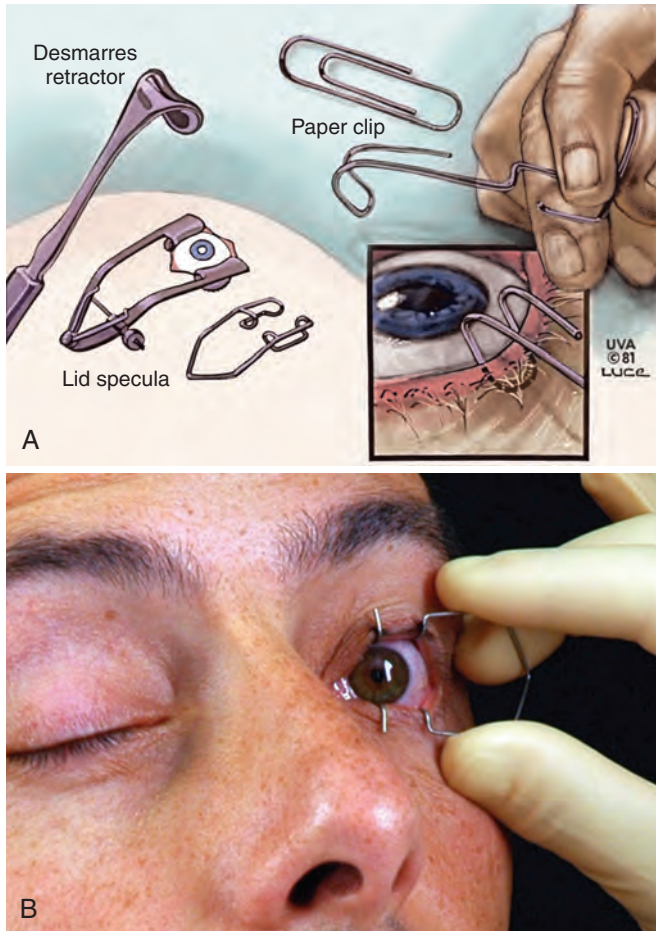

Figure 62.11 Devices for separating eyelids. **A**, A Desmarres retractor, lid specula, or retractor improvised from a paper clip allows active manipulation of the lids. Free-standing specula may require a seventh nerve block to reduce the blepharospasm. **B**, Lid retractor in place. (**A**, From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. In Haddad LM, Winchester JF, editors: *Clinical management of poisoning and drug overdose*, ed 2, Philadelphia, 1990, Saunders. Reproduced by permission.)

removed, will continue to produce damage for days because of slow dissociation of the cation from combination with proteins.³¹ Therefore prolonged irrigation is indicated and at least 2 L of solution should be used. Although rapid flushing with the first 500 mL is prudent, slow continuous irrigation, as discussed later, at a rate sufficient to generate a continuous trickle is often more effective and better tolerated than continued high-volume flushing. If the nature of the offending agent is unknown or in question, use prolonged irrigation.

Consult ophthalmology for all alkaline, hydrofluoric acid, and heavy metal acid injuries. Irrigation on an inpatient basis may be required for a period of 24 hours or longer, especially when the cornea is hazy or obviously thickened. Note that the magnesium contained in sparklers combines with water from tears to produce magnesium hydroxide.⁴⁸ Treat such fireworks injuries as alkaline injuries rather than as thermal injuries. Treat eye damage from hair straighteners,⁴⁹ phosphate-free detergents,⁵⁰ and automobile air bags⁵¹ as alkaline injuries also.

Measure the pH of the conjunctival fornices with a pH paper strip to check the effectiveness of irrigation (see

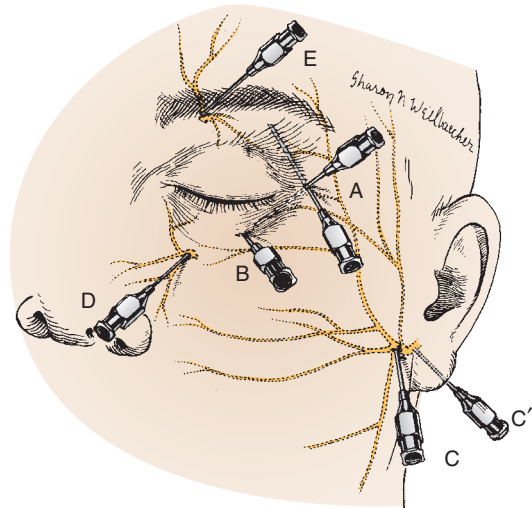

Figure 62.12 Injection points for facial and orbital anesthesia and akinesia. **A**, Van Lint technique for infiltration of the orbicularis. **B**, Retrobulbar injection site. **C**, O'Brien facial nerve block. **C'**, Alternative facial nerve block by injection into the tympanomastoid fissure. **D**, Infraorbital sensory block. **E**, Supraorbital sensory block. Injection of the orbicularis (**A**) or facial nerve (**C** or **C'**) permits examination and treatment of the eye in the setting of severe blepharospasm. Anesthetic is placed within several millimeters of the nerves. (From Deutsch TA, Feller DB, editors: *Paton and Goldberg's management of ocular injuries*, ed 2, Philadelphia, 1985, Saunders, p 17.)

Fig. 62.10, step 6). In addition to litmus paper, the pH indicator on urine multi-indicator sticks can be used. The pH indicator on urine dipsticks is conveniently closest to the handle; all the distal indicator squares can be cut off with scissors. Normal tear film pH is 7.4. Use the noninjured eye as a control if the results are equivocal. If the pH measured in the conjunctival fornices is still abnormal after the initial irrigation, continue to irrigate. If the pH is normal after irrigation, wait 20 minutes and check it again to make sure that it remains normal, especially if alkaline contamination has occurred. Delayed changes in pH are usually the result of incomplete irrigation and inadequate swabbing of the fornices. In anticipation of this deficiency, measure the pH deep in the fornices. Consider double-lid eversion with a lid elevator to expose the upper fornix for swabbing, irrigation, and pH testing.

Prolonged Irrigation

Alkaline burns may require prolonged irrigation, and it is essential to consult ophthalmology in such cases. The Morgan Therapeutic Lens is a contact lens-type irrigation device that can provide slow, continuous irrigation once the more vigorous initial irrigation has been completed (**Fig. 62.13** and **Video 62.3**). First, anesthetize the eye with topical anesthetic drops. Then place the device carefully on the surface of the eye with the lids closed around the intravenous tubing adaptor. Attach the intravenous tubing to the adaptor and provide continuous flow through the device onto the cornea and into the fornices. As the local anesthetic agents wash out during the irrigation process, the device can become uncomfortable, so reapply the anesthetic drops frequently during irrigation for patient comfort. Such short-term use of local anesthetics will not inhibit healing of the cornea.

Morgan Lens Irrigation

1

The Morgan therapeutic lens is a contact lens–type irrigation device that can provide slow, continuous irrigation once the more vigorous initial irrigation has been done.

2

Prior to insertion, anesthetize the eyes with topical anesthetic drops such as tetracaine HCl 0.5%. The anesthetic will wash out during the irrigation process, so reapply frequently for patient comfort.

3

Carefully place the device on the surface of the eye with the lids closed around the intravenous tubing adaptor.

4

Attach the adaptor to intravenous tubing and provide continuous flow through the device onto the cornea and into the fornices. Bilateral irrigation is easily achieved with this technique.

Figure 62.13 Morgan lens irrigation. A liter bag of saline or Ringer’s solution is connected to the Morgan lens with intravenous tubing and irrigated at a wide-open rate.

Complications

The only significant complication from irrigation is abrasion of the cornea or the conjunctiva. This can be a mechanical injury from trying to keep the lids open in an uncooperative patient, a small corneal epithelial defect from a Morgan irrigating lens, or fine punctate keratitis from the irrigation itself.⁵² For this reason, do not direct the stream directly onto the cornea. If a superficial corneal defect occurs, treat it in the usual manner. Deep or penetrating corneal injuries are likely to be a result of the caustic chemical and require emergency ophthalmologic consultation. Continue to provide slow continuous irrigation pending arrival of the ophthalmologist. Some

experimental evidence suggests that massive parenteral or oral ascorbic acid supplementation may prevent the development of deep corneal injury,⁵³ but such treatment has not gained universal acceptance.

Summary

Eye irrigation is easy, and complications associated with the technique are usually minimal. At times the clinician may be unsure whether a chemical injury is toxic enough to warrant irrigation. If any doubt exists, err on the side of irrigating the eye rather than omitting this vital procedure and risking progression of the eye injury.

Figure 62.14 Serious eye injuries. **A**, Corneal laceration with prolapse of the iris. The extruded iris is dark and mimics a corneal foreign body (*arrow*). Frequently, the only clue is an abnormal pupil, and the extruded iris may not be appreciated as intraocular tissue. The pupil is irregular (often pear or teardrop shaped) and points toward the laceration. **B**, A pear-shaped pupil without protrusion of the lens is a more subtle, yet characteristic indication of a perforated globe (*arrow*). **C**, Another indication of a penetrating globe injury is periorbital fat protruding from an upper eyelid laceration (*arrow*). This patient was stabbed with a knife. **D**, This patient has an obviously cloudy lens soon after trauma. A projectile entered the temporal portion of the globe and produced a seemingly minor scleral hemorrhage. Patients with penetrating injuries to the globe should be treated with systemic antibiotics (such as a combination of cefazolin and gentamicin), tetanus toxoid if indicated, and antiemetics to control vomiting (which raises intraocular pressure). (A, Courtesy Lawrence B. Stack, MD.)

GLOBE PROTECTION AND EVALUATION

In the evaluation of a patient in whom a penetrating injury to the globe is suspected, perform a careful expeditious examination of the eye, preferably with a slit lamp. Avoid any pressure on the eye or rapid eye movements. If perforation is obvious (e.g., teardrop pupil, flaccid globe, flat anterior chamber, prolapsed iris) or confirmed by slit lamp (positive Seidel test; see Fig. 62.8, *plate 4*), do not perform any procedures (except perhaps irrigation or ultrasound; see later) and consult ophthalmology early for definitive diagnosis and care (Fig. 62.14). Until the ophthalmologist arrives, protect the eye from further harm by keeping the patient quiet, elevating the head of the bed, and placing a protective shield over the eye. Commercial shields are available for this purpose. When a metal shield is not available, construct a makeshift protective shield with the material available (e.g., paper, plastic, or Styrofoam cups; Fig. 62.15). The protective shield helps avoid pressure on the globe and overlying tissue and assists in preventing extrusion of vitreous and other ocular contents. Extend the edges of the shield up to or beyond the bony orbital rim for this purpose. Apply adhesive tape over the shield from the forehead to the cheek to secure the shield in position.

If a patient has a globe perforation, treat with systemic antibiotics (a combination of cefazolin and gentamicin is a good initial choice), tetanus toxoid, and antiemetics in doses aggressive enough to halt vomiting.

Figure 62.15 When a penetrating globe injury is suspected and a metal shield is not available in the emergency department or prehospital setting, a makeshift shield can be fashioned with available material. A paper cup was used to fashion this shield.

BEDSIDE ED OCULAR ULTRASOUND

ED ocular ultrasonography has markedly advanced the emergency physician's (EPs) ability to quickly address important ocular conditions. In 2000, Blaivas and colleagues published the first series of patients who were successfully evaluated with bedside ocular ultrasound by EPs. Many subsequent studies have demonstrated that with proper training and equipment, EPs are competent and care is improved by using this noninvasive technology at the bedside.^{54–56}

Indications and Contraindications

Bedside ED ocular ultrasonography may be appropriately used as an adjunct in the evaluation of altered vision, suspected FB, ocular pain, headache, eye trauma, head injury, or altered mental status. Conditions that are reliably diagnosed include globe rupture, intraocular FB, vitreous hemorrhage, lens dislocation, retinal detachment, and elevated intraocular pressure.

There are no absolute contraindications for bedside ED ocular ultrasound, given proper equipment, an experienced sonographer, and a cooperative patient. The evaluation of a potential open globe deserves special mention. Whereas it is generally true that the eye should be protected from further manipulation after suspecting an open globe, evaluation with bedside ED ocular ultrasound is the exception. It is imperative that the EP performing the bedside ultrasound be mindful of the possibility of an open globe and utilizes the *no pressure technique* described later. An immediate benefit is gained when the EP carefully uses this technique to avoid a delay in diagnosis and treatment. Any delay incurs an increased risk of adverse outcome. In general, the benefit obtained from the use of bedside ED ocular ultrasound outweighs the risk of further examination of the eye in this setting. That said, if the physical exam obviously suggests open globe pathology, the clinician is discouraged from this procedure, as it carries the risk of vitreous extrusion (even with minimal globe compression) with little benefit to the diagnostic evaluation.

Equipment

Appropriate ultrasound machine with linear array transducer, 7.5 to 10 mhz or higher.

Procedure

Ensure ultrasound equipment is clean and disinfected. Adjust setting on machine for ocular ultrasound. Place the patient in a recumbent or semi-reclined position to minimize runoff of gel. Instruct the patient to keep eyes closed, but not clenched, to look straight ahead, and not to move the eyes. It is suggested that the closed eye be covered with a large piece of clear Tegaderm dressing (3M, St. Paul, MN) to facilitate the ultrasound examination without contaminating it with gel or the probe. Place a copious amount of gel over the Tegaderm dressing or closed eyelid to be examined, enough to completely fill the sulcus formed by the eye so that the transducer can touch the gel in a transverse plane without touching the eyelid and without breaking contact of the transducer with the gel (Fig. 62.16). Hold the transducer in such a way so that the examiner's hand can stabilize the probe against movement by resting the hand on the patient's forehead, bridge of the nose, or maxilla (Fig. 62.17). Barely touch the probe to the gel without applying

Figure 62.16 Retinal detachment (see Fig. 62.19) and intraocular foreign bodies (see Fig. 62.21) are readily identified with ultrasound. The large amount of gel placed over the closed eyelid forms an acoustic window for the ultrasound probe. This allows an image to be obtained without additional pressure applied to the eye.

Figure 62.17 It is essential that the sonographer maintain situational awareness about the position and weight of the probe at all times. This is accomplished by always maintaining stabilization of the probe against the patient's forehead or face. (Courtesy Mary Jo Chandler, PA-C.)

pressure to the eyelid (no-pressure technique) (Fig. 62.18). Maintain this contact throughout the examination. As soon as the probe touches the gel, the ocular structures should immediately come into view. Adjust probe position to obtain a clear cross section of the eye showing anatomic structures (anterior chamber, iris, lens, vitreous, retina, nerve sheath). Adjust gain for a clear image, starting with maximal settings and reducing it until structures come into view again. Position the optic nerve in the middle of the screen and adjust the depth to view approximately 1 cm of the optic nerve. Identify the optic structures (Fig. 62.19A). Identify abnormal findings (see Figs. 62.19B and C), and describe abnormal findings in the caption. Use multiple planes to clarify normal and abnormal findings. A direct and consensual pupillary light reflex can be observed by viewing the pupillary response to light via ultrasound.

Figure 62.18 Probe stabilization is accomplished by resting the sonographer's hand on the patient's nose and face while the probe is gently touched to the surface of the gel. The acoustic window can be seen underneath the probe. (Courtesy Mary Jo Chandler, PA-C.)

To measure optic nerve sheath diameter, ask the patient to adjust the gaze of the examined eye, approximately 10 degrees laterally. When viewed at this angle, the optic nerve is aligned with the ultrasound beam and decreases the possibility of obtaining a falsely widened measurement. This can occur if the optic nerve is imaged at an angle. Measure the width of the optic nerve sheath 3-mm deep to the retina (Fig. 62.20). Obtain at least two measurements and average for a final measurement. A diameter of greater than 5 mm is considered to be widened and suggests increased intracranial pressure.

Complications

Inadvertent pressure applied to an eye with a ruptured globe could result in further damage to the globe. Excessive scan times could exceed exposure limit guidelines.

Findings

Globe rupture, intraocular FB, vitreous hemorrhage, retinal detachment, dislocated lens, and elevated intraocular pressure may be seen. These findings will be obscured if periorbital or orbital emphysema is present or if there is excessive air in the gel.

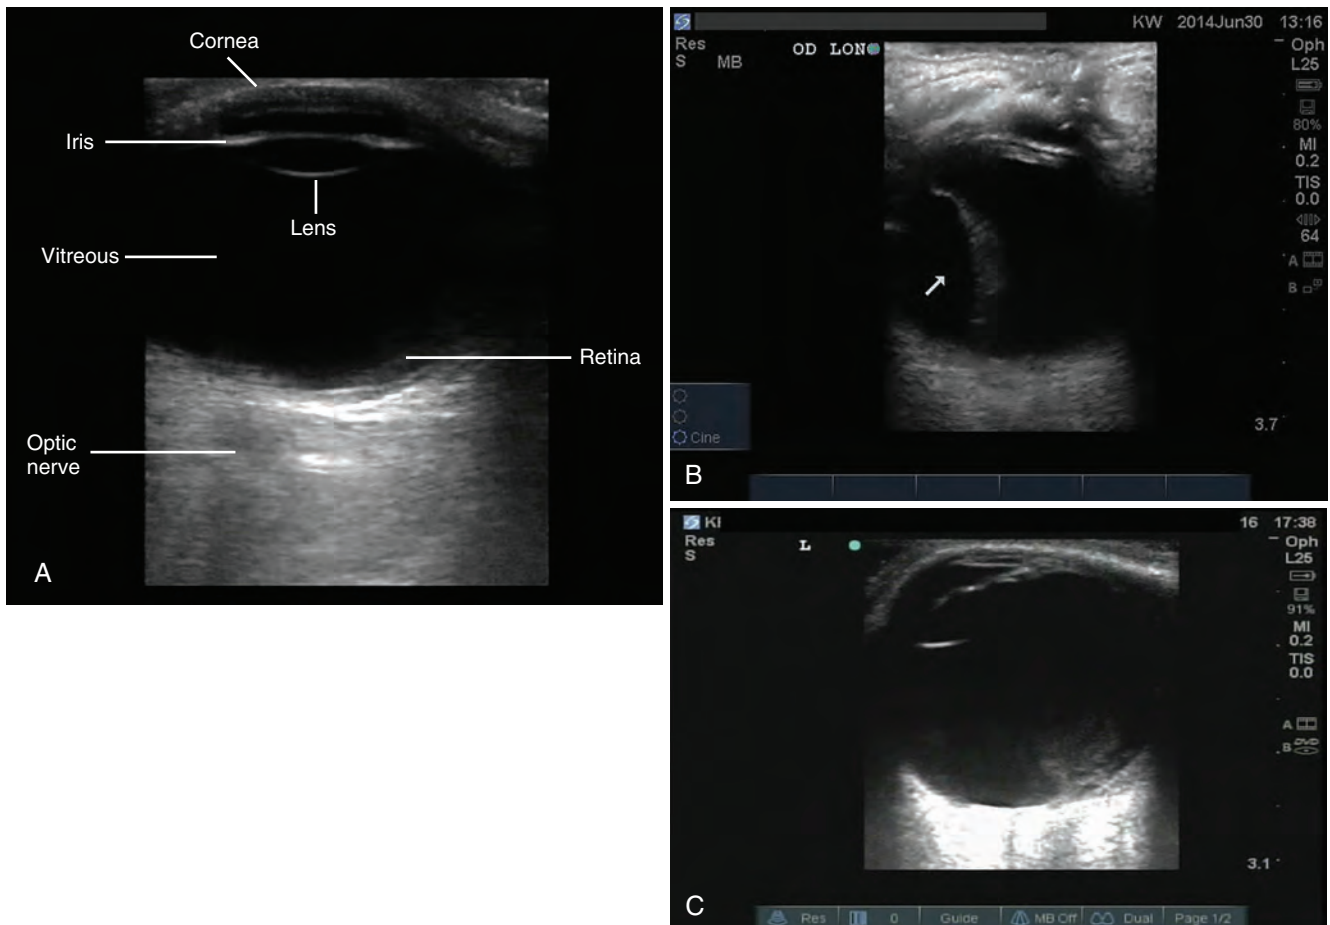

Figure 62.19 A, Normal anatomy is easily identified. Findings shown include: B, Retinal detachment, C, Vitreous hemorrhage. (Courtesy Lauren Oliveira, MD.)

Figure 62.20 Optic nerve sheath diameter measurements are shown for a normal eye. (Courtesy Lauren Oliveira, MD.)

Summary

ED bedside ocular ultrasound is a valuable technique that can be used by the EP to discover important findings in the ED setting. It offers significant advantages for evaluation of ocular and central nervous system complaints, and it is particularly applicable to a possible open globe injury. It can be performed reliably at the bedside by EPs trained in its use.

OCULAR FB REMOVAL

Patients with an external FB in the eye are frequently seen in EDs. They are often in pain and desperate for help. Maintain a high degree of suspicion for FB injuries and perforation of the eye because such injuries may be occult and not readily detected. Not all FB injuries are associated with pain. Glass embedded in the cornea may be particularly difficult to detect. This section reviews procedures for locating and removing extraocular FBs and for appropriate postprocedural care. Finally, a brief discussion covering evaluation of the eye for potential perforation of the globe and detection of the presence of an intraocular FB is provided.

Indications and Contraindications

Extraocular FBs must always be removed. The timing of removal and the technique required vary according to the patient's clinical status and the type of injury. For the most part, the emergency clinician can proceed directly to removal of the object via the techniques described in this section. When the patient is extremely uncooperative (e.g., an intoxicated patient, a mentally deficient patient, or a young child) or when the injury is complicated (e.g., deeply embedded object, multiple foreign objects from a blast injury, or possible globe penetration), consult ophthalmology immediately. A patient with a suspected FB or abrasion after exposure to a projectile (e.g., grinding wheel, hammering, metal objects colliding) should be rigorously evaluated for the presence of a deep intraocular

Figure 62.21 Metallic intraocular foreign body. Ultrasound shows a foreign body on the surface of the retina (*short arrow*). Note the marked shadowing just posterior to the foreign body (*long arrow*). (From Ryan SJ, Hinton DR, Schachat AP, et al, editors: *Retina*, ed 4, St. Louis, 2005, Mosby.)

FB. See further discussion later in this chapter. A penetrating injury of the cornea is of particular concern because the iris tissue may prolapse and have an appearance similar to a corneal FB (see Fig. 62.14). Hence, in addition to the history of projectile exposure, an irregular pupil, especially a pear-shaped pupil, should alert the clinician that a penetrating injury might have occurred.

Equipment

The following equipment is necessary for removal of an extraocular FB:

- Topical anesthetic, such as 0.5% proparacaine
- Sterile cotton-tipped applicators
- Fluorescein strips
- Magnification: loupes plus a Wood's lamp, Eidolon Bluminator ophthalmic illuminator, or slit lamp
- Eye spud or 25-gauge needle attached to a 1- or 3-mL syringe or to the tip of a cotton-tipped applicator
- Dilator drops, such as 5% homatropine
- Antibiotic ointment, such as erythromycin

Consideration of an Intraocular FB

When examining a patient with an ocular FB sensation, always remain cognizant of the potential for an intraorbital or intraocular FB. Penetrating injuries represent a greater threat to visual loss than an extraocular FB does and can be disastrous if overlooked. Note that an intraocular FB can be deceptively subtle on initial evaluation. Bedside ED ultrasound is a useful adjunct for identification of intraocular FBs (Fig. 62.21).

The clinical findings are most helpful in determining which patients are at risk for a penetrating injury to the globe. An individual who complains of an FB sensation in the absence of trauma or one whose history is simply that something “fell” or “blew” into the eye is at low risk for perforation of the globe. Conversely, there is a greater probability of globe penetration in an individual who has sustained a high-velocity wound to the eye (e.g., drilling, hammering, grinding metal, blasting rock). The presence of any of the following findings on physical examination should alert the clinician to a probable intraocular FB: irregular pupil, shallow anterior chamber on

Figure 62.22 Computed tomography scan showing a right intraocular foreign body (a BB pellet, *arrow*). (From Marx JA, Hockberger RS, Walls RM, editors: *Rosen's emergency medicine: concepts and clinical practice*, ed 7, St. Louis, 2009, Mosby.)

slit lamp examination, prolapsed iris, positive Seidel test (see earlier section on [The Fluorescein Examination](#)), focal conjunctival swelling, hemorrhage, hyphema, lens opacification, and reduced intraocular pressure (IOP). Do not perform tonometry if penetrating injury to the globe is suspected. Be aware that a penetrating injury may not be associated with eye pain. If there is strong historical evidence and physical findings to support a diagnosis of globe penetration, obtain emergency ophthalmologic consultation.

An intraocular FB is often not visible on direct ophthalmoscopy. Although orbital radiography for radiopaque objects and ultrasonography of the globe have been used for indirect FB localization,^{31,56} computed tomography of the orbit is considered the most useful technique ([Fig. 62.22](#)).^{58,59} When plain orbital radiography is performed to look for an intraocular FB, be aware that an eyelid FB may mimic an intraocular FB.⁶⁰ Patients with a suspected metallic FB should not undergo magnetic resonance imaging if the FB may be intraocular. Therapy for intraocular and intraorbital FBs must be individualized. Frequently, an ophthalmologist can localize an intraocular FB (if the vitreous is clear) with indirect ophthalmoscopy. The role of the emergency clinician is to suspect the diagnosis, protect the eye from further harm, and obtain ophthalmologic consultation. The remainder of this section addresses the problem of extraocular FBs.

Procedure

FB Location

The first step is to locate the FB. Apply a drop of topical anesthetic to the inside of the lower lid as described previously (see [Fig. 62.7A](#)). The presence of vertical corneal abrasions from FBs under the lids is helpful in localizing these hidden foreign objects (see [Fig. 62.8](#), *plate 7*). Use a penlight and loupes or a slit lamp to examine the bulbar conjunctiva by having the patient look in all directions. Examine the inside of the lower lid by pulling it down with the thumb while asking the patient to look up. Evert the upper lid by asking the patient to look down as the end of an applicator stick is pressed against the superior edge of the tarsal plate of the upper lid. Meanwhile, grasp the lashes and pull down, out, and then up to flip the eyelid over ([Fig. 62.23](#)).

Minute FBs under the lid may be missed with simple visual inspection. Ideally, examine the everted lid under magnification with loupes or a slit lamp. With simple lid eversion, it is still not possible to see the far recesses of the upper conjunctival fornix. Although double eversion of the upper lid is helpful, the best way to rule out an FB in the upper fornix is to sweep the anesthetized fornix with a moistened applicator as the upper lid is held everted. Examine the tip of the applicator for removed foreign material. Small conjunctival FBs not hidden by the lids are often best removed with a moistened nasopharyngeal swab (e.g., nasopharyngeal Calgiswab [Puritan, Guilford, ME]).

Reexamine the cornea. Most corneal FBs have an area of fluorescein staining around them. Use a slit lamp or other magnification device such as the Bluminator (Eidolon) to make the examination easier. If the clinician is limited to loupes and a penlight, shine the light diagonally on the cornea to locate the FB. With a history of a high-speed projectile hitting the eye, rule out an intraocular FB. In the case of a blast injury, multiple FBs may penetrate the eye. If an FB cannot be found on the surface despite a suggestive history, examine the eye for physical evidence of penetration, as discussed earlier. Dilate the pupil and examine the fundus. Though not foolproof, bedside ultrasonography may identify the presence of a metallic FB (sensitivity of 87.5%, specificity of 95.8%, and positive and negative predictive values of 96.5% and 85.2%, respectively).⁶¹ If in doubt regarding an intraocular FB, consider computed tomography and ophthalmologic consultation.

FB Removal

Once an extraocular FB is located, the technique for removal depends on whether it is embedded. Reapplication of topical anesthetic drops may be needed. If the FB is lying on the surface, eject a stream of water from a syringe through a plastic catheter, which will usually wash the object onto the bulbar conjunctiva. Once the FB is on the inner lid or bulbar conjunctiva, gently touch a wetted cotton-tipped applicator to the conjunctiva and the object will adhere to the tip of the applicator. Be aware that overzealous use of an applicator for removing corneal FBs can lead to extensive corneal epithelial injury. A spud device is required for removal of objects that cannot be irrigated off the cornea.

To remove embedded corneal FBs ([Fig. 62.24](#)), use a commercial spud device, a burr drill, a short 25- or 27-gauge needle on a small-diameter syringe (e.g., insulin or tuberculin syringe), or a cotton-tipped applicator. Use the applicator or syringe as a handle for the attached needle. Contrary to what one might expect, it is difficult to penetrate the sclera or the cornea with a needle, especially when it is applied tangentially to the cornea.⁴⁷ As with removal of conjunctival FBs, anesthetize the eye. Position the patient so that the head is well secured (preferably in a slit lamp frame). At this point, provide a simple explanation of the procedure, which usually ensures excellent compliance on the part of the patient. Rest your hand on the patient's cheek so that unexpected movements by the patient will not result in large movements of the removal device. Instruct the patient to gaze at an object in the distance (e.g., the practitioner's ear when a slit lamp is used) to further stabilize the eye. Bring the removal device close to the eye under direct vision; then while it is in focus, manipulate it under the magnification device (e.g., Wood's lamp, Eidolon Bluminator ophthalmic illuminator [see [Fig. 62.8](#)], or slit lamp) to remove the FB. Hold the device tangential to the globe, and pick up or scoop out the foreign

Lid Eversion and Foreign Body Removal.

1 To evert the upper eyelid, place a cotton-tipped applicator against the superior edge of the tarsal plate.

2 Grasp the eyelashes and pull them down, then out, and then up and over the applicator.

3 Hold the everted lid in place with the applicator. Use a second applicator to sweep the interior surface of the lid.

4 This patient complained of an FB in the eye despite irrigation. Lid eversion revealed a small speck (arrow) under the upper lid. This could cause a cornea abrasion characterized by vertical striations (see Fig. 62.7, plate 7).

5 The foreign body was easily removed (arrow) by touching it with a moistened cotton-tipped applicator.

6 This patient had a swollen and tender upper eyelid thought to be secondary to a sty. With lid eversion, a small pustule (arrow) was found under the upper eyelid.

7 With a 27-gauge needle, the pustule was incised and a drop of pus was expressed; she made a rapid and uneventful recovery.

Figure 62.23 Lid eversion and foreign body (FB) removal.

Corneal Foreign Body Removal

1 This embedded corneal FB is readily seen under slit lamp examination. A removal device (needle, spud, or bur drill) should be used for careful removal. A rust ring will remain if the FB has been there for only a few hours.

2 Rust rings (*arrow*) are retained FBs and are removed in a similar manner. Most rust rings should be removed, but there is no urgency. Small ones out of the line of sight may remain. A bur drill can be used for attempted removal, which if unsuccessful, can be reattempted in 24 hours. Alternatively, a small needle can be used to loosen the edges and then the ring scooped out. Both procedures will leave a corneal abrasion.

3 Under direct vision (not looking through the slit lamp), bring the syringe close to the eye while resting the hand on the patient's cheek. Be sure that the patient's forehead maintains continual contact with the crossbar on the slit lamp.

4 While looking through the slit lamp, bring the needle to the cornea and remove the FB.

5 Hold the side of the instrument (drill bit or beveled edge of the needle) tangential to the cornea.

6 A variety of instruments may be used for FB removal, including an eye spud (A), a cotton-tipped applicator (B), and a 25- or 27-gauge needle on a tuberculin syringe (C).

Figure 62.24 Corneal foreign body (FB) removal.

object. If a bur drill is used, press the side of the drill against the FB until removal is accomplished.

During removal, rest your hand against the patient's face. It may also be helpful to brace the elbow with a pad or half-full tissue box to provide further support for the arm while removing the FB. If right-handed, place the lower part of your hand against the left maxillary bone when removing a foreign object from the patient's left eye and against the bridge of the patient's nose or infranasal area when removing an object from the right eye. If left-handed, reverse these positions. Using loupes or a slit lamp for magnification is highly recommended to minimize further injury during removal. In particular, corneal contact with the spud device is more readily discerned when magnification is used. Only topical anesthesia is required to remove FBs from the cornea. Although patients may feel pressure during removal of FBs, pain should not be felt after the eye is anesthetized.

Rust Rings

A common problem with metallic FBs is that rust rings can develop (see Fig. 62.24, plate 2). They can develop within hours because of oxidation of the iron in the FB. There are two preferred techniques for removal of a rust ring. The most direct technique is to remove the ring at the same time as the FB, either with repeated picking away with a needle, spud device, or with a rotating bur. The second approach is to let the iron of the rust ring oxidize and kill the surrounding epithelial cells during a 24- to 48-hour period. After that, the rust ring will be soft and often comes out in one solid plug.⁶² Generally, a small rust ring produces little visual difficulty unless it is directly in the line of sight. If large, a rust ring may delay corneal healing. Close follow-up is important to ensure healing of the cornea and total removal of the rust ring and FB.

Multiple FBs

If multiple FBs are present in the eye, such as from an explosion, refer the patient to an ophthalmologist. One technique that may be chosen by the ophthalmologist is to denude the entire epithelium with alcohol and remove the superficial FBs. The deeper ones gradually work their way to the surface, sometimes years later.

Aftercare

After removing the FB, an antibiotic ointment is frequently instilled. Though commonly used, the value of the ointment for superficial corneal defects after removal of an FB is unproved, and no specific standard of care is supported by scientific evidence. Contrary to previous techniques, conjunctival and corneal abrasions do not need patching. Data suggest that eye patching offers no benefit in healing corneal abrasions secondary to FBs.⁶³ If a superficial injury is sustained from the FB, instruct the patient to return only if the eye does not feel completely normal or if there is any blurred vision. The majority of superficial injuries heal without difficulty. The patient should be warned that the FB sensation might return temporarily when the anesthetic agent wears off. One animal study involving direct ocular exposure to *Clostridium tetani* organisms suggested that nonpenetrating ocular injuries are unlikely to lead to tetanus.⁶⁴ Tetanus prophylaxis after corneal

FB removal is not standard, but it should be considered. However, tetanus prophylaxis appears to be essential for injuries that penetrate through the cornea or sclera.

Complications

Complications associated with ocular FB removal are rare. The most frequent problem is incomplete removal of the FB. In such cases the epithelium has difficulty healing over the affected area, and thus the eye stays inflamed. Eventually, the diseased epithelium either sloughs off and heals or heals over the FB remnants, which are gradually absorbed. In either case, adverse effects on the eye are minimal; a minute scar on the cornea, even directly in the center, will rarely affect vision. Nonetheless, incomplete removal of a corneal foreign object warrants ophthalmologic follow-up.

Conjunctivitis may develop after removal of an extraocular FB. In most cases the bacteria producing the infection are introduced by the patient rubbing the irritated eye.

Although perforation of the globe by the clinician's spud device is theoretically possible, this complication is exceedingly rare. Treatment of this type of corneal puncture wound consists of antibiotics, placement of an eye shield, and ophthalmologic consultation. In the absence of resultant endophthalmitis, permanent sequelae are unlikely to develop.

Epithelial injury can occur when cotton-tipped applicators are used to vigorously remove corneal FBs. Indeed, the use of cotton-tipped applicators for embedded corneal FB removal is condemned.

Summary

Ocular FBs are one of the most common eye emergencies. Searching for and removing the FB is usually straightforward. The only real trap is missing an intraocular FB. This must be ruled out if there is a history of a high-speed projectile hitting the eye or if the findings on physical examination suggest globe penetration.

EYE PATCHING

Patching the lids shut has traditionally been the last step in the treatment of a number of common eye emergencies; however, multiple studies have shown that eye patching offers no benefit in pain relief or healing rates in patients with conjunctival or corneal abrasions.⁶⁵⁻⁶⁷ A meta-analysis of studies on eye patching and corneal abrasions or ulcers showed that patching might actually slow healing rates and patients might actually have worsening of their pain. This was found to be true in children as well.⁶⁸⁻⁷⁰ Patching is also contraindicated in contact lens wearers and in situations in which the abrasion or ulcer may be infected.⁶⁶ In summary, eye patching is no longer indicated and might actually worsen the ophthalmologic process that it once was thought to help. Application of a therapeutic bandage contact lens directly to the cornea has been recommended as a possible treatment of corneal epithelial defects. Evidence from several small studies suggests that a bandage contact lens is safe, effective, and well tolerated and allows a significant number of patients to immediately resume their regular activities while maintaining baseline visual acuity. Further study on the application of this modality in the ED setting is needed.^{12,71-73}

CONTACT LENS PROCEDURES

An estimated 24 million Americans wear a form of contact lenses.⁷⁴ Removal of these lenses in the ED may be required to permit further evaluation of the eye or to prevent injury from prolonged wear. Emergency clinicians also evaluate patients for “lost” contact lenses, which may be trapped under the upper lid. At times, patients may request that the clinician remove a lens that they have failed to extract from the cornea. Corneal ulcers can occur in patients who wear contact lenses and may require prompt treatment. This section on contact lens procedures addresses these concerns and discusses injuries associated with attempts at removal, the mechanism of injury from prolonged wear, and instructions to be given to patients at discharge. Furthermore, this section introduces the use of bandage contact lenses for the treatment of acute corneal abrasions.

The first contact lenses were scleral lenses made of glass. These lenses, which covered the cornea as well as much of the surrounding sclera, are reported to have been in use from 1888 to 1948.⁷⁵ Glass corneal lenses (sitting entirely on the cornea) made by the Carl Zeiss Optical Works of Jena were first described in 1912. A practical synthetic scleral lens using methyl methacrylate rather than glass was discussed by Obrig and Mullen in 1938.^{76,77} In 1947, Tuohy redeveloped the corneal lens with methylmethacrylate.⁷⁸ This was the forerunner of the current hard contact lens.⁷⁸ The development of lenses made of soft gas-permeable polymers was reported in Czechoslovakia in 1960.⁷⁹ These hydrogel (hydrophilic gelatinous-like) lenses have evolved into today’s soft contact lenses. Soft contact lenses now come in a variety of types, including extended and daily wear. The majority of soft contact lenses in use are now disposable. Soft contact lenses have been used therapeutically by ophthalmologists for decades.⁸⁰

Corneal Injury From Contact Lens Wear

Hard Contact Lenses

Oxygenation of the cornea is dependent on the movement of oxygen-rich tears under hard contact lenses during blinking. During the “adaptation” phase of early wear, a wearer of hard contact lenses produces hypotonic tears as a result of mechanical irritation from the lens.⁷⁶ This results in corneal edema, which reduces subsequent tear flow under the lens during blinking. Overwearing a lens at this time leads to corneal ischemia, with superficial epithelial defects found predominantly in the central corneal area (see Fig. 62.9), where the least tear flow occurs. With adaptation, the tears become isotonic and the blinking rate normalizes, thus permitting increased wearing time. During early adaptation, blinking is more rapid than normal and then slows to a subnormal rate during late adaptation. Mucous delivery to the cornea in the tear film may also play an important role in maintaining corneal lubrication. Tight-fitting contact lenses may never permit good tear flow despite an adaptation phase; individuals with tightly fitted lenses may never be able to wear their original contact lenses for longer than 6 to 8 hours. Lenses that are excessively loose can also cause irritation by moving during blinking. Rough or cracked edges can cause corneal abrasions.

In the ED, a patient with eye irritation caused by prolonged contact lens wear may be either a new or an adapted wearer. An adapted wearer may have been exposed to chemical irritants (e.g., smoke), which reduces the tonicity of tears and leads to

corneal edema and decreased tear flow. Alternatively, an adapted wearer with irritation may have ingested sedatives (e.g., alcohol) or may have fallen asleep wearing the contact lenses, thus decreasing blinking and tear flow. Another possibility is that the patient may actually be wearing tight-fitting contact lenses that have never allowed true adaptation despite many months of wear.

A patient with overwear syndrome usually awakens a few hours after removing the lenses. The patient experiences intense pain and tearing similar to that caused by an FB. The delay in onset of the symptoms until after removal of the lenses is caused by a temporary corneal anesthesia produced by the anoxic metabolic by-products that build up during extended lens wear.⁸¹ A second factor is the slow passage of microcysts of edema, which are pushed up to the corneal surface by mitosis of the underlying cells. When the cysts break open on the surface, the corneal nerve endings are exposed.⁸²

Most patients with overwear syndrome can be managed with reassurance, frequent administration of artificial tears, oral analgesics, and advice to “wait it out” in a darkened room. In the past some patients required patching for comfort. A patient who has experienced no problems with contact lenses before an overwear episode can return to using the lenses after 2 or 3 days of wearing glasses but should be advised to build up wearing time gradually. A patient who was having chronic problems with lens comfort before the episode should check with an ophthalmologist before using the contact lenses again.

Soft Contact Lenses

Although the cornea is also oxygenated by way of the tear film with soft contact lenses, only approximately one-tenth of the flow behind the lens that occurs with a hard lens is present during soft contact wear.⁷⁵ The high degree of lens gas permeability permits the majority of oxygenation to occur directly through the lens. A hydrogel lens is more comfortable than a hard contact lens because lid motion over the lens is smooth. The minimization of lid and corneal irritation allows a more rapid adaptation phase because the initial reflex-induced changes in tearing and blinking are reduced. Nonetheless, the lenses may still lead to corneal edema and secondary hypoxic epithelial changes if worn for an excessive period when blinking is inhibited. Some individuals can tolerate the lenses for extended periods and may on occasion sleep with the contact lenses in place, although this practice is not encouraged. Newer extended-wear hydrogel lenses permit wear for up to 1 week without injury. These lenses are not discernible from standard soft lenses on examination.

Although the acute overwear syndrome that occurs with hard contact lenses can also occur with soft lenses, it is infrequent. More commonly, ocular damage from soft contact lenses falls into one of three categories:

1. Corneal neovascularization (Fig. 62.25A). Frequently, the patient is asymptomatic, but on slit lamp examination, fine vessels are seen invading the periphery of the cornea. Refer the patient to an ophthalmologist for refitting with looser or thinner lenses or with contact lenses that are more gas permeable.
2. Giant papillary conjunctivitis (see Fig. 62.25B).⁸³ The patient notes decreased lens tolerance and increased mucous production. On examination of the tarsal conjunctiva (best seen with eversion of the upper lid), large papillae are seen. These papillae appear grossly as a cobblestoned surface. Instruct the patient to discontinue wearing the lenses until

Figure 62.25 Complications from contact lenses. **A**, Corneal neovascularization. **B**, Giant papillary conjunctivitis. **C**, Corneal ulcer. See text for details. (A, From Friedman NJ, Kaiser PK, Pineda A: *Massachusetts Ear & Eye Infirmary Illustrated Manual of Ophthalmology*, ed 3, Philadelphia, 2009, Saunders. B, from Krachmer JH, Mannis M, Holland E, editors: *Cornea*, ed 3, St. Louis, 2010, Mosby. C, from Yanoff M, Duker JS, editors: *Ophthalmology*, ed 3, St. Louis, 2008, Mosby.)

the process reverses and to see an ophthalmologist to have the lenses refitted.

3. Sensitivity reaction to contact lens solutions (usually thimerosal or chlorhexidine).^{84,85} Diffuse conjunctival infection and sometimes superficial keratitis develop. Advise the patient to switch to preservative-free saline with the use of heat sterilization. Frequently, the contact lenses will need to be replaced before lens wear can be resumed.

All these problems with soft lenses have a bilateral, subacute onset and do not require emergency treatment. The only form of ocular damage associated with soft contact lenses that is a true emergency is a bacterial or fungal corneal ulcer (often

Pseudomonas or *Acanthamoeba* with soft contact lenses) (see Fig. 62.25C).⁸⁶⁻⁸⁸ Because the nature of soft contact lenses is to absorb water, they can also absorb pathogens, which then can invade the cornea, especially if the soft lens is worn continuously for extended periods. The patient has a painful, red eye with associated discharge and a white infiltrate on the cornea. Immediately consult an ophthalmologist for appropriate culturing and antimicrobial treatment. These infections can permanently affect the patient's visual acuity.

Indications for Removal

Remove a contact lens in the following situations:

1. Contact lens wearer with an altered state of consciousness. The emergency clinician should always be aware that a patient with a depressed or acutely agitated sensorium might be unable to express the need to have the contact lenses removed. Furthermore, it is likely that patients with a depressed sensorium will have decreased lid motion. During the secondary survey of these patients, identify the presence of the lenses and arrange for their removal and storage to prevent harm from excessive wear or possible accidental dislodgment at a later time. Without magnification, soft contact lenses may be difficult to see. Examine the eye with an obliquely directed penlight to reveal the edge of the soft lens 1 to 2 mm from the limbus on the bulbar conjunctiva.
2. Eye trauma with lenses in place. After measurement of visual acuity with the patient's lenses in place, remove them and perform a more detailed examination of the cornea. Fluorescein may discolor hydrogel lenses; when possible, remove extended-wear lenses before using this chemical. After the dye is instilled, flush the eyes with normal saline. Advise the patient to wait at least 1 hour before reinserting the lenses.¹² The availability of single-use droppers of 0.35% fluorexon (Fluoresoft, Alden Optical, Lancaster, NY) has permitted safe staining of eyes when soft lenses are to be worn immediately after the examination. Limited eye irrigation after the use of fluorexon drops is still recommended before the reinsertion of soft contact lenses.
3. Inability of the patient to remove the contact lens. A patient may have a hard contact lens that cannot be removed because of corneal edema from prolonged wear. Alternatively, the patient may have a "lost" contact lens believed to be located behind the upper lid. Because there is no urgency for removal of the contact lens in the out-of-hospital setting, it can wait until the patient has been evaluated by a clinician.

Contraindication to Removal

The only major problem with contact lens removal occurs when the cornea may be perforated. In this case the suction cup technique of removal, described later, is preferred.

Procedure

Hard Contact Lens Removal

A number of maneuvers have been devised for removal of a corneal lens. One technique is to first lean the patient's face over a table or a collecting cloth. Pull the lids temporally from the lateral palpebral margin to lock the lids against the edges of the contact lens. Ask the patient to look toward the nose and then downward toward the chin. This movement works

the lower eyelid under the lower edge of the lens and flips the lens off the eye. The technique requires a cooperative patient because the clinician must pull the patient's lids tightly against the edge of the contact lens. The movement of the patient's eye then flips the contact free.

In an unresponsive patient in the supine position, modify the technique. Take a more active role in lid movement by using the following procedure (Fig. 62.26A). Place one thumb on the upper eyelid and the other on the lower eyelid near the margin of each lid. With the lens centered over the cornea, open the eyelids until the margins of the lid are beyond the edges of the lens. Then press both eyelids gently but firmly on the globe of the eye and move the lids so that they are barely touching the edges of the lens. Press slightly harder on the lower lid to move it under the bottom edge of the lens. As the lower edge of the lens begins to tip away from the eye, move the lids together, which allows the lens to slide out sufficiently so that it can be grasped. Remember to use clean hands (and preferably wear examination gloves that have been rinsed in tap water or saline) when removing the lens.

Alternatively, move the lens gently off the cornea with a cotton-tipped applicator to guide the lens onto the sclera. Force the tip of the applicator under an edge of the lens and flip the contact loose. Apply topical anesthetic when using an applicator if the patient is awake. Take care with this technique to avoid contact of the applicator with the cornea when the lens is moved off the eye. Perhaps the easiest technique is to use a moistened suction-tipped device and simply lift the lens off the cornea (see Fig. 62.26B).

Scleral lenses (hard contact lenses that cover both the cornea and an amount of the sclera) can be removed by an exaggeration of the manual technique described earlier (see Fig. 62.26C). Elevation of the lens with a cotton-tipped applicator or a suction-tipped device is also an effective technique. Soft contact lenses should not be removed with a suction-tipped device because tearing or splitting of the lens might occur.

Soft Contact Lens Removal

With clean hands (preferably using gloves rinsed in saline or tap water), pull down the lower eyelid with the middle finger. Place the tip of the index finger on the lower edge of the lens. Slide the lens down onto the sclera and compress it slightly between the thumb and index finger. This pinching motion folds the lens so it can be removed from the eye (see Fig. 62.26D). Alternatively, use a cotton-tipped applicator (e.g., Q-Tip) instead of a gloved hand. Occasionally, a tight-fitting lens will be difficult to remove. One potential method is the use of topical anesthetic drops, lubricating eye drops (e.g., Refresh Celluvisc [Allergan plc., Dublin, Ireland] lubricant eye drops), and a cotton-tipped applicator to lift the edge of the lens from the limbus. This breaks the seal of the lens on the cornea and allows removal.

Lens Storage

After a contact lens is removed, store it in sterile normal saline solution. Use the patient's own storage container and lens solution if available. A variety of alternative sterile containers are available for use in the ED. Be certain to keep the right and left lenses separate and in appropriately labeled containers. The containers should be kept with the patient until a friend or family member can procure them, or they should be locked up with the patient's valuables.

Evaluation of a "Lost" Contact Lens

A patient may request examination for a "lost" contact lens. The patient may be unsure whether the lens is hidden under a lid, remains on the cornea, or is truly outside the eye. Evaluation of a patient with a lost contact should begin, as should all eye examinations, with measurement of visual acuity. Measure visual acuity preferably with a 20-ft eye chart. Diminished visual acuity in the eye with the lost contact is convincing evidence that the lens is missing. Though transparent, soft contact lenses in proper position are usually seen when viewed closely with loupes or a slit lamp. The lens forms a fine line at the point where it ends on the sclera several millimeters peripheral to the limbus. Hard contact lenses are even more evident as they change in position on the cornea.

If the contact lens is not evident on initial inspection, evert the lids as discussed in the earlier section on Ocular FB Removal (double eversion of the upper lid). If the lens is still not visible, place a drop of topical anesthetic in the eye. Gently sweep the upper fornix with a moistened cotton-tipped applicator while the patient looks toward the chin. If the lens is still not evident even though the patient remains insistent that it is in the eye, perform a fluorescein examination after explaining that the dye will color the lens (permanently). Evert the upper lid again and examine with an ultraviolet light source.

If the lens remains elusive, reassure the patient that a thorough examination was performed and that no object was located under the eyelids or on the cornea. Next, examine the cornea for defects that warrant antibiotic ointment for treatment of corneal abrasion. Follow-up with the patient's eye specialist for a replacement lens and to provide further reassurance is advised. Ask the patient to retrace his movements at the time that the contact began to give trouble or was missed. Check the clothing being worn at that time and look for the lens there. A final possibility is that the patient may have accidentally placed the two lenses together in the same side of the carrying case, thereby causing them to stick together. Take a methodical approach, as outlined earlier, to ensure that no lens remains hidden in the eye.

Complications of Lens Removal

A corneal abrasion can occur during lens removal. It is difficult at times to determine whether the injury was produced by the patient or was a result of removal by the clinician. Fortunately, the corneal injury is generally of a superficial nature and responds well to symptomatic care.

Summary

Contact lens removal is usually simple. Challenging situations include identifying patients at risk for corneal injury from overuse, helping patients who have lost a contact lens in the eye, and providing aftercare instructions for patients with contact lens-related problems.

BANDAGE CONTACT LENSES FOR TREATMENT OF CORNEAL ABRASIONS

Acute corneal abrasions can cause significant pain, limit function, and result in lost days of work. Several studies have shown that bandage contact lenses are very effective in reducing pain

Contact Lens Removal

A. Manual Removal of Hard Contact Lens

1. Separate the eyelids.

2. Entrap the lens edges with the eyelids.

3. Expel the lens by forcing the lower lid under the inferior edge of the lens.

C. Removal of a Hard Scleral Lens

1. Separate the eyelids.

2. Force the lower lid beneath the edge of the scleral lens by temporal traction on the lower lid.

3. Lift the lens off the eye.

B. Suction Cup Removal of Hard Contact Lens

Use a moistened suction cup to remove a hard contact lens.

D. Removal of a Soft Contact Lens

1. Separate the eyelids and then move the contact onto the sclera with the index finger.

2. Pinch the lens between the thumb and index finger.

Figure 62.26 Contact lens removal. (A, C, and D, From Grant HD, Murray RH, Bergeron JF, editors: *Brady emergency care*, ed, 5, Englewood Cliffs, NJ, 1990, Prentice Hall, p 338. Reproduced by permission.)

without a requirement for narcotic analgesia, in decreasing time away from work, and in returning to baseline functioning when used for uncomplicated acute corneal abrasions.⁸⁹⁻⁹¹ Yet bandage contact lenses are seldom used in the ED. An immediate benefit can be gained when the emergency practitioner selectively uses this treatment modality.

Indications and Contraindications

Bandage contact lenses may be used appropriately as an adjunct for the treatment of acute corneal abrasions resulting from minor trauma when symptomatic relief or rapid return of functionality is desired. Obtain a clear history of an acute traumatic abrasion and a fluorescein stain pattern consistent with this diagnosis.

Bandage contact lenses are contraindicated when the cause of the corneal epithelial defect is suspected to be due to infection. Ensure that a corneal ulcer is not present. The hallmark fluorescein stain pattern consistent with a corneal ulcer is a round stain with blurred margins, commonly in the central visual axis (midpupil region) (see Fig. 62.25C). Pain is disproportionate to the findings. An intense ciliary flush and anterior chamber reaction (cells and flare) may also be present. Avoid the use of bandage contact lenses in patients with a history of soft contact lens use and a nontraumatic abrasion in the central part of the cornea. Follow-up for removal of the bandage contact lenses and reevaluation of the eye are required to confirm improvement and identify complications. Unreliable patients who are not likely to be compliant with follow-up are at increased risk for infection and thus not good candidates for this modality.

Equipment

Hydrophilic bandage contact lenses are available and include, but are not limited to, Biomedics 55 (Ocular Sciences, Inc., San Francisco), -0.50 dioptic power, 8.6 posterior curvature, and 14.2 diameter of the lens, and Acuvue Oasys BC (Johnson & Johnson Vision Care, Inc., Jacksonville, FL), zero power (plano) or -0.50 diopter, 8.4 posterior curvature, and 14.0 diameter. Acuvue Oasys has been approved by the U.S. Food and Drug Administration (FDA) for up to 1 week of continuous wear.

Procedure

Assess and document the pain. Instill 1 drop of a fluoroquinolone ophthalmic solution in the affected eye as prophylaxis against infection at the time of lens placement. Use of topical anesthetics is not required, but they have often been used in the evaluation of abrasions. Use a gloved hand that has been rinsed with water to remove the talc. Orient the contact lens on the tip of the examiner's index finger. Ensure that the lens is not inverted. The normal configuration of the lens resembles a cup, whereas an inverted lens resembles a saucer with its edges flaring outward. Another method to determine orientation of the lens is to try to close the edges or have them meet together with your fingers. If the edges curve away from each other, the lens is inverted. Direct the patient's gaze upward and then pull the lower lid slightly downward while inserting the lens over the cornea. Ask the patient to gently blink and then assess for placement. After a few minutes, reassess and again document whether pain is present. Instruct the patient to return for follow-up in 1 day. On return, remove the soft lens

as described earlier, assess vision, document pain, and reevaluate the eye.

Complications

Because of the hypoxic microenvironment of the cornea, covering the cornea with a bandage contact lens could increase the opportunity for an infection to occur. Patients who do not disclose the use of soft contact lenses are at increased risk for corneal ulcers. Some patients may experience "tight lens syndrome" because of a lens that does not fit well or from drying out as the lens is exposed to the elements. Bandage contact lenses are usually of a generic size and thus do not offer a precise fit, but they are in place only for a short duration. Signs and symptoms of a tight lens may include redness, eye irritation, burning, a dry sensation, blurry vision, halos around objects, and lack of mobility of the contact lens over the cornea. Lack of mobility can reduce oxygen tension and thereby cause corneal edema and an even tighter lens. Rewetting solutions can improve hydration. Removal of a tight-fitting lens was described earlier.

Summary

Bandage contact lenses have been shown to be safe, effective, and comfortable in the treatment of corneal abrasions. Careful patient selection and proper technique will optimize this treatment modality when appropriately indicated for routine ED use. Patients will experience significantly decreased pain without the use of narcotic analgesics, significantly increased functionality, and decreased time away from work.

INFECTIOUS KERATITIS

Infectious keratitis with corneal ulceration can have a variety of causes, and commonly includes overwear of contact lenses. Diagnosis of a corneal ulcer requires the use of a slit lamp and accurate determination of the patient's history. Infectious keratitis is a frequent problem in ophthalmic practice. Herpes simplex is a common corneal pathogen. *Acanthamoeba* is another pathogen particularly associated with contact lens use and exposure to organism-tainted environments. When a patient is seen in the ED with a corneal ulcer, promptly refer the patient to an ophthalmologist. When immediate referral is not possible, obtain telephone guidance from an ophthalmologist for initiation of therapy, and arrange for ophthalmology follow-up within 24 hours.

Patients with herpes simplex keratitis often give a history of previous episodes of the disease. Patients who undergo almost any form of corneal stress may sustain an activation of preexisting corneal disease. Herpes simplex keratitis is classically recognized by its dendritic pattern on fluorescein staining (see Fig. 62.8, plate 9).

Acanthamoeba keratitis is a disease with potentially devastating consequences. Its frequency seems to be increasing, particularly in contact lens wearers, and its pathophysiology is not completely understood. Patients often have a red eye in which the initial bacterial culture results are negative.

Bacterial keratitis occurs in a variety of settings. Organisms range from the relatively common *Staphylococcus* (including methicillin-resistant *Staphylococcus aureus*) or *Streptococcus* to *Mycobacterium*, which can be difficult to identify. A variety of

antibiotics are used against bacterial agents. Ciprofloxacin is a quinolone that has demonstrated efficacy against most of the common causative agents. Bacterial organisms in the cornea can develop resistance to any antibiotic, and resistance to fluoroquinolones has also been observed.⁹² Ideally, treatment follows acquisition of material from the ulcer for culture.

In instances in which a cellular infiltrate is seen on slit lamp examination and there will be a delay of hours before an ophthalmologic consultant can perform the culture, it is prudent to initiate therapy with topical fluoroquinolones such as ciprofloxacin. In such circumstances, obtain corneal samples for culture under the telephone guidance of the consultant before starting the antibiotic. One approach is to lightly touch a culture medium–moistened cotton-tipped swab against the ulcer and then streak standard culture media. If the ulcer is chronic or the patient is immunocompromised, a fungal organism may be the causative agent. Finally, a saline-moistened cotton-tipped swab may be used to obtain a Gram stain of the ulcer. Initiation of therapy before obtaining specimens for culture makes subsequent identification of an organism difficult. For this reason, consider the circumstances of the individual case before initiating treatment.

TONOMETRY

▶ Tonometry (Video 62.4) is the estimation of IOP. It is obtained by measuring the resistance of the eyeball to indentation by an applied force. Prolonged elevated IOP is associated with visual field loss and blindness. A sudden elevation in IOP can result from trauma or primary angle-closure glaucoma. Patients with primary angle-closure glaucoma are often seen in the ED with systemic complaints, including nausea, vomiting, and headache. Occasionally, these patients are surprisingly free of pain in or about the eye. The emergency clinician must determine the IOP and its relationship to the systemic symptoms.

Ophthalmologists depended on tactile estimation of eye pressure until the 1860s, when von Graefe developed the first mechanical tonometer.^{19,29} Applanation tonometry was introduced in 1885 by Maklakoff⁹³ but was not popularized until Goldmann⁹⁴ improved the instrument. Schiøtz⁹⁵ developed an impression tonometer in 1905 and modified it in the 1920s; this form is still in use today. Aside from modifications in configuration, current tonometers closely resemble the devices popularized by Schiøtz⁹⁵ and Goldmann.⁹⁴ Pocket-sized tonometers using the principle of the MacKay-Marg tonometer are available. One such device is the Tono-Pen XL (Reichert Inc, Depew, NY).⁹⁶ These devices are portable, lightweight, and relatively accurate, with built-in provisions for calibration. They have the advantage of a one-time-use replaceable cover that eliminates concern about the possible transmission of an infectious agent. The Icare (Tiolat Oy, Helsinki, Finland) is a rebound tonometer that has recently appeared for use in clinical practice. This device uses a newer technology that calculates IOP from the rebound of a lightweight disposable plastic covered magnetized metal rod that is bounced off the cornea. Its advantages include portability and lack of need for corneal anesthesia, and correlates closely with the Tonopen-XL.^{97,98} Whereas the Schiøtz and Tono-Pen XL tonometers are the most commonly used devices for measuring IOP in the ED, the Icare shows promise to be useful in the ED and primary care settings.

Tonometric Techniques

Four tonometric techniques are reliable and clinically useful for estimating IOP:

1. The impression method uses a plunger (3 mm in diameter) to deform the cornea, and the “indentation” is then measured. This technique was popularized by Schiøtz⁹⁵ and commonly bears his name.
2. The MacKay-Marg method⁹⁹ is a refined version of the impression technique in which smaller amounts of cornea are indented.
3. In the applanation method, a planar surface is pressed against the cornea.
4. Rebound tonometry is an induction-based impact method in which a very lightweight magnetized probe is bounced off the cornea.¹⁰⁰

The Schiøtz tonometer actually measures total IOP (initial pressure plus the pressure added by the weight of the tonometer and the plunger). Friedenwald¹⁰¹ empirically found that a “rigidity coefficient” could be introduced to allow an estimation of the true IOP. One must be aware, however, that calculated conversion tables for Schiøtz tonometers use an average estimate of the rigidity coefficient and hence are not accurate when eye rigidity is altered (e.g., after scleral buckle procedures for retinal detachment or with extreme myopia).

Measurement of IOP in the ED by tonometry is a technique available to most emergency clinicians. Tonometry is not a standard procedure for many eye-related complaints, but in the following special situations, tonometry may be particularly helpful:

- Confirmation of a clinical diagnosis of acute angle-closure glaucoma. For example, a middle-aged or elderly patient with acute aching pain in one eye, blurred vision (including halos around lights), and a red eye with a smoky cornea and a fixed midposition pupil needs a pressure reading (Fig. 62.27A). Sometimes the findings are less dramatic, and sometimes the patient complains mostly of nausea and vomiting, which suggests “flu” rather than an eye disorder.
- Determination of a baseline ocular pressure after blunt ocular injury. Patients with hyphema often have acute rises in IOP because of blood obstructing the trabecular meshwork (see Fig. 62.27B).¹⁰² Later, angle recession can cause a permanent form of open-angle glaucoma. Arts and colleagues¹⁰³ suggested that an IOP greater than 22 mm Hg or a difference of 3 mm Hg or greater between the eyes is a good marker of “ocular injury” in the setting of an orbital fracture.

Tonometry may also be considered in the following scenarios:

- Determination of a baseline ocular pressure in a patient with iritis. Both open- and closed-angle glaucoma, as well as corticosteroid-induced glaucoma, can develop in patients with iritis. Because most cases of iritis are referred, tonometry may also be deferred unless signs of increased IOP are present.
- Documentation of ocular pressure in a patient at risk for open-angle glaucoma. All patients older than 40 years with a family history of open-angle glaucoma, optic disc changes, visual field defects, and pressure of 21 mm Hg or higher should be referred to an ophthalmologist for further workup. Referral should also be made for patients with suspiciously cupped discs who have normal pressure; some of these patients may have “low-pressure” glaucoma associated with

Figure 62.27 Indications for tonometry. **A**, This patient complained of severe headache, nausea, and blurry vision. The eye was obviously inflamed, with corneal edema (note the fragmented light reflex) and a mid-dilated pupil. This is acute angle-closure glaucoma. **B**, Hyphema (layering of red blood cells in the anterior chamber) (*arrow*) in a patient who was struck in the eye with a racquetball. (From Palay DA, Krachmer JH, editors: *Primary care ophthalmology*, ed 2, St. Louis, 2005, Mosby.)

visual field defects. This is usually part of an ophthalmologist's examination.

Contraindications to Tonometry

Tonometry is relatively contraindicated in eyes that are infected unless one is using a device such as the Tono-Pen XL, which uses a sterilized cover.² Sterilize a tonometer before and after applying it to a potentially infected eye. Measure infected eyes with either a noncontact tonometer or a device with a covered tip (e.g., Tono-Pen). Swab the contact portions of any device with alcohol and allow it to dry before use on another eye. Not all viruses are destroyed by cleansing with alcohol. Hydrogen peroxide is effective in deactivating the human immunodeficiency virus (HIV) responsible for acquired immunodeficiency syndrome (AIDS). Ultraviolet sterilization, cold sterilizer bathing of the footplate and plunger, and ethylene oxide sterilization have all been advocated as alternatives to sterilizing the tip of the Schiøtz tonometer. The Schiøtz tonometer may also be used with sterile disposable coverings

(marketed as Tonofilm). Nonetheless, defer measurement of IOP in an obviously infected eye until a subsequent visit to the ED or private clinician unless the red eye demands an immediate determination of IOP.

Examples of indications for immediate tonometry in the setting of a red eye are suspected angle-closure glaucoma (acute onset of redness and pain in the eye with smoky vision, a cloudy cornea, and a fixed pupil in mid-dilation, often with headache and nausea) and iritis (ciliary injection with photophobia), in which secondary angle-closure glaucoma or corticosteroid-induced changes in pressure may occur. Reported cases of conjunctivitis spread by tonometry predominantly tend to be viral infections. Particular effort should be made to avoid use of the instrument on patients with active facial or ocular herpetic lesions or those who may have AIDS.

The presence of corneal defects also represents a relative contraindication to tonometry.^{19,29} Use of a tonometer on an abraded cornea may lead to further injury and is commonly deferred until a subsequent visit. Patients who cannot maintain a relaxed position (e.g., because of significant apprehension, blepharospasm, uncontrolled coughing, nystagmus, or uncontrolled hiccups) are unlikely to permit an adequate examination and can sustain a corneal injury when sudden movements occur during an examination. Furthermore, tonometric examination, with the exception of the palpation technique (through the lids) and the noncontact method, should not be performed on a cornea without complete anesthesia.

Tonometry should not be performed on a patient with a suspected penetrating ocular injury.² Globe perforation may be exacerbated by pressure on the globe with resultant extrusion of intraocular contents. Slit lamp examination can be used for detection of a possible perforation.

Procedure

Palpation Technique

All forms of tonometry are essentially ways of determining the ease of deforming the eye; an eye that is easily deformed has low pressure. The most direct way to do this is simply to press on the sclera through the lids and grossly compare one eye with the other. One can easily distinguish the rock-hard eye of acute glaucoma from the normal opposite eye by this method. Direct the patient to look down without closing the lids. Rest both hands on the patient's forehead and apply just enough digital pressure on the involved eye to indent it slightly with one index finger. With the other index finger, alternately feel and compare the compliance of the other eye (Fig. 62.28, *plate 1*). An experienced examiner is able to estimate IOP within 3 to 5 mm Hg of the actual IOP with the palpation technique, but most emergency clinicians do not have enough experience to trust this method.⁴⁷

Another method is to anesthetize the eyes topically and press a wetted applicator on the sclera of each eye. Again, eye deformation is inversely related to ocular pressure. Rigidity of the globe is also a factor in this crude method of tonometry.

Impression (Schiøtz) Technique

Use of the Schiøtz tonometer requires relaxation on the part of the patient and steadiness on the part of the clinician. After placing the patient in either a supine or a semi-recumbent position, instruct the patient to gaze at a spot directly above the eyes. A spot on the ceiling should suffice; alternatively, patients can stretch their arm up over their head and gaze at

Tonometry: Palpation And Schiøtz Techniques

1 A relatively unskilled examiner can detect the very high intraocular pressure of acute angle-closure glaucoma with tactile tonometry. The examiner rests both hands on the patient's forehead and alternately applies just enough digital pressure on the globe to indent it slightly with one index finger while feeling the compliance of the globe with the other.

2 Before using the Schiøtz tonometer, test it on a flat surface to ensure smooth motion of the device and that the zero line is achieved.

3 Apply lid separation pressure to the bony orbital rims. An assistant may separate the lids while you concentrate on proper placement of the tonometer. Hold the tonometer vertically during use, and rest your hand against the patient's facial bones. After anesthetic drops are instilled, the patient will not experience any pain from this procedure. It is important to have a relaxed patient because squinting and blepharospasm may interfere with the reading. Note: Gloves should be worn.

4 Schiøtz Tonometry*

Tonometer Scale Reading (Units)	Tonometer Weights (g)		
	5.5 (mm Hg)	7.5 (mm Hg)	10 (mm Hg)
2.50	27	39	55
3.00	24	36	51
3.50	22	33	47
4.00	21	30	43
4.50	19	28	40
5.00	17	26	37
5.50	16	24	34
6.00	15	22	32
6.50	13	20	29
7.00	12	18	27
7.50	11	17	25
8.00	10	16	23
8.50	9	14	21
9.00	8	13	20
9.50	8	12	18
10.00	7	11	16

* The table provides estimates of intraocular pressure to the nearest mm Hg for the different weight of the Schiøtz tonometer. Accuracy is most dependable with scale readings greater than 5. If the scale reading is less than 5, use the next highest weight that will give a reading of 5 or more.

Use the above chart to determine the converted reading based on the reading and the amount of weight on the scale.

Figure 62.28 Tonometry: palpation and Schiøtz techniques.

their thumb. Place a drop of topical anesthetic in each eye. After the irritation of the drop passes, allow the patient to blink while blotting the tears away with a tissue. Rubbing the eyes lowers IOP. Reassure the patient that further discomfort will not occur during the procedure.

Ask the patient to keep both eyes wide open and fixed on an object. Separate the eyelids on the side where you are standing. Test the tonometer on a flat surface to confirm smooth movement of the device (see Fig. 62.28, plate 2). Take care to direct pressure onto the orbital rims rather than the orbit

because pressure directed into the orbit falsely raises the reading. Hold the tonometer momentarily over the open eye, and inform the patient that the instrument will block vision in that eye. Instruct the patient to continue to gaze at the fixation point as though the instrument were not there. After the patient relaxes the involuntary muscle contraction that occurs when the instrument is first placed in the line of sight, gently lower the instrument onto the middle portion of the cornea (see Fig. 62.28, plate 3). This is a painless experience for patients with an anesthetized cornea. Vertically align the instrument with the footplate resting on the cornea; the reading should be in midscale. Should the reading be on the low end of the scale (< 5 units), place additional weight on the plunger after the instrument has been removed. Repeat the process as before with the additional weight.

Measure the opposite eye in the same fashion. Use the chart provided to determine the converted reading based on the reading and amount of weight on the scale. Refer to ophthalmology if the converted scale reading is higher than 21 mm Hg (see Fig. 62.28, plate 4). Patients with elevations in IOP of 30 mm Hg or greater require more urgent consultation and initiation of therapy. Associated symptoms or signs of angle-closure glaucoma (primary or secondary) represent an ophthalmologic emergency.¹⁰⁴

Errors With Impression Tonometry

Inaccurate readings can occur with the Schiøtz tonometer for a variety of reasons. Falsely low readings may occur if the plunger is sticky. Check plunger motion and the zero point of the tonometer on a firm test button before use. If the plunger is sticky, clean it with isopropyl alcohol and dry it with a tissue. Inadvertently directing pressure onto the orbit when the lids are held open may elevate IOP and provide a falsely elevated reading. The following eye movements have been found to elevate IOP: closing the lids (increases by 5 mm Hg), blinking (increases by 5 to 10 mm Hg), accommodation (increases by 2 mm Hg), and looking toward the nose (increases by 5 to 10 mm Hg).¹⁰⁵ Repeated or prolonged measurements have been found to lower IOP approximately 2 mm Hg and may also lower pressure in the opposite eye.¹⁰⁶ As mentioned in the introduction to this section, calibration of the Schiøtz tonometer is based on a mean rigidity coefficient. Factors that produce a reduction in ocular rigidity falsely lower the measured pressure. Such factors include high myopia, anticholinesterase drugs, overhydration (e.g., four large cups of coffee or six cans of beer), and scleral buckle operations.^{107,108}

Ocular pressure measurements can vary with ocular perfusion. When measured after a premature ventricular contraction, IOP may be reduced as much as 8 mm Hg.¹⁰⁵ Similarly, decreased venous return as produced by breath holding, the Valsalva maneuver, or a tight collar can increase IOP.¹⁰⁵

Impression (Tono-Pen XL, Tono-Pen AVIA) Technique (Fig. 62.29)

When using these devices, the preparations for testing are similar to those for the Schiøtz device. Encourage the patient to relax, and apply a topical anesthetic to numb the cornea. Ask the patient to stare with both eyes at a distant object during testing. As noted previously, help separate the eyelids but do not apply direct pressure on the globe. One major advantage of using the Tono-Pen is that the patient may be evaluated in any position as long as the device is applied perpendicular to the corneal surface. Another advantage is

that the devices can be used in patients with irregular or high corneal astigmatism.

Ideally, the complete instructions provided with the device should be consulted before each use; however, the following synopsis is provided to help in circumstances in which instructions are unavailable.

First, spray the tip of the probe with compressed gas to clean the mechanism and ensure free movement. Place an Ocu-Film (latex; Reichert) cover snugly (but without tension) over the probe tip.

Calibration

To perform calibration of the Tono-Pen XL (required before use at least once each day), depress and release the activation switch momentarily. The liquid crystal display (LCD) should show a single dashed line “—”. If the device beeps and double dashed lines “= = =” appear on the LCD, push the activation switch again so that “—” reappears. If the previous calibration shows “bAd” on the LCD, a long beep sounds, followed by “CAL” on the LCD. A short beep follows and then the desired “—” is displayed. Once “—” is displayed, hold the probe vertically with the tip pointing straight down. Press and release the activation switch twice in rapid succession. Two beeps will then sound and “CAL” will appear on the LCD. Hold the probe in this position (up to 20 seconds) until a beep sounds and “-UP-” appears on the LCD. Immediately turn the probe 180 degrees so that the tip points straight up. In a few seconds, another beep occurs and the LCD changes. If the LCD reads “Good”, the calibration was successful. If the LCD reads “bAd”, the calibration was unsuccessful.

With an unsuccessful calibration, repeat the calibration steps described earlier until two consecutive “Good” readings are obtained. If further attempts are unsuccessful, loosen the Ocu-Film tip cover and repeat the calibration process. If attempts are still unsuccessful, press the reset button and repeat the process. If still unsuccessful, use compressed air to clean the uncovered tip of the probe and repeat the process. If still unsuccessful, the battery should be replaced and the process repeated. Continued failure warrants a call to Reichert Technical Support at 1-888-849-8955.

The Tono-Pen AVIA (Fig. 62.30) does not require daily calibration but can be “verified” if spurious readings are suspected in a manner similar to the calibration described previously. The procedure is abbreviated, and begins with pressing and holding the activation button for 5 seconds. A beep occurs with each passing second followed by the display showing “dn”. At this point, continue as in the previous instructions for calibration. A properly functioning device will read “Pass”, and will go into the applanation mode with one press of the activation button. Verification should be repeated if a reading of “Fail” is shown.

Measurement

To proceed to measurement, prepare the patient as outlined earlier. Depress and release the activation switch to obtain “= = =” on the LCD. A beep will occur when ready. If the switch is not depressed long enough, the LCD will be blank. If a blank screen is seen, press and release the activation switch again to obtain “= = =” on the LCD. Hold the probe like a pen and touch it to the cornea briefly and lightly. Touch the cornea four times. A click will sound and a reading will appear on the LCD each time that a valid reading is obtained. In the Tono-Pen XL, after four valid readings, a final beep will sound

and the averaged measurement will appear on the LCD. The number represents IOP in millimeters of mercury. The associated bar reflects statistical reliability (a reading $> 20\%$ reflects an unreliable measurement and should be repeated). In the Tono-Pen AVIA, after depressing the activation button, a green light and beep signal that the unit is ready for a measurement. The dual sided LCD display shows “= = =” and the unit can be operated as described earlier. When 10 readings are obtained within 15 seconds, the LCD displays an IOP with a statistical confidence indicator. (Fig. 62.31)

If single dashes (“—”) appear on the LCD after the final beep, too few valid readings were obtained. In such a case, reactivate the probe (without recalibration) and repeat the measurement procedure. If the probe is not reactivated within 20 seconds, the LCD will clear, but the device can be activated as noted previously without recalibration.

The values are interpreted as outlined earlier for the Schiøtz device. Readings may be affected by the same features noted as causes of error with impression tonometry via the Schiøtz device. Store the device with an unused Ocu-Film cover protect-

ing the tip of the probe. As with any device, be familiar with the manufacturer's instructions for use.

Impression/Rebound (Icare) Technique

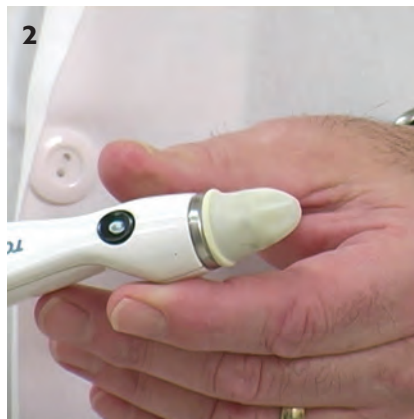

When using the Icare tonometer, the preparations for testing are similar to the Tono-Pen described earlier, except that this device can be used without topical anesthetic drops. Review the user's manual to become familiar with the instructions before use. The following brief synopsis is provided if instructions are not available. Various parts of the tonometer are shown in Fig. 62.32 and referred to in these instructions.

Use of the wrist strap is recommended. Press the measuring button to turn on the device. When the display shows “LoAd”, load the single use probe into the probe base, being careful not to drop the probe out of the tonometer. Again, press the measuring button which will magnetize the probe, preventing it from falling out. The display should then indicate “OO” when the tonometer is ready to use. Align the tonometer with the patient's eye, ensuring that the central groove is in a horizontal position (Fig. 62.33). Keep the tip of the probe at a

Tonometry: Tono-Pen Technique

1 Spray the probe tip with compressed gas prior to use to clean debris away from the tip.

2 Cover the Tono-Pen probe tip with a new Ocu-Film tip cover.

3 Hold the Tono-Pen vertically with the tip pointing down, and press the switch twice in rapid succession.

4 After pressing the switch, 2 beeps will sound and “CAL” will appear on the screen.

5 Wait (up to 20 seconds) until a beep sounds and “-UP-” appears on the screen.

6 Quickly turn the probe so that the tip is pointing straight up.

Figure 62.29 Tonometry: Tono-Pen (Reichert Inc, Depew, NY) technique. IOP, intraocular pressure.

Tonometry: Tono-Pen Technique

7 Wait a few seconds. If the calibration was successful, a beep will sound and “Good” will appear on the LCD screen.

8 Instill a drop of topical anesthetic (e.g., tetracaine 0.5%) into both eyes.

9 Hold the Tono-Pen as you would hold a pencil, and brace your hand against the patient’s cheek for stability.

10 Activate the Tono-Pen by pressing the switch. A beep will sound and “== =” will appear on the LCD screen.

11 Touch the Tono-Pen against the cornea lightly and briefly. Repeat several times; a click will sound every time that a pressure is measured. After four valid readings, a final beep will sound, and the averaged measurement will appear on the LCD.

12 Check the reading on the screen. The number represents IOP in mm Hg. The bar below the number represents the statistical reliability. (A reading > 20% reflects an unreliable reading and should be repeated.)

Figure 62.29, cont’d

Figure 62.30 The Tono-pen AVIA (Reichert Inc, Depew, NY) is designed to fit comfortably in the hand, and has a large dual-sided LCD display.

APPLANATION MODE - USER INTERFACE SEQUENCE OF EVENTS		
	User Interface Ready to Measure	LED On, 1 Beep Ready to Begin IOP Testing (15 seconds for testing before Time Out)
	User Interface Testing Display	LED On During Test, screen shows number of applanations achieved (in this case 4 of 10) Each applanation taken equals 1 Chirp
	User Interface Test Complete	LED Off, 1 Beep Test Complete Patient has an IOP of 16 with a statistical confidence indicator of 95

Figure 62.31 The Tono-pen AVIA (Reichert Inc, Depew, NY) LCD display indicates that the device is ready to measure with double dashed lines (top). During the measuring mode, the display indicates the number of successful measurements (middle). Once 10 measurements are completed successfully, the display will show the IOP (large number) and a statistical confidence indicator (bottom).

Figure 62.32 Various parts of the Icare are shown in this drawing. (With permission Icare USA, Inc; <http://www.icare-usa.com>.)

Figure 62.34 The probe position should be 90 degrees to the frontal plane of the eye so that the probe will contact the central cornea. The distance of the probe to the cornea must be between 4 and 8 mm or 1/6 to 1/3 inch for a successful measurement to occur (with permission Icare USA, Inc; <http://www.icare-usa.com>).

distance from the cornea of 4 to 8 mm, or 1/6 to 1/3 inch (Fig. 62.34). Adjust the forehead support wheel if necessary. To initiate measuring, lightly press the measuring button repeatedly for six measurements. The probe will be activated and bounce off the cornea for each measurement. A video demonstration can be viewed at <https://www.youtube.com/watch?v=YPtDxGmQpFQ>. It is not necessary to look at the LCD display during measurements. A short beep will sound with each measurement and a longer beep will sound and the letter “P” with the IOP shown on the display when the required six measurements are made. If the “P” is blinking, or if there is a dash next to the middle or top of the “P” then a repeat measurement is indicated. A line near the bottom of the “P” indicates a slightly different, but insignificant standard deviation of the combined measurements. A double beep will sound if an incorrect measurement is made. Common reasons for an error code are holding the probe too far away from the cornea and aligning the tonometer incorrectly. Clear the error code by pressing the selector button once, then proceed with further measurements. See instruction manual for additional error codes. Abnormal findings should prompt a repeat measurement. The device will power off if not used after 2 minutes of

Figure 62.33 Note the proper alignment of the device in relation to the patient. The central groove should be in a horizontal position for an upright patient. (With permission Icare USA, Inc; <http://www.icare-usa.com>.)

inactivity, but can be manually turned off by pressing either selector or measuring button once. After the LCD shows “byE”, pressing either button again will turn off the device.

Complications

When tonometric instruments are used properly and reasonable precautions are taken, complications are unusual. An eye with preexisting corneal injury should be spared the additional trauma of tonometer placement. Corneal abrasions can be produced or worsened by ocular movement during testing. In particular, patients with uncontrollable nystagmus, hiccups, coughing, or those who are extremely apprehensive should not be subjected to tonometry. Infection can be transmitted by use of the instrument. Careful cleansing of the device and avoidance of tonometry in patients with obvious conjunctivitis, corneal ulcers, or active herpetic lesions should minimize the risk of spreading the infection to the unaffected eye or to subsequent patients. Although protective coverings can be placed over the tonometer contact, tonometry can usually be postponed in the aforementioned individuals until the risk for infection is minimal. Extrusion of ocular contents with penetrating injuries is a potential, but rare complication.

SLIT LAMP EXAMINATION

The slit lamp is an extremely useful instrument for examination of the anterior segment of the eye. The instrument can reveal pathologic conditions that would otherwise be invisible, such as minor corneal defects, anterior chamber hemorrhage, and inflammation.

Indications and Contraindications

The slit lamp can be used in the majority of eye examinations (Video 62.5). It is especially useful in the ED for the diagnosis of corneal abrasions, FBs, and iritis.⁴⁷ The slit lamp facilitates

Figure 62.35 A portable slit lamp can be used to evaluate patients who cannot tolerate an upright sitting position or cannot be easily moved to the examination chair.

FB removal and is also used in conjunction with most applanation tonometers. Portable slit lamp instruments are readily available (Fig. 62.35) but seldom used in the ED; thus, emergency practitioners generally have access only to a stationary, upright device. Therefore in the absence of a portable device, a slit lamp examination is contraindicated in patients who cannot tolerate an upright sitting position (e.g., those with orthostatic syncope).

Equipment

The slit lamp has three essential components: a binocular microscope mounted horizontally, a light source that can create a beam of variable width, and a mechanical assembly to immobilize the patient's head and manipulate the microscope and light source. The location and arrangement of the knobs that control these components vary in devices made by different manufacturers. Usually, by simply turning each knob and watching the results, one can quickly master a new machine. Fig. 62.36 illustrates the location of the functional controls on one particular instrument.

First, locate the on/off switch for the instrument. Frequently, this switch incorporates or is adjacent to a rheostat that provides two or three different power settings. The lowest setting is adequate for routine examination and will preserve bulb life. One can use a high-intensity setting when examining the anterior chamber with a narrow slit beam. Often, these controls are located on a transformer placed beneath the table to which the slit lamp has been attached. The second knob that one should find is the locking nut for the mechanical assembly. Loosen the nut so that the assembly can be moved relative to the stand.

Make adjustments so that the patient is comfortable while sitting with the head in the device. Ask the patient to press the forehead firmly against the headrest with the chin in the chin rest. By varying the height of the table and height of the chin rest, one should be able to maximize comfort of the patient's neck and back. Adjust the chin rest to align the patient's eye level with the mark on the headrest support rods.

The binocular microscope has a control for varying the magnification. Usually, low powers such as 10 \times or 16 \times are the most useful. Use a higher power to examine the anterior

chamber for cells and flare and when the cornea is examined in minute detail. Adjust the binocular interpupillary distance to match that of the examiner. Focus the eyepieces by moving the instrument forward and backward until the narrowed vertical beam is sharpest on the patient's cornea when viewed with the unaided eye. Then, while viewing through each eyepiece individually, adjust the focus of each to produce a sharp image of the anterior surface of the cornea.

Notice that the light source is mounted on a swinging arm. Find the knobs that adjust the width and the height of the light beam. Click various filters in as needed, usually white and blue filters for standard examination. Alter the angle of the slit lamp beam to vertical from horizontal. The vertical alignment is preferred for routine examinations in the ED.

Both the microscope and the light source are mounted on swivel arms linked at their base to the movable table. Change the position of this table by pushing on any part of it. Use the joystick on the table for finer movements. Vary the height of the microscope and the light source by twisting either the joystick or a separate knob at the base, depending on the design of the instrument.

Procedure

There are three setups that every slit lamp operator must know.¹⁰⁹ The first is for an overall screening of the anterior segment of the eye. For examination of the patient's right eye, swing the light source to your left at a 45-degree angle while the microscope is directly in front of the patient's eye. Set the slit beam to the maximum height and the minimum width using the white light. To scan across the patient's cornea, first focus the beam on the cornea by moving the entire base of the slit lamp forward and backward. Then move the whole base of the mechanical apparatus left and right to scan across the cornea. The 45-degree angle between the microscope and the light source is the default position. The most common mistake is to try to scan by swinging the arm of the light source in an arc; this does not work because the light beam will remain centered on the same point of the patient's eye. Scan across at the level of the conjunctiva and the cornea and then push slightly forward on the base or joystick and scan at the level of the iris. The depth of the anterior chamber is easily appreciated with this low-magnification setup (Fig. 62.37). When the depth of the anterior chamber is reduced, suspect a corneal perforation or a predisposition to angle-closure glaucoma.

Use this basic setup to examine the conjunctiva for traumatic lesions, inflammation, and FBs. Examine the eyelids for hordeolum, blepharitis, or trichiasis. Completely evert the lids (as described in the earlier section on [Ocular FB Removal](#)) in conjunction with the slit lamp examination to permit evaluation of the undersurface of the upper lid for FB retention.

Corneal FB removal can be enhanced by use of the slit lamp. In particular, the instrument allows stabilization of the patient's head. Magnification also minimizes corneal injury during FB or rust ring removal. The upper eyelid may be immobilized with a cotton-tipped applicator, as discussed previously. The clinician's hand can be steadied against the patient's nose, cheek, or forehead or against the support rods of the headrest. The patient should be instructed to stare straight ahead at a fixed light or at the clinician's ear during removal of the FB.

The second setup is essentially the same as the first but uses the blue filter. The purpose is to identify any areas of

Figure 62.36 Slit lamp (BM 900, Haag-Streit, Mason, OH).

Figure 62.37 Slit lamp photograph of a normal left eye under low power. The curved slit of light on the right is reflected off the cornea and the slit on the left is reflected off the iris. The depth of the anterior chamber can easily be appreciated under this low-magnification setup. Note that the light source is on the patient's left side to examine the left eye, with the path of the light going in a temporal-to-nasal direction. (Courtesy D. Price.)

fluorescein staining. After fluorescein is applied, “click” the blue filter into position and widen the beam to 3 or 4 mm. A patient can tolerate a wider beam without photophobia if it is blue. Search for corneal defects (as discussed in the earlier section on [The Fluorescein Examination](#)) with this setup. The blue filter may also be used with applanation tonometry, as discussed in the earlier section on [Tonometry](#).

The purpose of the third setup is to search for cells in the anterior chamber, either the white cells of iritis or the red cells of a microscopic hyphema. Shorten the height of the beam to 3 or 4 mm and make it as narrow as possible. Switch the microscope to high power. Focus the beam on the center of the cornea and then push forward slightly so that it is focused on the anterior surface of the lens. Pull the joystick back again to a focus point midway between the cornea and the lens, where it will be focused on the anterior chamber ([Fig. 62.38](#)). Keep the beam centered over the pupil so that there is a black background. Normally, the aqueous humor of the anterior chamber is totally clear. Small particles seen floating up or down through the beam are usually circulating cells. If the beam lights up the aqueous like a searchlight in the fog, the examiner has found the protein flare that accompanies iritis. Note that fluorescein can penetrate an abraded cornea and produce a fluorescein flare on slit lamp evaluation. To avoid confusion, some clinicians prefer to examine for anterior chamber flare before the stain is used. A variety of conditions evaluated by the slit lamp are pictured in [Fig. 62.39](#).

UNILATERAL LOSS OF VISION

There are a variety of reasons why an individual may sustain complete loss of vision in one eye, but most commonly, such loss is caused by occlusion of the central retinal vein, occlusion of the central retinal artery, or optic nerve damage. Less commonly, pressure on the orbit from a retroorbital hemorrhage may compromise the ophthalmic artery.

Figure 62.38 Appearance of the left eye during examination of the anterior chamber under low power: *a*, corneal epithelium; *b*, corneal stroma; *c*, corneal endothelium; *d*, anterior chamber (potential location of cells or flare); *e*, iris; *f*, lens reflection. The slit of light shines in the temporal-to-nasal direction at a 45-degree angle to the anterior surface of the cornea. The depth of the cornea and anterior chamber examinations are best done under high power in a dark room.

Although discussion of all the potential causes of unilateral loss of vision is beyond the scope of this text, amaurosis fugax deserves special mention. Amaurosis fugax is a transient loss of vision that is most commonly due to cholesterol or platelet emboli from atherosclerotic carotid occlusive disease. When plaques are visualized in the retinal vasculature, auscultate the neck for carotid bruits and consider referring the patient for a more thorough evaluation including ultrasound examination of the carotid artery.^{110,111}

Central Renal Artery Occlusion

A patient with central retinal artery occlusion (CRAO) has generally experienced a recent sudden painless (complete or nearly complete) unilateral loss of vision. On examination, there is an afferent pupillary defect (APD) (i.e., sluggish or nonreactive pupil in the affected eye with direct illumination and a normal consensual response) and reduced visual acuity. Immediately after the event the fundus may appear nearly normal; however, it soon becomes pale and a classic “cherry-red spot” in the macula may be evident as a result of patent choroidal vessels showing through the transparent fovea ([Fig. 62.40](#)).

Therapy

Visual recovery has been noted to occur up to 3 days after CRAO. Start treatment if the patient is seen within 24 hours after the onset of symptoms.¹¹² Consult ophthalmology while initiating therapy. In many centers, CRAO is considered an ischemic event and neurology as well as ophthalmology are often involved in acute management. In some stroke centers, patients with CRAO are admitted to neurology on confirmation of the diagnosis.

Most of the emergency techniques suggested for treating vascular insults to the eye in the ED are theoretically sound but are not supported or refuted by rigorous scientific data. No specific standard of care has been promulgated for these interventions by emergency clinicians. Techniques discussed later are probably safe and possibly useful and may be attempted in an emergency situation. It is unknown whether these interventions will be vision saving.

Slow rebreathing into a paper bag is believed to increase the arterial carbon dioxide level, thus aiding vasodilation, permitting the occlusion to move more peripherally, and possibly

Figure 62.39 Various ocular pathologies. (From Palay DA, Krachmer JH, editors: *Primary care ophthalmology*, ed 2, St. Louis, 2005, Mosby.)

reducing the ischemic area, although its effectiveness and safety in the presence of additional comorbidities has not been well elucidated. In the past, this was often accompanied by digital globe massage, and can certainly be applied without the paper bag rebreathing. Digital massage can be accomplished with the patient lying supine, and applying firm steady pressure with the thumbs to the affected globe over the patient's closed lids. Apply pressure for 5 seconds and then abruptly release it (Fig. 62.41). Immediately repeat this maneuver several more times for up to 20 minutes. The objective of this technique is to help break up the occlusion and encourage movement of it more peripherally.

A more aggressive therapy, generally performed only by ophthalmologists, is anterior chamber paracentesis. In the absence of available consultation, consider this technique when CRAO is recent and unresponsive to the previously described therapeutic approaches. For this procedure, keep the patient supine with the head and eyelids secured. Anesthetize the cornea with topical anesthetic drops (e.g., 0.5% proparacaine drops). Inject the conjunctiva adjacent to the limbus with a 27- or 30-gauge needle until the entire perilimbal area is infiltrated and has the appearance of chemosis in all quadrants. During the remainder of the procedure, ask an assistant to firmly grasp the conjunctiva with toothless forceps at the 3 and 9 o'clock

Figure 62.40 Central retinal artery occlusion with a cherry-red spot in the fovea (arrow). (From Friedman NJ, Kaiser PK, Pineda A: *Massachusetts Ear & Eye Infirmary illustrated manual of ophthalmology*, ed 3, Philadelphia, 2009, Saunders.)

Figure 62.41 To perform digital globe massage, apply firm steady pressure with the thumb on the globe for approximately 5 seconds and then abruptly release the pressure for 5 to 10 seconds. Repeat the process for up to 20 minutes or until improvement in vision is observed.

positions to stabilize the eye. Insert a 30-gauge needle on a tuberculin syringe obliquely just adjacent to the limbus at either the 4:30 or the 7:30 position, and direct it toward the 6 o'clock position to avoid the lens (Fig. 62.42). Apply gentle pressure on the globe and, after 1 to 2 drops of aqueous are expressed, withdraw the needle.^{113,114} As stated earlier, this procedure is best performed by the consultant ophthalmologist rather than the EP. It should also be noted that CRAO can be considered as an acute vascular event near enough to the central nervous system that neurology should be involved as soon as the diagnosis is entered. Some centers will include CRAO as part of a stroke syndrome involving both neurology and ophthalmologic emergent consultations.

One study described a systematic approach in which ocular massage, sublingual isosorbide dinitrate, 10 mg; acetazolamide, 500 mg intravenously; 20% mannitol (1 mg/kg); or oral 50% glycerol (1 mg/kg); anterior chamber paracentesis; methylprednisolone, 500 mg intravenously; streptokinase, 750 kIU; and retrobulbar tolazoline, 50 mg, were given until the visual

Figure 62.42 Anterior chamber paracentesis. After topical and subconjunctival anesthesia (see text), a 30-gauge needle is directed obliquely from the 4:30 or 7:30 position toward the 6 o'clock position to avoid the lens. An assistant stabilizes the globe with forceps and grasps the conjunctiva (see text). *Top*, anteroposterior projection; *bottom*, tangential projection. (Top and bottom, from Knoop K, Trott A: Ophthalmologic procedures in the emergency department: I. Immediate sight-saving procedures, *Acad Emerg Med* 1:408, 1994.)

symptoms improved or all steps were complete.¹¹⁵ Of the 11 patients in this arm of the study, eight had improved visual acuity. In those who improved, all had their symptoms improved in 12 hours or less. The presumed cause was either a platelet-derived or cholesterol embolus from atheroma or glaucoma.¹⁰⁸ Although this study is small, it supports emergency ophthalmology consultation and aggressive treatment of patients seen within 12 to 24 hours of the onset of symptoms.

Complications

Overzealous globe massage has the potential to produce intraocular trauma, including retinal detachment and intraocular hemorrhage. Anterior chamber paracentesis may produce hemorrhage, infection, or mechanical injury to the cornea, iris, or lens.¹¹⁶ Although these complications are rare, ophthalmologic consultation for assistance with the underlying CRAO and surveillance for these potential complications should be initiated on an emergency basis.

Orbital Compartment Syndrome

Acute facial trauma or recent retrobulbar anesthesia may produce retrobulbar hemorrhage with sufficient pressure to compromise the ophthalmic artery and result in an orbital compartment syndrome (Fig. 62.43). A form of posttraumatic glaucoma may also occur when the retrobulbar hematoma forces the globe against the eyelids. In this case, IOP rises precipitously because the globe is in a relatively closed space as a result of the firm attachment of the eyelids to the orbital rim by the medial and lateral canthal ligaments. The optic

Figure 62.43 A, Retrobulbar hemorrhage of the left eye demonstrating proptosis, lid swelling (*short arrow*), chemosis (*long arrow*), and restricted extraocular motility on upgaze. B, Computed tomography scan demonstrating significant proptosis and radiodensity posterior to the left eye (retrobulbar hemorrhage indicated by the *arrow*). The intraocular pressure was measured to be 40 mm Hg and was rapidly lowered to 20 with a lateral canthotomy and cantholysis. Indications for lateral canthotomy and cantholysis include decreased visual acuity, ocular pressure greater than 40 mm Hg, proptosis, afferent papillary defect (Marcus Gunn pupil), cherry-red macula, ophthalmoplegia, optic nerve pallor, and severe eye pain. A ruptured globe is a contraindication.

nerve, its vascular supply, and the central retinal artery are compressed, which can result in ischemia and subsequent visual loss. In this situation, emergency lateral canthotomy may be considered for relief of the pressure on the eye. Although not a commonly performed procedure for many EPs in the proper scenario, it may be a prudent sight-saving intervention.

In this situation, ophthalmoscopic evaluation reveals a blanched ophthalmic artery in the presence of obvious retrobulbar pressure and ecchymosis around the eye. The patient exhibits decreased visual acuity, and an afferent pupil defect is often seen. IOP is markedly elevated but may be relieved by emergency lateral canthotomy and cantholysis. Such a procedure needs to be performed quickly because the ischemic

retina will not retain function if it is deprived of blood for a long period.

Technique: Lateral Canthotomy and Cantholysis (Fig. 62.44 and Video 62.6)

The goals of the procedure are to release pressure on the globe and decrease IOP sufficiently to reinstitute retinal artery blood flow. Because retinal recovery is unlikely to occur if rapid relief of ischemia is not accomplished, taking extra time to clean the eye beyond simple saline cleansing of the lids and lateral canthus must be carefully considered. Stabilize the patient's head and lids and anesthetize the lateral canthus by injecting 1% to 2% lidocaine with epinephrine. Before incising, crush the lateral canthus with a small hemostat for 1 to 2 minutes to minimize bleeding. Incise the canthus with iris or Steven's scissors. Take precautions to avoid injury to the protruding globe. Begin the incision at the lateral canthus and extend it toward the orbital rim. Find the superior and inferior crura of the lateral canthal tendon and release them from the orbital rim. Some operators prefer to release the inferior crus and reassess IOP before considering release of the superior crus. An instructional video of the procedure on an actual ED patient can be found at https://www.youtube.com/watch?v=bUAagMd_Q8A.

Complications

Although hemorrhage, infection, and mechanical injury might result from the procedure, these complications generally respond to therapy better than retinal injury from prolonged ischemia. Emergency ophthalmologic consultation should be obtained, although when the procedure is indicated, it may be considered by the emergency clinician. Lateral canthotomy incisions generally heal without suturing or significant scarring.

REDUCTION OF GLOBE LUXATION

Although luxation of the globe is uncommon, the emergency clinician should be aware of the condition and its mechanisms, know how to reduce the globe, and know when to prioritize ophthalmologic consultation. With luxation of the globe there is extreme proptosis, which permits the lids to slip behind the globe equator (Fig. 62.45). Subsequent spasm of the orbicularis oculi muscles sustains the luxation and limits extraocular movement. Traction on the optic nerve and retinal vessels may produce direct or indirect injury to the optic nerve and retina.

Luxation may be spontaneous, voluntary, or traumatic. A variety of conditions (e.g., orbital neoplasms, Graves' disease, histiocytosis X, cerebral gumma, and craniofacial dysostoses) may predispose the patient to luxation. Triggering events include maneuvers that increase IOP (e.g., the Valsalva maneuver), trauma to the orbit or forehead, or eyelid manipulation.

Indications and Contraindications

Early globe reduction is indicated to relieve symptoms and minimize visual impairment. Attempts at reduction in the ED are relatively contraindicated when there is obvious rupture of the globe.

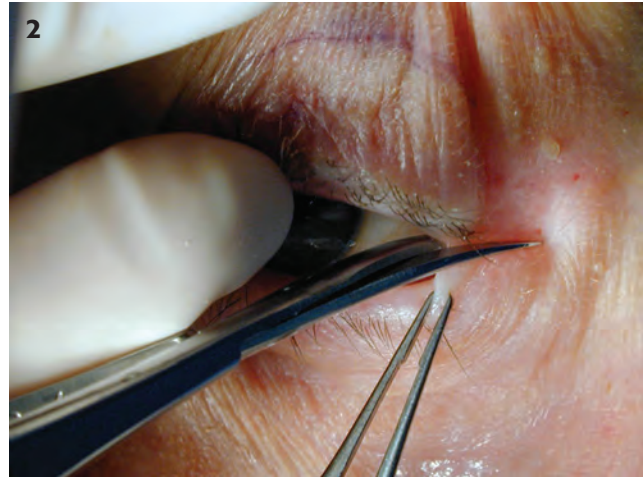

Technique

Before globe reduction, perform a rapid eye examination to document visual acuity, range of eye motion, pupillary reactivity,

Lateral Canthotomy And Cantholysis

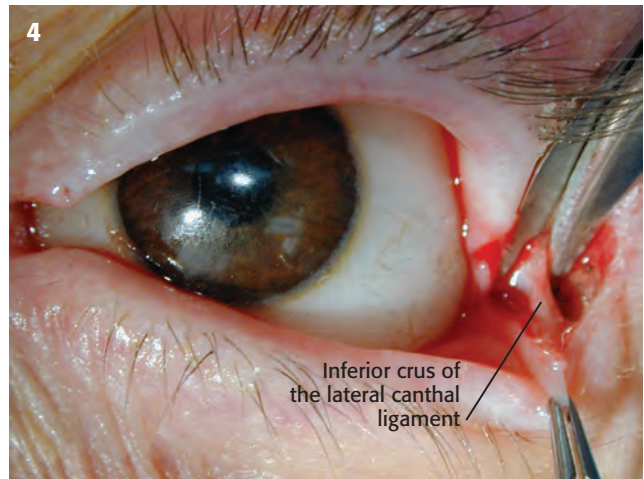

1 Identify the lateral canthus (*arrow*). Cleanse the area with antiseptic and anesthetize with 1% lidocaine with epinephrine. (The left eye is depicted in this image sequence.)

2 Crush the lateral canthus with a hemostat for 1 to 2 minutes to reduce incisional bleeding (not shown). Then, cut through the crushed tissue with iris scissors (as depicted above) to perform the canthotomy.

3 Pull the lower eyelid away from the globe with toothed forceps (*arrow*).

4 “Strum” the tissue under the canthotomy with the scissors to identify the inferior crus of the lateral canthal ligament. Cut through this ligament with scissors to perform the inferior cantholysis. Note that the scissors are directed inferiorly during this step, perpendicular to the canthotomy incision.

5 The eye after canthotomy and cantholysis. This procedure relieves increased intraocular pressure by allowing the globe and orbital contents to move forward.

NOTE:

If intraocular pressure remains elevated after inferior cantholysis, the superior crus of the lateral canthal ligament may be released in a similar fashion.

Figure 62.45 Appearance of a luxated globe. **A**, This globe protruded when the lower eyelid was retracted downward to examine the conjunctiva for anemia. **B**, It was easily reduced with slight manual pressure on the closed upper lid. **C**, Afterward, the patient had no eye or vision complaints. This is a normal variant in some people.

and any evidence of globe rupture (see earlier discussion).¹¹⁷ Place the patient in a recumbent position and administer a topical ocular anesthetic agent (e.g., 0.5% proparacaine). When the lashes are visible, ask an assistant to apply steady outward and upward traction while the globe is gently pushed behind the lids. Use gloved fingers to apply steady scleral pressure and to manipulate the globe back into the orbit. When the lashes cannot be grasped, introduce a lid retractor behind the lid to provide countertraction. Others recommend placing a suture through the anesthetized skin of each lid to provide countertraction.

After the procedure, repeat the eye examination to document visual acuity and extraocular movement. It is not uncommon for return of full visual function to be delayed for several days or occasionally longer.

Complications

It is common with this procedure for lashes to be retained in the conjunctival fornices. Evaluate for and remove any free lashes to prevent corneal injury. Edema, retrobulbar hemorrhage, or orbital deformity may prevent outpatient reduction. When reduction is not possible in the ED, saline drops should be applied to the globe and a noncontact eye shield used.

Aftercare

Patients with spontaneous luxation and no visual impairment in whom the globe is easily reduced warrant follow-up within 24 to 48 hours. Instructions to avoid potential triggering maneuvers should be given. Recurrent luxation may warrant lateral tarsorrhaphy. Further evaluation of potential precipitating factors can be pursued on an outpatient basis.

Patients with traumatic luxation are at greater risk for underlying ophthalmic injury and warrant emergency consultation. A computed tomography scan of the orbit is helpful for evaluating both the soft tissue and the bony structures about the globe.

STYE

A stye, or hordeolum, is an acute purulent inflammation (bacterial infection) of the eyelid characterized by pain, swelling, and redness. It can be quite annoying and painful to the touch. A small nodule or abscess first develops in an eyelid hair follicle or a modified sebaceous gland at the margin of the eyelid. This may be external (pointing at the lid margin) or internal (pointing under the conjunctival lid; Fig. 62.46). An obvious pustule may be seen, and if so, incising it with a small needle and expressing pus produces a faster cure. The lid may be inverted to find a small pustule on the inner surface of the lid that can be nicked with a 25-gauge needle (see Fig. 62.23, plates 6 and 7). *S. aureus* is the organism most frequently isolated from the infection.¹ Treat with warm compresses on the eyelid as frequently as possible. One method is to fill a sink with very hot water and alternate wet washcloths for 15 to 20 minutes. Topical ophthalmic antibiotics (drops every 2 hours or ointment five to six times a day) are usually prescribed. Erythromycin ointment is often suggested. Topical treatment is generally sufficient, but antistaphylococcal oral antibiotics (dicloxacillin, cephalosporins) might occasionally be needed, especially if in patients with significant surrounding lid cellulitis. More formal incision and drainage may be necessary if the infection is unresponsive to conservative therapy.¹¹⁸ Spread of the infection can lead to preseptal cellulitis.

APD OR MARCUS GUNN PUPIL

An APD, or Marcus Gunn pupil, is caused by a variety of diseases of the afferent, or “in-going,” pathways of the eye. It is produced by a *unilateral* lesion of the retina or optic nerve. Causes include optic neuritis (as seen with multiple sclerosis), ischemic optic neuropathy, optic tumor, and retrobulbar hematoma (an indication for lateral canthotomy). To evaluate for an APD, the swinging flashlight test may be used (Fig. 62.47).¹¹⁹ Normally, shining a light in either eye causes bilateral

Figure 62.46 Stye (hordeolum). **A**, External hordeolum. An erythematous, tender swelling at the lid margin points externally. **B**, Internal stye. This may form a pustule on the inner surface of the lid that may be incised and pus expressed (see also Fig. 62.39).

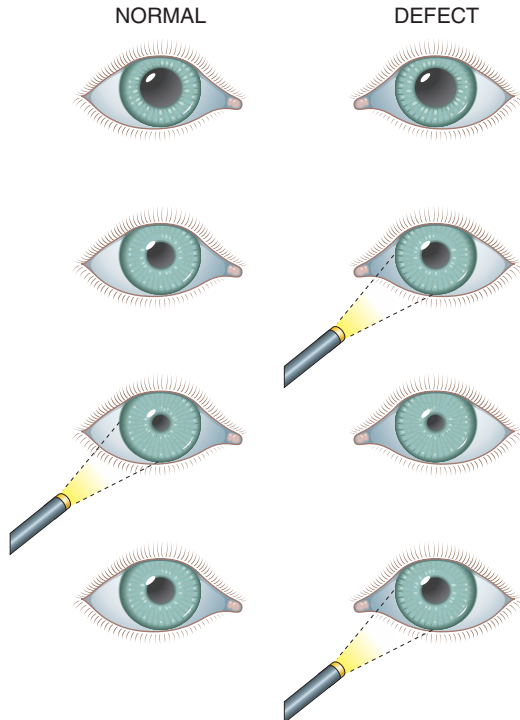

Figure 62.47 Relative afferent pupillary defect (Marcus Gunn pupil). This patient has an abnormal left optic nerve. In ambient light (*top row*), the pupils are equal. As the abnormal eye is illuminated (*second row*), only modest constriction is noted. As the light is swung to the normal eye (*third row*), the pupils constrict briskly. When the light is swung back to the abnormal eye (*bottom row*), paradoxical dilation is noted. (From Friedman NJ, Kaiser PK, Pineda A: *Massachusetts Ear & Eye Infirmary illustrated manual of ophthalmology*, ed 3, Philadelphia, 2009, Saunders.)

Figure 62.48 Subconjunctival hemorrhage. Although very alarming to most patients, a spontaneous subconjunctival hemorrhage or the development after vomiting or coughing is a benign condition; no treatment is indicated. A painless bright red hemorrhage of the sclera is noted. The cornea and anterior chamber are unaffected, and there are no visual symptoms.

pupil constriction. To evaluate for an APD (no light reaching the brain via the optic nerve on the affected side), record the pupil size at baseline. Shine a light into the affected eye. Record the direct response (constriction of the illuminated pupil in response to light) and the indirect or consensual response (constriction of the opposite pupil in response to light). Next, shine the light into the other eye and record the direct and indirect responses. Repeat this procedure back and forth until the pattern of response to light is identified. With an APD, there is a decreased direct response to light along the afferent or in-going pathways, whereas the efferent or “out-going” pathways to the opposite eye are preserved. Thus, light shined into the affected eye will cause neither a direct nor a consensual response, but light shined into the unaffected eye will cause bilateral pupillary constriction.

SUBCONJUNCTIVAL HEMORRHAGE

Subconjunctival hemorrhage may occur spontaneously (often noticed on awakening) or after straining, vomiting, or severe coughing. The patient notices a painless bright red hemorrhage in the eye (sclera). It may be bilateral (Fig. 62.48). Vision is not affected. Although this is concerning to the patient, it is benign. No laboratory evaluation is required unless the patient has taken anticoagulants, in which case clotting studies should be considered. The hemorrhage will disappear spontaneously over a few weeks and turn various colors as it recedes. No treatment will hasten resolution.

ACKNOWLEDGMENT

The authors recognize the many contributions by Jerris R. Hedges, MD, to this chapter through the first five editions of the textbook.

Otolaryngologic Procedures

Ralph J. Riviello

▶ The procedures presented in this chapter are most effectively performed with special equipment and techniques (Videos 63.1–63.10). Some are within the realm of general emergency medicine clinical expertise; others are not. They are reviewed from the perspective of the emergency clinician who must decide whether the patient needs treatment acutely in the emergency department (ED), can be managed with timely referral, or requires urgent consultant expertise.

PHARYNX AND LARYNX

Examination of the Larynx

Visualization of the larynx and pharynx is a critical part of the complete evaluation of patients with complaints of sore throat, hoarseness, foreign body (FB), or stridor.

Anatomy

The pharynx is the part of the throat located posterior to the mouth and the nasal cavity and superior to the esophagus and larynx. It is commonly divided into three sections, the nasopharynx, the oropharynx, and the laryngopharynx (hypopharynx). The nasopharynx is the most cephalad portion and extends from the base of the skull to the upper surface of the soft palate. The oropharynx is behind the oral cavity and extends from the uvula to the level of the hyoid bone. Its anterior wall consists of the base of the tongue and the vallecula; its lateral wall consists of the tonsils, tonsillar fossa, and pillars; and its superior wall is formed by the inferior surface of the soft palate and the uvula. Pharyngeal branches of the ascending pharyngeal artery, ascending and descending palatine arteries, and pharyngeal branches of the inferior thyroid artery supply blood to the pharynx. The pharyngeal plexus and the maxillary and mandibular nerves innervate the pharynx.

The larynx in adults is located in the anterior part of the neck at the level of the C3–C6 vertebrae. It connects the inferior portion of the pharynx (hypopharynx) with the trachea. The larynx extends vertically from the tip of the epiglottis to the inferior border of the cricoid cartilage. It consists of nine cartilages. Branches of the vagus nerve, the superior laryngeal nerve, and the recurrent laryngeal nerve innervate the larynx. The relevant anatomy is depicted in Fig. 63.1.

Laryngoscopy Indications and Contraindications

Laryngoscopy is indicated for the evaluation of patients with complaints of dysphagia or odynophagia. More specifically, it

should be performed in patients complaining of dysphagia, hoarseness, FB ingestion or sensation in the throat, angioedema, and in patients who require assessment of their airway status. In general, laryngoscopy can be used to evaluate a problem, to exclude airway compromise, and to diagnose several other diseases such as gastroesophageal reflux, cancer, and allergy.¹

Laryngoscopy has traditionally been discouraged in patients with impending airway compromise; however, it may be performed carefully in stridulous patients as long as a pre-designated team (usually consisting of an anesthesiologist, otolaryngologist, or another physician skilled in the management of a difficult airway) is readily available and able to intervene if necessary. Care should be taken to avoid accidental trauma to the laryngopharynx, which may exacerbate swelling and further compromise the airway.

Equipment

The equipment required depends on the type of laryngoscopy procedure performed. For flexible laryngoscopy a standard flexible nasopharyngolaryngoscope, a light source, gloves, a nasal speculum, surgical lubricant, antifogging solution, decongestant spray, anesthetic spray, and a wall suction setup with a Frazier suction-tip catheter are needed (Fig. 63.2, plate 1). Many choices of decongestant are available; however, 0.05% oxymetazoline (Afrin, Bayer, Whippany, NJ) or 0.1% to 1% phenylephrine is commonly used. Lidocaine (4%) is typically used as the anesthetic. A 5% cocaine solution serves as both an anesthetic and decongestant. If nasal spray formulations are not available, medication-soaked cotton pledgets, an atomizer bottle, or a syringe atomizer may be used.

Mirror laryngoscopy requires a curved dental mirror, an external light source (preferably a headlamp), 4- × 4-inch gauze, and an antifogging solution. If antifogging solution is not available, hot water can be used to prevent fogging of the mirror. Anesthetic solution may be required if the patient cannot tolerate the procedure.

Procedure

Flexible Laryngoscopy

Attach the nasopharyngolaryngoscope to its light source and the suction tubing to its port (if available). Ensure that both are functioning properly before beginning. Before inserting the scope, adjust the eyepiece to your visual acuity; it is helpful to check the focus on newsprint or a small object. Review the scope's directional controls. Examine both nares and choose the more patent one to enter. Anesthetize and vasoconstrict the naris (see Fig. 63.2, plate 2). Because this procedure is irritating, allow enough time for these medications to become effective. You may also anesthetize the pharynx to minimize gagging (see Fig. 63.2, plate 3). Warm the end of the scope in warm water to help prevent fogging. Place the patient in the seated position with the head placed against a headrest in the “sniffing position.” Insert the tip of the lubricated scope just inside the naris. (Some authors recommend a series of soft nasal trumpets to gradually dilate the nasal cavity and allow easier passage of the scope.) Movement of the scope against the inside of the nasal passage may be irritating to the patient. Minimize this sensation by resting your fourth and fifth fingers on the bridge of the patient's nose while stabilizing and guiding the scope between your thumb and index finger (see Fig. 63.2, plate 4).

While looking through the eyepiece, slowly advance the endoscope past the middle turbinate into the nasopharynx or through the lumen of a nasal trumpet. To clear fogging or mucus off the lens, ask the patient to swallow, wipe the lens against the pharyngeal mucosa, or use the suction. Once the scope is in the nasopharynx, direct the tip inferiorly by using the thumb control near the eyepiece. Use the thumb control to accomplish up and down movements of the scope. Rotate the scope about its axis and then apply thumb control to provide lateral movement and visualization. At this point the base of the tongue and the tonsils will come into view. Slide the scope farther caudad to bring the larynx into focus. Once again, systematically view the patient's anatomy and function during both respiration and phonation (see Fig. 63.2, plate 6).

If the nasopharyngeal scope will not pass through either naris, pass it through the oropharynx. Properly anesthetize the oropharynx and avoid contacting the posterior portion of the tongue to prevent gagging. A plastic bite block can be used. Alternatively, cut a 10-mL syringe (without the plunger) in half and ask the patient to hold it in the mouth between the incisors (see Fig. 63.2, plate 5). Pass the fragile endoscope

through this tube into the oropharynx to prevent accidental biting of the scope.

Mirror Laryngoscopy

Otolaryngologists most commonly use mirror laryngoscopy, but it can be used in the ED setting if the necessary equipment is readily available. Clinicians unfamiliar with this method should practice frequently because significant eye-to-hand coordination is required to reflect the light beam off the angulated mirror onto the larynx. When this procedure is properly performed, most patients are able to tolerate it without anesthesia of the oropharynx. Fiberoptic nasopharyngoscopy has largely replaced mirror laryngoscopy in the ED when the equipment is available.

Establish rapport with the patient by explaining how the examination will be performed. Have the patient sit erect in the sniffing position, with the feet flat on the floor and leaning slightly forward. Attach your headlamp and adjust the beam of light (Fig. 63.3). Warm the mirror with warm water to prevent fogging, but check the temperature of the mirror with your hand before placing it into the oropharynx so that the

Flexible Laryngoscopy

Basic equipment required for flexible laryngoscopy. Additional items include anesthetic spray, a nasal speculum, surgical lubricant, and antifogging solution.

Anesthetize and vasoconstrict the naris before inserting the scope. Oxymentazoline (e.g., Afrin) spray is an ideal vasoconstrictor. Atomized 4% lidocaine can be used as an anesthetic.

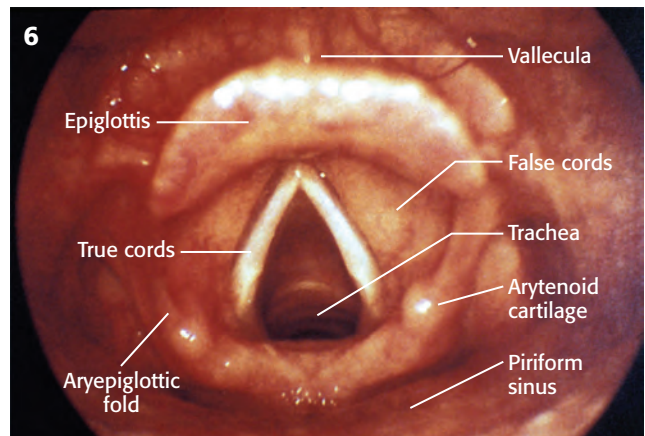

Anesthetize the oropharynx with benzocaine spray or atomized 4% lidocaine to prevent gagging.

Rest your fingers on the bridge of the patient's nose while stabilizing and guiding the scope between the thumb and middle finger.

To pass the scope orally, first anesthetize the oropharynx (with atomized 4% lidocaine or benzocaine spray). Use a plungerless 10-mL syringe with the end cut off as a bite block to prevent accidental biting of the scope.

Laryngeal anatomy as seen through the nasopharyngoscope.

Figure 63.2 Flexible laryngoscopy.

Figure 63.3 A good light source (headlamp) and an assistant facilitate any ear, nose, and throat examination or procedure. Retraction of the corner of the mouth by the assistant helps visualize the pharynx.

Figure 63.4 Indirect mirror evaluation of the oropharynx. Grasp the patient's tongue between the thumb and first finger while using a gauze pad to provide traction. Elevate the upper lip with the middle finger. Advance the warmed (prevents fogging) laryngeal mirror into the posterior of the oropharynx while taking care to not stimulate the posterior part of the tongue or pharynx. Remember that the structures in the mirror will be reversed. Always follow universal precautions.

patient is not burned. Alternatively, apply an antifogging solution to the mirrored side. Wrap the patient's tongue with gauze to prevent it from slipping or being injured by the lower incisors and then grasp it with the nondominant hand (Fig. 63.4). Apply gentle traction on the tongue with your thumb and index finger and lift the patient's upper lip with your middle finger. Slide the mirror into the oropharynx with the glass surface parallel to the tongue but not touching it. Place the back of the mirror against the uvula and soft palate and smoothly lift until the larynx is visualized. Although this should not induce gagging, try to make only slight changes in the mirror's position to inspect the appropriate structures.

In patients who cannot tolerate this procedure without gagging, apply topical anesthetic to aid in the examination.

Figure 63.5 Instruct the patient to say “eeeeee” in a high-pitched voice during the examination. This lifts the epiglottis out of your field of view and allows excellent visualization of the glottis. In this picture the vocal cords close with phonation. A paralyzed cord is easily discerned from one that is normal.

Benzocaine (Hurricane spray [Beutlich Pharmaceuticals, LLC., Bunnell, FL] or Cetacaine gargle [Cetylite Industries, Inc., Pennsauken, NJ]) or aerosolized tetracaine or lidocaine may be used. One or two quick sprays of benzocaine into the posterior aspect of the oropharynx is sufficient. Though rare, prolonged or repeated spraying of benzocaine can result in methemoglobinemia. Reassure the patient beforehand that although this may make the throat feel as though it is swelling or paralyzed, in actuality, it is just the numbness that accounts for the sensation. The tendency to gag can also be minimized by having the patient concentrate on breathing efforts and keep the eyes open and fixed on an object in the distance.

Once the patient is anesthetized, repeat the steps described earlier and position the mirror against the soft palate. Rotate the angle of the mirror and systematically inspect the base of the tongue, valleculae, epiglottis, piriform recess, arytenoids, false and true vocal cords, and if possible, the superior aspect of the trachea (see Fig. 63.2, plate 6). Observe for masses, evidence of infection, asymmetry, or FBs. Further evaluate the anterior structure of the larynx and function of the vocal cords by having the patient say “eeee” in a high-pitched voice. This should move the epiglottis away from blocking the view of the larynx and bring the true cords together at the midline (Fig. 63.5).

Complications

There are very few complications with laryngoscopy. Occasionally, it may not be possible to complete the procedure because of a prominent gag reflex or patient apprehension and discomfort. Complications include traumatic abrasions and bleeding anywhere along the path of the laryngoscope or on the soft palate or pharynx if a mirror is used. Epistaxis and hemoptysis are uncommon. In patients with head injury, there is always a slight risk of passing the scope intracranially if a basilar skull fracture has occurred; use of a soft nasal trumpet significantly reduces this risk. Laryngospasm and acute airway compromise can be induced in patients with paraglottic infections.

Peritonsillar Abscess Drainage

Indications

Clinical suspicion of peritonsillar abscess (PTA)
 Signs and symptoms of PTA include
 Asymmetric tonsillar bulging
 Uvular deviation (away from the bulging)
 "Hot potato" voice

Contraindications

Severe trismus
 Coagulopathy
 Uncooperative patient

Complications

Failure to completely drain the abscess
 Aspiration of pus and/or blood
 Hemorrhage
 Carotid artery puncture

Equipment

Review Box 63.1 Peritonsillar abscess drainage: indications, contraindications, complications, and equipment. Use a long 25- to 27-gauge needle and a 3- to 5-mL syringe for local anesthesia and a 10-mL syringe for aspiration. Larger syringes obscure the operator's view of the anatomy.

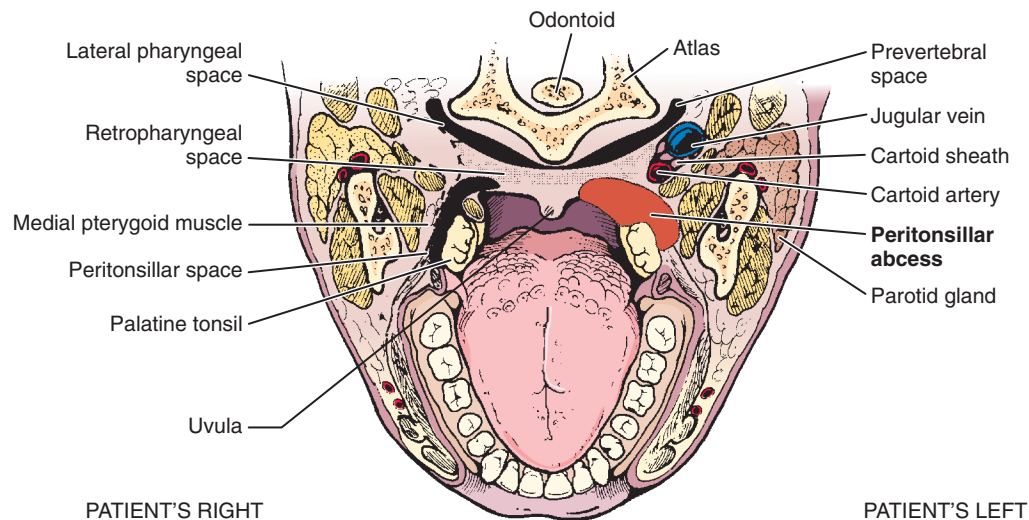

Figure 63.6 Anatomy of a peritonsillar abscess. The palatine tonsil and peritonsillar space are identified on the patient's right. A peritonsillar abscess is shown on the patient's left. Note that the abscess can extend medially and displace the uvula. The carotid artery and jugular vein are posterior and lateral to the abscess. Avoid lateral angulation of the aspirating needle and use a needle guard to limit depth of penetration (see Fig. 63.10).

TONSIL: PERITONSILLAR ABSCESS

Peritonsillar abscess (PTA), also known as quinsy, is most common during the second and third decades. It is rarely seen in children younger than 6 years and is the most common head and neck abscess in anyone older than 6 years. Treatment of PTA has undergone significant change in the past 100 years and continues to do so at this writing. A myriad of opinions exist on the appropriate treatment method, although most agree that some form of drainage procedure is usually required and should be performed in conjunction with the administration of antibiotics and pain control medication. Three options for

surgical drainage include needle aspiration (most common), incision and drainage, and immediate (quinsy) tonsillectomy.

Anatomy

Understanding the relative anatomy before attempting to treat PTA is important (Fig. 63.6). The palatine tonsils are located between the anterior and posterior pillars of the throat, bound in a capsule, and covered by mucosa. The superior pharyngeal constrictor muscle defines the lateral wall of the tonsil. Of great importance is the internal carotid artery, which lies approximately 2.5 cm posterolateral to the tonsil.

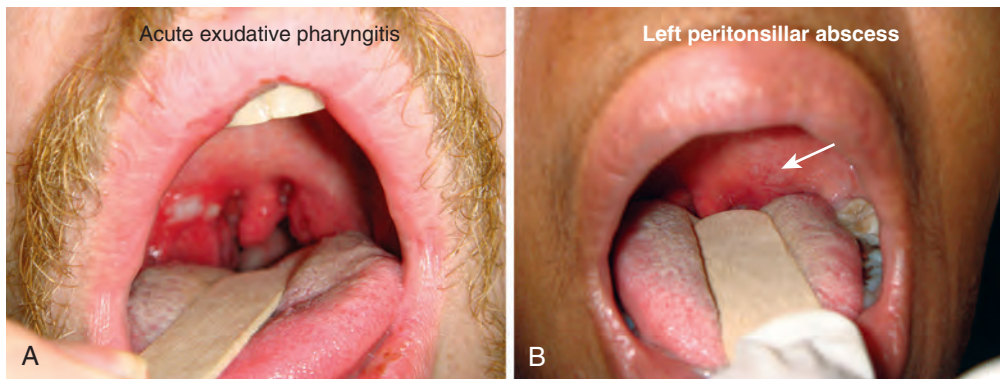

Figure 63.7 Exudative pharyngitis versus peritonsillar abscess. **A**, Acute exudative pharyngitis is characterized by bilateral tonsillar edema, erythema, and exudate. Note that the edema is for the most part symmetric and that the uvula lies in the midline. **B**, A peritonsillar abscess (*arrow*) is characterized by asymmetric tonsillar bulging, with the uvula deviated away from the side of the abscess.

The abscess is defined as a collection of pus between the tonsillar capsule, the superior constrictor muscle, and the palatopharyngeus muscle (Fig. 63.7). The abscess is not within the tonsil itself. PTA is believed to arise from spread of infection from the tonsil or from the mucous glands of Weber located in the superior tonsillar pole. The abscess is most commonly initiated from the upper pole of the tonsil. However, it can also spread from the middle or inferior poles.

Pathophysiology and Clinical Findings

PTAs can occur in patients with inadequately treated tonsillitis and in those with recurrent tonsillitis, but in some patients they arise *de novo*. There are no data proving that antibiotics, even the correct ones in proper doses, invariably prevent the progression of tonsillitis to abscess formation. The abscess is generally unilateral, and bilateral involvement is rare.²

Patients with PTA have a sore throat, odynophagia, low-grade fever, and a variable degree of trismus. The trismus develops secondary to irritation of the pterygoid muscle. The patient may also complain of ipsilateral otalgia. As the abscess expands, the patient may experience dysphagia with drooling. Patients may be dehydrated secondary to poor oral intake. Changes in voice are common (“hot-potato voice”) and caused by transient velopharyngeal insufficiency and muffled oral resonance. Rancid breath is also common. Tender ipsilateral anterior cervical lymphadenopathy is usually present. Although leukocytosis is often present, a complete blood count and other laboratory tests are nonspecific.

The differential diagnosis for this acute process includes unilateral tonsillitis, peritonsillar cellulitis, retropharyngeal abscess, infectious mononucleosis, epiglottitis, herpes simplex tonsillitis, retromolar abscess, neoplasm, FB, and internal carotid artery aneurysm. Chronic conditions include leukemia, carcinoma, and tumor in the parapharyngeal space. Differentiation of PTA from peritonsillar cellulitis may be difficult, especially in the early stages of an abscess. The history and time course of the two disease processes are quite similar. Trismus and uvular deviation are uncommon with peritonsillar cellulitis.³

Complications of PTA may include pharyngeal obstruction or extension into the closely approximated neurovascular bundles and parapharyngeal space. Specific complications

include airway obstruction, rupture of the abscess with aspiration pneumonia, septicemia, internal jugular vein thrombosis, suppurative thrombophlebitis of the jugular vein (Lemierre’s syndrome), carotid artery rupture, mediastinitis, necrotizing fasciitis, and cardiac and renal sequelae of group A streptococcal infection.

Indications and Contraindications

The indication for PTA drainage is usually straightforward, but some advocate that initial medical options exist, especially in children. If obviously present in an adult, the PTA may be drained. However, the difficulty can be in the diagnosis of PTA. As an option to immediate surgical intervention, patients with suspected PTA and no airway symptoms, who do not appear to be in a toxic state clinically, may be admitted to the hospital without imaging for 24 hours of hydration; for empirical intravenous antibiotics to cover group A streptococci, *Staphylococcus aureus*, and respiratory anaerobes (clindamycin is often used); and for analgesia. If a rapid response to medical therapy is not seen, drainage or tonsillectomy should be performed. Approximately 50% of patients, predominately children rather than adults, will respond to medical therapy alone.

It may be difficult to differentiate cellulitis from abscess. To diagnose PTA, in addition to visualization, place a gloved index finger into the mouth to feel for hardness or fluctuance in the peritonsillar region (Fig. 63.8).

Intraoral sonography may augment diagnostic accuracy and direct localization for drainage (Fig. 63.9; see Chapter 66). It is performed with an intracavitary probe. Blavis and coworkers² found that ED ultrasound was effective in diagnosing and aiding drainage in five cases of PTA. Ultrasound excluded the diagnosis in one. If there is still a question regarding the diagnosis or actual location of the abscess, computed tomography (CT) may be helpful but is not regularly performed and is not standard before a drainage procedure in straightforward cases.

There are very few, if any, contraindications to draining a PTA. One contraindication is the absence of a PTA; however, needle aspiration may be performed to confirm the presence of an abscess. Other contraindications can include severe trismus, coagulopathy, and inability of the patient to cooperate with the procedure.

Figure 63.8 Clinical symptoms and visual inspection may not be sufficient to differentiate a peritonsillar abscess from cellulitis. The clinician's gloved index finger is used to palpate the peritonsillar area to search for fluctuance and localized swelling. Computed tomography or ultrasound will further elucidate the diagnosis, but they are not needed in straightforward cases.

Figure 63.9 Ultrasound, transverse view, of a peritonsillar abscess showing a hypoechoic, heterogeneous abscess (arrow) with an intracavitary probe. Color Doppler can be used to delineate the vascular structures.

Equipment

The equipment required depends on the technique that is going to be used to drain the PTA. For needle aspiration, you will need a light source, tongue blade, injectable (1% lidocaine with 1:100,000 epinephrine) or topical (Cetacaine spray or 4% lidocaine) anesthetic, 3- to 5-mL syringe with a long 25-gauge needle for injection of anesthetic, and a standard or long 18- to 20-gauge needle (spinal needle) on a 10-mL syringe for aspiration (see [Review Box 63.1](#)). Long needles and small syringes will not obscure the operator's view of the anatomy. It is also helpful to have wall suction with a Frazier or Yankauer suction-tip device available.

For incision and drainage, the same examination, suction, and anesthetizing equipment are required. In addition, a No. 11 or 15 scalpel blade and Kelly forceps will be required.

For either procedure, the patient should be given intravenous pain medication and may require mild sedation or even procedural sedation. One should administer parenteral narcotic analgesia, mild sedation, or both, before attempting aspiration. Fentanyl, 1 to 3 $\mu\text{g}/\text{kg}$ administered intravenously a few minutes before the procedure, is often ideal. Midazolam may be used judiciously, but the patient should not be overly sedated. The combination of midazolam, ketamine, and glycopyrrolate is reported to be safe and effective for outpatient peritonsillar drainage in children.⁴

Procedure

Before describing the procedures for drainage of a PTA, one needs to know the clinical circumstances under which to perform the different procedures. A myriad of opinions exist on the appropriate treatment method, although most agree that some form of drainage procedure should be performed in conjunction with the administration of antibiotics and pain control. Three options for surgical drainage include needle aspiration (most common), incision and drainage, and immediate (quinsy) tonsillectomy. Each method is discussed.

Needle aspiration is relatively simple, can be performed by emergency clinicians, does not require special equipment, and is relatively inexpensive. Other benefits of needle aspiration over incision and drainage include decreased pain and trauma. Many believe that this should be the initial surgical drainage procedure for adults and children. The recurrence rate after aspiration is 10%,³ and its cure rate is 93% to 95%.⁵ Approximately 4% to 10% of patients require repeated aspiration.^{3,5,6} One drawback is that needle aspiration may miss the PTA and therefore allow misdiagnosis as peritonsillar cellulitis. For this reason, some authors propose admission of patients with negative aspirations and the presumed diagnosis of peritonsillar cellulitis for intravenous antibiotics and observation to prevent further morbidity. Although most studies involved hospitalization and intravenous antibiotics, selected outpatient treatment with oral antibiotics has also been successful and is usually the option chosen unless the patient appears to be in a septic state.⁶

The incision and drainage procedure is commonly done on an outpatient basis under local anesthesia. It is usually performed after pus is obtained by needle aspiration, but occasionally it is the primary procedure. It seems most logical to first attempt needle aspiration and follow with incision and drainage only if additional pus is suspected or other extenuating circumstances are present. The success rate for incision and drainage is high, with a recurrence rate similar to or lower than that with aspiration alone.⁵

Treatment guidelines based on a review of the literature^{3,5-7} suggest that patients with PTA should initially be treated by needle aspiration. Incision and drainage and immediate tonsillectomy should be reserved for treatment failures or recurrences. These procedures can be performed in conjunction with hospital admission and administration of intravenous antibiotics or as outpatient treatment with oral antibiotics. One evidence-based review analyzed 42 articles, 5 of which were clinical studies on surgical technique.⁵ All three techniques were found to be effective in treating PTA, and the recurrence rate was low (grade C recommendation). The approach depends on the patient's clinical status and medical history. The emergency clinician makes decisions about the treatment of PTA in the ED, but as local protocols dictate, consultation with an otolaryngologist may be appropriate.

The two procedures described here include needle aspiration and incision and drainage. They should be performed only in a cooperative patient without severe trismus. As the carotid artery is located 2.5 cm behind and lateral to the tonsil, there is minimal room for error, patient movement, or poor anesthesia.

Needle Aspiration

Have the patient sit upright with a support behind the head. This is best done as a two-person procedure. Ask an assistant to retract the cheek laterally to maximize visibility. A headlamp provides optimal lighting; a double-tongue blade setup aids in visualization of the operative area (see Fig. 63.3). Administer a parenteral narcotic analgesic, a mild sedative, or both before attempting aspiration.

Use digital palpation to locate the fluctuant area of the abscess. Anesthetize the area topically or with local infiltration. Infiltrate with 2 to 3 mL of 1% lidocaine with epinephrine via a 25- to 27-gauge needle. Use a 3- to 5-mL syringe with a long needle so it is possible to visualize the area to be injected (Fig. 63.10, step 1). A large syringe can block the operator's view. Displacing the tongue with a finger rather than a tongue blade may provide a better view. Infiltrate the lidocaine intramucosally for the best results, but be careful to not increase the size of the abscess by direct injection into the abscess cavity. The area should blanch. With proper local infiltration, the patient will not feel the penetration of the aspirating needle. If the trismus is so pronounced that it prevents adequate anesthesia, it will probably be too difficult to aspirate or incise the abscess properly.

Novel techniques to assist in the drainage procedure have recently been described. Afarian and Lin described the use of a laryngoscope with a curved blade (Fig. 63.11A and B).⁸ The blade is inserted into the patient's mouth as far posteriorly as the patient can tolerate. The blade shines light from inside the mouth onto the posterior aspect of the pharynx. In addition, the laryngoscope provides better exposure of the area because the handle is below the patient's mouth and the holding hand does not obscure the view. Moreover, the curved blade sweeps the tongue out of the way and the weight of the handle will help overcome trismus. Braude and Shalit described a similar process involving the use of a disassembled disposable vaginal speculum with a fiberoptic light (see Fig. 63.11C).⁹ One advantage of both techniques is that an assistant can hold either light source without getting in the way of the operator. Finally, Chang and Hamilton reported that performing the procedure with the patient in the Trendelenburg position and the operator seated behind the patient's head provides comparable success rates and patient comfort.¹⁰

For abscess aspiration, attach a long 18- to 20-gauge needle to a 10-mL syringe. Fashion a needle guard by cutting off the distal 1 cm of the plastic needle cover, replace the cover on the needle, and securely attach this guard to the needle and syringe with tape to prevent inadvertent displacement (see Fig. 63.10, step 2). Ensure that the needle protrudes only 1 cm beyond the cover to limit the depth of needle penetration and lessen the risk of entering any major vascular structures. If pus is not obtained at a 1-cm depth, deeper penetration is discouraged. Insert the needle into the most fluctuant (or prominent) area as previously determined, which is most commonly the superior pole of the tonsil (see Fig. 63.10, step 3). Importantly, advance the syringe and needle in the sagittal plane only; do not angle to the side toward the carotid artery. Do not aspirate

the tonsil itself because the abscess develops in the peritonsillar space surrounding the tonsil. Continually aspirate while advancing the needle in the sagittal plane and do not direct it laterally, where it could injure the carotid artery. If the aspirate is positive for pus, remove as much purulent material as possible. If the aspirate is negative, attempt aspiration again in the middle pole of the peritonsillar space, approximately 1 cm caudal to the first aspiration. If still negative, perform a third and final attempt at the inferior pole (see Fig. 63.10, step 4). Up to 30% of abscesses will be missed if only the superior pole is aspirated. It must be stressed that a negative aspirate does not rule out a PTA.

Usually, 2 to 6 mL of pus is obtained. It is unusual to recover more than 8 to 10 mL (see Fig. 63.10, step 5). Although culture is recommended, the results rarely alter subsequent therapy. When significant amounts of pus are aspirated, the patient usually feels immediate improvement in pain and dysphagia. After the needle is removed, some bleeding will be noted (see Fig. 63.10, step 6). Slight oozing may occur for a few hours, especially if warm water rinses are used. Drainage of pus may continue and is often sensed as a foul taste by the patient. Significant additional drainage of pus may be an indication for repeated aspiration, incision and drainage, or hospital admission.

Some clinicians advise a formal incision and drainage procedure if frank pus is obtained, whereas others now accept needle aspiration (with close follow-up) as the definitive initial treatment. Combined aspiration and formal drainage in the same visit may be indicated if large amounts of pus are obtained (> 5 to 6 mL) or if pus continues to drain from the aspiration site. There are no agreed standards regarding the best practice for this issue.

A new device, the Reciprocating Procedure Device (RPD; AVANCA Medical Devices, Inc., Albuquerque, NM), has been developed that allows one-handed aspiration of the abscess (Fig. 63.12).¹¹ The RPD consists of two syringe barrels and plungers. The plungers are linked by a pulley system in opposing fashion, which results in a set of reciprocating plungers. When one plunger is pressed with the thumb, the syringe injects; when the accessory plunger is depressed, the syringe aspirates. The RPD allows stable finger positioning and finer control of the needle and syringe. To use the RPD, attach a needle to the RPD. Press the injection plunger with the thumb while advancing the RPD simultaneously in the oral cavity until the needle penetrates the abscess. Once the mucosal surface has been penetrated, depress the aspiration plunger to provide a vacuum for aspiration without moving the needle tip. Studies have shown that the RPD allows enhanced needle control, safer and more accurate aspiration procedures, and decreased complications by 35% to 60%.¹²⁻¹⁴

Incision and Drainage

To incise a PTA, anesthetize the area as described earlier. Prepare a No. 11 or 15 scalpel blade by taping over all but the distal 0.5 cm of the blade to prevent deeper penetration (Fig. 63.13, step 1). Incise the area of maximal fluctuance or the area where a preceding aspiration (if one was performed) located pus. Do not incise the tonsil itself; instead, incise the peritonsillar area where pus accumulates. Incise the mucosa in an area 0.5 cm long in a posterior-to-anterior direction. A stab incision with a No. 11 blade usually suffices (see Fig. 63.13, step 2). Warn the patient that the pus will flow posteriorly and must be expectorated. Expect bleeding because this is a

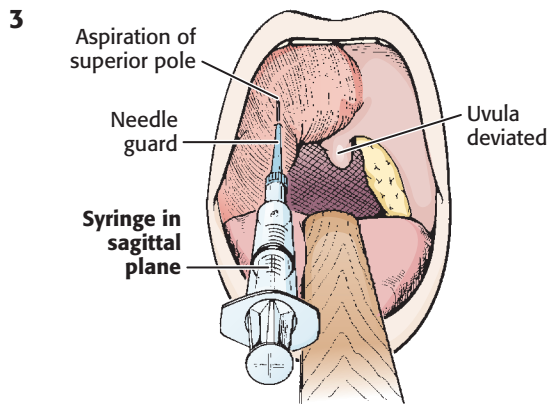

Peritonsillar Abscess: Needle Aspiration

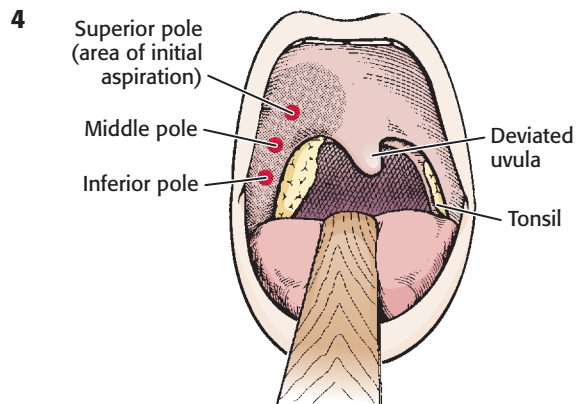

1 Use a 25- to 27-gauge needle to inject the mucosa with 1–2 mL of lidocaine with epinephrine; observe for blanching. Often, the tongue is best displaced with the finger rather than a tongue blade. Topical anesthetic spray (e.g., Hurracaine) may be used prior to injection.

2 Use a long 18- to 20-gauge needle for aspiration. As a safeguard to prevent overpenetration of the needle, remove the plastic needle guard and cut off the distal 1 cm. Then, replace the cut-off guard on the needle (*arrow*) and secure it to the hub.

3 While applying continuous suction, direct the needle in the sagittal plane only (directly anterior to posterior), not to the side toward the carotid artery. Aspirate the superior pole initially.

4 If pus is not obtained from the superior pole, next try the middle pole. The inferior pole may be aspirated last if needed. Note that the tonsil itself is not aspirated.

5 Usually, 2–6 mL of pus is obtained. It is unusual to recover more than 8–10 mL. If substantial amounts of pus are obtained, the patient usually notices immediate improvement in symptoms.

6 After needle removal, some bleeding will be noted (*arrow*). Slight oozing of blood and pus may continue for several hours. Significant additional drainage may be an indication for repeated aspiration, incision and drainage, or hospital admission.

Figure 63.10 Drainage of a peritonsillar abscess: needle aspiration technique.

vascular area. Suction the incised area with a No. 9 or 10 Frazier suction tip or a tonsil suction tip to aid in removal of the purulent material. Place a closed Kelly clamp into the opening and gently open it to break up the loculations (see Fig. 63.13, *step 3*). Allow the patient to rinse and gargle with

a saline or dilute peroxide-saline solution. Packing is not used in the drainage of this abscess. After aspiration or incision, it is prudent to observe the patient for approximately an hour to watch for complications (e.g., bleeding) and to ensure that the patient is able to tolerate oral fluids. Most patients can be

Figure 63.11 A and B, Laryngoscope and blade used to illuminate the posterior aspect of the pharynx. C, Disassembled disposable plastic speculum with a fiberoptic light source used to illuminate the posterior aspect of the pharynx.

Figure 63.12 The Reciprocating Procedure Device (AVANCA Medical Devices, Inc., Albuquerque, NM).

discharged with 24-hour follow-up. Toxic patients, those with excessive volumes of aspirate, those with persistent bleeding, and those unable to take oral antibiotics are candidates for admission or more prolonged observation. Frequent rinses with warm saline are quite helpful in relieving postaspiration symptoms.

Complications of Surgical Drainage

Needle aspiration is an accepted, safe, and effective technique for treatment of PTA in the ED. There is an approximate 10% failure rate and need for subsequent drainage.^{3,5,6} Complications can include aspiration of pus or blood and hemorrhage. If the patient has cellulitis, the aspiration will be of no help, but it will not worsen morbidity. Failure to obtain pus should prompt high-dose antibiotics and reevaluation in 24 hours. Many clinicians will opt for admission in such instances. Though often feared, injury to the carotid artery has not been reported as a complication of needle aspiration of PTA. Catastrophic hemorrhage may result from the extremely rare and largely theoretical aspiration of a pseudoaneurysm mimicking a PTA or similarly rare necrosis of the carotid artery. In addition, incisions that are too large or too small may lead to poor healing or an inability to completely evacuate the abscess, respectively.

Antibiotic Therapy

After drainage, empirical oral antibiotics are used in outpatients and intravenous antibiotics are administered to inpatients. PTAs are often polymicrobial, and hence culture of aspirated pus is

prudent, although the results rarely affect subsequent treatment. The predominant bacterial species are *Streptococcus pyogenes* (group A streptococcus), *S. aureus* (including in rare cases methicillin-resistant *S. aureus* [MRSA]), and various respiratory anaerobes (including *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Veillonella* species). *Haemophilus* species are found occasionally. Aerobes and anaerobes may be recovered simultaneously if appropriate culture techniques are used. Appropriate oral antibiotics for outpatient therapy in areas where *S. aureus* remains susceptible to methicillin include amoxicillin-clavulanate or clindamycin. For inpatients, administer ampicillin-sulbactam or clindamycin. Penicillin plus metronidazole is also a recommended antibiotic regimen. In septic patients, it is prudent to also cover for MRSA. Although clindamycin may be adequate for MRSA, some clinicians add vancomycin or linezolid to the aforementioned initial antibiotic regimens if MRSA is suspected or predominant in the population. It is prudent to initially cover for MRSA in septic or very toxic patients.

Glucocorticoid Therapy

It is common practice for clinicians to administer short-term corticosteroids, such as intravenous dexamethasone or methylprednisolone, as an adjunct to other therapies in an attempt to provide relief from the symptoms of PTA. Evidence of the benefits of glucocorticoids in the management of PTA is inconsistent, but such intervention may hasten improvement of symptoms in adolescent and adult patients treated with needle aspiration and intravenous antimicrobial therapy. The benefits may be marginal, but as there are no significant complications, it is reasonable to empirically treat adults with short-term corticosteroids. A single intramuscular dose of dexamethasone (10 mg) is a common protocol. Additional data are necessary before the routine use of glucocorticoids can be recommended in the management of PTA in children.

EAR

Anatomy

The ear consists of three sections, the outer, middle, and inner ear. The outer ear includes the pinna (auricle), the external

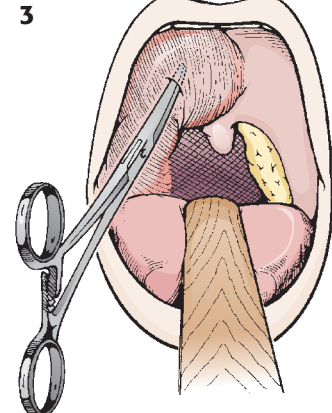

Peritonsillar Abscess: Incision and Drainage

Place adhesive tape around a No. 11 or 15 scalpel blade so that only the distal 0.5–1 cm is exposed. This prevents overpenetration.

Incise the area of maximal fluctuance (or the area where previous aspiration located pus). Expect pus and blood to flow from the incision; have suction ready to remove the purulent material.

Use a Kelly clamp to gently break up loculations. Packing is not used. Observe the patient for about an hour to watch for complications such as bleeding.

Figure 63.13 Drainage of a peritonsillar abscess: incision and drainage technique. Aspiration is often the only procedure required to successfully treat a peritonsillar abscess, but it has a 10% failure rate. In some instances the clinician will opt for incision and drainage of a peritonsillar abscess. This procedure may be used initially or after aspiration if copious pus is aspirated or pus continues to drain or reaccumulate.

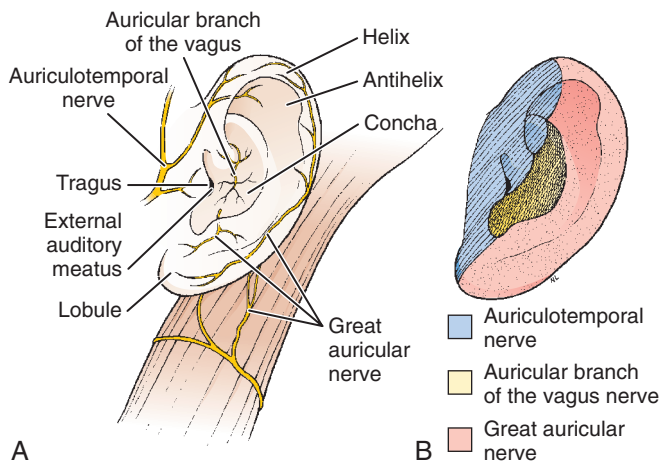

Figure 63.14 A, Anatomy of the ear and innervation of the auricle. B, Sensory distribution of nerves of the ear.

auditory canal (EAC), and the tympanic membrane (TM) (Fig. 63.14A). For the purpose of this chapter, only the parts of the external ear will be discussed. The pinna is flesh-covered cartilage and serves both hearing and cosmetic functions. The EAC extends from the head to the external auditory meatus in the skull and measures approximately 2.5 cm in adults. It is relatively short and straight in early infancy but begins to take on its adult S-shape and overall antero-caudal orientation at 2 years of age. Initially, the EAC is almost entirely cartilaginous, but by adulthood its medial two thirds is composed of bony support with an overlying thin, stratified squamous

epithelium. The lateral third has a less sensitive, thicker hairy epithelium that produces cerumen and retains its cartilage as support. The arterial supply to the EAC originates from the external carotid artery via the posterior auricular, maxillary, and superficial temporal branches. The mandibular branch of the fifth cranial nerve (V3) and the vagus nerve innervate the ear.

Other important anatomic considerations include two natural narrowings in the EAC, which are important when considering FBs. One is located at the junction of bone and cartilage and the other lies just lateral to the TM. A blind spot may occur in the tympanic sulcus (inferior and anterior to the TM) because of the oblique orientation of the TM. An examiner using a simple otoscope may not visualize an FB in this sulcus.

Anesthesia of the External Ear

Auricle

Indications for local anesthesia of the auricle include closure of extensive lacerations or performance of other painful procedures such as incision and drainage of hematomas (Fig. 63.15). Four nerve branches supply the external ear; knowledge of their anatomy is required to understand the location for injection of anesthetic (see Fig. 63.14B). The great auricular nerve (branch of the cervical plexus) innervates most of the posteromedial, posterolateral, and inferior aspect of the auricle. A few branches of the lesser occipital nerve may contribute to this area. The auricular branch of the vagus supplies the concha and most of the area around the auditory meatus. The auriculotemporal nerve (from the mandibular branch of the trigeminal nerve) supplies the anterosuperior and antero-medial aspects of the auricle.

Figure 63.15 Closure of extensive lacerations of the ear such as this require a nerve block of the auricle.

Procedure

Fill a 10-mL syringe with either 1% lidocaine or 0.25% bupivacaine. Mix with epinephrine if a regional block is planned in an area without evidence of traumatized vascularity. Attach the syringe to a 25- or 27-gauge needle (5 to 7 cm in length). One of several methods may be used to induce partial or complete anesthesia, depending on the area of concern. To anesthetize the nerve branches of the great auricular and lesser occipital nerve branches, inject between 3 and 4 mL of anesthetic into the posterior sulcus (Fig. 63.16, plate 1). Insert the needle behind the inferior pole of the auricle and gradually aspirate and inject toward the superior pole along the crescent-shaped contour of the posterior aspect of the auricle. Anesthetize the auriculotemporal nerve anteriorly by placing 3 to 4 mL of anesthetic just superior and anterior to the cartilaginous tragus. Provide anesthesia to the auricular branch of the vagus nerve and the more central areas of the auricle by using the technique shown in Fig. 63.16, plates 3 and 4.

Anesthesia of the Ear

Auricular Field Blocks

1

Inject anesthetic along the course of the posterior sulcus

2

Deposit 2–3 mL of anesthetic along each path

One method of auricular block uses approximately 3–4 mL of anesthetic injected both at the posterior sulcus (red arrow) and at a point just anterior to the tragus (blue circle).

An alternative auricular block deposits 2–3 mL of anesthetic in four separate injections that encircle the ear. Begin each new injection in a region that is already anesthetized.

External Auditory Canal Blocks

Ear speculum

4

Four-quadrant field block. Inject anesthetic subcutaneously in the four quadrants of the lateral portion of the ear canal. Use the largest speculum that will fit to guide the injections. Withdraw the speculum, tilt it toward each of the four quadrants, and insert the needle subcutaneously (x). Inject 0.25–0.50 mL of anesthetic to produce a slight bulge in the soft tissue. A total of 1.5–2.0 mL of anesthetic is usually sufficient to anesthetize the ear canal and permit painless removal of a foreign body. Ketamine procedural sedation may facilitate the procedure.

Diagram of injection sites for an alternative technique to anesthetize the ear canal and central concha. Inject each site with approximately 0.5 mL of 1% lidocaine. Do not inject if external signs of infection are present.

Figure 63.16 Anesthesia of the ear.

Another and possibly more effective option is the regional block shown in Fig. 63.16, plate 2. Insert the needle subcutaneously approximately 1 cm above the superior pole of the auricle and direct it to a point just anterior to the tragus. Be sure to inject the skin of the scalp while avoiding the auricular cartilage. Aspirate and then slowly withdraw the needle while injecting anesthetic until the needle is almost to the puncture site. Redirect the needle posteriorly and repeat the process while aiming at the skin just behind the mid-auricular area. Remove the needle and perform the same procedure, but insert the needle just inferior to the insertion of the ear lobule and anesthetize it in a superior direction. Again, block the auricular branch of the vagus as described in Fig. 63.16, plates 3 and 4, if additional anesthesia of the concha is required.

Use caution if adding epinephrine to the anesthetic solution when performing regional nerve blocks of the ear, especially if the blood supply has already been traumatically reduced. Do not include epinephrine when directly infiltrating wounds of the auricle because restriction of blood flow through the end-arteries may result in tissue necrosis. Other complications related to local anesthesia and regional blocks of the head and neck are reviewed elsewhere in this text.

EAC and TM

The EAC is innervated by the auricular branch of the vagus nerve (inferiorly and posteriorly) and by the auriculotemporal nerve (superiorly, anteriorly, and inferiorly). The primary indication for local anesthesia of the auditory canal is for removal of FBs, including débridement of otitis externa or removal of significant impacted cerumen. It is nearly impossible for even the most cooperative patient to be able to tolerate even minimal manipulation of the auditory canal or TM. It is very difficult to achieve adequate anesthesia of the inner ear and TM for painful procedures. Simply stated, no easy and completely effective procedure consistently works well. If total anesthesia is required, general anesthesia, especially in children, is often the only alternative. Ketamine is an ideal agent for short procedures, especially for children with foreign objects in the ear. Topical anesthetics are inadequate because of their poor absorption through the rather impermeable and keratinized epithelial surface of the EAC. The editors advise instilling 4% cocaine solution to fully fill the ear canal of the supine patient (affected ear facing upward), and waiting a full 20 minutes for anesthesia of the TM to occur. Some anesthesia of the canal is also achieved with topical cocaine. Though effective for some procedures, injection of local anesthetics into and around the auditory meatus is quite painful and often difficult to perform in a struggling and uncooperative patient. Certain instances warrant adjunctive use of procedural sedation. Auralgan, a combination of benzocaine and other ingredients, may provide analgesia for painful earaches secondary to otitis, but it does little to benefit painful procedures.

Procedure

For local anesthesia use a 25- or 27-gauge needle (3 to 5 cm in length) attached to a syringe containing 1% lidocaine with epinephrine. A 1:10 mixture of 8.4% sodium bicarbonate to lidocaine helps reduce pain during injection in this sensitive area. Place a speculum just inside the auditory meatus, inject 0.3 to 0.5 mL of the anesthetic into subcutaneous tissue, and stop after a small bulge is raised in the skin. Inject all four quadrants in this manner by moving the speculum after each injection (see Fig. 63.16, plate 3). If additional anesthesia is

necessary, give two more small injections. Inject the same amount slightly farther into the canal, once along the anterior wall and again at the posterior wall at the bone-cartilage junction.

Another similar technique involves depositing the anesthetic just lateral, or exterior, to the external auditory meatus. Using the same size of needle and type of anesthetic solution as just described, inject approximately 0.5 to 1.0 mL into each of five points around the auditory meatus and tragus (see Fig. 63.16, plate 4).

Examination

Several methods can be used to examine the EAC and TM. In all methods, grasp the superior aspect of the pinna and pull cephalad and posterior to straighten the slightly tortuous EAC. Examination is most commonly done with a fiberoptic otoscope (Fig. 63.17). Place a plastic or metal speculum into the auditory meatus for examination and use a headlamp or head mirror/lightbulb as a light source. After inspection, the operating hand can be used to pass instruments into the EAC and to maneuver them more easily. Although this technique provides excellent illumination, the use of magnifying loupes can improve visualization during procedures. The ideal setup for removal of cerumen or an FB consists of an operating microscope and a speculum. This provides binocular vision and frees the examiner's hands for instrumentation. Unfortunately, this equipment is seldom found outside the otolaryngology clinic setting. If using a standard otoscope, stabilize the hand holding the otoscope against the temporal part of the patient's skull to prevent inadvertent injury to the canal if the patient moves unexpectedly.

Removal of Impacted Cerumen

Excretions from the ceruminous or apocrine and sebaceous glands, together with cells exfoliated from the EAC, combine

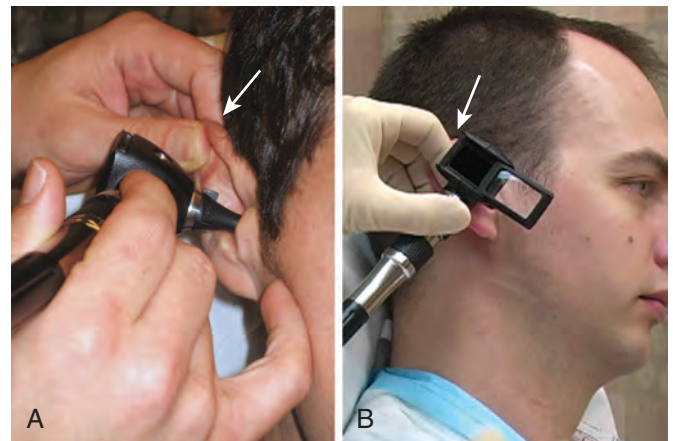

Figure 63.17 Examination of the ear canal. **A**, Retract the pinna in a superior and posterior direction to straighten out the ear canal (arrow). Hold the scope in the other hand and stabilize it against the patient's head. This prevents inadvertent injury if the patient moves unexpectedly. **B**, The pinna can be retracted and the scope held with a single hand that is also resting against the patient's head (arrow). This technique is useful if instruments are to be passed through the otoscope.

Cerumen Impaction Removal

Indications

Symptomatic cerumen impaction
Sudden hearing loss in the setting of cerumen impaction
Evaluation of otitis media in the setting of cerumen impaction

Contraindications

Few if any absolute contraindications

Contraindications to irrigation:

Patient aversion to irrigation	Foreign bodies
History of middle ear disease	Uncooperative patient
History of ear surgery	Occluding aural exostoses
Perforated tympanic membrane	Inner ear disturbance
Severe otitis externa	Radiation therapy in the area
Narrow ear canals	

Complications

Otitis externa
Tympanic membrane perforation
Middle ear injury
External auditory canal trauma

Equipment

Review Box 63.2 Cerumen impaction removal: indications, contraindications, complications, and equipment.

to form cerumen. One study found that cerumen is composed of lipids, complex proteins, and simple sugars.¹⁵ Cerumen repels water, has documented antimicrobial activity, and forms a protective barrier against infection. Cerumen often becomes impacted, which results in complaints of a “blocked” ear, sudden-onset impaired hearing, or dizziness.

Indications and Contraindications

Symptomatic impaction is an indication for removal, although symptoms are rare until complete obstruction is present. Sudden loss of hearing is a common complaint in patients with totally occluding, impacted cerumen. Cerumen obstructs visualization of the TM and can be evacuated as a part of the evaluation of a febrile child or a patient complaining of ear pain. However, removal of cerumen in a child is rarely indicated in the ED simply to visualize the TM.

There are few, if any, true contraindications to removal of impacted cerumen. Cerumen is usually impacted for prolonged periods, and vigorous attempts to remove it may precipitate otitis externa. It is reasonable to instill antiseptics (acetic acid otic solution) (VoSol [ECR Pharmaceuticals Co., Inc., Richmond, VA] and others) or antibiotic ear drops for a few days after removal of the cerumen to prevent otitis externa. Neomycin-containing ear drops are best avoided because of precipitation of a contact dermatitis (Fig. 63.18A). Caution should be used in removing impacted cerumen in diabetic patients. Diabetics commonly experience otitis externa after seemingly minor manipulation of the ear canal (see Fig. 63.18B).

Contraindications to irrigation include the following¹⁶:

- Patient aversion to or a history of injury from previous syringe irrigation.
- History of middle ear disease.
- History of ear surgery.
- Known or suspected perforated TM.
- Severe otitis externa.

Figure 63.18 A, Extensive contact dermatitis from the use of neomycin-containing ear drops. B, Malignant otitis externa in a diabetic patient developed after the patient manually removed cerumen with a cotton swab and a pencil, but it may develop without manipulation of the canal.

- Narrow ear canals.
- FBs, especially sharp objects and vegetable matter.
- Uncooperative patient.
- Occluding aural exostoses.
- Known inner ear disturbance, especially if the patient has severe vertigo.
- History of radiation therapy encompassing the external or middle ear, base of the skull, or mastoid.

Procedure

Removal of cerumen can be accomplished by irrigation, manual extraction, or a combination of both. Generally, the procedures used to remove cerumen are safe; however, otologic injury has

occurred after this “minor” procedure and has even resulted in litigation.¹⁷

Irrigation is an effective approach for removal of cerumen and has the advantage of being painless and simple to perform. It is usually most successful after the instillation of a ceruminolytic (see later). Because the patient does not have to remain completely still, it is ideal for the pediatric population. It is estimated that 150,000 ears are irrigated in the United States each week.¹⁷ Though usually more time-consuming and messy than manual extraction, irrigation is an appropriate initial method to attempt and can be performed by technicians with guidance from the clinician.

A 2004 evidence-based review concluded that the current evidence suggests little difference in the efficacy of water-based and oil-based preparations for removing cerumen.¹⁸ Non-water-, non-oil-based preparations appear to be most effective in clearing cerumen and improving syringing, but further research is needed.¹⁸ Whichever of the following techniques are used, some tips for successful removal of cerumen include proper lighting, attention to patient comfort, and abrupt cessation when the patient’s comfort level is breached.

Ceruminolytics

These products may soften hardened or impacted cerumen. They are used as adjuncts to other procedures; simply instilling ceruminolytics into the canal will not remove enough cerumen to aid the emergency clinician. If irrigation fails, continued outpatient use of ceruminolytics is often prescribed, usually combined with home irrigation via a bulb syringe or a repeated visit in a few days. Although many products are available as ceruminolytics, a 5% or 10% solution of sodium bicarbonate disintegrates cerumen much more quickly and efficiently than commercially prepared ceruminolytics and other products.¹⁹ Cerumenex (Purdue Frederick Company, Stamford, CT), Cerumol (Thornton and Ross Ltd., Huddersfield, United Kingdom), Auralgan, Buro-Sol, alcohol, and oils were all tested and took more than 18 hours to disintegrate cerumen versus approximately 90 minutes for the sodium bicarbonate solutions.¹⁹ Cerumenex and Cerumol have been since removed from the market due to otic cell toxicity. Hydrogen peroxide is another commonly used ceruminolytic, but its use has not been systematically studied. One study found that the liquid preparation of the stool softener docusate sodium (Colace, Purdue, Stamford, CT) was much more effective than Cerumenex as a ceruminolytic.²⁰ An evidence-based review of agents found that docusate sodium administered 15 minutes before irrigation was most effective in facilitating removal of cerumen. Triethanolamine (Cerumenex) and olive oil were the next most effective treatments.²¹

Place the patient in the supine position with the affected ear up, instill the solution, and wait at least 15 to 30 minutes before attempts at removal (Fig. 63.19, *step 1*). Repeat the instillation between attempts at manual extraction or irrigation.

Irrigation (Ear Syringing)

After a ceruminolytic has been instilled and left in the canal for 15 to 30 minutes, irrigation of the canal is often effective in flushing out impacted cerumen. Ask the patient to sit upright and hold an emesis or ear irrigation basin flush tightly against the skin just below the earlobe. Insert the irrigation tip into the EAC only as far as the cartilage-bone junction, and direct the stream of water superiorly to wash the impacted cerumen away from the TM (see Fig. 63.19, *step 2*). It is

important to warm the water to body temperature to prevent caloric stimulation. Multiple attempts may be necessary, and intermittent attempts at manual removal of loosened cerumen may help hasten the process. During the irrigation, ask an assistant to apply traction to the pinna to straighten the canal for more efficient irrigation. Patients usually feel some discomfort with forceful irrigation, but not severe pain.

Attach a 30- to 60-mL syringe to a 19-gauge or larger butterfly device, cut off the needle and wings, and use the resultant tubing for irrigation. A large plastic or Teflon intravenous catheter (16- or 18-gauge with the needle removed) can similarly be affixed to a syringe.

The most common way to irrigate an ear is with a syringe and catheter. The use of oral jet irrigators (Waterpik, Fort Collins, CO) is another accepted method, but a syringe-catheter setup is readily found in the ED and unlikely to generate enough pressure to cause injury. After irrigating the EAC, apply several drops of isopropanol to the EAC to facilitate evaporation of residual moisture. Do not use isopropanol if the TM is ruptured. Furthermore, topical steroid-containing suspension drops (ciprofloxacin/hydrocortisone) may be soothing after prolonged irrigation. Because severe otitis externa can develop in diabetics after irrigation, some clinicians routinely prescribe antibiotic ear drops (e.g., fluoroquinolones) for a few days after irrigation in high-risk patients.

Manual Instrumentation

Manual instrumentation is more advantageous because it is usually quicker and the examiner may more easily remove hardened or larger concretions of cerumen under direct visualization. However, it is difficult to manually remove cerumen without causing significant pain, so irrigation is preferred. Manual removal may be the initial procedure in some cases, followed by irrigation when the cerumen is partially disrupted. Place the diagnostic or operating head of the fiberoptic otoscope or a speculum as a protective port through which instruments are passed and manipulated (see Fig. 63.19, *step 3*). An operating microscope works best in this situation but, again, is not usually available. To prevent startling or agitating an already anxious patient, allow the patient to experience the sensation of an instrument in the canal by first placing it softly against the wall of the ear canal.

Instruments used for removal of cerumen include flexible plastic or wire loops, right-angle hooks, suction-tipped catheters, or plastic scoops (see Review Box 63.2 and Fig. 63.19, *steps 4 to 6*). The spoonlike instruments and irrigation are both more effective in removing softer cerumen. Firm cerumen is ordinarily more easily withdrawn with loops or right-angle hooks. Gently tease the cerumen off the canal wall with loops and then pass hooks or loops around the cerumen and withdraw it slowly. Take care to keep both hands in contact with the patient’s head because any sudden movement may cause trauma to the canal or the TM.

Complications

Complications from removal of cerumen are rare but can have serious consequences. Although complications from ear syringing are more common with jet irrigators, they may occur with any method of ear irrigation and include otitis externa, TM perforation, or middle ear injury from a preexisting defect in the TM. If the patient is experiencing sudden pain, tinnitus, hearing loss, nausea, or vertigo, stop the irrigation and examine the TM. If the membrane is ruptured, give prophylactic oral

Cerumen Impaction Removal

1 Instill a ceruminolytic solution into the ear at least 15 minutes before attempts at removal (see text for discussion of various agents). Repeat the instillation between attempts.

2 Irrigate with body-temperature water via a syringe with a plastic IV catheter (with the needle removed). Apply traction to the pinna during irrigation to straighten the ear canal. Periodic attempts at manual removal of loosened cerumen may be beneficial.

3 For manual removal, use the otoscope (with the view piece retracted) as a port for passage of the instrument.

4 Gently tease the cerumen off the canal wall with a loop or plastic ear scoop. This should be performed only under direct visualization.

5 Remove dislodged pieces of cerumen from the canal with an instrument such as alligator forceps.

6 A suction-tip catheter may also be used. However, this should be done under direct visualization only to prevent iatrogenic injury to the fragile ear canal.

Figure 63.19 Cerumen impaction removal. Place liquid ducolax or other ceruminolytic into the canal for 20 to 30 minutes prior to wax removal. Most wax is removed with irrigation alone, but multiple irrigations may be required. When removal of cerumen is unsuccessful in the emergency department, discharge the patient with a ceruminolytic and attempt irrigation again in 24 to 48 hours. *IV*, Intravenous.

antibiotics for otitis media, keep the ear canal perfectly dry with cotton, and refer the patient to an otolaryngologist. This complication is usually benign.

Complications from manual extraction most commonly occur when inadvertent contact is made with the thin, friable skin of the bony canal. Trauma may cause EAC laceration, otitis externa, or perforation of the TM.

Ear Canal Débridement and Wick Placement

Débridement of the ear canal and wick placement are essential components in the management and treatment of otitis externa or “swimmer’s ear,” an acute inflammation of the skin of the EAC. This is essentially a cellulitis of the ear canal. Precipitants of otitis externa include water exposure and trauma. Excessive moisture in the canal raises the pH and removes the cerumen. Keratin cannot absorb water, thereby creating a medium for bacterial growth. Trauma, especially self-manipulation with FBs (e.g., cotton swabs, fingernails), causes abrasions in the ear canal and introduces infection. Removal of cerumen by water irrigation is a well-recognized risk factor for the development of otitis externa.¹⁹

Diabetics and other immunocompromised patients, especially human immunodeficiency virus–positive patients, are susceptible to malignant (necrotizing) otitis externa, a life-threatening form of otitis externa caused by *Pseudomonas* (see Fig. 63.18B). Deep tissue necrosis, osteomyelitis, intracranial extension, and systemic toxicity are hallmark features. Malignant otitis externa is difficult to treat and the mortality rate can be as high as 53%.¹⁹ The diagnosis of malignant otitis externa should be considered in a diabetic or immunocompromised patient with significant symptoms who fails to respond to initial outpatient treatment.

Indications and Contraindications

In patients with suspected otitis externa, attempts should be made to clean debris from the canal to aid in healing. In addition, wick placement will be helpful in delivering antibiotic medications to the swollen canal. It has been touted that the key to successful treatment is adequate removal of canal debris. However, vigorous attempts to remove debris on the first visit are frequently painful, of unproven value, and often eschewed.

Removal of debris is contraindicated in cases of suspected malignant otitis externa and otolaryngology consultation is required.

Procedure

Because of patient discomfort and canal swelling, use small swabs (e.g., urethral swabs) to gently remove debris. Irrigate the canal gently, but realize that many patients will be cured without extensive débridement. Perform irrigation only in the absence of TM perforation.^{16,22} Because the inflamed canal is susceptible to trauma, removal of debris by suctioning under direct visualization with the open or operating otoscope head and a 5- or 7-Fr Frazier suction tip may be a better option (see Fig. 63.19, step 6). For more advanced cases with significant exudate and edema, removal of debris is necessary but intensely painful. Filling the ear canal with 4% cocaine and waiting 20 minutes for effect will often anesthetize the canal enough for gentle manipulation. Another approach is to use a local block of the EAC (see Fig. 63.16) as long as the cellulitis has not extended to the tragus or concha. Administer parenteral analgesics if additional control of pain is required.

When edema, debris, and exudate are marked enough to impede antibiotic drops from contacting the skin of the canal, use an ear wick. The wick works as a conduit to deliver the antibiotic solutions to the ear canal. The true benefit of wick implantation is unknown and it is often not performed because it is painful. One approach is to place a 0.25-inch strip of Nu-Gauze dressing (Johnson & Johnson, New Brunswick, NJ) covered with an antibiotic and steroid cream (Cortisporin Otic cream, Monarch Pharmaceuticals, Inc., Bristol, TN) into the external acoustic canal in a fashion similar to the technique used for anterior nasal packing. Using an otoscope and alligator forceps, place the leading edge of the gauze deeply in the canal until it is fully packed. Withdraw the otoscope and finish by also packing the lateral aspect of the canal. Cotton may be used as well (Fig. 63.20A).

An easier alternative is to use commercially available ear wicks, such as the Pope Merocel ear wick (Medtronic, Langhorne, PA). Place this dehydrated and trimmed wick into an edematous canal and apply antibiotic/hydrocortisone drops onto it (see Fig. 63.20B). The wick swells and helps reduce edema by the antimicrobial and antiinflammatory effects of the solution and through pressure exerted against the walls as it expands. Keep the wick moist with drops and leave it in place until the patient is seen again in 24 to 48 hours for removal and further evaluation. Though relatively safe to use, the ear wick is designed for short-term use. Generally, these wicks will fall out of the canal as the edema subsides. However, wicks can harbor bacteria with prolonged retention and cause tissue ingrowth, which results in long-term problems for the patient.²³

Complications

There are very few complications with canal débridement and ear wick placement. Usually, the wick will fall out as edema in the canal subsides; if not, it may become an FB of the EAC. Care should be taken to not injure the already friable skin of the EAC, which can lead to bleeding and possible infection or cellulitis of the EAC when placing or removing a wick.

FBs in the Ear Canal

Despite its small size, the EAC may play host to numerous types of FBs.^{24,25} Living insects account for most FBs found in adults. Children frequently place food (e.g., peas, beans), organic matter (e.g., grass, leaves, flowers), and inorganic objects (e.g., beads, rocks, dirt) into their ear canals during play, and they often fail to admit this to parents. Button batteries may cause significant tissue destruction in a matter of hours, and it is vital to immediately obtain otolaryngology consultation for removal if the button battery is not easily extracted. Symptoms of FB retention usually consist of ear pain, fullness, or impaired hearing in adults; pediatric patients may not be encountered until an associated otitis externa with a purulent discharge has developed.

As described previously, the anatomy of the EAC predisposes to entrapment of FBs in either a lateral or a deeper position. Removal of more medial objects can be much more painful, and anesthesia is usually required. Even the most cooperative patient may become difficult after feeling pain during manipulation of the ear canal. It is probably impossible to adequately immobilize the head of an uncooperative awake child and to delicately extract an FB.

Ear Wick Placement

A Cotton or 0.25-inch Nu-Gauze packing strip can be coated with Cortisporin Otic cream and placed into the external auditory canal with alligator forceps.

B An easier solution is to use a Merocel ear wick. Place the dehydrated wick into the canal and apply Cortisporin Otic drops to it. Instruct the patient to place the drops directly on the wick until the follow-up visit.

Figure 63.20 Placement of an ear wick. Ear wicks are used for the treatment of otitis externa and function to deliver antibiotic medications to the swollen external auditory canal.

Some authorities claim that injecting local anesthetics makes extracting FBs even more difficult because of soft tissue distortion, although swelling should be minimal if proper amounts of anesthetic are used. Anesthesia of the EAC may be difficult to achieve. Topical anesthetics have a partial effect, and a four-quadrant technique may not produce complete anesthesia, especially of the TM (see Fig. 63.16, step 3).^{24,25} The editors advise filling the ear canal with 4% cocaine and waiting 20 minutes for topical anesthesia of the canal and TM. Procedural sedation (preferably an analgesic-sedative combination or dissociative anesthetic) can aid in the removal of FBs in a distraught child by preventing further struggling and potential canal trauma. Ketamine is an excellent anesthetic for simple FB removal in the outpatient setting. The care provider must weigh the inherent risks related to procedural sedation against those of general anesthesia and the cost of hospital admission.

Adequate visualization of the object is needed for successful removal. One study showed that canal lacerations occurred in 48% of patients in whom removal was attempted without a microscope and in 4% when it was used.²⁵ The otoscope is the traditional ED instrument for viewing FBs in the ear canal. It is less likely to be useful for retrieval because it is difficult to insert the instrument through or around the end of the speculum. A specialized ear, nose, and throat (ENT) speculum allows more space for instrumentation. A headlamp provides a good light source and leaves both hands free. Magnifying loupes also provide hands-free magnification.

Indications and Contraindications

In the majority of cases, removal of an FB should be attempted in the ED. Before initiating removal, the clinician should set realistic limits on the number of attempts to be made. Even the best clinician can become too aggressive as frustration builds with failed attempts to extract the object. Early consultation with an otolaryngologist should not be considered a failure

with difficult FBs. Indeed, with the proper equipment and experience, most objects can be removed atraumatically.

Severely impacted objects and concomitant EAC infection are relative contraindications to removal, and ENT consultation should be obtained. In addition, patient cooperation is essential for successful removal. The only other contraindication to removal of FBs from the EAC involves certain circumstances when irrigation will be the technique used. Irrigation should not be performed in cases of known or suspected TM rupture (tinnitus, vertigo, significant hearing loss, or bleeding from behind the object). In addition, irrigation should not be performed if the object is soft or if it is a seed or other vegetable or organic matter because the water may cause the object to swell.

Procedures

Make a judicious effort to remove an ear FB in the ED setting. Avoid prolonged traumatic attempts because this often terrifies the patient, complicates subsequent attempts, and can cause bleeding and swelling, thus making subsequent efforts more difficult. Most approaches to removal of FBs are anecdotal and found in the literature as case reports or case series rather than as prospective clinical trials. Familiarize yourself with several techniques because the most appropriate choice depends on the size, shape, consistency, and depth of impaction of the object.

Irrigation is the least invasive method; the techniques were explained in detail earlier in this chapter (see section on Removal of Impacted Cerumen and Fig. 63.19). Irrigation works particularly well with small rocks, dirt, or sand that lie deep in the canal next to the TM.

Suction-Tipped Catheters

This technique works well with objects that are round and difficult to grasp. Suction is readily available in the ED but should provide 100 to 140 mm Hg of negative pressure to be

Figure 63.21 The Hognose device for removal of a foreign body (FB). The Hognose attaches to the otoscope and to wall suction. Occlusion of the open insufflation port (*arrow*) engages suction and removes the FB. The Hognose device is available through IQDr, Inc. (<http://iqdr.com>).

useful. To avoid iatrogenic injury, inform the patient of the impending noise to prevent sudden movements caused by a startle reflex. Place either the blunt or the soft plastic tip against the object and withdraw it slowly. If using a suction instrument with a thumb-controlled release valve (as with the Frazier suction tip), remember to cover the port to activate the suction.

The Hognose (IQDr, Inc., Manitou Springs CO), a commercially available device designed by an emergency clinician, aids in the removal of FBs in the auditory canal. It is used in combination with an otoscope and suction setup. It is essentially an otoscope speculum with suction attachment and a soft self-molding tip that can attach to objects. The flange comes in three color-coded sizes: 4, 5, and 6 mm. To use, first attach the Hognose to the otoscope and set the standard wall suction at a low to medium vacuum setting (Fig. 63.21). Next, under direct visualization, approach the FB with the otoscope. Finally, engage suction by applying finger pressure on the open insufflation port and withdraw.

Manual Instrumentation

This approach can be attempted with various instruments (Fig. 63.22, *plate 1*). Use the diagnostic or operating head of a fiberoptic otoscope for illumination and magnification. Ask an assistant to hold the pinna back and out so that you can hold the otoscope with one hand and manipulate the instrument with the other. A speculum and either a headlamp or a head mirror/light source can also provide illumination; magnifying loupes are usually required for adequate visualization. Use small alligator forceps to remove objects with edges that can be grasped, but avoid trying to encircle an impacted round FB because this may cause trauma to the canal wall. A small right-angle hook is another choice. Place the tip past the object, rotate it 90 degrees, and then pull the object from the canal. Fine tissue or Adson forceps, curets, and skin hooks are other instruments used occasionally. Use of these instruments is commonly associated with abrasions and bleeding of the ear canal.^{24,25} Instruments should be used only on compliant, cooperative patients. Direct visualization of the object is essential.

Fogarty Catheters

Small Fogarty catheters (biliary or vascular) may be used in a manner similar to that described later in this chapter, in the

section on **Nasal FB Removal**. Attach the tip of the catheter to a 3-mL syringe. Pass the catheter beyond the FB. Once the tip is past the object, gradually inflate the balloon and drag the FB out along with the balloon. Immediately deflate the balloon if pain suddenly occurs because rupture of the TM is a potential complication.

Cyanoacrylate (Superglue)

The use of glue to remove FBs was first reported in India in 1977.^{25,26} Glue is most effective in removing smooth, round objects that are difficult to grasp (see Fig. 63.22, *plate 2*). The FB should be dry and easily visualized. Apply a small amount of glue to the tip of a thin paintbrush, a straightened paper clip, or the blunt end of a wooden cotton-tipped applicator. Allow the glue to become tacky. Place the tip against the object, allow it to dry, and then carefully withdraw the FB. Minor complications are possible if the tip dries against the canal wall (abrasion, excoriation) or if the glue spills or drips onto the wall (thereby creating a new FB). This technique may be more useful in adults because cooperation is required.²⁶

Removal of Insects

Cockroaches are the most commonly found live insects in the ear (see Fig. 63.22, *plate 3*). A suggested treatment is to instill various substances into the ear canal to immobilize or kill the insect before removing it. This helps in retrieval by allowing a stationary target and also halts the disturbing and painful movement of the insect. Controversy exists about which agent can most effectively accomplish this task. Mineral oil has traditionally been used, but lidocaine has been reported to paralyze insects and allow easier extraction than with the more viscous mineral oil. An in vitro comparative study showed that immersion in microscope oil versus 2% or 4% lidocaine solution killed roaches in less than 60 seconds (≈ 27 and 41 seconds, respectively).²⁷ The roaches struggled less in the viscous oil than in the lidocaine, which did not appear to cause paralysis. Other substances (isopropanol, water, succinylcholine, hydrogen peroxide) were shown to be ineffective in killing the roaches in a reasonable amount of time. Once disabled, insects are removed by mechanical extraction as described previously; pieces can be suctioned out if fragmentation occurs.

If an insect cannot easily be removed or if parts remain, it is quite acceptable to prescribe outpatient antibiotic drops for 24 to 48 hours and try irrigation again or refer to a specialist. As with any FB in the ear canal, prolonged attempts at removal in the ED are counterproductive.

Complications

Hearing should be evaluated before and after removal of an FB, especially in patients with suspected TM or middle ear injuries. Also examine the opposite ear and the nose of children to search for the rare but possible second FB. Minor lacerations or excoriations of the canal usually heal quickly with or without antibiotic ear drops, as long as the canal is kept clean and dry. Document preexisting canal trauma or suspected TM rupture before attempts at removal; otherwise, this may be falsely attributed to iatrogenic causes at a later date. Indications for otolaryngology referral include failed removal of the object in the ED, existent injury to the EAC or TM, TM rupture, EAC infection, object wedged in the medial part of the EAC or up against the TM, glass or other sharp-edged FBs, and special circumstances (disk batteries and putty). Generally, no routine follow-up is necessary except in

Ear Canal Foreign Body Removal

Various devices for FB removal from the ear canal. **A**, Right-angle hook. **B**, Irrigation. **C**, Alligator forceps. **D**, Soft-tipped suction. Direct visualization of the canal is mandatory, as is patient cooperation. Abrasions of the ear canal and subsequent bleeding are common.

Putting superglue on a stick and allowing it to attach to an FB may be successful. This technique is most effective in removing smooth, round objects that are difficult to grasp. The FB should be dry and easily visualized. A high degree of patient cooperation is required.

Removal of an insect can be a disaster or relatively easy. An easy way is to use ketamine anesthesia with careful direct extraction. No patient can cooperate with more than minimal manipulation of the inner ear canal. Instilling mineral oil or lidocaine into the canal to kill the insect before extraction is recommended.

Figure 63.22 Removal of a foreign body from the ear canal. Avoid excessive and prolonged attempts in the emergency department to remove difficult FBs. For difficult-to-extract insects, it is appropriate to prescribe outpatient antibiotic drops for 24 to 48 hours and again try to irrigate the insect or refer to a specialist. Adequate anesthesia is essential because no patient can fully cooperate with painful deep ear canal manipulation. *FB*, Foreign body.

cases of infection, severe trauma, or perforation of the TM. Parents should be educated to reduce the exposure of children to potential FBs.

Drainage of Auricular Hematomas

Auricular hematomas occur after the application of a shearing force to the ear, most commonly in wrestlers, boxers, and rugby players after fights. A subperichondrial hematoma forms and separates the perichondrium from cartilage. The hematoma may also arise from the cartilage itself. Recurrent or untreated injuries allow the development of new cartilage, which subsequently deforms the auricle (cauliflower ear).

Indications and Contraindications

Diagnosis of an auricular hematoma is based on the history and physical examination (Fig. 63.23). The presence of tender, anterior auricular swelling following trauma that deforms the anatomy of the pinna should prompt drainage of the hematoma. The goal is to prevent cartilage damage and deformation of the pinna.

If the patient is initially seen more than 7 days after injury, drainage may be difficult because of the formation of granulation tissue, and these patients should be referred to an otolaryngologist. In addition, patients with concomitant cellulitis, perichondritis, or recurrent and chronic hematomas should be referred to a specialist.

Auricular Hematoma Evacuation

Auricular hematomas manifest after trauma with anterior auricular swelling. The hematoma forms between the cartilage and perichondrium and will lead to permanent deformity if not treated.

Anesthetize the pinna via local infiltration of 1% lidocaine without epinephrine or via an auricular block.

Use a scalpel to incise the skin along the natural skin folds at the edge of the hematoma. Follow the natural curve of the pinna.

Gently peel the skin and perichondrium off the hematoma and underlying cartilage. Completely evacuate the hematoma and irrigate the pocket with normal saline.

A compression dressing must be placed to prevent reaccumulation of the hematoma. Place dry cotton into the EAC and fill all external auricular crevices with saline-soaked or Vaseline gauze.

Carefully conform the material into all the convolutions of the auricle. Vaseline gauze, saline-soaked 1/4-inch packing gauze, or saline-soaked cotton may be used. Place gauze behind the ear.

Place three to four layers of gauze behind the ear as a posterior pack, and then cover the entire ear with multiple layers of fluffed gauze.

Secure the dressing to the head with Kerlix or an elastic wrap.

Figure 63.23 Evacuation of an auricular hematoma. *EAC*, External auditory canal.

Procedure

Treatment of an auricular hematoma is complete evacuation of the subperichondrial hematoma and approximation of the perichondrium to the cartilage.

Needle Aspiration

Though used widely, this technique is no longer recommended by most authorities because of the high risk for reaccumulation of the hematoma. Aspiration is often inadequate and other management is required. Other sources recommend needle aspiration followed by incision and drainage if reaccumulation occurs.²⁸

Aspiration of an auricular hematoma is performed by perforating the hematoma with a 20-gauge needle. “Milk” the hematoma between the thumb and forefinger until the entire hematoma is evacuated. Apply a pressure dressing. Reexamine the ear frequently for reaccumulation of the hematoma. Reaccumulation of blood requires reaspiration. For small hematomas that are acute, needle aspiration alone with a bolster dressing is adequate therapy.²⁸

A newer variation of needle aspiration has been described by Brickman and coworkers.²⁹ In their method, after preparation and local anesthesia, needle aspiration was performed using an 18-gauge angiocath and 10-cc syringe. After the collection was aspirated, the syringe and needle were removed, leaving the plastic catheter in place. A compressive dressing was then applied and patients were closely followed up. The catheter was removed in 5 days. Of the 53 patients enrolled, 94.3% initially had adequate hematoma drainage with excellent long-term results. In the initial 72 hours, six patients had catheter dislodgement, with hematoma reaccumulation in three patients (5.6%). These were successfully drained by reaspiration and there were no further recurrences.

Incision (see Fig. 63.23)

An auricular hematoma may be incised along the natural skin folds. Anesthetize the pinna by local infiltration of 1% lidocaine (without epinephrine) or with an auricular block (described

earlier). Incise the skin with a No. 15 blade at the edge of the hematoma and follow the curvature of the pinna. Gently peel the skin and perichondrium off the hematoma and underlying cartilage. Completely evacuate the hematoma and irrigate the remaining pocket with normal saline.

After removing the hematoma, apply antibiotic ointment and reapproximate the perichondrium to the cartilage with a pressure dressing. A compression dressing, noninvasive or surgical, must be applied because a simple dressing will allow the hematoma to reaccumulate. First, dry cotton should be placed into the EAC. Next, fill all external auricular crevices with mineral oil, saline-soaked gauze, or Vaseline gauze. Then place three to four layers of gauze behind the ear as a posterior pack. Cut a V-shape out of the gauze first to allow a snug fit. Cover the packed external ear with multiple layers of fluffed gauze. Bandage the fluffed gauze in place with Kerlix or an elastic wrap.

A surgical compressive dressing involves suturing dental rolls over the area. To accomplish this, pass a 4-0 nylon suture through the entire thickness of the ear and over the hematoma. Wrap the suture around a dental roll on the posterior aspect of the ear and then pass the needle back through the pinna. Wrap and tie the suture around a second dental roll on the anterior aspect of the pinna. A second suture may be placed to secure a third dental roll. The dressing should firmly reapproximate the perichondrium to the cartilage without compromising the vasculature. Remove the dressing in 1 week. The procedures are compared in Table 63.1.³⁰

Prescribe antistaphylococcal antibiotics and instruct the patient to inspect the wound frequently for evidence of vascular compromise, infection, or both. Reevaluate the wound in 24 hours for recurrence of the hematoma. Treat infection by removal of the bandage, surgical drainage, and intravenous antibiotics.

Complications

There are a few complications associated with management of auricular hematomas. The first is incomplete evacuation

of the hematoma, which can lead to destruction of cartilage (cauliflower ear). The hematoma can reaccumulate. Local site infection can develop and result in the development of chondritis. Finally, scar formation leading to deformity is possible.

NOSE

Anatomy

The nose consists of the vestibule, nasal septum, lateral wall, and nasopharynx. The vestibule is the anterior-most portion of the nares and is composed of skin and hair follicles. The nasal septum is the midline structure and is composed of cartilage anteriorly and bone posteriorly. The lateral wall of the nose contains the superior, middle, and inferior turbinates, as well as the auditory tube opening.

Three major arteries supply the nose and conjoin via anastomoses. The sphenopalatine artery emerges from the sphenopalatine foramen, which is located at the posterior aspect of the middle turbinate (Fig. 63.24). This is the most common source of posterior epistaxis. This artery supplies the lateral turbinates and the posterior septum. The anterior and posterior ethmoidal arteries branch off the ophthalmic artery and penetrate the cribriform plate to supply the superior nasal mucosa. The superior labial branch of the facial artery completes the triad and supplies the nasal septum and vestibule. The watershed area on the anterior septum, also known as Kiesselbach's plexus, is the most common source of anterior epistaxis (Fig. 63.25).

Anesthesia of the Nose

Most nasal anesthesia can be accomplished topically. Numerous preparations are available. Cocaine (4% solution) is the preferred agent for both vasoconstriction and anesthesia. Unfortunately, cocaine is not routinely stocked. Alternatively, 2% lidocaine with epinephrine (local anesthetic solution) may be used but is less effective. Be aware of the total amount of lidocaine

being administered and stay within recommendations for the maximum safe dosage. This is an issue primarily with elderly patients who have cardiovascular disease. Lidocaine 4% is also quite effective for anesthesia of the nose. A solution of 1% tetracaine and 0.05% oxymetazoline (Afrin, Bayer) is an effective topical anesthetic and vasoconstrictor.³¹

Apply the local anesthetic and vasoconstrictor to cotton swabs (Fig. 63.26). If a larger area of anesthesia is needed, use cotton pledgets. Fig. 63.27 describes the procedure of making pledgets. Soak each pledget in an anesthetic or vasoconstrictor and then squeeze the excess fluid out of the pledget. Place each pledget horizontally on the floor of the nasal cavity and stack the next pledget on top. Three pledgets are usually required to pack the nasal cavity. They can be replaced with new pledgets in 5 minutes if the desired anesthetic effect is not achieved. Benzocaine (Hurracaine, Beutlich Pharmaceuticals) spray may also be used as a topical anesthetic. Remind the patient that excess anesthetic may numb the throat but will not inhibit swallowing.

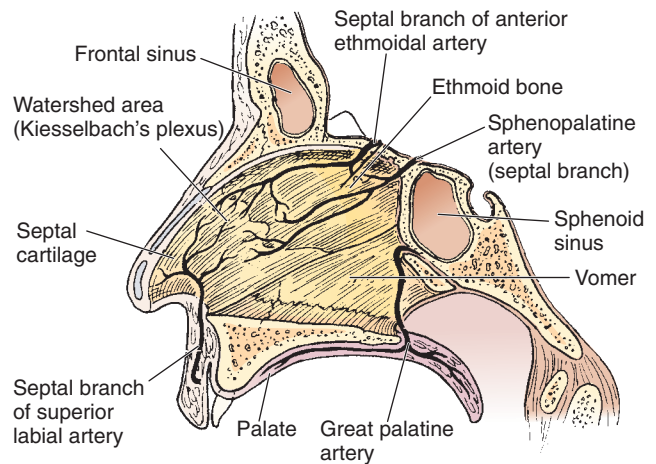

Figure 63.25 Vascular supply to the nasal septum. The most common site of anterior epistaxis is within the area labeled Kiesselbach's plexus. (From Maceri DR: Epistaxis and nasal trauma. In Cummings CW, editor: *Otolaryngology—head and neck surgery*, ed 2, St. Louis, 1993, Mosby-Year Book, p 728.)

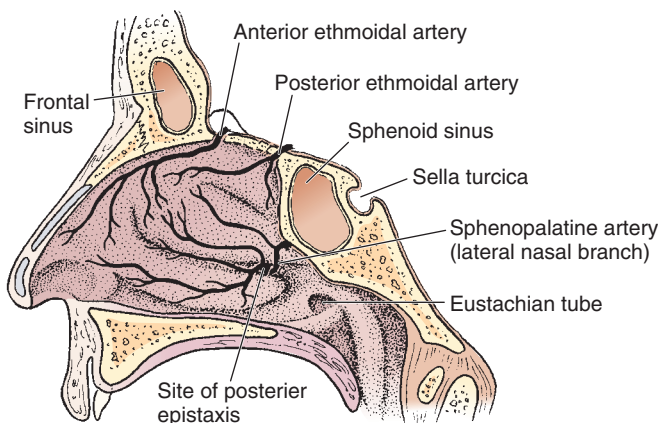

Figure 63.24 Vascular supply to the lateral wall of the nose. The most common site of posterior epistaxis is the sphenopalatine artery as it emerges posterior to the middle turbinate. (From Maceri DR: Epistaxis and nasal trauma. In Cummings CW, editor: *Otolaryngology—head and neck surgery*, ed 2, St. Louis, 1993, Mosby-Year Book, p 728.)

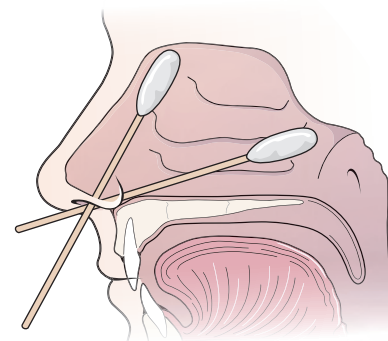

Figure 63.26 Placement of local anesthetic in the nose to block the anterior ethmoidal nerve superiorly and the sphenopalatine ganglion at the posterior end of the middle turbinate before reducing a nasal fracture. Cocaine is the preferred agent. (From Schuller DE, Schleuning AJ, DeMaria TF, et al, editors: *DeWeese and Saunders otolaryngology: head and neck surgery*, ed 8, St. Louis, 1994, Mosby, p 152.)

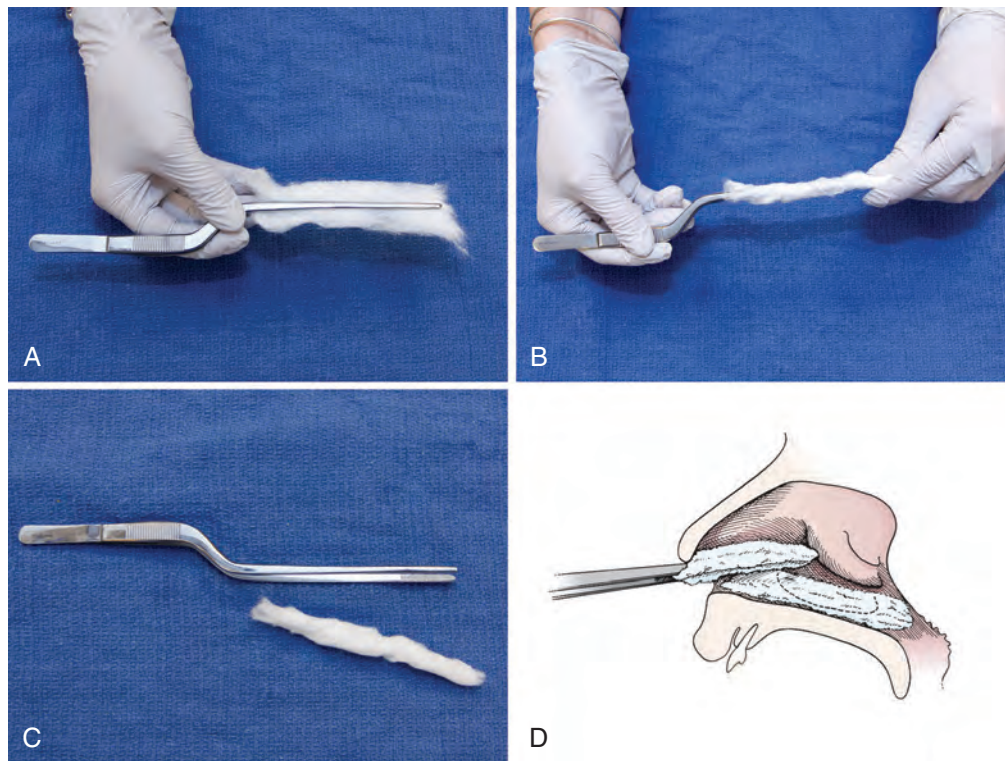

Figure 63.27 Topical anesthetic and vasoconstrictors are applied on individually made cotton pledgets. The size of the pledget may be changed according to the extent of the nasal cavity to be anesthetized and the size of the patient. **A**, Grasp an appropriately sized cotton pledget with bayonet forceps. **B**, Then grasp the cotton with the opposite hand and rotate the forceps. **C**, The pledget is removed and is ready for insertion. **D**, To completely anesthetize the nasal cavity, three pledgets are necessary. The first is placed on the floor of the nose, the second in the middle meatus between the inferior and the middle turbinates, and the third in the roof of the nasal cavity and the anterior nasal vestibule. Note: This pledget technique can be used to make a cotton wick for the treatment of otitis externa.

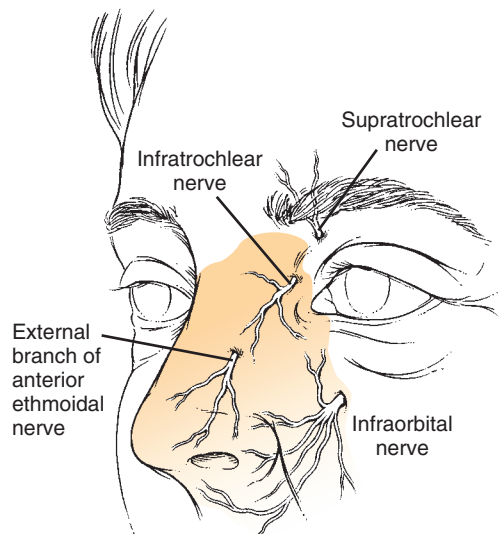

Figure 63.28 Sensory innervation of the nose. (From Flint PW, Haughey BH, Lund VJ, et al, editors: *Cummings otolaryngology: head and neck surgery*, ed 5, Philadelphia, 2010, Mosby Elsevier.)

A local nasal block can be performed for more painful and prolonged procedures. The sensory innervation of the nose is illustrated in Fig. 63.28. It begins with topical anesthetic as just described. Next, using a thin 25- or 27-gauge needle, inject 1% lidocaine with 1:100,000 epinephrine along the

septum, lateral walls, and nasopalatine nerves. Depending on the procedure, it may be necessary to anesthetize both sides. First, inject along and beneath the soft tissue of the nasal dorsum (infratrochlear nerve). Next, inject in the area of the infraorbital foramen to anesthetize the infraorbital nerve. Finally, inject at the base of the columella (base of the nose between the nasal septa) and along the floor of the nasal cavity. Interestingly, studies have shown that the use of EMLA (eutectic mixture of local anesthetics) cream applied over the nose 1 hour before reduction, in combination with topical intranasal anesthetic, provides similar nasal anesthesia for reduction of nasal fractures with less discomfort than occurs with needle infiltration.³²

Examination

Examination of the nares is relatively straightforward, albeit often quite stressful to the patient. When using a nasal speculum, insert it into the naris with the handle parallel to the floor and slowly open the blades in a superior-to-inferior direction. It is a common error to attempt to spread the nares horizontally. Stabilize your hand on the patient's nose to prevent damage to the mucosa from unexpected movement (Fig. 63.29). When attempting to visualize the nasal passageway, remember to have the patient keep the floor of the nose parallel to the ground. Tilting the head allows a view of only the anterosuperior area. A nasopharyngoscope may be used to view the nasal passageways as well, and its use is described in the previous section on examination of the pharynx.

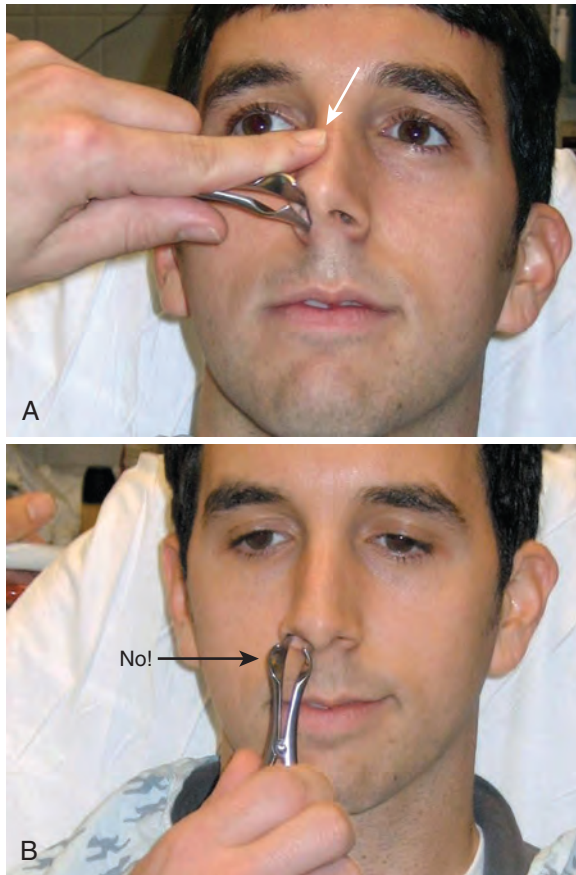

Figure 63.29 To properly examine a nose, use a nasal speculum. **A**, The clinician rests the index finger on the bridge of the nose (*arrow*) and spreads the speculum in an inferior-to-superior direction. **B**, It is incorrect to spread the speculum laterally or to use the instrument in an unsupported manner.

Management of Epistaxis

Patients with nasal hemorrhage are commonly seen in the ED and account for approximately 1 in 200 visits.³³ Epistaxis occurs more frequently in the young (< 10 years) and old (70 to 79 years). Most cases are traumatic and occur in the winter months. Approximately 6% require hospitalization.³⁴

Identification of the source of bleeding and subsequent control are paramount to the treatment of epistaxis. Although this can be frightening to both the clinician and patient, a systematic approach with the proper equipment will lessen the anxiety associated with the situation (Fig. 63.30). The goal of the procedure is to tamponade or cauterize the bleeding site. If the source is anterior, this may be the final treatment. For posterior bleeding, temporizing maneuvers are generally used until the process stops or a consultant can complete a definitive hemostatic procedure. The procedures can be performed in the ED with proper lighting and the equipment listed later in this section. Controlling epistaxis may be a time-consuming process without proper equipment or patient cooperation.

In preparation for any procedure to treat epistaxis, evaluate the patient's hemodynamic status by assessing vital signs and orthostatic symptoms and by quantifying the amount of blood lost. If the patient is symptomatic in any of these areas or if the blood loss is deemed significant, consider starting a

Figure 63.30 A nosebleed is frightening and interventions are most unpleasant. Judicious use of parenteral sedation and analgesia, with attention to aesthetics, results in a more rewarding encounter. If required, intravenous morphine is a good choice.

large-bore intravenous line for administration of fluid boluses. Hematologic testing is rarely useful and not required for most patients, but in extenuating circumstances, obtain a complete blood count and consider a type and screen. Coagulation studies are not routinely indicated but should be undertaken in patients taking anticoagulants, those with underlying hematologic abnormalities, or individuals with recurrent or prolonged epistaxis.³⁴

Many patients with epistaxis are hypertensive as well, often transiently secondary to stress and anxiety. No direct causal correlation between hypertension and overt epistaxis has been proved. The hypertension that is so often seen with epistaxis is probably a stress response instead of an inciting event. In a hypertensive patient, one can administer intravenous opioids (such as morphine) to relieve stress and anxiety, thereby usually also lowering blood pressure. In most cases, hypertension does not require treatment until evaluation after the bleeding is controlled and the anxiety of the situation has resolved. However, any patient exhibiting other signs of a true hypertensive emergency needs immediate antihypertensive treatment in addition to control of the epistaxis.

Epistaxis is rarely a manifestation of a nasopharyngeal neoplasm, unknown blood dyscrasia, nasal FB, nasal cocaine use, chronic use of nasal corticosteroid sprays, or aneurysm of the carotid artery.

Anticoagulated Patients With Epistaxis

Anticoagulated patients are at high risk for nosebleeds. However, the need for cessation and reversal of oral anticoagulants (i.e., warfarin) is controversial and not well studied. It is reasonable to continue warfarin when hemostasis is achieved and the international normalized ratio (INR) is in the intended therapeutic range. An excessive INR calls for temporary cessation of warfarin and reversal if markedly abnormal. Methods to reverse newer, non-vitamin K oral anticoagulants (i.e., dabigatran, rivaroxaban) are also elsewhere in the text. Specific factor replacement will be required in patients with hemophilia.

Additional Testing for Epistaxis

Although an evaluation of coagulation parameters (prothrombin time, INR, platelet count) is not standard for patients

Epistaxis Management

Indications

Persistent epistaxis

Contraindications

Massive facial trauma with the possibility of a basilar skull fracture

Complications

Cautery

Nasal septal injury/perforation
Rebleeding

Anterior packing

Sinusitis

Dislodgment	Arrhythmias
	Myocardial infarction
	Death

Equipment

Other equipment not depicted: light source/headlight, protective equipment, tongue depressors, kidney basin, gauze, silver nitrate sticks, 12-Fr Foley catheters. See text for details.

Review Box 63.3 Epistaxis management: indications, contraindications, complications, and equipment.

with epistaxis, these studies should be ordered routinely for anticoagulated patients. In addition, if the patient has chronic persistent bleeding, an evaluation of coagulation is prudent. A complete blood count is suggested for those with prolonged or recurrent bleeding to assess for significant blood loss. Though a rare consideration in the ED, epistaxis is a significant problem for patients with hereditary telangiectasia, von Willebrand's disease, and hemophilia. Generally, these conditions are already known. CT or magnetic resonance imaging of the nasopharynx may be considered for elderly patients with recurrent epistaxis to evaluate for neoplasm.

Indications and Contraindications to Treatment of Epistaxis

Any continuing episode of epistaxis can be treated with the techniques listed in the section on [Procedure](#). Massive facial trauma with the possibility of a basilar skull fracture would preclude the use of an intranasal balloon or packing because it may travel into the skull cavity.

Equipment

Preparation is the key to successful management of a patient with epistaxis. The following list of equipment should be readily available to the emergency clinician (see [Review Box 63.3](#)):

- chair with a headrest or gurney with an inclinable back
- headlight with a light source and head mirror
- wall suction with multiple suction catheters
- gloves, mask, and gown for the clinician
- gown or drapes for the patient
- topical anesthetic
- topical vasoconstrictor
- nasal speculum

- tongue depressors
- small red rubber catheters
- bayonet forceps
- scissors
- kidney basin
- gauze (4 × 4 inch, 2 × 2 inch), dental rolls or cotton, No. 2 surgical silk ties
- 1.2-cm-wide Vaseline gauze or 0.5-inch-wide Nu-Gauze (Johnson & Johnson) packing
- antibiotic ointment
- silver nitrate sticks or electrocautery
- pediatric Foley catheters (12 Fr)
- nasal tampons
- dual-balloon pack

Procedure

Because most patients are frightened by continued epistaxis and because nasal instrumentation can be annoying or painful, provide reassurance to the patient that the bleeding can be controlled with minimal discomfort. Judicious use of parenteral sedation or narcotic analgesia is well supported to make the entire interaction more palatable to the patient and ultimately more successful. Drape the patient with a gown to protect clothing from the bleeding. Have the patient hold an emesis basin to collect any continued bleeding and as a precaution to emesis of swallowed blood. Minor anterior bleeding is usually easily controlled with minimal techniques.

Ask the patient to sit upright in the sniffing position with the neck flexed and the head extended ([Fig. 63.31](#)). The base of the nose should remain parallel to the floor. After putting on a face shield, gown, and protective gloves, position yourself in front of the patient, level with the patient's nose. Have the

Epistaxis Management: Initial Steps

1 Position the patient sitting upright in the sniffing position with the base of the nose parallel to the floor. Proper lighting with a headlamp or mirror is essential.

2 Ask the patient to blow his nose to remove all blood and clots from the nasal passage.

3 Alternatively, gently suction the nasal cavity. Suction from front to back along the nasal septum and then laterally.

4 If bleeding is minimal, attempt to locate the specific bleeding source. Use a nasal speculum to maximize visibility.

5 If bleeding is too profuse for visualization, apply a topical vasoconstrictor such as oxymetazoline.

6 Alternatively, cotton pledgets soaked in cocaine may be inserted into the nasal cavity with bayonet forceps.

Figure 63.31 Management of epistaxis: initial steps.

patient blow the nose to remove clots or suction the nasal passageway carefully. This may temporarily increase bleeding but can aid in identifying the bleeding site. Suction from front to back along the nasal septum and then laterally. If the bleeding is minimal, attempt to locate the specific bleeding source. If the bleeding is too profuse for visualization of the source, administer a topical anesthetic and vasoconstrictor. One method is to insert lidocaine with epinephrine-soaked cotton swabs into each nare. Ask the patient to clamp the nostrils to limit bleeding and promote contact with the mucosa. If a discrete bleeding site is initially identified, an effective way to provide hemostasis and anesthesia is to inject the mucosa at the base of the bleeder with 2% lidocaine with epinephrine via a tuberculin needle and syringe device.

Insert the nasal speculum into the naris and use the suction catheter to evacuate any blood. Reapply anesthetic or vasoconstrictor if necessary. Because most cases of anterior epistaxis occur in Kiesselbach's plexus, inspect this area closely for areas of bleeding, ulceration, or erosion. After vasoconstriction, the only evidence of the former bleeding site may be a small prominent vessel. Many clinicians will gently stroke the septum with a cotton swab to initiate bleeding so that an exact area of pathology can be identified and then cauterized. If no bleeding source is found and the bleeding has ceased, pack the nose only if the epistaxis is recurrent. Wait 15 to 20 minutes before deciding on further intervention. If no anterior source

is found and bleeding continues down the posterior aspect of the pharynx, assume a posterior source and consider packing the nose with anterior and posterior packs.

Cautery

After an anterior source of bleeding is identified, cautery may be used to achieve hemostasis (Fig. 63.32). Silver nitrate sticks may be used to cauterize but will not work on an actively bleeding source; hemostasis must be achieved first. For brisk bleeding inject lidocaine with epinephrine at the base of the vessel with a tuberculin syringe. Silver nitrate works well for a small, circumscribed area of bleeding. To apply, hold the tip of the silver nitrate stick against the site for 4 to 5 seconds. Apply again if necessary. Wipe away any excess silver nitrate to prevent inadvertent cautery of other areas of the nose. Most patients will sneeze after the application of silver nitrate, so be careful of blood splatter. If bleeding restarts, the initial cautery was insufficient and should be applied again. The cauterized area immediately turns white or gray. Electrocautery works in the same manner but will penetrate more quickly than silver nitrate does. With either cautery technique, be careful to not cause septal perforation with overaggressive or repeated cautery. If cautery has not been successful after two attempts, use another technique.

Multiple attempts at cautery can significantly injure the nasal septum, and bilateral cautery should not be performed.

Epistaxis Management: Cautery

Cautery is used if an anterior bleeding source is identified. If no bleeding source is seen, brush the septum with a cotton swab under direct vision to stimulate the bleeding site. If there is active bleeding, cautery will not work and should not be attempted.

Cautery should be attempted only under direct vision; do not blindly cauterize. To apply, hold the tip of the silver nitrate stick against the site for 4 to 5 seconds. Most patients will sneeze after the application of silver nitrate.

The cauterized area will turn whitish gray. If bleeding restarts, the initial cautery was insufficient and should be reapplied. Avoid multiple cautery attempts and bilateral cauterization because these practices may lead to septal injury or perforation.

Figure 63.32 Management of epistaxis: cautery.

If this is the initial bleeding and hemostasis is achieved, no packing is necessary. If it is recurrent bleeding within 72 hours of another or if cautery does not provide hemostasis, pack the anterior cavity. If hemostasis is accomplished, apply petroleum jelly or antibiotic ointment to the area to prevent desiccation. Loughran and coworkers³⁵ found antimicrobial ointment to be better than petroleum jelly in preventing bleeding. Do not administer aspirin or nonsteroidal antiinflammatory drugs for 4 days after epistaxis. If bleeding recurs at home, instruct the patient to pinch the nostrils closed for 20 minutes. Instruct the patient to return to the ED if this maneuver is unsuccessful or if the bleeding is profuse.

Anterior Nasal Packing

Anterior packing achieves hemostasis, prevents desiccation, and protects the area from trauma. However, improperly placed packing may further abrade the area, dislodge prematurely, or migrate into the posterior pharyngeal area. Anterior packing must be placed with adequate analgesia, proper visualization, and deliberate movements. Coating any packing material with antibiotic ointment (if not contraindicated by the manufacturer) aids in placement and theoretically helps prevent infections and toxic shock syndrome (TSS) secondary to nasal packing. Areas that continue to ooze after cautery can be treated with an anterior pack.

Easier-to-use commercial devices have largely supplanted traditional petrolatum gauze. Packing is applied in an “accordion” fashion so that each layer extends the entire length of the nasal cavity (Fig. 63.33A). Place the speculum properly to allow visualization of the floor of the nasal cavity. Lay a strip of petrolatum gauze 1.2 cm across the nasal floor, with the starting end of the gauze at the naris. Gently pack the gauze strip into the floor of the nose. Measure the gauze so that it is twice the length of the nasal cavity. Grasp the gauze at the midpoint and insert this point all the way back to the posterior aspect of the nasal cavity. Attempt to place this layer of gauze without movement of the underlying layer. Continue this pattern, with replacement of the speculum after each layer, until the cavity is filled.

When compared with gauze packing, compression devices are easier to place, better tolerated, and very successful. These are preferred over gauze packing by the editors. Preformed nasal packing products are convenient alternatives to anterior nasal packing (Figs. 63.34 and 63.35). The Merocel packing consists of compressed polyvinyl acetate with or without a drawstring that markedly expands on contact with fluid and thereby exerts pressure on the bleeding site. The pack can be trimmed with scissors or a scalpel before insertion. The Merocel Doyle nasal pack (Medtronic) has an airway tube in the center of the compressed material and a more anatomic shape. Each is available in various sizes, but usually an 8- × 1.5- × 2-cm standard Merocel or 8- × 1.5- × 3-cm Doyle will suffice. The Rapid Rhino Stat Pac (ArthroCare ENT, Austin, TX; see Fig. 63.34) is a high-volume, low-pressure balloon device with an open lumen air passage, a pilot cuff to check pressure, and a specialized Gel-Knit (carboxymethyl cellulose) covering designed to promote platelet aggregation. Numerous variations for anterior, posterior, and combination packs are available.

The easily applied nasal tampon is a reasonable first choice for most anterior bleeding (see Fig. 63.33B). Lubricate the tampon generously with antibiotic ointment and trim the length and width carefully to minimize trauma to the nose. Using bayonet forceps, advance the packing carefully along the floor of the nose. Remember to direct it parallel to the floor, not upward toward the top of the nose. Insertion may be painful, so use a single rapid movement. Once the packing is in the nasal cavity, expand it with 5 to 10 mL of saline, although contact with the moisture of the nose will often cause it to swell spontaneously. It is sometimes necessary to place two tampons side by side before inserting them, to fill the nasal cavity and provide better pressure on the areas of bleeding.^{36,37} Observe for 10 minutes after anterior packing to identify continued bleeding either anteriorly from the naris or running down the posterior aspect of the pharynx. Advantages of the Merocel tampon include rapid insertion, little discomfort, ease of use even by inexperienced personnel, and possible inhibition of bacterial growth.

Epistaxis Management: Anterior Packing

A Accordion Petroleum Gauze Pack

1

Place the packing in accordion fashion so that part of each layer lies anteriorly, which prevents it from falling posteriorly. Place the first layer on the floor of the nose and then remove the bayonet forceps.

2

Place a second layer on top of the first in an identical manner. After several layers have been placed, use the forceps to push the previous layers down onto the floor of the nose and pack them tighter.

3

A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavity and will stay in place until the clinician or patient removes it.

B Nasal Tampon (Merocel)

1

Trim the length and width of the tampon to fit the nose, lubricate with antibiotic ointment, and advance posteriorly, parallel to the nasal floor.

2

Once inserted, expand the tampon with 5–10 mL of saline.

3

If the tampon comes with a drawstring, it can be tied around a piece of gauze to prevent posterior displacement.

C Rapid Rhino Device

1

Soak the device in sterile water for 30 seconds. Do not soak in saline because this can inhibit its gelling characteristics.

2

Insert the Rapid Rhino along the floor of the nasal cavity parallel to the hard palate until the plastic ring is well within the nasal cavity.

3

Inflate the device with air (do not use water or saline) until the pilot cuff becomes rounded and feels firm to the touch.

Figure 63.33 Management of epistaxis: anterior packing.

The Rapid Rhino device is first soaked in sterile water for 30 seconds (see Fig. 63.33C). Do not use saline because it can inhibit its gelling characteristics. In addition, lubricants or antibacterial ointments are not needed. Insert the device along the nasal septal floor parallel to the hard palate until the plastic ring is well within the nasal cavity. Use a 20-mL syringe to inflate the device with air only. Stop inflating when the pilot cuff becomes rounded and feels firm to the touch.

Corbridge and colleagues³⁶ found no significant difference in efficacy, patient tolerance, or complications between commercial products and gauze packing. Singer and associates³⁸ found that the Rapid Rhino nasal tampon is less painful to insert and easier to remove than the Rhino Rocket (Shippert Medical Technologies, Centennial, CO) and that both were similarly effective in stopping nosebleeds.

Anterior packs are usually left in place for 3 to 5 days. Premature removal may result in rebleeding. A pack or device

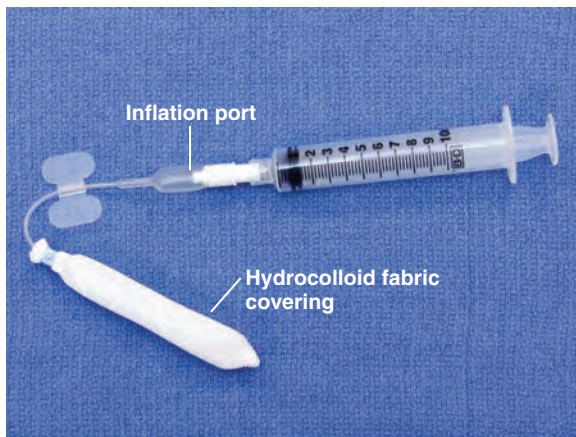

Figure 63.34 Preformed nasal packing devices. Preformed devices are easier to place and better tolerated than traditional gauze packing. The Rapid Rhino epistaxis device (ArthroCare ENT, Austin, TX) shown here has an air-inflatable balloon covered by a hydrocolloid fabric covering that allows easy insertion and removal. Various lengths and configurations are available. A wide variety of similar products are offered by other vendors. Although insertion techniques for preformed devices follow the same basic steps, review the package inserts of the equipment available at your institution before use.

may stimulate mucous production and act as an impetus for infection. Oral antibiotics (e.g., cephalexin, amoxicillin, or trimethoprim-sulfamethoxazole) may be prescribed with any nasal packing after emergency treatment because of the minimal risk for sinusitis and TSS.³⁹ The necessity of antibiotics for short-term anterior packing is unproved. Decongestants are also prescribed to decrease secretions. Practices vary and no common standards exist.

During use and before removal, keep the nasal tampon hydrated with saline. If it contains an airway tube, first remove the tube, irrigate the space once occupied by the tube, and then remove it. To remove the Rapid Rhino, first remove the air and then slide the device out.

Complications

Minor oozing of blood can be expected. Any packing in the anterior nasal cavity may obstruct drainage of the paranasal sinuses or block the nasolacrimal ducts and lead to sinusitis. Occasionally, blood will exit the nasolacrimal duct and be noted in the eye (Fig. 63.36). Other complications can include nasal mucosal pressure necrosis from the packing, balloon migration, and aspiration of the packing. Hollis⁴⁰ reported massive pneumocephalus after insertion of a Merocel nasal tampon in an elderly woman, presumably from fracture of the ethmoid plate. There have been case reports of ethmoid fracture after anterior nasal gauze packing and with the use of an intranasal balloon.

Posterior Nasal Packing

If no bleeding source is found anteriorly and the patient continues to hemorrhage down the posterior aspect of the pharynx, the patient most likely has a posterior source of epistaxis (Fig. 63.37). Posterior epistaxis may respond to topical vasoconstrictors. However, anterior nasal packing will not provide hemostasis for posterior bleeding because it will not cover the source of the bleeding. A posterior pack directly

Figure 63.35 Various packs for epistaxis in a cadaver model. **A**, A posterior Merocel sponge, not inflated, will stop most nosebleeds and is more comfortable than some balloon devices. **B**, Anterior/posterior Rapid Rhino (ArthroCare ENT, Austin, TX) in place. **C**, Double-balloon posterior pack with the balloon inflated.

compresses the sphenopalatine artery and prevents the passage of blood or anterior packing into the nasopharynx.

Posterior Gauze Pack

A posterior nasal gauze pack is the classic method of treating posterior epistaxis (Fig. 63.38). However, because balloon devices are easier to use and less distressing to the patient, formal posterior nasal packing is less commonly used. To place a formal traditional posterior nasal gauze pack, anesthetize the patient's nares and posterior pharynx with topical anesthetic. Prepare a roll of gauze with two silk ties (2-0) secured around

Figure 63.36 After packing, blood coming from a nosebleed exiting via the nasolacrimal duct gives the appearance that the eye is bleeding. Though benign, it can be alarming to the patient.

Figure 63.37 Posterior bleeding is usually readily controlled, but blood loss can be significant. Epistaxis is rarely a feature of nasopharyngeal neoplasm, unknown blood dyscrasias, nasal foreign body, cocaine use, or aneurysm of the carotid artery. This elderly patient was very anxious and quite hypertensive, and judicious use of intravenous morphine made the procedure tolerable and reduced blood pressure. Hypertension alone is not a cause of epistaxis.

the middle and extending in opposite directions. One set of ends will be used to place the posterior pack and the second will remain extruding from the oral cavity to remove the pack. Place a No. 10 red rubber catheter through the bleeding nostril. When it is seen in the posterior of the pharynx, grasp it with forceps and guide it out of the mouth. Attach it to one set of the ends of silk ties secured to the gauze pack. Retract the red rubber catheter, thus carrying the No. 2 silk tie through the nasopharynx and out of the nose. Grasp the suture and pull the pack into the nasopharynx. Guide the pack swiftly into the oral cavity and nasopharynx with the other hand. Attach the silk tie that remains in the oropharynx to the patient's cheek to aid in removal or rescue of the posterior pack. Use the silk ties exiting the nostril to maintain the position of the

posterior pack. Pack the anterior passage as described for anterior epistaxis. Secure the silk ties over a gauze pad or dental roll. In the past, patients with traditional posterior packing were often admitted to the hospital for the duration of the posterior packing. Administering humidified air or oxygen often makes this pack more comfortable.

Inflatable Balloon Packs

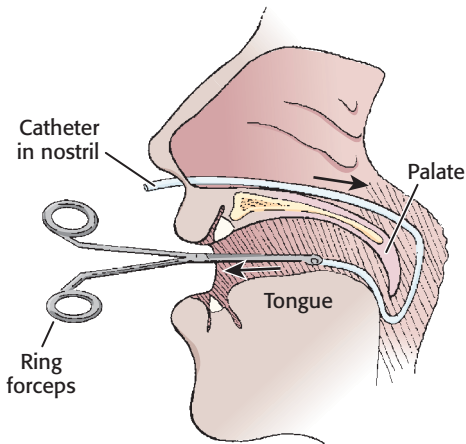

Inflatable balloons come in two varieties. A Foley catheter is often used as a posterior pack because of its availability, ease of use, and successful tamponading effect (Fig. 63.39A). Insert a 12-Fr Foley catheter through the bleeding naris into the posterior aspect of the pharynx. Inflate the balloon halfway with approximately 5 to 7 mL of normal saline or water. Slowly pull the Foley catheter into the posterior part of the nasopharynx and secure it against the posterior aspect of the middle turbinate. Finish inflating the balloon with another 5 to 7 mL of normal saline or water. If pain or inferior displacement of the soft palate occurs, deflate the balloon until the pain resolves. Ensure proper placement before completely inflating the balloon because the balloon will remain too posterior in the nasopharynx and fail to achieve hemostasis. While maintaining constant gentle anterior tension on the Foley catheter, place anterior nasal packing of layered petrolatum gauze. Pack the opposite nasal cavity to counteract septal deviation. Finally, place a short section of plastic tubing over the catheter and secure it with a nasogastric tube clamp or umbilical clamp. Be careful to not exert undue pressure on the nasal alae to avoid causing necrosis.

The second type of inflatable balloon pack is the premade dual-balloon tamponading system (see Fig. 63.39B). These devices have been a significant advance in the treatment of epistaxis. Several balloon devices are available (Goitschach Nasostat [Sparta Surgical Corp, Hayward, CA], Xomed Epistat [Medtronic Xomed], and Epi-Max Balloon Catheter [Shippert Medical]). The dual-balloon pack has a posterior balloon that inflates with approximately 10 mL of air and an anterior balloon that inflates with approximately 30 mL of air. Each device may vary slightly. After appropriately anesthetizing the naris, place the lubricated pack along the floor of the affected naris as far back as possible. Inflate the posterior balloon approximately halfway with air, and then, with traction, pull the balloon into place up against the posterior aspect of the middle turbinate. Complete the inflation of the posterior balloon with air. Some clinicians prefer to inflate all balloons with saline instead of air because air may deflate slowly. Inflate slowly, and stop if pain is felt. This is usually an uncomfortable sensation to the patient. If the patient complains of pain or if the posterior soft palate deviates downward, deflate the balloon until the symptoms are relieved. Maintain the position of the balloon and inflate the anterior balloon with up to 30 mL of air. Again, halt inflation if the patient experiences increasing pain or deviation of the nasal septum. Some authors suggest packing the opposite naris to prevent such lateral deviation. Place a small piece of gauze between the nose and the external catheter hub to decrease skin irritation.

Most patients with a posterior pack, especially the elderly and those with pulmonary and cardiovascular diseases, should be admitted to the hospital for sedation and monitoring. This recommendation was common for formal posterior packs, but the ease and safety of balloon devices now allow selected patients to be treated as outpatients despite the presence of posterior packing.

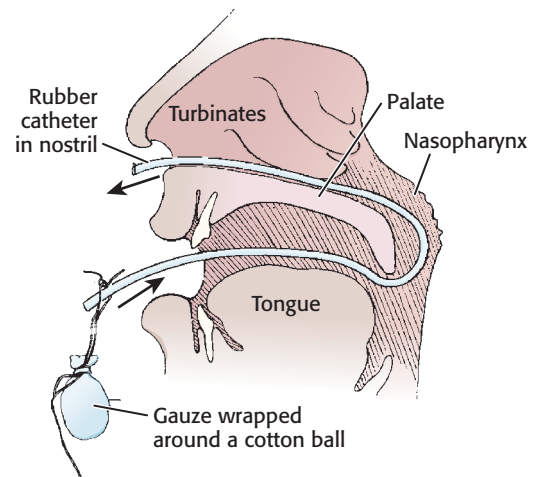

Epistaxis Management: Traditional Posterior Packing

1

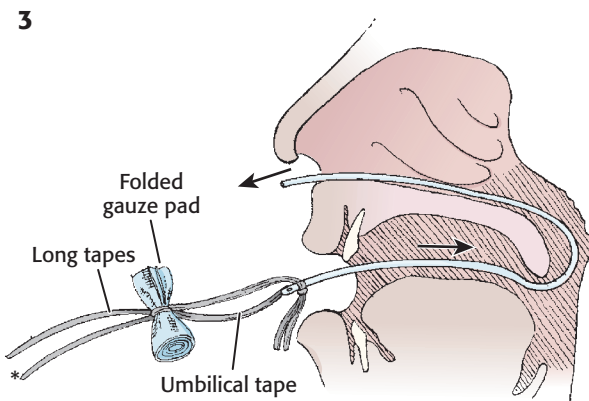

After applying topical anesthetic, pass a red rubber catheter through the nose, carefully grasp it in the oropharynx with ringed forceps, and bring it out through the mouth.

2

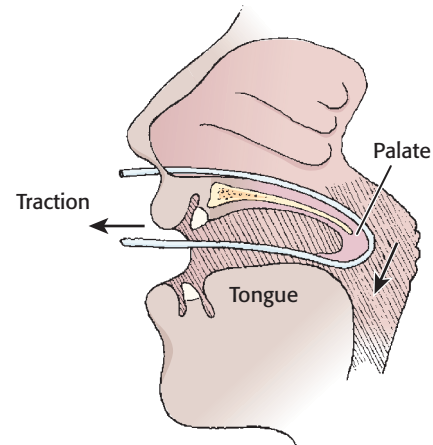

Make a posterior nasal pack by wrapping a cotton ball in a 4 x 4-inch gauze pad and tying two long silk sutures or umbilical tape around the neck of the pack. Leave one tie long so that it can be taped to the cheek until needed for removal of the pack.

3

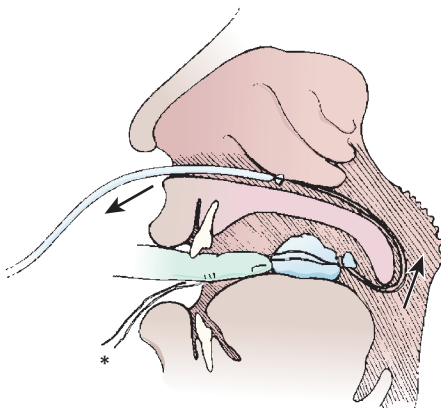

Alternatively, fold a gauze pad, roll it into a cylinder, and tie it with two strings. Use two of the long strings to tie the pack to the tip of the catheter, and use the other two to remove the pack.

4

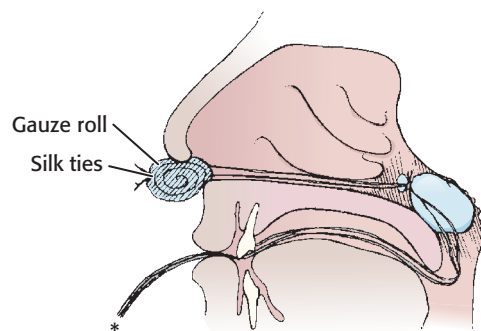

As an option, use a second catheter that has been passed through the nonbleeding side and brought out the mouth to retract the palate forward to aid in placement of the pack.

5

Remove the optional "retraction" catheter after the pack is in the proper position. Digitally guide the pack into the nasopharynx.

6

Use a gauze roll to secure the pack to the nose, and tape the rescue ties to the cheek.

Figure 63.38 Management of epistaxis: traditional posterior packing.

Epistaxis Management: Posterior Packing With Inflatable Devices

A Foley Catheter Technique

1 Insert a 12-Fr Foley catheter through the nares and into the posterior pharynx.

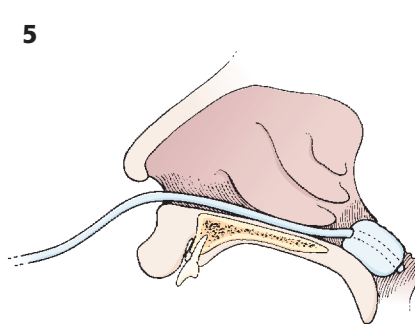

2 Look into the mouth to confirm that the catheter is properly positioned.

3 Inflate the balloon halfway with about 5–7 mL of water.

4 Slowly pull the catheter into the posterior nasopharynx up against the posterior aspect of the middle turbinate.

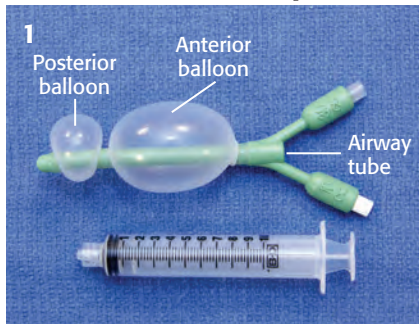

5 Foley catheter in proper position in the posterior nasopharynx. Inflate the balloon with another 5–7 mL of water.

6 While maintaining traction, place anterior packing with layered gauze. Packing of the opposite side may be required to prevent septal deviation. Place a piece of gauze on the exposed catheter and secure with an umbilical clamp.

B Dual-Balloon Tamponade Catheter

1 Double-balloon epistaxis catheters have both an anterior and posterior balloon, and some have an integral airway tube. These devices serve as both an anterior and a posterior pack. They are easily inserted and are often successful in temporary control of posterior epistaxis in the ED.

2 Insert the lubricated device along the nasal floor as far back as possible. Inflate the posterior balloon halfway with air, apply traction to pull the balloon up against the middle turbinate, and then complete the inflation. Maintain the position of the balloon and then inflate the anterior balloon with 30 mL of air.

3 This patient with posterior epistaxis was successfully treated in the ED and discharged. Historically, most patients with posterior packs were admitted to the hospital; however, the ease and safety of balloon devices allow selected patients to be treated as outpatients. Consider admission for the elderly, and those with pulmonary or cardiovascular disease.

Figure 63.39 Management of epistaxis: posterior packing with inflatable devices. *ED*, Emergency department.

Other Techniques

ENT consultation may be required for posterior nosebleeds that do not respond to the posterior packing techniques. Other treatment options that consultants may consider include ligation or embolization of the internal maxillary artery and posterior endoscopic cautery.

Complications

Posterior nasal packing is uncomfortable and often painful, but serious medical complications from posterior packing are rare. Complications associated with posterior packing include infection, dysphagia, dysfunction of the Eustachian tube, tissue necrosis, and dislodgment. Other serious complications rarely and often anecdotally associated with posterior packing are hypoxia, hypercapnia, aspiration, hypertension, bradycardia, arrhythmias, myocardial infarction (MI), and death.⁴¹ It is questionable whether packing alone is the cause of these associated complications. Rebleeding may also be seen with early pack removal; one series found that removal of the packing within 48 hours increased the risk for rebleeding.⁴² Most posterior packs are left in place for 72 to 96 hours.

Dysphagia from the packing can lead to poor oral intake and possibly necessitate intravenous fluid hydration.

A decrease in the arterial partial pressure of oxygen (PaO₂; 7.5 to 11 mm Hg) and an increase in the arterial partial pressure of carbon dioxide (PaCO₂; 7 to 13 mm Hg) can be seen in patients with nasal packing who are treated with sedation.⁴¹ However, despite traditional theoretical concerns, such altered pulmonary physiology cannot be attributed to posterior packing alone. Although it has been hypothesized that a posterior pack will cause vagal stimulation and thereby result in varying degrees of bradycardia and bronchoconstriction because of the so-called nasopulmonary reflex, studies have failed to substantiate substantial physiologic changes attributed to posterior packing. Observe patients with significant cardiopulmonary disease and posterior nasal packs in a monitored setting.

Tissue necrosis of the nasal ala, nasal mucosa, and soft palate secondary to improper placement or padding has been described. Protect the skin with gauze placed under the device to reduce skin maceration. The risk for necrosis increases with the duration of the packing, so all packing should be removed in 3 to 5 days.

If the posterior pack becomes dislodged, it will fall into the oropharynx and place the patient at risk for asphyxiation, vomiting, and aspiration. The patient and nursing personnel need to be familiar with the technique for removing the pack. To remove the pack, cut the anterior sutures that exit the nares from the gauze roll if they have not already broken. Grasp the sutures exiting the mouth and guide the packing out of the nasopharynx. It may be necessary to extract the packing with forceps or digits.

Antibiotics Following Nasal Packing

Posterior packing is associated with a risk for infection, including nasopharyngitis, sinusitis, and rarely, TSS.^{37,43} Packing blocks the sinus ostia, which prevents proper drainage of the sinuses. TSS has been described rarely with nasal packing³⁹ and is estimated to occur in approximately 16 per 100,000 packings. The syndrome is caused by a toxin released by *S. aureus* infection of the packing. A sudden onset of vomiting and diarrhea with high fever, as well as the development of an erythematous rash, heralds the onset of the disease. A systematic review did not find any methodologically rigorous studies evaluating the

incidence of TSS following nasal packing; simply small, retrospective, observational, and nonrandomized prospective studies. None of the studies reported TSS as a complication of nasal packing. There is no strong evidence to support or refute the practice of prescribing antibiotics. The choice is left up to the provider.³⁹ Awareness of the condition is paramount. Importantly, antibiotics will not eradicate the carrier state of MRSA or other nasopharyngeal flora.

Likewise, no data support or refute the routine use of prophylactic antibiotics after nasal packing to reduce the incidence of bacterial sinus infections. Short-term anterior packing is not likely to be a cause of bacterial infection of the nasopharynx and does not call for antibiotic prophylaxis. As with all forms of antibiotic prophylaxis, routine antibiotic use is associated with risks and side effects, including the selection of resistant bacterial strains. Despite the lack of proven efficacy, many clinicians provide prophylaxis against TSS and bacterial infection for patients with posterior packing for the duration of the packing. There are, however, no universally accepted standards or mandates regarding this issue. It may be reasonable to provide prophylaxis to patients at greater risk for infection, such as those with diabetes, advanced age, or an immunosuppressed state. If used, an antibiotic with staphylococcal coverage should be selected, such as amoxicillin-clavulanate. Topical mupirocin may also be used on various packing material, but the efficacy of this is unknown.

Patient Disposition Following Nasal Packing

After successful cautery or a simple anterior pack, patients can be discharged with follow-up in 48 to 72 hours. Aspirin is avoided. Packs should be left in place. Merocel packs should be moistened by the patient three times a day with saline or water. If no packing is used, the patient can coat the cauterized area four times a day with antibiotic ointment or Vaseline and should avoid the urge to pick the nose or remove any debris. If minimal bleeding recurs, oxymetazoline spray is usually effective. After 48 to 72 hours, the packing is removed and the condition reassessed.

Healthy, stable patients with various forms of packing or commercial packs can usually be discharged if the bleeding is controlled in the ED for 1 to 2 hours. Minor bleeding may be experienced, but return of significant bleeding requires reevaluation and generally hospitalization. Hospitalization is often appropriate for those with posterior packs, especially the elderly or those with concerning underlying medical conditions. Clinical judgment is the best arbitrator for admission decisions.

Tranexamic Acid

In cases of poorly controlled epistaxis, tranexamic acid (TXA) may be considered. TXA is an antifibrinolytic agent that is 10 times more potent than aminocaproic acid, with a longer half-life. TXA reversibly binds to plasminogen and inhibits binding to fibrin. In turn, this prevents plasminogen activation and transformation to plasmin. Currently, TXA is U.S. Food and Drug Administration (FDA)-approved for short-term use in hemophiliacs to prevent hemorrhage and reduce the need for factor replacement during and following dental extraction and for heavy menstrual bleeding. Despite these limited and specific indications, TXA has been evaluated in cardiac surgery, orthopedic surgery, trauma, spinal surgery, postpartum hemorrhage, gastrointestinal bleeding, hyphema, dental extractions, and epistaxis.⁴⁴

Two studies have evaluated TXA for the management of epistaxis. In a randomized, double-blind, parallel-group study of 68 patients,⁴⁵ 60% of patients treated with TXA topical gel had control of epistaxis within 30 minutes compared to 76% receiving placebo. Rebleeding rates at 8 and 30 days were 11% and 44% for TXA, and 31% and 66% for placebo. A 2013 randomized control trial by Zahed⁴⁶ and colleagues used injectable TXA applied topically to the nares. They compared a 15-cm cotton pledget soaked in injectable TXA (500 mg in 5 mL) to anterior nasal packing. The authors found that within 10 minutes of treatment, bleeding stopped in 71% of the TXA group compared to 31% of the anterior nasal packing group (odds ratio 2.27; 95% confidence interval 1.68–3.06, $p < 0.001$). In addition, more patients in the TXA group were discharged in 2 hours or less. Rebleeding rates were less in the TXA group. Finally, a 2015 case report demonstrated that TXA was effective in controlling epistaxis in a patient on rivaroxaban.⁴⁷ Oral TXA has been shown to be effective in preventing recurrent epistaxis in patients with hereditary hemorrhagic telangiectasia.⁴⁸

Given these results, TXA seems to be an effective agent to treat epistaxis. It should be used when conventional therapies fail to halt bleeding and should also be given to prevent rebleeding in patients with hereditary hemorrhagic telangiectasia. The injectable form can be applied topically to the nares in soaked pledgets. TXA also shows promise in controlling epistaxis in patients being treated with novel oral anticoagulants, though its use cannot routinely be recommended for this indication at the time of this writing.

To date, TXA has not been studied in patients with posterior epistaxis. Due to its antifibrinolytic effect, venous thromboembolic events (VTE), MI, and stroke can be seen following its administration. Importantly, a Cochrane review of topical TXA found no adverse events related to VTE, MI, or stroke. It was noted that TXA decreased the need for blood transfusion by 45%.⁴⁹

Septal Hematoma

Trauma to the anterior portion of the nasal septum may cause a hematoma to form. A buckling stress tears the submucosal blood vessels. If the mucosa remains intact, the blood will accumulate between the mucoperichondrium and the septal cartilage. Stagnant blood is an excellent medium for bacterial growth and the formation of an abscess. Common bacteria include *S. aureus*, *Streptococcus pneumoniae*, and group A β -hemolytic streptococci. Other complications of an untreated hematoma include septal perforation and cartilage destruction with a resultant saddle nose deformity. Septal hematomas may occur immediately after the trauma or, more commonly, in the first 24 to 72 hours after the injury.⁵⁰ The hematoma can cause significant destruction of the nasal cartilage and result in a cosmetic deformity.

Indications and Contraindications

The presence of a nasal septal hematoma requires drainage to prevent a cosmetic defect, septal necrosis, and other complications. The most common symptoms of a septal hematoma are nasal obstruction, pain, rhinorrhea, and fever. Most patients will complain of an inability to breathe through the affected side, but the absence of nasal obstruction does not rule out a septal hematoma. It is usually possible to diagnose a septal hematoma by inspecting the nasal septum with a speculum for

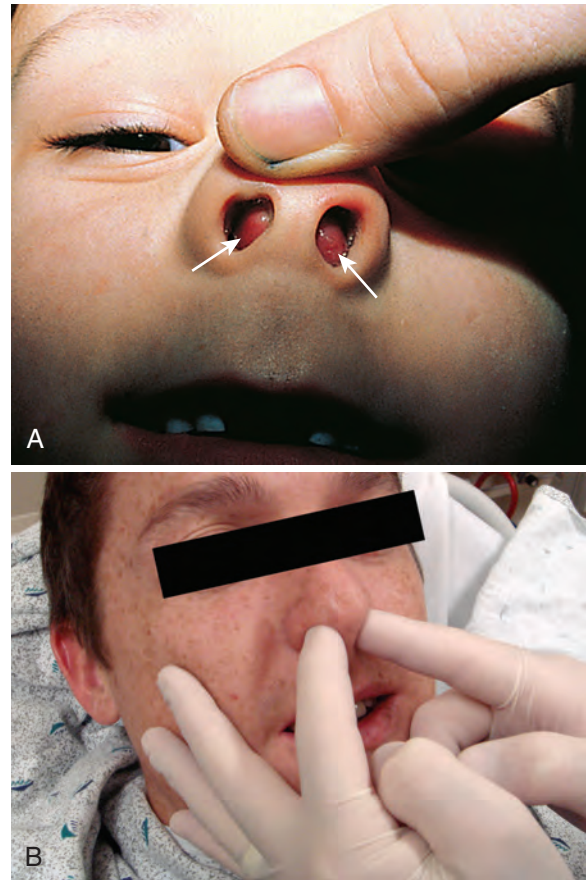

Figure 63.40 Septal hematoma. **A**, Bilateral septal hematoma in a 6-year-old child. Obstruction is present on both sides of the nose (arrows). There was no response to vasoconstriction. **B**, If visual inspection of the nose with a speculum does not rule out a septal hematoma, the clinician's gloved fingers, passed posteriorly along both sides of the septum, may feel bulging or fluctuance. A normal septum is thin and smooth. (**A**, Image courtesy Robert Hickey, MD, Children's Hospital of Pittsburgh, PA; **B**, from Flint PW, Haughey BH, Lund VJ, et al, editors: *Cummings otolaryngology: head and neck surgery*, ed 5, Philadelphia, 2010, Mosby Elsevier.)

swelling, pain, and a fluctuant area (Fig. 63.40). The presence of septal asymmetry with a bluish or reddish hue of the mucosa is suggestive of a septal hematoma. To some it looks like a grape. Inspect both sides because bilateral hematomas are possible. Direct palpation with the littlest finger may be necessary because newly formed hematomas may not yet be ecchymotic. Palpation can further differentiate septal hematoma from septal deviation, which may appear to be similar because of asymmetry. The best way to palpate for a septal hematoma is to insert the gloved small fingers in each side of the nose and palpate the entire septum to feel for swelling, fluctuance, or widening of the septal space.

There are no absolute contraindications to drainage of a nasal septal hematoma. Caution should be used in those with known bleeding diathesis or those who are taking anticoagulants.

Equipment

Very little equipment is required to drain a nasal septal hematoma. A topical or injectable anesthetic should be used.

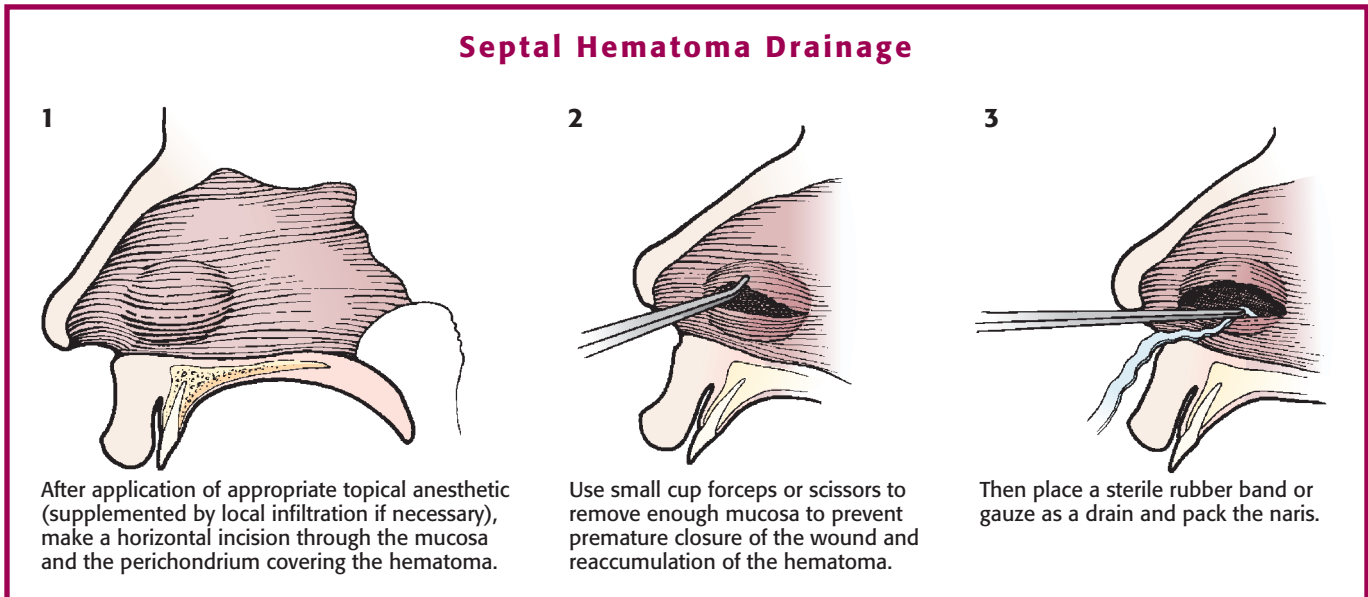

Figure 63.41 Drainage of a septal hematoma.

For the procedure itself, a light source, a nasal speculum, a No. 11 scalpel blade, suction apparatus, scissors, nasal saline, small Penrose drain, and some form of nasal packing material are all that is needed.

Procedure

Treatment of a septal hematoma consists of evacuation of the clot with subsequent reapproximation of the perichondrium to the cartilage (Fig. 63.41). To drain the hematoma, incise the mucosa over the hematoma horizontally after adequate anesthesia is achieved. Suction out all the clot and then irrigate with normal saline. Excise a small amount of mucosa to prevent premature closure of the incision and place a section of a sterile rubber band to act as a drain. Pack the nostril, as for anterior epistaxis, to reapproximate the perichondrium to the cartilage.

Prescribe broad-spectrum antibiotic therapy. Inspect the septum daily for signs of infection, recurrent hematoma, or necrosis. Evacuate recurrent hematomas. When there is no further hematoma formation over a 24-hour period, remove the drain. Pack the affected naris for one more day to complete the apposition of perichondrium to cartilage where the drain had been. If any evidence of infection is present, admit for intravenous antibiotics and surgical débridement.

Complications

Though rare, nasal septal abscess formation is the most common complication of septal hematomas. The infection can spread to the sinus cavities and lead to meningitis, cavernous sinus thrombosis, intracranial abscess, and orbital cellulitis.

A large or rapidly expanding hematoma may cause pressure on the septum and lead to avascular necrosis of the septal cartilage. The nasal septum can collapse and lose its shape, which causes a noticeable cosmetic defect.

After drainage, the hematoma may recur and should be treated by repeated drainage to prevent cartilage damage. Reaccumulation can be prevented by incising a piece of mucosa before packing the nasal cavity.

Reduction of Nasal Fractures

A nasal fracture is the most common facial fracture. Nasal fractures are accompanied by a broad range of symptoms, including mild swelling, epistaxis, and periorbital ecchymosis with obvious deformity. As with any trauma involving the head, evaluate for coexistent intracranial injury or neck injury. In the evaluation of nasal trauma, rule out the existence of a septal hematoma or cerebrospinal fluid rhinorrhea. In most cases the swelling and soft tissue deformity prevent adequate evaluation, treatment, or both. Evaluation of a patient with a suspected nasal fracture includes a thorough history, external nasal examination, and internal nasal examination using a nasal speculum with or without the use of a rigid nasal endoscope. Nasal radiographs are not routinely needed because they will not alter the course of treatment or injury.⁵¹ Ask the patient to apply ice to the area and keep the head elevated to reduce soft tissue swelling. Refer the patient to an otolaryngologist or plastic surgeon for reexamination and definitive treatment in 3 to 5 days. Stress the importance of reevaluation within 10 days so that the bones do not set in a misaligned state.

Indications and Contraindications

The indications for reduction of a nasal fracture are first based on the type of deformity and degree of swelling present (timing of reduction). Only simple nasal bone or nasal-septal complex fractures, nasal obstruction or airway compromise from a deviated septum, and fracture of the nasal-septal complex with nasal deviation less than half the nasal bridge should be reduced in the ED. Other indications include less than 3 hours after injury in adults and children if minimal edema is present, reduction 6 to 10 days after injury in adults once the edema has resolved but before setting of the fracture fragments, and reduction 3 to 7 days after injury in children once the edema has resolved. The presence of nasal obstruction or airway compromise from a deviated septum should prompt reduction in the ED.

Contraindications to reduction of nasal fractures in the ED include severe comminution of the nasal bones and septum, associated fractures of the orbital wall or ethmoid bone, deviation of the nasal pyramid greater than half the width of the nasal bridge, caudal septal fracture-dislocation, open septal fractures, and any fracture older than 3 weeks.

Equipment

The standard equipment of nasal decongestant and anesthetic are needed; in addition, nasal speculum, bayonet forceps, Frazier suction tip, anterior nasal packing material, a good light source, and some specialized equipment are needed, including elevators

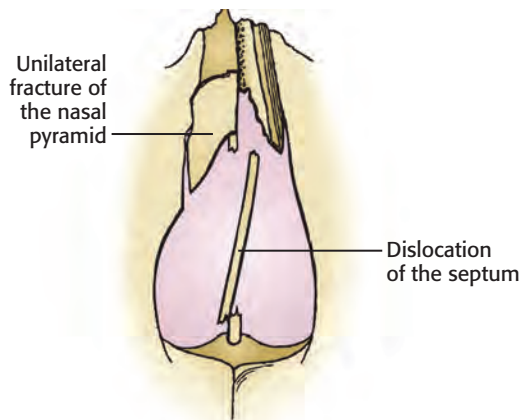

(Goldman, Boies, Salinger, Ballenger), Walsham forceps for grasping the nasal bones, and Asch forceps for reduction of the septum. An external nasal splint is also needed.

Procedure

Most fractures and patients with significant soft tissue swelling should be seen in follow-up for definitive evaluation and possible reduction of the fracture. Complicated fractures and septal injuries are usually referred for follow-up. Simple fractures with minimal local swelling can be treated by closed reduction (Fig. 63.42). Some patients prefer immediate correction, are not concerned with aesthetics, or are unable to comply with

Nasal Fracture Reduction

1

Nondisplaced and minimally displaced nasal fractures often do not require manipulation, but the true extent of the deformity is difficult to appreciate initially. Note that the septum may also require subsequent intervention. Reduction of a depressed and dislocated nasal bone fracture is usually performed in 3 to 7 days, after the swelling has subsided and the true deformity is obvious.

2

Closed nasal reduction. Minor deformities with minimal swelling may be reduced in the ED and mitigate further therapy. After marking the distance of the intercanthal line on the elevator with a thumb, the tip of the instrument is used to reduce the medialized fragment by elevating it. The opposite thumb may simultaneously reduce a contralateral outfractured nasal bone (pyramid). Use the handle of a scalpel if an elevator is unavailable.

3

Asch forceps can be used to reduce a displaced nasal septum. Insert each arm of the instrument on either side of the nasal septum.

4

Use upward and outward force, perpendicular to the plane of the dorsum, to lift the septum until it is no longer overlapping. Then push with the instrument arms until the ends are aligned properly.

Figure 63.42 Reduction of a nasal fracture. *ED*, Emergency department. (Steps 3 and 4, from Flint PW, Haughey BH, Lund VJ, et al, editors: *Cummings otolaryngology: head and neck surgery*, ed 5, Philadelphia, 2010, Mosby Elsevier.)

follow-up, so ED intervention may be an option. To minimize potential litigation, obtain written consent and take prereduction and postreduction photographs. Inform the patient that the outcome is not guaranteed because impacted fractures may not reduce and greenstick fractures may deform again after reduction. Acute swelling may obscure the extent of the injury.

If minor manipulation is reasonable, anesthetize the mucosa as described earlier. For more involved manipulation, add a nasal nerve block. Intravenous sedation and analgesia may be necessary.

Most closed reductions can be done with a blunt elevator. A specific nasal elevator (Boies or Joker) or the handle of a metal scalpel can be used. The depth of insertion is determined by placing the instrument against the surface of the skin on the lateral aspect of the nose, with the distal tip at the intercanthal line. Mark the position of the instrument at the alar rim, insert the instrument into the nose, and stop 1 cm short of the measured depth. Only the tip of the instrument should contact the medial side of the nasal bone. Lift the elevator anteriorly and laterally until the depressed fragment is in proper position. Use the opposite hand to pinch the nasal bones and mold the segments. If reduction with the elevator is unsuccessful, use Walsham forceps to manipulate the nasal bones. Insert one arm of the forceps into the nasal cavity and the other against the surface of the skin. Firmly grasp the displaced bone, disimpact, and reposition it into the correct location.

Use Asch forceps to reduce the nasal septum (see Fig. 63.42, plates 3 and 4). Insert each arm of the instrument on either side of the nasal septum and position it. Use an upward and outward force perpendicular to the plane of the dorsum to lift the septum until it is no longer overlapping. Then push the arms of the instrument until the ends are aligned properly.

Be careful to not perforate the cribriform plate when using surgical instruments. After the maneuvers, assess the reduction for proper alignment or subsequent displacement secondary to a greenstick fracture. If either occurs, refer the patient to an otolaryngologist to see whether open reduction is necessary.

Stabilize the reduction internally with nasal packing and externally with an exterior splint dressing (Thermaplast or Aquaplast). Some authors believe that splinting will mask an incomplete reduction or adversely manipulate the reduction during placement. Remove the packing in 5 days and the splint in 7 to 14 days. Antibiotic coverage is recommended.

Complications

Not all fractures will be reducible and such fractures should be referred for open reduction by a cosmetic facial surgeon (ENT, plastic, or oral and maxillofacial surgeon). Incomplete reduction may result in a poor cosmetic outcome. Reduction may produce a nasal septal hematoma, which if untreated, can lead to cartilage destruction and deformity. Reduction can also cause excessive bleeding. This can be managed with direct pressure and nasal packing. Direct infiltration of anesthetic may result in nerve damage, dysesthesias, or paresthesias after the effects of the anesthetic wear off. Finally, if nasal packing is placed, there is a risk for sinus infection.

Nasal FB Removal

Nasal FBs most frequently occur in pediatric patients, but it is not uncommon to find them in psychiatric or cognitively impaired patients as well. Usually, a family member has witnessed the event or the patient complains of discomfort from

the FB. Patients may also have unilateral purulent or bloody nasal discharge, unilateral sinusitis, or recurrent unilateral epistaxis. Retained FBs, especially plastic ones, often initially fail to cause pain or other symptoms.⁵² The lack of a history of FB insertion is of little value in children because many will not admit it. Therefore emergency clinicians need to maintain a high level of suspicion for nasal FBs.

Types of nasal FBs vary widely and include food (e.g., meat, nuts, beans), rubber erasers, paper wads, pebbles, marbles, sponges, beads, jewelry, hardware (e.g., nuts, screws), and even certain living larvae or worms.^{52,53}

Alkaline button batteries pose a unique problem because they may cause significant nasal injury within hours to days.^{54,55} They are composed of heavy metals such as mercury, zinc, silver, nickel, cadmium, and lithium. Injuries can occur and include mucosal burns, ulcerations, liquefaction necrosis, septal perforation, synechia, and stenosis of the nasal cavity.^{54,55} It is imperative that these batteries be removed promptly before tissue damage occurs as a result of leakage of the battery contents, electrical currents, or direct pressure. A relatively new and interesting nasal FB is the magnetic nose ring. These small, commercially available earth magnets are usually worn on either side of the alar cartilage and give the appearance of a pierced nasal stud. The magnets can be displaced and become polarized across the nasal septum. The magnetic attraction can be quite strong and may lead to pressure necrosis of the nasal mucosa and possibly septal perforation. This attraction can also make removal difficult, as well as painful for the patient.^{55,56} Suggested techniques include using polarized or nonferromagnetic tools.⁵⁷

Many nasal FBs come to rest on the floor of the anterior or middle third of the nose. Metallic or calcified objects may show up on radiographs, but physical examination remains the most reliable means for diagnosis. Maxillary, ethmoid, or sphenoid sinusitis may also accompany FB retention. Plain radiographs or facial CT scanning may be of value in detecting sinusitis, although these studies are not usually necessary with an acutely retained object.

Inability to remove a nasal FB should necessitate ENT consultation and may result in admission for removal under anesthesia; therefore it behooves emergency clinicians to be skilled in this procedure. Although admission incurs increased cost, has inherent procedural risks, and causes psychological stress in parents and patients, providers should be prepared to call a consultant after several attempts. As with the removal of auricular FBs, removal of nasal FBs can be both frustrating and time-consuming.

Indications and Contraindications

Attempt removal of a nasal FB only if it is likely to be retrieved. ENT consultation is needed if there is any doubt about the ability to successfully retrieve the object. Repeated attempts may result in trauma and displacement of the object into a less favorable location.

Do not attempt mechanical removal if the object appears to be out of range of the instruments. In addition, do not attempt removal in an uncooperative patient unless sedation is provided. Use sedation cautiously because it may increase the risk for aspiration, especially when using agents that blunt the protective airway reflexes.

Equipment

The majority of the equipment used for removing FBs in the ear canal can also be used for nasal FB removal. Topical nasal

anesthetic and vasoconstrictor solutions, such as oxymetazoline, can greatly aid in the removal of nasal FBs.

Procedure

A cooperative patient is essential. Weigh the risks and benefits of using simple or procedural sedation. Ketamine anesthesia works well for children. Before attempting removal, anesthetize and vasoconstrict the mucosa of the affected naris topically. Ask an assistant to stabilize the patient's head, and immobilize a younger patient if necessary. Place more cooperative patients in the sniffing position and use a headlamp for proper illumination. Several of the techniques previously mentioned for removing an FB from the EAC can also be used in the management of a nasal FB, including the use of cyanoacrylate glue.

Manual Instrumentation

Use alligator forceps or bayonet forceps to retrieve anteriorly lodged FBs that have edges amenable to grasping (Fig. 63.43, plate 1). For harder or larger objects, carefully pass a wire loop

(one can be made using 24-gauge wire loop grasped by a hemostat),⁵⁸ a right-angle hook (if unavailable, one can be made out of an 18-gauge needle), or even a properly bent paper clip. Carefully insert it beyond the object and rotate it to allow the FB to be pulled from the naris. Direct mucosal trauma and epistaxis may occur with any of these methods. For a nasal FB with smooth, round edges that are difficult to grasp or get behind, attempt to extract it with a suction-tipped catheter in a manner similar to that described earlier for FBs in the EAC. The Hognose catheter described earlier also works well for nasal FBs (see Fig. 63.21). Local vasoconstriction and anesthesia are helpful, and 2% lidocaine with epinephrine (local anesthetic) may be used.

Balloon Catheter

For an object that cannot be removed with anterior instrumentation, one consideration is to attempt removal with a balloon catheter. A Fogarty catheter can be highly effective in removing a nasal FB (see Fig. 63.43, plates 2 and 3). A No. 4 or 5 vascular Fogarty catheter, a 12-Fr Foley catheter, and a No. 6 biliary

NASAL FOREIGN BODY REMOVAL

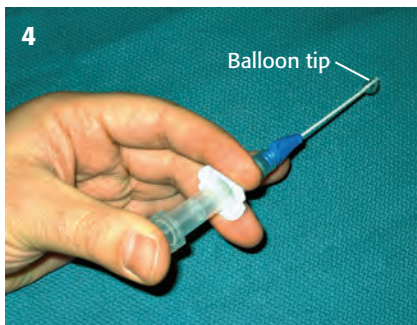

1 Following vasoconstriction and anesthesia (2% lidocaine with epinephrine was dripped into the nose), some FBs may be easily extracted with forceps.

2 A Fogarty catheter may be used to extract a nasal FB. Insert the lubricated catheter tip above the FB and then gradually inflate the balloon.

3 Slowly withdraw until resistance is met and then pull the object out of the naris.

4 The Katz Extractor (InHealth Technologies, Carpinteria, CA). This device is used in an analogous fashion to the Fogarty catheter.

5 Bag-valve-mask technique to blow an FB out of the naris. Ensure that the face mask forms a tight seal around the patient's mouth and that the unaffected nostril is completely occluded. Attempt to firmly compress the bag as the patient exhales (an assistant is helpful to hold the mask snugly and to occlude the other nostril). This technique works best with objects that completely occlude the nostril.

6 To blow an FB out of the nose, have the parent blow into the mouth while occluding the unaffected side with the thumb.

Figure 63.43 Removal of a nasal foreign body. FB, Foreign body.

Fogarty catheter have all been described in the literature for this use. A biliary catheter is reportedly less apt to rupture. Place the patient in the supine position and apply a vasoconstrictor and anesthetic to the nasal mucosa. With a 5-mL syringe attached and the catheter lubricated with lidocaine gel, pass the tip above the object and into the nasopharynx. Inflate the balloon with air or water (≈ 2 mL in small children and 3 mL in older children) and control the syringe plunger and balloon size with your thumb. Withdraw the catheter until resistance is felt, and then slowly pull the object out. The Katz Extractor otorhinologic FB remover (InHealth Technologies, Carpinteria, CA; see Fig. 63.43, plate 4) is a disposable, single unit composed of a flexible catheter with a balloon tip attached to a syringe. The procedure is similar to that for the Fogarty catheter. Complications mentioned in the literature include mild post-traumatic bleeding, as well as the theoretical risk for airway obstruction by the balloon or aspiration from further displacement of the object.

Positive Pressure

Another approach to a posteriorly placed nasal FB is to blow the object out with positive air pressure. The simplest way is to ask patients to blow their nose while occluding the unaffected nostril. This is only really effective in older children and adults. Alternatively, place a bag-valve-mask device⁵³ over the child's mouth to provide positive pressure (see Fig. 63.43, plate 5). Occlude the opposite nostril and apply the Sellick maneuver to prevent passage of air into the esophagus. This technique often requires restraint and can also be threatening to a young child.

The "parent's kiss" technique may be used in children.^{53,59,60} First gain the child's cooperation by saying that parent is going to "give them a big kiss." The technique is performed by having the child lie supine. Ask the parent to occlude the child's unaffected nostril with the thumb (see Fig. 63.43, plate 6). Next, as in mouth-to-mouth resuscitation, ask the parent to make a firm seal with his or her mouth over the child's open mouth and then give a short, sharp puff of air briskly into the mouth to produce outward pressure behind the object. Keep the opposite nostril occluded throughout the procedure. If successful, the object will move within grasping reach of an instrument or pop completely out of the naris. If it fails, the technique can be repeated. Studies of the parent's kiss technique have found it to be highly effective, nontraumatic, and preferable to restraint or instrumentation.^{59,60}

A modification of the technique that may be easier for some parents to master uses a drinking straw placed between the parent's mouth and the child's mouth. Instruct the child to make a tight seal, as though drinking, and ask the parent to deliver a quick puff.

Another similar technique may be successful.⁶¹ After a nasal decongestant is instilled into the affected side, place a 6- to 10-inch section of 1/4- or 1/8-inch wide rubber or soft vinyl tubing into or at the contralateral nostril and hold the tubing in place with the fingers of one hand. Place the free hand gently over the child's mouth, take a good-sized breath, and blow forcefully through the tubing. This step may be repeated up to four times. In one study, success was reported in 40 of 41 cases.⁶¹ Navitsky and colleagues modified this technique to reduce the risk for transmission of disease.⁶² Turn a wall oxygen source to a flow of 10 to 15 L/min. Use a male-to-male adapter at the end of oxygen tubing to direct the flow of oxygen into the contralateral (nonobstructed) nostril.

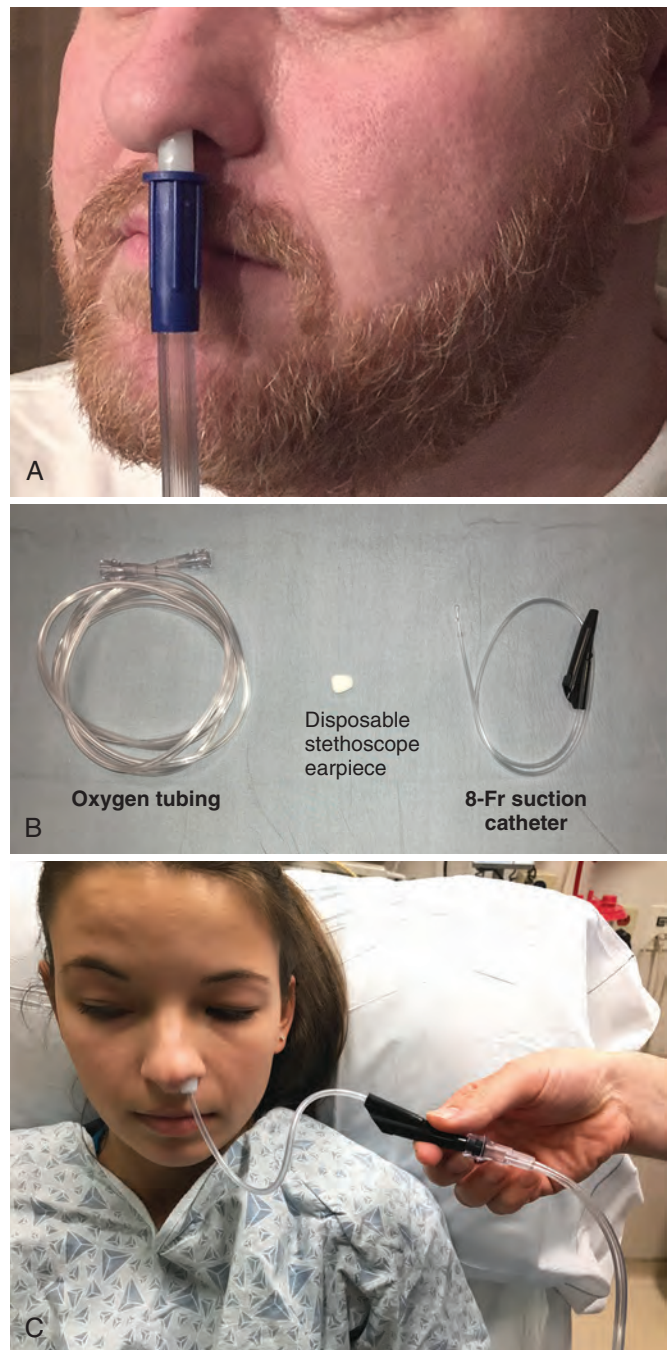

Figure 63.44 Additional techniques for positive pressure removal of nasal foreign bodies. **A**, Attach suction tubing to wall oxygen or medical air, and use a suction adapter inserted in the contralateral naris. **B**, An alternative technique uses oxygen tubing, an earpiece from a disposable stethoscope, and an 8-Fr suction catheter. **C**, Equipment assembled and positioned for use.

Two other techniques using positive pressure have been described and use simple equipment and oxygen or medical air. In the first technique,⁶³ wall oxygen or medical air, suction tubing, and a suction-tubing adapter are needed (Fig. 63.44A). Have the patient sit upright and lean forward with the head tilted down. Attach one end of standard suction tubing to the wall oxygen or compressed air unit. The plastic suction-tubing adapter should be firmly placed into the opposite end of the suction tubing. Insert the tubing with the adapter into the

Figure 63.45 Mandible dislocations. **A** and **B**, This patient yawned and then could not close his mouth. This was a recurrent bilateral mandible dislocation. **C**, This patient was suspected of having a dystonic reaction because she could not speak and her mandible was misaligned. It was a unilateral mandibular dislocation.

contralateral nostril. Titrate the oxygen to high flow (usually 10 to 15 L/min) until the foreign object is expelled.

The other technique uses a disposable stethoscope earpiece, 8-Fr suction catheter or feeding tube, oxygen, and oxygen tubing⁶⁴ (see Fig. 63.44B and C). Attach the earpiece to the 8-Fr suction catheter. Connect the set to a standard oxygen wall setup. At 15 L/min of oxygen, a pressure of 100 to 160 mm Hg is achieved. Patient positioning is determined by patient age. If the patient is older than 3 years of age, place the patient in a lateral position with the nostril containing the FB face down. If the patient is less than or equal to 3 years old, have the child sit in the parent's lap. Connect the device to the oxygen source with tubing and set the oxygen to 15 L/min. Bend the hose to occlude passage of pressure. Next, place the device in the unaffected nostril, release the pressure, and immediately remove the device. If the object is not removed, make another attempt. In a study of 18 patients, the device was successful in 94.4% of patients on the first attempt. If an 8-Fr feeding tube is not available, an 8-Fr suction catheter may be used as an alternative.

Complications

Most complications are due to the FB itself and include pain, obstruction, rhinorrhea, ulceration of the nasal mucosa, septal perforation, infection, and nasal or choanal stenosis. Bleeding and mucosal laceration are the most commonly reported complications of removal. The bleeding is usually minor and generally resolves with simple pressure. It may occur as a result of the object itself or from trauma during removal. Inadvertent posterior dislodgement of the object may occur and result in ingestion or aspiration of the object. Theoretically, barotrauma to the lungs and TMs may occur with positive pressure techniques.

Dislocation of the Mandible

Mandibular dislocation is more properly known as temporomandibular joint (TMJ) dislocation. It is actually the mandibular condyles that dislocate. It may result from trauma but more commonly follows extreme opening of the mouth such as may occur while eating, laughing, or yawning. It may also be seen

with dystonic reactions to medications. Patients with a previous history of TMJ dislocation are more prone to repeated dislocations. The condition can be unilateral or bilateral (Fig. 63.45).

TMJ dislocation occurs when the mandibular condyle moves anteriorly along the articular eminence and becomes locked in the anterosuperior aspect of the eminence. Spasm of the masseter, internal pterygoid, and temporalis muscles occurs during an attempt to close the mandible. Trismus then results and the condyle cannot return to its normal position. Predisposing factors include anatomic disharmony between the mandibular fossa and the articular eminence and weakness of the capsule and the temporomandibular ligaments.

Indications and Contraindications

The presence of mandibular dislocation is the indication for reduction. The diagnosis is usually straightforward, but the condition can be misinterpreted as an acute dystonic reaction. With dislocation, patients cannot close their mouth, and speech is affected. Pain varies, and patients are often very anxious. With unilateral dislocation, the jaw will deviate to the opposite side. More commonly, bilateral dislocation occurs. With traumatic dislocation, radiographic evaluation should be performed to exclude a fracture. A mandibular series, Panorex, TMJ radiographs, and facial CT are acceptable. In the absence of a fracture, there are no real contraindications to reduction.

Equipment

Minimal equipment is required. An ENT or dental chair is helpful. Gloves, gauze, and a bite block should be available. Items to protect the operator's fingers such as tongue blades or plastic finger splints can be used.

Procedure

Reduction of a TMJ dislocation is fairly straightforward. Because anterior dislocations are far more common, these techniques will be discussed here. The key to reduction is to direct the mandibular condyle out of its displaced location anterior to the articular eminence⁶⁵ (Fig. 63.46A). Procedural sedation is usually required for easy and successful reduction. In addition, local anesthetics can be injected into the TMJ space or

Mandible Dislocation Reduction

A Anatomy

In the normally closed position, the mandibular condyle rests in the mandibular fossa behind the articular eminence.

In the maximally open position, the condyle is just under and slightly behind the eminence.

In the dislocated position, the condyle moves forward and upward slightly above the eminence; muscle spasm then occurs.

B Reduction Maneuver

Sedate the patient or locally inject the TMJ with lidocaine. Wrap your thumbs with gauze and place them in the mouth on the back molars. Apply downward pressure on the lower molar ridge near the angle of the jaw.

Continue to apply downward pressure and push the mandible posteriorly. A rocking motion may be helpful.

C Alternative Techniques

Recumbent approach with the operator at the head of the patient.

Ipsilateral extraoral approach.

Wrist pivot method.

Figure 63.46 Reduction of mandibular dislocation. *TMJ*, Temporomandibular joint. (C, From Chan TC, Harrigan RA, Ufberg J, et al: Mandibular reduction, *J Emerg Med* 34:435–440, 2008.)

directly into the lateral pterygoid muscle. For TMJ injection, prepare the skin anterior to the ear, and introduce the needle into the TMJ space at the palpable depression caused by the dislocated condyle. Direct the needle anteriorly and superiorly onto the inferior surface of the glenoid fossa, and inject 2 mL of local anesthetic. For the pterygoid muscle, inject 2 to 3 mL of anesthetic into the muscle posterior to the maxillary tuberosity.

Classic Technique (see Fig. 63.46B)

With the patient seated and the head stabilized against the headrest, place a bite block in the mouth to prevent injury to the clinician. Wear gloves to protect your thumbs. Stand and face the patient and place your thumbs on the patient's lower molar teeth. The level of the mandible should not be higher than the operator's elbow. Once the thumbs are positioned on the molars as far posteriorly as possible, curve the fingers and hand around the angle and body of the mandible along the jaw and chin. Then exert steady, constant downward pressure on the lower molar region, and direct the mandible inferiorly and posteriorly back into the temporal fossa. Be careful because once reduced, reflex spasm of the jaw muscles can suddenly snap the mandible shut and injure your thumbs. Alternatively, place the thumbs on the mandibular ridge instead of the molars. For bilateral dislocations, both sides can be reduced simultaneously, but it is easier to do one side at a time.

Recumbent Approach (see Fig. 63.46C)

With the patient lying recumbent, stand in front of the patient. Apply caudal and posterior force on the mandible as for the classic technique. Alternatively, stand behind the patient's head and place your thumbs on the molars. Apply downward and backward pressure for reduction.

Posterior Approach

With the patient seated, stand behind the patient. Place your thumbs posterior to the last molar on the retromolar gum and along the ramus of the mandible. Exert downward force in this position. This procedure carries less risk of the fingers being bitten, but proper positioning of the thumbs may be difficult to accomplish.

Ipsilateral Approach (see Fig. 63.46C)

The ipsilateral approach involves three routes, extraoral, intraoral, and combined, which are conducted in sequential fashion. With this technique one side at a time is reduced. Stand at the patient's side. Attempt the extraoral route first. Use the thumb of your dominant hand to apply downward pressure on the displaced condyle just inferior to the zygomatic arch. Use the other hand to stabilize the patient's head.

If unsuccessful, attempt the intraoral approach. Exert downward pressure intraorally on the ipsilateral molar teeth. If unsuccessful, use the combined approach. Apply extraoral pressure with one thumb and intraoral pressure with the other thumb on the ipsilateral side.

Alternative Manual Method

This is similar to the extraoral technique described earlier. Place your fingers directly over the preauricular prominence of the dislocated condyle. Massage the condyle in a posterior and inferior direction to induce relaxation of the muscles and guide the condylar head back into the fossa. This pressure on the condyle may be uncomfortable for patients.

Wrist Pivot Method (see Fig. 63.46C)

Face the patient and place your thumbs at the apex of the mentum of the mandible. Wrap the other fingers laterally around the mandible and onto the occlusal surface of the inferior molars. Apply an upward force on the chin with your thumbs, and apply a downward force on the mandible with your fingers. Move the wrists in the direction of ulnar deviation. With these maneuvers, rotate the condyles inferiorly and posteriorly into the fossa.

Gag Reflex Method

The gag reflex method uses a component of jaw relaxation and transient descent of the mandible inferiorly. Induction of the gag reflex has been described as a successful method for reduction of mandibular dislocations. Provide tactile stimulation of the soft palate with a dental mirror or tongue blade in an awake patient. Muscle relaxation occurs and the mandible descends caudally so that the condyle moves inferiorly and relocates back into place.

Syringe Technique (Fig. 63.47)

The syringe technique is a novel, hands-free method for reduction of nontraumatic mandible dislocations that is fast, safe, effective and does not require procedural sedation. In one study, 97% of patients were successfully reduced, with the majority occurring in less than 1 minute.⁶⁶ In this method, with the patient seated, place a 5-mL or 10-mL syringe between the posterior upper and lower molars or the gums on the affected side. Instruct the patient to bite down and grasp the syringe between the teeth or gums. Next, ask the patient to roll the syringe back and forth, resulting in reduction of the dislocated TMJ joint. Syringe size varies with each patient and is determined by the distance between the upper and lower molars or gums and the ability to open the mouth on the affected side to allow syringe placement. The syringe acts as a rolling fulcrum. The mandible and maxilla apply pressure on the syringe. As the molars or gums move over the syringe, the gliding action moves the mandible posteriorly. The displaced condyle moves posteriorly to allow the condyle to slide back into its normal position. In bilateral dislocations, reducing one side will spontaneously reduce the other.

After relocation and on discharge, advise the patient to avoid extreme mouth opening and to eat soft food for 1 week. Warm compresses, nonsteroidal antiinflammatory agents, and muscle relaxants may be helpful. The patient may be referred to an ENT or oral and maxillofacial surgeon for further care. Patients with chronic dislocation may require surgical fixation.

Complications

Complications include injuries to both the patient and operator. Patient injuries include redislocation, mandibular fracture (rare), joint cartilage injuries, torn ligaments or muscles, and dental or gum injuries as a result of trauma from the attempt at reduction. There may be complications associated with procedural sedation as well.

Operator injuries are prominent in techniques that require placement of the operator's fingers in the mouth or on the teeth. These are usually caused by sudden masseter spasm after reduction. This results in the patient involuntarily biting down on the operator's thumbs. Take measures such as gauze and plastic finger splints to prevent such injuries to the thumbs.

Figure 63.47 **A**, Dislocated temporomandibular joint (TMJ) where the condyle is displaced anterior to the articular eminence with syringe placement between the posterior molars. **B**, Gliding of the mandible posteriorly as the molars roll over the syringe. **C**, Normal TMJ with syringe placement. *C*, Condyle, *Z*, zygomatic bone. (From Gorchynski J, Karabidian E, Sanchez M: The “syringe” technique: a hands-free approach for the reduction of acute nontraumatic temporomandibular dislocations in the emergency department, *J Emerg Med* 47(6):676–681, 2014.)

Uvulitis/Angioedema of the Uvula

Most cases of acute angioedema of the uvula (uvula hydrops), also known as Quincke’s disease, are spontaneous and no cause can be found. Affected patients wake up with a lump in their throat or a fullness when swallowing, look in the mirror, and

Figure 63.48 **A**, Very elongated uvula secondary to idiopathic angioedema that measured approximately 3 cm and reached past the midportion of the tongue. **B**, A globular-shaped enlarged uvula caused the sensation of a lump in the throat. Both cases were treated on an outpatient basis with antihistamines and prednisone after two doses of subcutaneous epinephrine (0.3 mg) in the emergency department. Both resolved over a 48-hour period without sequelae.

see an enlarged uvula (Fig. 63.48). It appears as an edematous, pale, and watery-filled structure.⁶⁷ It is not painful. Most patients are young and otherwise healthy.

Although most of the time the cause remains unidentified, there are numerous known precipitants, including smoking of marijuana and cocaine (crack), trauma to the uvula by endotracheal tubes or suction catheters during general anesthesia, and sticking a finger down the throat to induce vomiting. Do not confuse this condition with hereditary angioedema (hereditary angioneurotic edema), which is due to C1 esterase inhibitor deficiency, a recurrent and potentially fatal condition. Rarely, uvulitis may be caused by bacterial infection, particularly *Haemophilus influenzae* B, and can coexist with epiglottitis. Angiotensin-converting enzyme inhibitor use does not seem to be related, but nonspecific allergic reactions (food, environmental) have been postulated. This condition, though annoying, is usually benign, self-limited, and resolves in 24 to 48 hours. Airway compromise is a theoretical concern but occurs only rarely. Evaluating and maintaining the airway are

Figure 63.49 Typical appearance of the oral cavity 5 to 7 days after bilateral tonsillectomy. This is a common time for bleeding.

the most important concerns with uvulitis. The enlarging uvula can cause upper airway obstruction, particularly in children.

There are no controlled studies evaluating therapy, but numerous anti-angioedema interventions have been used. Treatment includes topical epinephrine (applied with a cotton swab), subcutaneous epinephrine, intravenous H₁ and H₂ histamine blockers, and parenteral or oral corticosteroids.⁶⁸ Inhalation of nebulized vasoconstrictors (such as epinephrine or racemic epinephrine) is an attractive, yet unproven intervention. For severe cases, otolaryngology consultation is warranted, and invasive techniques such as needle decompression (scoring the uvula with a needle) to drain fluid has been described. Uvulectomy may be necessary. In an acute airway emergency when intubation is not possible, clamp the base of the uvula with a hemostat and amputate the distal portion.

Posttonsillectomy Bleeding

Hemorrhage is the most serious complication of adenotonsillectomy, with reported rates of 0.5% to 10%, depending on the technique (Fig. 63.49).⁶⁹ Bleeding is categorized as intraoperative, primary (within 24 hours), and secondary (between 24 hours and 10 days). Bleeding is serious at all times and must be evaluated and controlled quickly if active. The most common time for patients to be seen in the ED with delayed bleeding is between the fifth and seventh postoperative days. Although some bleeding is minor, sudden severe hemorrhage can be fatal if not managed appropriately. If active bleeding is confirmed by physical examination, consult otolaryngology. Minor bleeding 5 to 10 days postoperatively secondary to eschar separation may be evaluated and treated in the ED. However, multiple bleeding episodes are common in those who bleed, and minor bleeding may herald more significant subsequent hemorrhage. A severely bleeding patient should be taken to the operating room immediately for

Figure 63.50 Posttonsillectomy bleeding is a serious complication that is difficult to control in the emergency department; an ear, nose, and throat surgeon and the resources of the operating room are often required. Massive bleeding can be fatal. This cooperative patient tried to tamponade her bleeding with direct pressure with a 4- × 4-inch pad on a hemostat, without success. She eventually became hypotensive and required urgent tracheal intubation and control of the bleeding in the operating room.

hemostasis. Up to 50% of patients who have major postoperative bleeding require control in the operating room. It is difficult and occasionally impossible to even initially control severe hemorrhage in the ED. Do not hesitate to intubate a massively bleeding patient to protect the airway and more easily perform local hemostatic maneuvers. Until the surgeon arrives, apply pressure directly on the bleeding area with a sponge on a long clamp (Fig. 63.50). The sponge may be dipped in epinephrine or thrombin powder if available. The bleeding area can also be infiltrated with lidocaine with epinephrine.

If a patient is seen in the ED with a complaint of posttonsillectomy bleeding but no active bleeding is found on examination and a blood clot is present, do not remove the clot. It may be tempting to discharge stable patients but definitive treatment and disposition are best made by the surgeon. If bleeding is present, or has temporarily stopped, it is prudent to admit the patient for observation. Obtain a sample of blood for a coagulation profile and a complete blood count. Blood transfusions may be required.

Emergency Dental Procedures

Kip R. Benko

Complaints pertaining to the teeth and supporting maxillofacial structures are common, and patients frequently go to the emergency department (ED) for evaluation. Complaints may range in scope from a simple chipped tooth to an odontogenic deep space infection or a maxillofacial injury. Treating these patients can be challenging and frustrating for busy emergency clinicians. Many emergency clinicians and other acute care providers do not receive specific training in dental emergencies during their training, yet it is important for them to be able to recognize and treat a wide range of dental and related maxillofacial problems. Some dental emergencies can lead to significant morbidity such as loss of teeth, chronic pain, infection, and craniofacial abnormality, whereas others can lead to life-threatening airway compromise.

Management of specific dental emergencies requires a thorough understanding of adult and pediatric dentition. The relevant anatomy of both populations is outlined. The techniques described for management of the various traumatic and infectious problems are, in most cases, temporizing until definitive dental or maxillofacial surgery referral can be obtained. Conditions that require emergency consultation are discussed. Topical, local, and regional anesthesia are of particular importance and utility in the management of odontogenic emergencies, so the clinician should be very familiar with these techniques.

Although this chapter describes the diagnosis and treatment of dental injuries that may confront emergency clinicians, no standard of care mandates that complex dental problems (e.g., replacement of avulsed teeth, drainage of infection) be definitively handled in the ED setting. Advances in ED equipment and clinician training, as well as the introduction of dental skills laboratories into the resident curriculum, are gradually raising the existing standard of care. The initial stabilization of fractured, subluxed, luxated, and avulsed teeth, as well as bleeding and dry sockets, is now within the treatment realm of the emergency clinician. Likewise, abscesses and infections should be properly identified and drained if necessary. It is appropriate to refer all significant dental pathology to a dentist or oral surgeon.

TEETH

The adult dentition normally consists of 32 teeth: 8 incisors, 4 canines, 8 premolars, and 12 molars. From the midline to the back of the mouth on each side, there is a central incisor, a lateral incisor, a canine (cuspid), two premolars (bicuspid), and three molars, the last of which is called the wisdom tooth (Fig. 64.1). The 20 primary or deciduous (baby) teeth include 8 incisors, 4 canines, and 8 molars. From the midline to the back of the mouth, there is a central incisor, a lateral incisor,

a canine, and two molars (Fig. 64.2). There are no premolars in the primary dentition. *Agenesis*, or lack of proper formation of a tooth or teeth, is not uncommon, especially in the maxilla. Likewise, *supernumerary*, or extra, teeth may also occur. The adult teeth are numbered from 1 to 32, with the first tooth being the right upper third molar and the 16th tooth being the left upper third molar. The left lower third molar is the 17th, and the 32nd tooth is the right lower third molar. Numerous classification and numbering systems of the teeth exist; however, it is best for clinicians to simply describe the location and type of tooth in question (e.g., upper left second premolar, lower right canine). This removes any question when discussing a case with a consultant.

A tooth consists of the central pulp, the dentin, and the enamel (Fig. 64.3). The pulp contains the neurovascular supply of the tooth, which is responsible for carrying nutrients to the dentin, a microporous substance that consists of a system of microtubules. The dentin makes up the majority of the tooth, is a primary determinant of tooth color, and cushions the tooth during mastication. The enamel is the relatively translucent, outermost portion of the tooth and the hardest part of the body. The tooth may also be described in terms of the crown (coronal portion) and the root (apex portion). The crown is the portion covered in enamel; the root is the part that serves to anchor the tooth in the alveolar bone.

The following descriptive terminology is used for the different anatomic surfaces of the tooth. These terms are useful when describing the specific tooth injury to a consultant or colleague:

- **Facial:** the part of the tooth that faces the opening of the mouth. This is the part that you see when somebody smiles. It is a general term applicable to all teeth.
- **Labial:** the facial surface of the incisors and canines.
- **Buccal:** the facial surface of the premolars and molars.
- **Oral:** the part of the tooth that faces the tongue or the palate. This is a general term applicable to all teeth.
- **Lingual:** toward the tongue; the oral surface of the mandibular teeth.
- **Palatal:** toward the palate; the oral surface of the maxillary teeth.
- **Approximal/interproximal:** the contacting surfaces between two adjacent teeth.
- **Mesial:** the interproximal surface facing anteriorly or closest to the midline.
- **Distal:** the interproximal surface facing posteriorly or away from the midline.
- **Occlusal:** biting or chewing surface of the premolars and molars.
- **Incisal:** biting or chewing surface of the incisors and canines.
- **Apical:** toward the tip of the root of the tooth.
- **Coronal:** toward the crown or the biting surface of the tooth.

THE PERIODONTIUM

The *periodontium*, also known as the attachment apparatus, consists of two major subunits and is necessary for maintaining the integrity of the normal dentoalveolar unit.

The *gingival subunit* consists of the junctional epithelium and gingival tissue. Gingival tissue is composed of keratinized, stratified squamous epithelium; it can be divided into the free gingival margin and the attached gingiva. The free gingiva is the cuff of tissue formed around the neck of the tooth. The

Figure 64.1 Anatomy of the teeth, primary and permanent. *Note:* an avulsed primary tooth need not be reimplanted if it is lost traumatically. (Netter illustrations used with permission of Elsevier, Inc. All rights reserved.)

gingival sulcus is the space between the free gingiva and the tooth. It is rarely greater than 2 to 3 mm in depth in normal healthy dentition. The attached gingiva is the portion of gingiva attached to alveolar bone and extends apically (away from the tooth) to the mucogingival junction (or the mucobuccal fold). At this point the tissue, loose and nonkeratinized, is called the alveolar mucosa (or buccal mucosa).

The *periodontal subunit* includes the periodontal ligament, alveolar bone, and the cementum of the root of the tooth. The periodontal ligament consists of collagen that extends from the alveolar bone to the root of the tooth. One end of the periodontal ligament inserts into the alveolar bone and the other end into the cementum.

The gingival subunit is primarily responsible for maintaining the integrity of the periodontal subunit. Certain disease states such as gingivitis weaken the attachment apparatus and can result in loss of a tooth.

ACUTE TOOTHACHE IN THE ED

Patients with an acute toothache (odontalgia) often come to the ED for dental evaluation and relief of symptoms. Although multiple problems can initially cause pain in the area of the teeth, the cause is usually pulpitis, abscess, or dental trauma. Pulpitis can be either acute or chronic and the physiology,

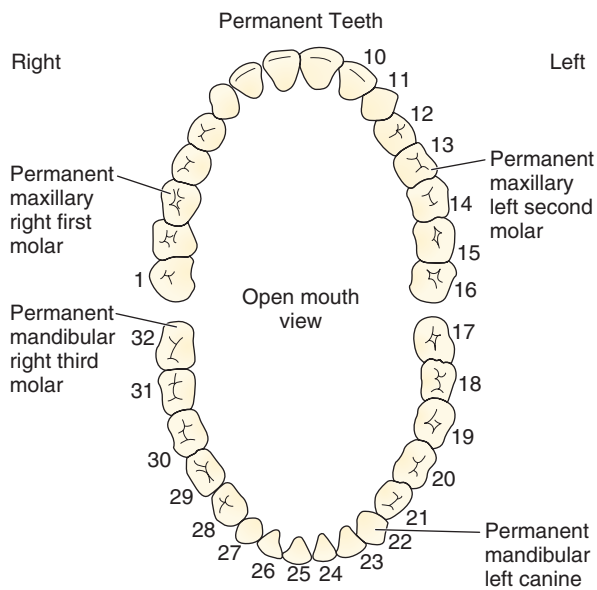

Figure 64.2 Identification of teeth, adult and child. Each tooth has a number assigned to it. By 14 years of age, all primary teeth should normally be lost. Do not reimplant an avulsed primary tooth; rather, refer to a dentist to prevent future misalignment of the permanent teeth.

treatment, and prognosis are different for each patient. Unfortunately, many patients have irreversible pulpitis by the time they seek emergency care.¹

Pain in a tooth when exposed to hot liquids usually indicates pulpal inflammation. Sensitivity to cold can signify simple sensitivity or gum recession but can also indicate decay. Pain while biting down or to percussion can indicate a fractured tooth, abscess, or decay.

Many fillings can leak and cause pain, and microcracks can occur and not be readily apparent to someone who is not a dentist. One cause of microcracks, or even a totally fractured tooth, is constant trauma from the metal balls implanted with tongue piercing.

Referral to a dentist is the logical definitive course of action for odontalgia, but pain relief can be initiated in the ED. Nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, opioids, and local nerve blocks can all provide relief of

Figure 64.3 The dental anatomic unit.

pain, depending on the scenario. Hile and Linklater² reported significant pain relief in a fractured tooth by applying 2-octylcyanoacrylate tissue adhesive (Super Glue) directly to the tooth. This intervention is currently anecdotal but may also provide temporary pain relief for patients with open decay when air and temperature exacerbate the pain. Dry the tooth thoroughly with gauze, and generously apply a few layers of the product to the affected area. This intervention lasts less than 24 hours before enzymatic breakdown occurs. Note that the use of skin adhesives has not been approved for intraoral use; they tend to break down quickly in the oral cavity.

For years, clove oil (containing eugenol) has been a popular and reasonably effective short-term home remedy for an acute toothache or inflamed gingiva. For a cavity or gingiva pain, saturate a piece of cotton in clove oil and place the cotton directly in the cavity or along the gum. This will provide relief for a few hours. Clove oil should not be used more than a few times because of irritation and possible nerve damage. Another simple method of pain management is to apply viscous lidocaine directly onto the tooth or saturate a small cotton ball with the gel and place it in a cavity. This treatment is temporary, and caution should be exercised if reapplication is considered. Do not exceed the total recommended dosage of lidocaine.

Acute dental pain may also be referred pain, so a complete evaluation should be conducted if the anatomy in question appears to be normal (Fig. 64.4). For example, acute sinusitis can cause tooth pain and vice versa. Obvious dental infection should be treated with antibiotics (e.g., penicillin, clindamycin, erythromycin, metronidazole, amoxicillin-clavulanate) while awaiting dental evaluation. Chronic acetaminophen overdose is a known complication of overaggressive use of analgesics by patients unable to obtain dental care for an acute toothache.³

Antibiotics provide no benefit for pain from a simple toothache, dental cavity, or pulpitis, although some clinicians prescribe them because follow-up dental care may be delayed or difficult to obtain.⁴ The emergency clinician, likewise, doesn't

Figure 64.4 This physician had severe pain in his jaw thought to be related to a dental problem. Two days after onset of the pain, the rash of herpes zoster appeared, which was the cause of the pain.

know whether a periapical abscess exists and so if definitive care is likely to be delayed, antibiotics are a reasonable choice.

Individual teeth (except the posterior molars) can be temporarily anesthetized with total pain relief by simply giving a supraperiosteal injection of a local anesthetic (see [Chapter 30](#)). Bupivacaine has a long duration of action (4 to 12 hours) and has been shown to decrease the narcotic requirement of postoperative oral surgery patients even after the anesthetic properties of the medication have worn off. Molars, which are more difficult to anesthetize with supraperiosteal injections, can be anesthetized via different nerve block techniques, such as the inferior alveolar nerve block.

DENTOALVEOLAR TRAUMA

Dental Fractures

Dentoalveolar trauma is a common reason for ED visits. Injury to the maxillary central incisors accounts for between 70% and 80% of all fractured teeth.⁵⁻⁷ Acute trauma to the teeth is not usually life-threatening; however, the morbidity associated with poorly managed dental fractures can be significant and includes failure to complete eruption, change in color of the tooth, abscess, loss of space in the dental arch, ankylosis, abnormal exfoliation, and root resorption. Dental injuries are often associated with intraoral lacerations. When a tooth is chipped or missing and there is a concomitant intraoral laceration, there is a risk that the missing portion of the tooth is embedded in the depths of the laceration ([Fig. 64.5](#)).

Some general principles apply to the evaluation and management of dental trauma. First, identify all fracture fragments and mobile teeth. Percuss each tooth surface for mobility and sensitivity. If a tooth is missing, it cannot always be assumed that it has been avulsed. Teeth can be aspirated into the respiratory tract, swallowed into the gastrointestinal tract, or fully intruded into the maxillary sinus, alveolar bone, or nasal cavity. Take radiographs if there is any suspicion of aspiration of tooth fragments or intrusion of fragments into the gingiva or alveolar bone. Second, the dentition is much more easily manipulated if the patient is not in significant discomfort. Tooth injection and common dental blocks should be part of the emergency

Figure 64.5 A chipped front tooth after a punch to the mouth can result in a piece of tooth being aspirated or embedded in the laceration. When this lip laceration was explored, a piece of tooth was found embedded within the laceration. If this foreign body is not removed, an infection is certain to occur within a few days. Note the obvious chipped upper tooth, the source of the piece found in the upper lip laceration.

clinician's armamentarium. Third, topical tooth remedies and analgesics, both over-the-counter and prescribed, should be discouraged because their long-term use can lead to the development of sterile abscesses and soft tissue irritation. Fourth, administer tetanus vaccine if needed.

Management of fractured teeth depends on the extent of fracture with regard to the pulp, the degree of development of the apex of the tooth, and the age of the patient. Dentoalveolar injuries and, in particular, tooth fractures can be classified in many ways.⁸ The Ellis classification is one system often cited in the emergency medicine literature; however, many dentists and maxillofacial surgeons do not use this nomenclature, thus making it less than ideal when discussing these types of injuries with specialists ([Fig. 64.6](#)).⁶ The most easily understood method of classification is one based on a description of the injury.

Crown fractures may be divided into uncomplicated and complicated categories. Uncomplicated crown fractures result from injuries to the enamel alone or to a combination of the enamel and dentin. Complicated crown fractures extend into the pulp.

Ellis Class I Fractures

Uncomplicated crown fractures through only the enamel are known as *Ellis class I fractures* (see [Fig. 64.6B](#)). They are not usually sensitive to either temperature or forced air. These fractures generally pose minimal threat to the health of the dental pulp. They may feel sharp to the patient's tongue, lips, or buccal mucosa. Immediate treatment is not necessary but may consist of smoothing the sharp edge of the tooth with an emery board or rotary disk sander. The patient should be reassured that a dentist can restore the tooth to its normal appearance with composite resins and bonding material. Follow-up is important with these injuries because pulp necrosis and color change can occur in some cases (< 3%).^{6,9,10}

Ellis Class II Fractures

Uncomplicated fractures through the enamel and dentin are called *Ellis class II fractures*. Fractures that extend into the dentin are at higher risk for pulp necrosis and therefore need more

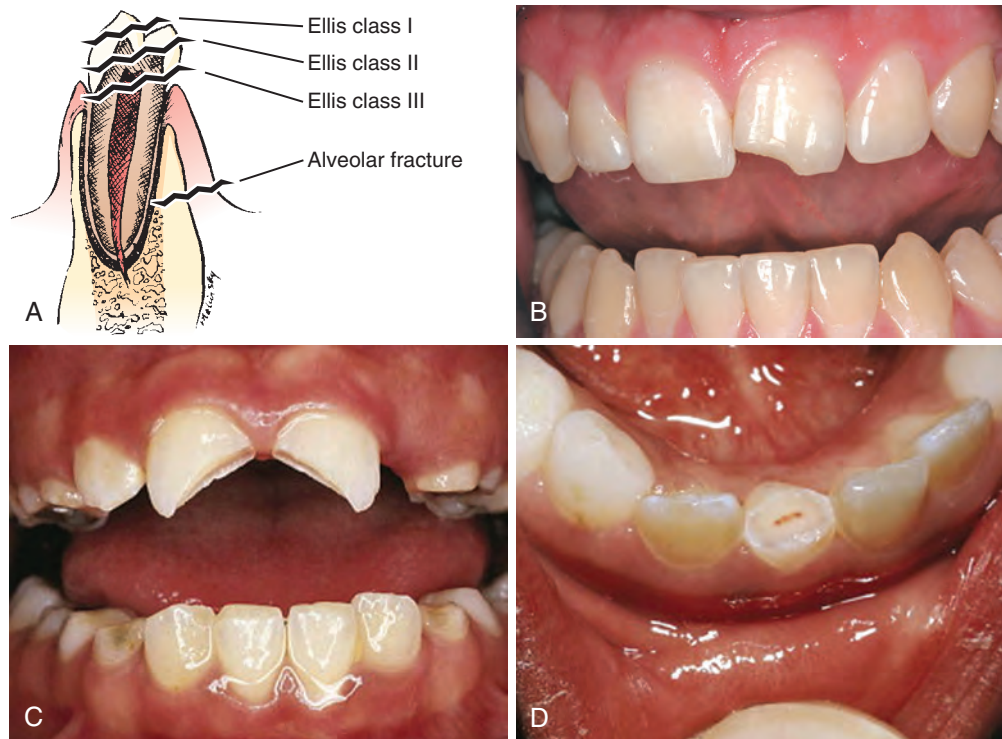

Figure 64.6 A, The Ellis classification for fractured alveolar teeth. The easiest method to classify fractured teeth is by description (e.g., fracture through the dentin of the first upper right molar). B, Ellis class I: only the enamel is fractured. These fractures pose no threat to the dental pulp and are not sensitive to temperature or forced air. C, Ellis class II: the crown fracture demonstrates involvement of the enamel and dentin, without exposure of the pulp. Immediate dental referral is necessary to prevent contamination of the pulp through the dentinal tubules. D, This crown fracture involves enamel, dentin, and the soft tissue of the pulp as well. Immediate dental referral is mandatory to save the tooth. (C and D, from Zitelli BJ McIntire SC, Nowalk AJ, editors: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, St. Louis, 2012, Saunders.)

aggressive treatment by the emergency clinician (see Fig. 64.6C). The risk for pulp necrosis in these patients is less than 10%, but it increases as treatment time extends beyond 24 hours.⁶ These patients often complain of sensitivity to heat, cold, or forced air. Physical examination reveals the yellow tint of the dentin in contrast to the white hue of the enamel. With fractures closer to the pulp cavity, the dentin will have a pink tinge. The tooth is usually sensitive to percussion with a tongue blade. The porous nature of dentin allows passage of bacteria from the oral cavity to the pulp, which may result in inflammation and infection of the pulp chamber. This is more likely to occur after 24 hours of dentin exposure but occurs sooner if the fracture site is closer to the pulp. Likewise, patients younger than 12 years have a pulp-to-dentin ratio larger than that in mature adults and are at increased risk for pulp contamination. For this reason, younger patients should be treated aggressively and be seen by a dentist within 24 hours.^{10,11}

The goal of treating dentin fractures is twofold: to cover the exposed dentin and thus prevent secondary contamination or infection and to provide relief of the pain. After the tooth is covered, the dentist, using modern composites, can often rebuild the tooth directly over the calcium hydroxide (CaOH) cap that was placed in the ED. Perform supraperiosteal injection or a regional tooth block before any manipulation of the tooth. This will make application of the dressing easier because manipulation of the tooth will not cause discomfort. Dressings

that may be applied to the surface of the tooth include CaOH, zinc oxide, skin adhesives, and glass ionomer composites. Some literature suggests that glass ionomer may be superior to other coverings; however, the difference is probably slight, and the increased cost of glass ionomer is not justified for routine use in the ED at this time.^{5,12} Certain composites may be cured with a bonding light. This is routinely done in the dentist's office and is beyond the scope of most emergency practice. Bone wax and skin glue such as the cyanoacrylates are not recommended as dressings. Many dressings come as a base and a catalyst which require mixing, but are often available in premixed formulations as well. This is easily accomplished with a dental spatula and a mixing pad, which can be obtained from any dental supply house. A commonly used ED dressing is CaOH (Dycal [Dentsply Sirona, York, PA], Preline [Henry Schein, Melville, NY], or other similar products). Mix the catalyst and the base in equal portions, and place a small amount on the exposed area with an applicator such as a dental spatula or another appropriate instrument (Fig. 64.7). The fracture site must be dry before application of the CaOH to ensure adherence.

To dry the surface of the tooth, have the patient bite into gauze pads or mouth breathe. Likewise, connecting a nasal cannula to high-pressure wall O₂ and aiming it at the tooth will facilitate drying. CaOH will dry within minutes after being exposed to the moist environment of the mouth. Although

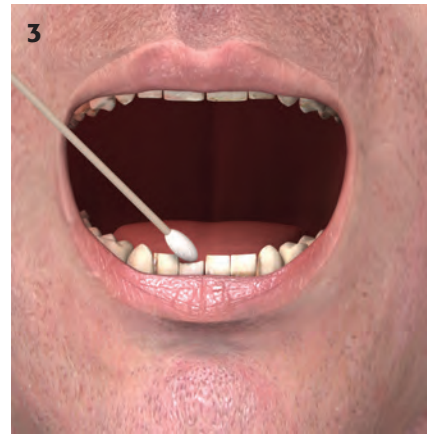

Calcium Hydroxide Application

Calcium hydroxide is used to treat dentin fractures and aids in prevention of infection and pain relief. It is supplied in separate tubes of catalyst and base.

Mix equal portions of catalyst and base on the mixing pad that is supplied with the product. A dental spatula is an ideal tool; however, a simple cotton applicator will suffice.

Dry the tooth surface prior to application by having the patient bite down on a gauze pad. Then place a small amount of the paste onto the exposed surface. It will dry within minutes.

Figure 64.7 Calcium hydroxide application for the treatment of dentin fractures.

placing dental foil over the CaOH dressing is recommended in some texts, it is not necessary if the patient plans to follow up with a dentist within 24 to 36 hours. It is also not technically easy to perform. To prevent dislodgment of the CaOH dressing, instruct the patient to eat only soft foods until seen by a dentist. Although there is no evidence to support antibiotic therapy for fractured teeth in the ED, many consultants recommend initial treatment with penicillin or clindamycin until definitive dental care can be obtained.¹³

Many patients who sustain a fracture through the dentin will require a root canal or other definitive endodontic treatment. Timely application of an appropriate dressing in the ED, however, may prevent contamination of the pulp and make root canal therapy unnecessary. As with any trauma to the anterior teeth, explain to the patient that disruption of the neurovascular supply is possible and that long-term complications such as pulp necrosis, color change, and resorption of the root might occur.

Ellis Class III Fractures

Complicated fractures involving the pulp are also known as *Ellis class III fractures* (see Fig. 64.6D). Complicated fractures of the crown that extend into the pulp of the tooth are true dental emergencies. These fractures result in pulp necrosis in 10% to 30% of cases even with appropriate treatment, so the vast majority of these injuries end up with root canal therapy.⁶ They may be distinguished from fractures of the dentin by the pink color of the pulp. Wipe the fractured surface of the tooth with gauze and observe for frank bleeding or a pink blush, which indicates exposure of the pulp. Fractures through the pulp are often excruciatingly painful, but occasionally there is lack of sensitivity secondary to disruption or concussion of the neurovascular supply of the tooth.

Immediate management includes referral to a dentist, oral surgeon, or endodontist. The patient usually requires pulpectomy (complete removal of the pulp) or, in the case of primary

Figure 64.8 Application of periodontal calcium hydroxide paste to the fractured surface of the tooth. The paste hardens quickly in the moist environment of the mouth.

teeth, pulpotomy (partial removal of the pulp) as definitive treatment.^{5,9} The longer the pulp is exposed, the greater the likelihood of contamination and abscess formation. If a dentist cannot see the patient immediately, attempt to relieve the pain and cover the exposed pulp (Fig. 64.8). If significant pain is present, perform a supraperiosteal injection. Subsequently,

cover the tooth with one of the dressings described earlier. The bleed can be brisk at times. Control such bleeding by having the patient bite onto a gauze pad that has been soaked with a topical anesthetic containing a vasoconstrictor such as epinephrine. Alternatively, inject a small amount of anesthetic/vasoconstrictor into the pulp to control bleeding. After the covering is applied, instruct the patient to follow up as soon as possible with a dentist. Antibiotics with coverage directed at oral flora (e.g., penicillin, metronidazole, or clindamycin) should be considered, with recommendations to eat only soft food and to avoid mastication on the affected side. Removal of the pulp with specialized instruments by the emergency clinician is not recommended, although some authors have advocated this in the past. This procedure is the realm of the dental professional and is likely to result in complications if not done properly.

Luxation, Subluxation, Intrusion, and Avulsion

Luxation and Subluxation

Subluxation refers to teeth that are mobile but not displaced. *Luxation* refers to teeth that are displaced, either partially or completely, from their sockets. Luxation injuries are divided into four types (Fig. 64.9):

1. *Extrusive luxation* is an injury in which the tooth is forced partially out of the socket in an axial direction (see Fig. 64.9A).
2. *Intrusive luxation*, or intrusion, occurs when the tooth is forced apically. It may be accompanied by crushing or fracture of the tooth apex (see Fig. 64.9B).
3. *Lateral luxation* occurs when the tooth is displaced either facially, lingually, mesially, or distally (see Fig. 64.9C). This injury is often associated with injuries to the alveolar wall.
4. *Complete luxation*, also known as complete avulsion, results in loss of the entire tooth from the socket.

Even minor trauma to the oral cavity requires meticulous examination for loose or missing teeth. Examine each tooth

for mobility by applying a back-and-forth motion on each side of the tooth surface with either the fingertips or two tongue blades. Any blood in the gingival crevice (area where the gingiva touches the tooth) suggests a traumatized tooth.

Teeth that are minimally mobile and are not displaced do very well with just conservative treatment. The tooth will tighten up in the socket if not retraumatized or reinjured in any way. Instruct patients to eat only a soft diet for 1 to 2 weeks and see their dentist as soon as possible. Note that a seemingly lost (avulsed) tooth may actually be deeply intruded into the soft tissue (Fig. 64.10).

Grossly mobile teeth require some form of stabilization as soon as possible. It is important to note that in certain patients with poor gingival health, luxated teeth may not be salvageable because of preexisting disease of the attachment apparatus. Stabilization is best performed by a dental specialist with enamel bonding material or wire ligation. Although many different “home remedies” exist for splinting loosened teeth in the ED, the clinician must be aware of the possibility of aspiration if the splint fails. Avoid the use of unapproved medications in the mouth. Splinting techniques are suitable for the emergency clinician to perform as temporizing measures until definitive care can be arranged. One simple technique for emergency use is to apply periodontal paste, commercially available as Coe-Pak (GC America Inc., Alsip, IL) or other similar commercial products (Fig. 64.11). These products usually consist of a base and a catalyst that when mixed, form a moderately sticky claylike dressing that becomes firm after application. It is applied over the enamel and gingiva, as well as the adjacent teeth, to splint the subluxed tooth into place. Although the splint performs best if placed on the facial and buccal surfaces of the teeth, it is usually sufficient to apply the paste only to the front (facial) surface of the teeth. Make sure that the gingiva and enamel are completely dry. Lubricate gloves with water or lubricating jelly before applying the dressing. Apply the dressing into the grooves between the teeth, as well as on the adjacent teeth. Remind the patient to eat a soft diet until seen in follow-up within 24 hours. Periodontal pastes are usually

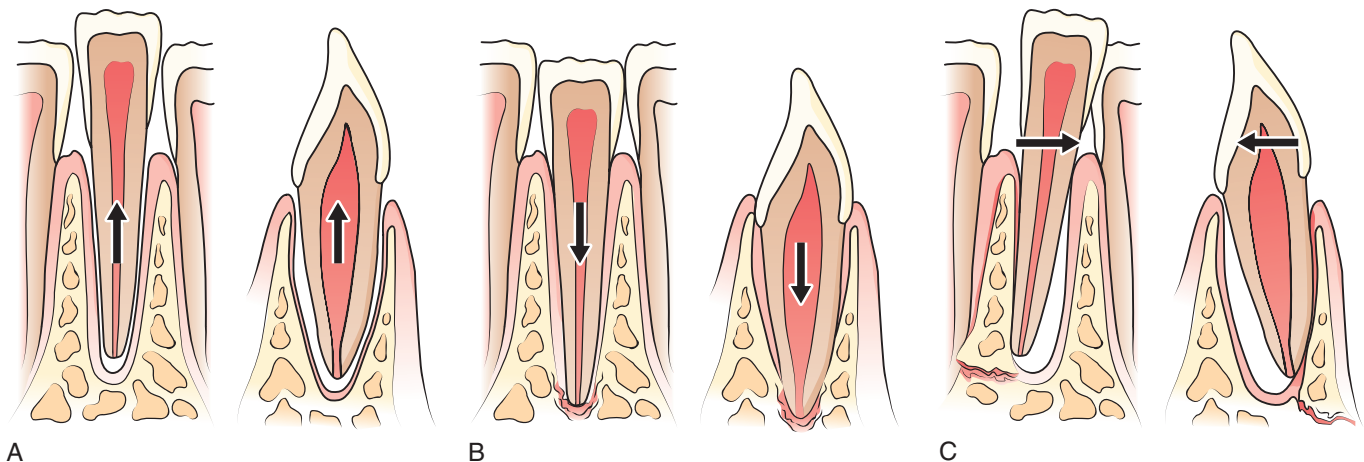

Figure 64.9 Classification of tooth trauma. **A**, Extrusive luxation occurs when the tooth is forced partially out of the socket in an axial direction. **B**, Intrusive luxation of a tooth compresses the periodontal ligament and vascular supply of the pulp. It may even crush the apical bone. **C**, Lateral luxation occurs when the tooth is displaced in a lingual, mesial, distal, or facial direction. Fractures of the alveolus frequently accompany lateral luxation injuries. (A–C, Adapted from King R: Orofacial infections. In Montomery MT, Redding SW, editors: *Oral-facial emergencies—diagnosis and management*. Portland, OR, 1994, JBK Publishing.)

Figure 64.10 Intruded tooth secondary to trauma. **A**, On superficial examination it appears that the tooth was simply knocked out. This missing tooth could be simply lost, fully intruded, aspirated, or swallowed. **B**, In some cases a dental radiograph or computed tomography scan is necessary to determine intrusion or avulsion. Intruded teeth create the potential for infection or cosmetic deformities. Intrusion of an upper tooth into the maxillary sinus can cause recurrent sinusitis. Teeth can also intrude into the nasal cavity and cause infection or bleeding, or they can be aspirated into the airway. The incisors are the teeth most commonly intruded.

fairly simple for the dentist to remove during formal restoration. They are also useful in treating difficult-to-repair gingival lacerations which are not associated with alveolar ridge fractures. The laceration is covered with periodontal paste and removed in 5 to 7 days by the follow-up dentist.

Teeth that are luxated in either the horizontal or the axial plane or are slightly extruded can also be splinted with the techniques described earlier. It is important that the loosened tooth be in as perfect alignment as possible when the final adjustments are made at the dentist's office. However, the alignment does not need to be as precise when the tooth is splinted in the ED. The important point is that the tooth be splinted adequately and follow-up ensured.

Intrusion and Avulsion

Intruded teeth are those that have been forced apically into the alveolar bone. This often results in disruption of the attachment apparatus or fracture of the supporting alveolar bone, especially in permanent teeth with mature roots.^{11,14} These teeth are usually immobile and do not require stabilization in the ED. Intruded teeth frequently require endodontic treatment because of pulp necrosis. It is important to consider the possibility of an intruded tooth anytime there is a space in the dentition (see Fig. 64.10). Undiagnosed intrusion of the

teeth can lead to infection and craniofacial abnormalities. Obtain radiographs when it is uncertain whether a tooth is intruded or simply avulsed. Intruded teeth are best managed by a dentist or dental specialist; referral should take place within 24 hours. Permanent teeth often require repositioning and immobilization, but primary teeth are usually given a trial period to erupt on their own before any intervention is taken.

Primary teeth are not replaced after avulsion because they can fuse to the alveolar bone and potentially cause craniofacial abnormalities or infection. Reimplanted primary teeth may also interfere with eruption of the secondary teeth. The parents of these patients need to be reassured that a prosthetic replacement for the avulsed teeth can easily be made and worn until the permanent teeth erupt, if desired. See Figs. 64.1 and 64.2 as a guide to identifying permanent versus primary teeth.

Avulsed permanent teeth are those that have been completely removed from their ligamentous attachments. These are true dental emergencies. The majority of patients seen in the ED with an avulsed tooth will lose that tooth, so patient and physician expectations should not be overly optimistic. Under ideal circumstances, such as arrival at a dentist's office with a properly stored tooth avulsed less than 60 minutes previously, this situation may result in successful reimplantation 80% to 90% of the time but often requires specialized procedures and endodontics (root canal). Emergency clinicians are not expected to save an avulsed tooth, but prompt action may give that replanted tooth some chance for survival.

The first consideration in treating dental avulsions is to ask, "Where is the tooth?" Missing teeth may have been intruded, fractured, aspirated, swallowed, or embedded into the soft tissues of the oral mucosa. Therefore radiographs should be considered anytime that an avulsed tooth cannot be located. Management of an avulsed tooth in the ED depends on a number of factors, including the age of the patient, the amount of time that has elapsed since the tooth was avulsed, associated trauma to the oral cavity such as alveolar ridge fractures, and the overall health of the periodontium.¹⁴ Time is the other important consideration when deciding whether to replace an avulsed tooth. In general, the longer the tooth is out of the socket, the higher the incidence of necrosis of the periodontal ligament and subsequent failure of reimplantation. Periodontal ligament cells generally die within 60 minutes outside the oral cavity if they are not placed in an appropriate transport medium.¹⁵ A significant amount of research has been conducted on different media used to keep cells of the periodontal ligament alive. Various transport media have been studied, including milk, Hank's Balanced Salt Solution (Thermo Fisher Scientific, Waltham, MA), Save-A-Tooth (Phoenix Lazarus, Portland OR), saliva, cell culture media, and water. Although certain cell culture media have been developed to stimulate cells of the periodontal ligament to proliferate and remain viable, milk and the commercially available Save-A-Tooth and EMT Toothsaver (Smart Practice, Inc., Phoenix, AZ) are the best and easiest for both prehospital care and ED storage (Fig. 64.12).^{15,16} Milk will preserve the periodontal ligament for 4 to 8 hours; the commercial products will preserve the ligament for 12 to 24 hours. However, reimplantation (Video 64.1) should take place at the earliest possible opportunity after the socket has been adequately prepared. The key is to get the tooth into the transport medium immediately because even 10 minutes outside some type of storage medium can cause desiccation and death of the periodontal ligament cells. Use saliva at the scene if milk, EMT Toothsaver, or

Dental Splint (Coe-Pak) Application

1
Coe-Pak is a periodontal paste used to splint loosened or avulsed teeth. Like calcium hydroxide, it is supplied as a catalyst and a base.

2
Mix equal parts of the catalyst and base on the mixing pad supplied with the product.

3
Roll the claylike mixture between your fingers into an elongated roll. Apply lubricating jelly to your gloves prior to handling the product to prevent it from sticking.

4
Dry the teeth and gingiva with gauze prior to application. Press the Coe-Pak into the grooves between the teeth, as well as across the adjacent teeth and gingiva. This type of splint works best when applied to both the front and back surfaces of the teeth, although it is usually sufficient to apply it only to the front.

Figure 64.11 Dental splint (Coe-Pak, GC America Inc., Alsip, IL) application.

Save-A-Tooth is not available. The patient should reimplant the tooth in the prehospital setting if possible. Do not have the patient place the tooth in the cheek or lip as this risks aspiration. The principles cited here should be followed when providing instructions to prehospital providers or to a patient who calls for advice. It is always preferable to refer such patients directly to a dentist rather than the ED if this is practical. Patients should be requested to do the following:

- Determine whether this is a permanent tooth. By 14 years of age, all primary teeth should have been replaced by permanent teeth.
- Handle the tooth by the crown only because handling the tooth by the root can damage the periodontal ligament.
- Do not replace the tooth if it is fractured or if significant maxillofacial trauma has occurred such as an alveolar ridge fracture.
- If the tooth can be replaced in the prehospital setting, gently rinse off the root first to remove any debris. Do not

wipe off the root because this removes the periodontal ligament.

- If the tooth cannot be reimplanted successfully in the field, place it in a transport medium as described earlier. Do not transport the tooth in the oral cavity such as inside the cheek because of the risk for aspiration. This location is also not ideal for keeping the periodontal ligament alive because of the bacterial flora and low osmolality of saliva. Once the patient arrives in the ED, confirm proper placement and alignment. It is not important that the tooth be in perfect position because the dentist can make final adjustments. Splinting the repositioned tooth with periodontal paste or composite as outlined earlier may be necessary if mobility is present.

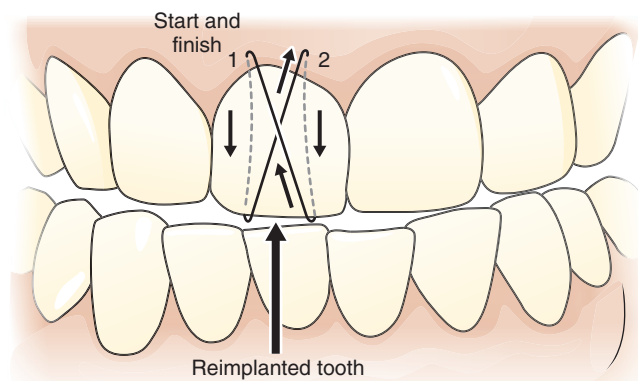

Should reimplantation not be successful in the prehospital setting, it must be done in the ED according to the following guidelines:

- Store the tooth in an appropriate medium if reimplantation is delayed for any reason.

Figure 64.12 With the **A**, Save-A-Tooth (Phoenix Lazarus, Portland OR) or **B**, EMT Tothsaver (SmartHealth, Phoenix, AZ) systems, an avulsed permanent tooth is placed into the container and closed. Avulsed primary teeth are not replanted. The preservative will increase the lifespan of traumatized periodontal ligament cells. Unpreserved teeth replanted after 60 minutes rarely survive; those that do require root canal procedures and close follow-up. This system prolongs the time to successful reimplantation but does not ensure success.

- Perform supraperiosteal injection with a local anesthetic before manipulating or replacing teeth to make the procedure more comfortable for the patient and easier to perform.
 - Check the oral cavity for trauma. If an alveolar ridge fracture is present or the socket is significantly damaged, do not reimplant the tooth.
 - Gently suction the socket first with a Frasier suction tip to remove any accumulated clot. Be careful to not damage the walls of the socket because this can further damage periodontal ligament fibers. Irrigate gently after suctioning. If the clot is not removed, reimplantation and realignment will be difficult. Rinse off any debris on the tooth with saline but do not scrub it. Implant the tooth into the socket with firm, but gentle pressure. Remember to handle the tooth only by the crown.
 - Ask the patient to bite down gently on gauze to help align the tooth. The tooth may require splinting after replacement. This can be performed in the ED or urgent care clinic with periodontal pastes.
 - Update the patient's tetanus status as necessary.
 - Prescribe a liquid diet until the patient is seen in follow-up.
- Antibiotics are controversial in the treatment of fractured and avulsed teeth. Although the American Association of Endodontics does not recommend the routine use of antibiotics for fractures or avulsions, other authors recommend the use of antibiotics effective against mouth flora (e.g., penicillin, clindamycin) to decrease inflammatory resorption of the root.^{6,17} It is probably reasonable to use antibiotics if the root or socket is heavily soiled; otherwise, treatment should be tailored to the individual patient and discussed with a knowledgeable and experienced consultant.

A

B

C

Figure 64.13 Temporary suturing to hold a replanted tooth in place. **A**, Use a silk suture. Start by puncturing the gingiva at the border of the replaced tooth (1). Bring the suture behind the tooth and then cross over the front of the tooth to the other side. Penetrate the gingiva (2), go behind the tooth, cross over the front again, and tie the suture (**A**). **B** and **C**, Multiple teeth can be reimplanted.

Ideally, the patient is immediately referred to a dentist, and the reimplanted tooth is held in place by biting on gauze. The tooth may be temporarily held in place with periodontal paste or another similar product (see Fig. 64.11) or the technique described in Fig. 64.13.

Prognosis

The prognosis of a reimplanted tooth depends on many things. As discussed earlier, the time until reimplantation is critical. Likewise, the age of the patient, the stage of development of the root (younger is better), and the overall health of the gingiva are also very important. An individual with gingival disease is more likely to have an unsuccessful reimplantation.

The goal in any tooth avulsion or fracture is to keep the native tooth if at all possible. A tooth that has been avulsed and reimplanted usually loses the majority of its neurovascular supply and undergoes pulp necrosis, necessitating root canal therapy. However, if the periodontal ligament remains intact, there is a greater chance of a functional tooth. It is important that the patient be aware that some root resorption is always going to occur after reimplantation and that loss of the tooth might occur.

Alveolar Bone Fractures

Trauma involving the anterior teeth may be associated with fracture of the alveolus, which is the tooth-bearing portion of the maxilla or mandible. Alveolus or alveolar ridge fractures often occur in multitooth segments and will vary in the number of teeth involved, the amount of displacement, and the mobility of the affected segment. The patient generally complains of pain, as well as malocclusion. The diagnosis is usually clinically apparent and is notable for a section of teeth that are misaligned and variable in mobility (Fig. 64.14). Avulsed teeth, fractured teeth, or displaced teeth may be present within the alveolar segment itself. Dental bite-wing radiographs confirm the diagnosis. In the ED, Panorex or facial x-ray films may show the fracture line just apical to the root of the involved teeth; however, these films are often inconclusive or have normal findings. Facial computed tomography (CT) may provide additional information (Fig. 64.15).

Treatment of alveolar ridge fractures involves rigid splinting after repositioning the involved segment. The displaced alveolar ridge should not be repositioned by the emergency clinician as this often converts a nonmobile displaced segment into a mobile displaced segment. Repositioning is usually beyond the scope of the emergency clinician, and urgent consultation with an oral surgeon or dentist is necessary. The role of the emergency clinician is to identify the injury, as well as any avulsed or fractured teeth, and preserve as much of the alveolar bone and surrounding mucosa as possible. Alveolar bone that is lost, débrided, or missing is difficult to restore properly.¹² Alveolar ridge fractures, if not mobile or bleeding, may be

Figure 64.14 Alveolar ridge fracture. Note that a section of teeth is misaligned. Clinically, the section is mobile and malocclusion will be present. (From Baren JM, Rothrock SG, Brennan J, et al, editors: *Pediatric emergency medicine*. Philadelphia, 2007, Saunders.)

discharged if urgent follow-up is arranged for within 24 hours. If bleeding or movement of the segment is a risk, specialty consultation will need to take place within the hospital.

Lacerations and Dentoalveolar Soft Tissue Trauma

Trauma to the face and perioral region is often associated with soft tissue injuries such as abrasions or lacerations. Before any repair can take place, thoroughly inspect all wounds and abrasions to determine the extent of the wound and whether foreign bodies are present. Through-and-through lacerations are easily overlooked, as are small foreign bodies and debris such as tooth fragments. Obtain radiographs if there is any question of tooth fragments. Evaluate the patient for potential airway compromise.

As a general rule, repair injured teeth before undertaking soft tissue repair because manipulating the soft tissue while repairing teeth may damage sutures already in place in the soft tissues. Begin repair in the perioral region with standard wound care. After appropriate local or regional anesthesia, débride devitalized, crushed, or macerated tissue. Irrigate profusely. The role of antibiotics in mucosal trauma has not been conclusively established, and there is no definitive standard of care. Several studies suggest a minimal benefit; however, this remains to be completely proved.¹⁸ A reasonable guideline to follow is to use antibiotics if a significant amount of devitalized or crushed tissue is present, if there is significant wound contamination, or if the wound is a through-and-through laceration. Coverage of oral flora (e.g., penicillin, metronidazole, or clindamycin) is fine for mouth lacerations, and additional skin coverage (e.g., clindamycin, or dicloxacillin) should be considered for through-and-through lacerations. Dentoalveolar trauma may present the emergency clinician with several different situations that should generally be approached as follows.

Buccal Mucosa

Most small lacerations and abrasions of the buccal mucosa heal quickly and rapidly without repair, but large lacerations (> 1 to 2 cm) should be repaired. Use any absorbable suture such as chromic gut or Vicryl (Ethicon US LLC, Somerville,

Figure 64.15 Facial computed tomography provides a definitive diagnosis of alveolar fracture. Here, axial and reformatted coronal images show a comminuted displaced fracture of the mandible involving the alveolar ridge. (From Soto JA, Lucey B: *Emergency radiology: the requisites*. St. Louis, 2009, Mosby.)

NJ) in the mouth, but place the sutures so that the knots are buried. Silk is an alternative but has higher reactivity and is nonabsorbable. Avoid using nylon because it is sharp and irritating to tissues.

Through-and-through lacerations of the oral cavity present a special situation. Evaluate for damage to the salivary ducts (Wharton's duct and Stensen's duct) and to the facial nerve. If they are intact, proceed with the repair. Guidelines for closure are controversial, but larger lacerations (> 1 to 2 cm) should generally be closed. Close the mucosa with absorbable sutures as noted earlier, and close the skin aesthetically with 6-0 nylon, Prolene (Ethicon), or a rapidly absorbable suture. Close the mucosa first so that the skin repair is not disturbed. If the mucosal wound is small or is a puncture wound, it is reasonable to close only the skin layer. Refer very large, gaping, or complicated lacerations to an oral surgeon.

Recheck large or through-and-through lacerations of the oral cavity in 2 to 3 days. Remove nonabsorbable sutures in 7 to 10 days. Advise the patient to rinse four to six times a day with saline solution. Prescribe a soft diet. Apply a topical skin antibiotic for 24 to 48 hours.

Gingiva

Small lacerations of the hard gingiva overlying the maxillary or mandibular alveolus usually heal uneventfully without repair. If the laceration is large, if a flap is present, or if bone is exposed, approximate the gingiva with a 4-0 or 5-0 Vicryl (Ethicon) or Dexon (Medtronic, Minneapolis, MN) suture. As mentioned earlier, silk is another option. It is difficult to suture gingiva because there is little supporting soft tissue underneath. A helpful technique is to wrap the suture around the teeth circumferentially and use the teeth as anchors (Fig. 64.16). Large lacerations should be repaired to approximate the gingiva and cover the base of the teeth (Figs. 64.17 and 64.18). Nongaping, nonbleeding gingival lacerations may be covered with periodontal paste as described earlier in lieu of suturing, as long as dental or maxillofacial follow-up is assured.

Frenulum

The maxillary frenulum rarely requires sutures for simple lacerations. If the laceration is extensive or extends significantly into the surrounding mucosa or gingiva, approximate it with chromic, Vicryl (Ethicon), or Dexon (Medtronic) suture. These wounds are often significantly painful. Prescribe analgesic medications even if the wound does not require suturing. The lingual frenulum is very vascular in nature and will often need a suture or two to control hemostasis. Use a local anesthetic with a vasoconstrictor to aid in hemostasis while the wound is repaired.

The Tongue

▶ Tongue lacerations are challenging (Video 64.2). Although they may be tempting to suture, most large lacerations of the body of the tongue, such as those that occur from a seizure, will heal well without suturing (Fig. 64.19). Tongue lacerations that have the wound edges approximated do not need to be sutured. Repair larger lacerations that gape because the cleft left by the wound will epithelialize and leave a grooved, bifid, or lateral flap appearance. Approximate wounds that are bleeding profusely, are flap shaped, involve muscle, or are on the edge of the tongue. Small avulsions (divots) or those in the center of the tongue usually heal without intervention.

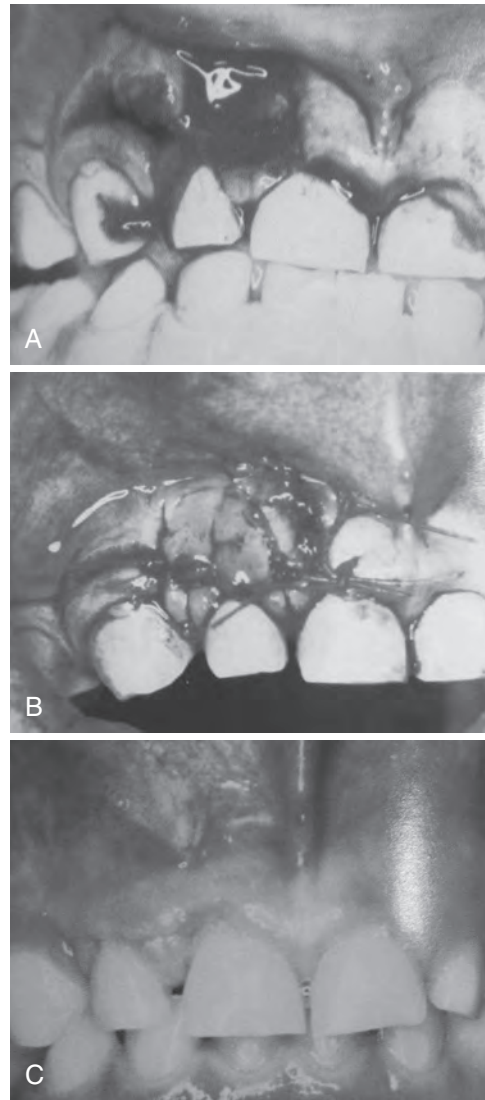

Figure 64.16 A, Gingival lacerations sometimes leave little tissue for approximation. B, The teeth can be used as anchors for sutures and to help approximate the lacerated tissue. C, Gingival lacerations usually heal rapidly.

Figure 64.17 Large gingival avulsions should be approximated to an anatomic position with interrupted sutures.

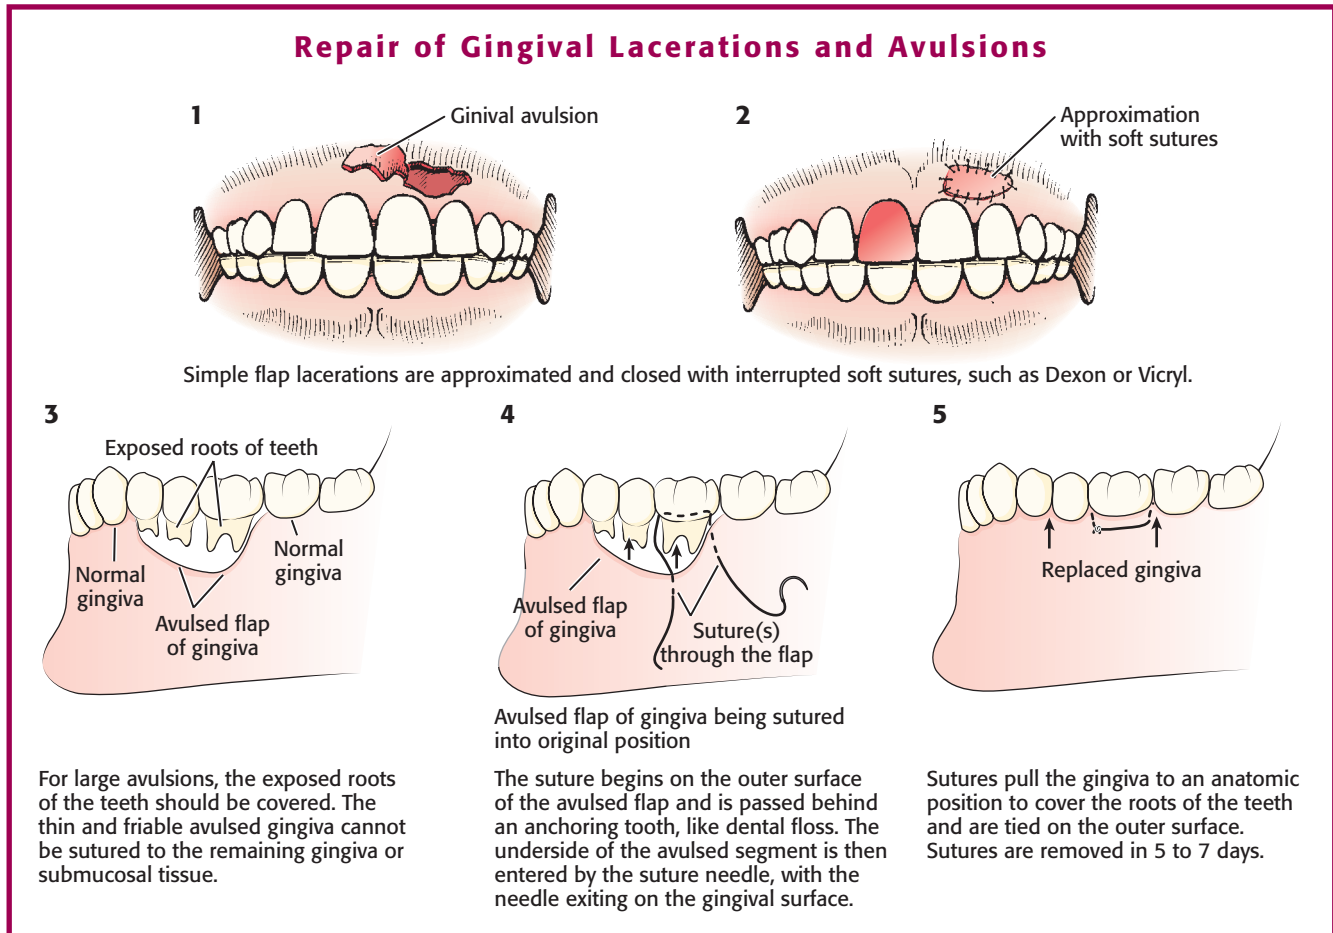

Figure 64.18 Repair of gingival lacerations and avulsions.

Explain the procedure in detail to the patient before repairing these wounds. Ask an assistant to secure the tongue by holding it with gauze. If the tongue cannot be secured in this manner, apply a towel clip to the end of the anesthetized tongue. Children with tongue lacerations that need repair generally require sedation or repair by a specialist in the surgical suite, but many of these lacerations are small and heal uneventfully on their own.

Begin the repair with either local injection of an anesthetic or a lingual block (see [Chapter 30](#)). To promote hemostasis, infiltrate locally with lidocaine with epinephrine. Use absorbable sutures such as 4-0 chromic, Vicryl (Ethicon), or Dexon (Medtronic). Silk can be used, but it must be removed in 7 to 10 days. Do not use nylon because it is very irritating to the surrounding tissues. For lacerations extending through muscle, close with one deep stitch penetrating both the mucosa and the muscle. When possible, bury the knots of absorbable suture because they will often work their way loose. Full-thickness lacerations can be closed in a number of ways. Place a suture through all three layers or close the top mucosa and muscle together and do the same thing on the underside of the tongue. Bleeding from large lacerations is almost always controlled with primary repair. In some instances, hemostasis can be achieved without the use of sutures by using Gelfoam (Pharmacia and Upjohn Company, Kalamazoo, MI) impregnated with topical thrombin ([Fig. 64.20](#)).

ORAL HEMORRHAGE

Bleeding from the oral cavity is not unusual and is most commonly associated with dental procedures, such as extracted teeth. It is important to ascertain whether any recent dental work has been performed and what was done. Spontaneous bleeding of the gingiva or oral cavity not associated with dental manipulation or trauma is suggestive of advanced periodontal disease or an underlying systemic process. Ask the patient about other medical conditions that predispose to bleeding (e.g., liver disease, platelet abnormalities), as well as historical factors that may suggest a bleeding abnormality or clotting factor deficiency. Find out whether the patient is taking aspirin or other anticoagulants. Consider laboratory testing if pathologic coagulopathy is a significant concern, but not routinely in a patient seen after dental manipulation.

Control gingival bleeding after scaling or minor dental procedures with direct pressure and saline or hydrogen peroxide rinses. Persistent bleeding from the gingival areas despite pressure and rinses raises suspicion of a bleeding abnormality. A much more common cause of oral hemorrhage seen in the ED is postextraction bleeding. Minor oozing after dental extractions, such as wisdom tooth extraction, is normal for 2 to 4 days after surgery, but many patients get concerned when the bleeding persists despite warnings from the oral surgeon. These patients usually go to the ED when their dentist cannot

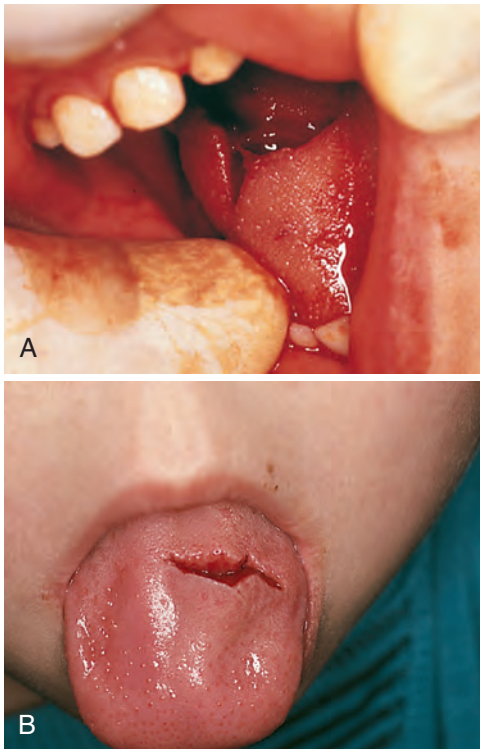

Figure 64.19 Tongue lacerations. **A**, A large gaping tongue laceration in a toddler produced by the upper front teeth being forced through the tissue by a fall with the tongue protruded. This type of injury requires suturing. **B**, This small laceration, though gaping slightly, does not require surgical closure. (From Zitelli BJ, McIntire SC, Nowalk AJ, editors: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, St. Louis, 2012, Saunders.)

be contacted and after futile attempts to stop the bleeding at home. The emergency clinician has a number of options to achieve hemostasis of postextraction bleeding.

Direct Pressure

Although the patient may have been using this technique at home, a few simple procedures may make it more effective. If a clot is present inside a recently removed tooth socket, leave it intact. If excessive clot has built up around the oozing site, remove the excess clot with a Frasier suction catheter and then gently irrigate the area. Once the clot is removed, place gauze as firmly as possible directly onto the bleeding site. This is best accomplished by using dental roll gauze (see later section on [Dental Material](#)). Insert it directly over the bleeding site and then cover it with 2- × 2-inch gauze. Dental roll gauze fits more precisely between the teeth and therefore affords more pressure; however, 2- × 2-inch gauze can be substituted. Moisten the roll gauze with a topical vasoconstrictor before placing it over the bleeding site. Instruct the patient to bite down and hold pressure for 15 minutes or so.

If active bleeding persists after 15 minutes, infiltrate the bleeding area and the gingiva surrounding the socket with lidocaine and epinephrine (1:100,000) until blanching occurs. Reapply the gauze over the site and instruct the patient to bite down for 15 more minutes. The injection serves two purposes: it causes vasoconstriction and it anesthetizes the area so that adequate pressure can be generated during biting.

A

B

Figure 64.20 **A**, For persistent bleeding of a tongue, mucosa, or dental extraction site, topical thrombin can be used (Thrombin-JMI, Pfizer Inc, New York, NY). Topical thrombin is available in a spray pump, in a syringe for application, or as a reconstituted powder to saturate absorbable Gelfoam (Pharmacia and Upjohn Company, Kalamazoo, MI). **B**, A tongue laceration such as this one will heal well without sutures once the bleeding is controlled. Topical thrombin may be an option if hemostasis is problematic, such as in a patient taking warfarin.

If the bleeding persists, insert a coagulation sponge, such as Gelfoam (Pharmacia and Upjohn Company), into the socket and then loosely close the gingiva surrounding the socket with a 3-0 absorbable figure-of-eight suture. Instruct the patient to bite down on gauze placed over the sutures. Soaking Gelfoam with topical thrombin before placement is a good way to halt minor persistent bleeding (see [Fig. 64.20](#)). Newer hemostatic dressings such as the Hemcon dental dressing (Tricol Biomedical Inc., Portland, OR) are specifically designed for postextraction and oral bleeding. This shrimp-based bandage forms a sticky matrix when it contacts blood, and it quickly forms a seal that stops the bleeding. Other hemostatic agents that should be considered include cellulose or collagen (Surgicel [Ethicon], Avitene [Bard Davol, Warwick, RI]). Tranexamic acid used as a soaked pledget (500 mg/5 cc) has also been recently described as being very useful for oral and nasal bleeding. If these measures fail to control the bleeding, consult a specialist. It is also reasonable to check blood counts and coagulation profiles at this time.

Patients whose bleeding is controlled can be discharged and instructed not to take anything by mouth for 4 hours and then only liquids and soft foods. If silk sutures are used, remove them in 7 days.

ALVEOLAR OSTEITIS (DRY SOCKET)

The pain associated with an extracted tooth is significant but usually manageable with current pharmacologic modalities.

The pain associated with a dry socket, however, can be very severe and often requires more definitive treatment. Alveolar osteitis, or dry socket (Video 64.3), is a localized inflammation that occurs when the alveolar bone becomes inflamed. This condition usually occurs when the clot that is normally present in the socket after a tooth extraction becomes dislodged or dissolves. It is most common in the 2- to 4-day period after a tooth extraction. The examination is essentially unremarkable with the exception of a missing clot where the tooth was extracted. Signs and symptoms of dry socket include the following:

1. Moderate to severe pain localized to the area or frequently radiating to the ear.
2. A foul odor or taste in the absence of purulence or suppuration.
3. Symptoms that occur 3 to 5 days after tooth extraction.
4. Absence of swelling, purulence, or lymphadenitis.
5. Duration of 5 to 40 days.

Anything that increases negative intraoral pressure in the mouth (e.g., smoking, excessive rinsing, spitting, drinking from a straw), as well as hormone replacement and periodontal disease, will predispose a patient to a dry socket. In only a small percentage of patients (2% to 5%) will a dry socket develop; however, this number increases with traumatic extractions or impacted third molars.^{13,19}

The following contribute to the development of a dry socket:

1. Excessive trauma during extraction.
2. Inadequate blood supply to the extraction site.
3. Preexisting localized infection.
4. Loss of clot from sucking, straw use, rinsing, or smoking.
5. Foreign bodies remaining in the socket.
6. Use of oral contraceptives.
7. Use of corticosteroids.
8. Pericoronitis.

The pain associated with a dry socket is extremely severe, and if a patient is seen several days after an extraction with relatively normal findings on examination and severe pain, it is probably a dry socket. It must be distinguished from osteomyelitis, which is characterized by fever, leukocytosis, malaise, and nausea. The pain related to a dry socket will not be relieved with traditional pain medications, but a dental block usually provides instant relief. Once the block is performed, the alveolar osteitis can be treated. Irrigate the socket and gently suction out any accumulated debris. Next, fill the socket to prevent recurrence of pain and allow healing to begin. A variety of materials are suitable to fill the socket again.

Gauze ($\frac{1}{4}$ inch) impregnated with eugenol (oil of cloves) or a local anesthetic may be used. The gauze should be packed into the socket to the level of the gingival cusps. Replace the gauze in 24 to 36 hours because it tends to dry out and loosen. The patient should be seen by a dentist the next day if at all possible. The socket may also be packed with a slurry of Gelfoam (Pharmacia and Upjohn Company) and eugenol. The Gelfoam acts as a matrix to hold the eugenol in the socket. A commercial product, such as Dry Socket Paste (Sultan Healthcare, York, PA) or Dressol-X (Rainbow Speciality and Health Products Inc., Niagara Falls, NY) (Fig. 64.21), can also be applied by itself into the socket or mixed with Gelfoam and placed into the socket. Dry Socket Paste is a very sticky thick paste containing eugenol. It may stay in place longer than gauze and does not dry out. Whichever packing material is used for a dry socket, one or more packings might be necessary before healing

Figure 64.21 Dry Socket Paste (Sultan Healthcare, York, PA).

is complete; therefore, the patient must be referred back to see the dentist who performed the extraction if possible.

Although antibiotics may be given to prevent alveolar osteitis, they are not usually necessary once the socket has been packed and should be prescribed at the discretion of the patient's oral surgeon or dentist.¹¹⁻¹³ NSAIDs should also be prescribed because they seem to work better than narcotics for dry socket.²⁰

DENTOALVEOLAR INFECTIONS

Infections of the oral cavity run the spectrum from minor, easily managed abscesses to severe, life-threatening, deep space infections that require airway management and operative drainage. Although dental infections of all severity are encountered in the ED, the most common are those related to pulp disease. Others are associated with the attachment structures of the teeth such as the gingiva, periodontal ligament, and alveolar bone. These infections are often chronic conditions, but they can progress to the point where periodontal abscesses form and emergency treatment is required.

Emergency clinicians will be called on to drain abscesses of dental origin that do not extend into the deep spaces and that have well-defined boundaries easily accessible by intraoral or external drainage.

Disease of the Pulp

Disease of the pulp can occur as a result of trauma, operations, or other unknown causes, but the most frequent cause is invasion of microorganisms after carious destruction of the enamel. As the enamel is destroyed, caries progresses more rapidly through the dentin and into the pulp chamber and causes an inflammatory response referred to as *pulpitis*. If the path of carious destruction through the tooth is adequate for drainage of the developing inflammation, the patient may be only mildly symptomatic or even asymptomatic for a long time. If drainage is blocked, however, the process may progress to rapidly involve the entire pulp cavity and the periapical space. The tooth is usually exquisitely tender at this point. Abscesses in the periapical region are generally picked up on dental x-rays and less commonly on a Panorex film. However, unless extension through the cortex exists, it is not important for the emergency clinician to make the distinction between pulpitis and a periapical abscess. Examination may reveal gross decay of one or

many teeth and tenderness of the abscessed tooth to percussion. A periapical abscess will follow the path of least tissue resistance if not treated. This may be through alveolar bone and the gingiva and into the mouth or into the deep structures of the neck. If the infection has progressed apically through alveolar bone and localized swelling and tenderness are present, incision and drainage should be performed (discussed subsequently).

In the ED setting it is uncertain whether a periapical abscess or simple pulpitis exists. Dental x-rays are not usually available. In the absence of trauma or recent instrumentation, it is prudent to begin antibiotic coverage for the typical oral flora. Penicillin, amoxicillin, metronidazole, and clindamycin are good choices. Analgesia should be provided as well. In most cases, perform a supraperiosteal injection (tooth block) with a long-acting anesthetic such as bupivacaine because this not only provides immediate and long-lasting relief but also decreases the requirement for narcotic analgesics once the anesthetic effect has dissipated. Avoid performing a supraperiosteal injection if the abscess has extended through gingival tissue and is present near the injection site. In this case a regional block away from the infected tissue may be more appropriate.

Disease of the Periodontium

Periodontal disease is also very common and affects practically all adults to some degree. *Periodontal disease* refers to infection of the attachment apparatus of the teeth: the gingiva, periodontal ligament, and alveolar bone. Unlike pulpal disease, periodontal disease is not usually symptomatic and is therefore rarely a primary reason to seek treatment in the ED. *Gingivitis* is an inflammation of the gingiva caused by bacterial plaque. In advanced disease, the gingiva becomes red and inflamed and tends to bleed easily. With chronic periodontal disease, an abscess can form when organisms become trapped in the periodontal pocket. The purulent material usually escapes through the gingival sulcus; however, it occasionally invades the supporting tissues, the alveolar bone, and the periodontal ligament (periodontitis). Periodontal abscesses that are not draining spontaneously through the sulcus can be drained in the ED. Saline rinses are encouraged to promote drainage. Antibiotics should be reserved for severe cases or for abscesses that cannot be drained. If it is uncertain whether the abscess originates from the pulp or the periodontium, prescribe antibiotics even if the abscess has been drained.^{13,19}

Pericoronitis is a localized inflammation that occurs when the gingiva overlying erupting teeth becomes traumatized and inflamed. Third molars are especially susceptible; however, any tooth can be affected. The gingiva overlying the crown may entrap bacteria and debris, and infection may subsequently develop. Typical signs of inflammation and infection may develop, including erythema, edema, pus, and foul breath. Examination of the overlying gingiva with a tongue blade or finger will elicit tenderness and may produce drainage from the infection underlying the tissue flap. The pain may be moderate to severe, and referral of the pain to an ear region is common. The localized infection occasionally spreads to deeper areas such as the pterygomandibular or submasseteric spaces. Clinically, patients with significant spread of a pericoronitis will have trismus secondary to irritation of the masseter and pterygoid muscles.

ED treatment of *pericoronitis* is directed at detecting regional spread to the deeper spaces. Trismus or other systemic signs of advanced infection require intravenous antibiotics and

urgent consultation for drainage procedures, which usually requires extraction of the offending tooth. If pericoronitis is localized, local or nerve block anesthesia is followed by removal of submucosal debris. Saline rinses and oral antibiotics are prescribed along with dental follow-up in 24 to 48 hours.

Drainage of Dentoalveolar Infections

The important determination for the emergency clinician to make is whether the odontogenic infection is localized, confined, and easily accessible or whether it is complex and involves several potential spaces. Likewise, determine whether the patient appears to be in a toxic state, has trismus, or exhibits any signs of airway compromise. Patients not meeting these criteria require specialist referral. Dental infections are not always obvious and can be mistaken for sinusitis, or vice versa (Figs. 64.22 and 64.23).

Several anesthetic techniques can make the drainage process more comfortable. Nerve blocks and local injections work best. Benzocaine 20% gel, 5% lidocaine gel, or a combination of lidocaine, prilocaine, and tetracaine generally provide good topical anesthesia before injection (Fig. 64.24). Application of these medications to the dry mucosa before injection of the local anesthetic decreases the pain associated with injection. After applying the topical anesthetic, slowly infiltrate local anesthetic with a vasoconstrictor until the tissue blanches. Either a short-acting anesthetic (2% lidocaine) or a longer-acting anesthetic (0.5% bupivacaine) may be used, depending on the clinical circumstances. Regional or dental blocks may be performed instead of local infiltration if needle placement would track already infected tissues into healthy areas. Otherwise, consider local infiltration over the site of the abscess. Instruments necessary for drainage of dentoalveolar abscesses are those usually found on a standard incision and drainage tray and include hemostats, scalpel (No. 15 or 11 blade), packing material ($\frac{1}{4}$ -inch gauze), and a fenestrated Penrose drain.

Intraoral Technique

Intraoral abscesses do not routinely require any antiseptic mucosa preparation before drainage. After anesthetizing the region, make a small incision (0.5 to 1.0 cm) over the area of fluctuance while keeping the point of the blade directed toward the alveolar bone. Use a hemostat to bluntly dissect the abscess and break up any loculations. Cultures are not necessary unless the patient is immunocompromised. Irrigate the wound profusely with normal saline. If the wound is large enough to place a drain or gauze inside, tack one end to the mucosa with a silk suture to prevent aspiration. Advise the patient to perform saltwater rinses hourly and arrange follow-up in 24 to 48 hours with a dentist or oral surgeon to remove the drain and provide continued management. Because the source of the abscess is not always known to the emergency clinician, prescribe antibiotics.

Extraoral Technique

Most simple dental infections can be drained intraorally, but occasionally, an abscess spreads to the face and requires drainage through the skin. It is important to realize that most dental infections should be drained through the mouth, if possible, because any extraoral drainage will cause some scarring. Never make any incisions on the face in direct proximity to important structures such as the facial nerve or the parotid gland and

Figure 64.22 **A**, This patient had facial swelling up to the right eye. She stated that her sinusitis had returned. She had minor tooth pain but mostly complained of an ache in her face. Radiographs revealed maxillary sinusitis with an air-fluid level. **B**, Intraoral examination revealed a pea-sized pointing abscess (*arrow*) at the base of an upper tooth, the cause of the sinusitis. After a local anesthetic was applied, a No. 11 blade was used to puncture the abscess, and copious pus was drained. **C**, A hemostat was inserted into the abscess cavity and spread open to yield more pus. Intravenous antibiotics (clindamycin) were administered followed by oral antibiotics, and the patient saw her dentist the next day. She recovered fully.

Figure 64.23 Osteomyelitis manifested as a dental infection. **A**, This patient had a chronic toothache for months and got minimally better with antibiotics from numerous emergency departments. No history of trauma was forthcoming. There was diffuse soft tissue swelling with malocclusion. **B**, A Panorex radiograph revealed nonunion of a fractured mandible with osteomyelitis. **C**, In this case a fractured mandible with osteomyelitis produced an obvious abscess. She had been treated for a presumed dental abscess many times in the past and got temporary relief.

duct. Refer to [Chapter 37](#) for more details on the incision and drainage technique.

Remember that not all infections about the mouth are the result of a simple dental infection. Osteomyelitis of the mandible, various tumors, and other exotic diseases can simulate a dental infection.

Deep Space Infections of the Head and Neck

It is not unusual for odontogenic infections to spread into the various potential spaces of the face and neck ([Fig. 64.25](#)). The signs and symptoms consist of fever, chills, pain, difficulty with

speech or swallowing, and trismus. Although infections of certain teeth usually spread to particular contiguous spaces, the rapid spread of these infections often makes localizing the exact space difficult. Any space, including the buccal, temporal, submasseteric, sublingual, submandibular, parapharyngeal, and others, may be involved ([Fig. 64.26](#)).

Maxillary extension of periapical abscesses can spread into the infraorbital space and, subsequently, to the cavernous sinus through the ophthalmic veins and result in cavernous sinus thrombosis. Cavernous sinus involvement is associated with periorbital cellulitis, as well as meningeal signs or a decreased level of consciousness. Periapical infections of the anterior

mandibular teeth often spread to the buccinator space or the sublingual space, whereas those of the mandibular molars spread into the submandibular space.

The submandibular space connects with the sublingual space. Infection involving both these spaces is known as *Ludwig's angina*, which can be life-threatening. The source is usually a decayed lower tooth, with the tooth itself being relatively asymptomatic (Fig. 64.27). Initially, this infection may be subtle, but it can progress rapidly. As the infection progresses, the submandibular, submental, and sublingual spaces all become edematous, and there may be elevation of the tongue and the soft tissues of the mouth (Fig. 64.28). This is not a simple abscess that can be readily drained. It is considered a true oral emergency. Interventions include definitive airway management, intravenous antibiotics, and emergency ear, nose, and throat (ENT) or oral surgery consultation for emergency operative

intervention. Patients with established cases of Ludwig's angina are admitted to the hospital and undergo operative intervention often involving multiple drains. Minor early cases can be treated and observed for 6 to 8 hours in the ED with close follow-up if the infection is deemed benign, but care must be taken as Ludwig's angina sometimes presents rather unimpressively. The soft tissues of the posterior aspect of the pharynx can also become involved. Securing the airway becomes of paramount importance. The suprahyoid region of the neck appears tense and indurated, and landmarks may be obscured. A CT scan is usually used to clarify deep space involvement, but emergency oral and maxillofacial (OMF) or ENT consultation, initiation of antibiotic therapy, and definitive airway management should be instituted immediately. This rapidly progressive disease can cause unexpected or rapid-onset airway compromise, and surgical intervention is warranted, as is consultation with the team that handles difficult airways.

Treatment of complicated odontogenic head and neck infections, including Ludwig's angina, centers on airway management, surgical drainage, and antibiotics. If it is uncertain whether the deep spaces are involved, obtain a CT scan to delineate any extension of the infectious process, but be sure to involve the appropriate consulting services as soon as possible. Perform airway interventions early if there is any question of compromise, and consider tracheostomy. Consult an OMF or ENT surgeon because drainage and removal of necrotic tissue might be necessary. Administer antibiotics to slow spread of the infection and decrease hematogenous dissemination. The bacteria involved are typically polymicrobial, involving both aerobic and anaerobic bacteria from the primary source. There has been an emergence of β -lactamase-producing organisms in upward of 40% of isolates from odontogenic neck abscesses.¹⁹ Antimicrobials of choice for complicated odontogenic infections usually include the penicillins. The expanded-spectrum penicillins (ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam) are effective against β -lactamase-producing bacteria and also

Figure 64.24 Apply a dollop of 20% benzocaine gel to dry mucosa before injection of local anesthetic to decrease the pain of infiltration.

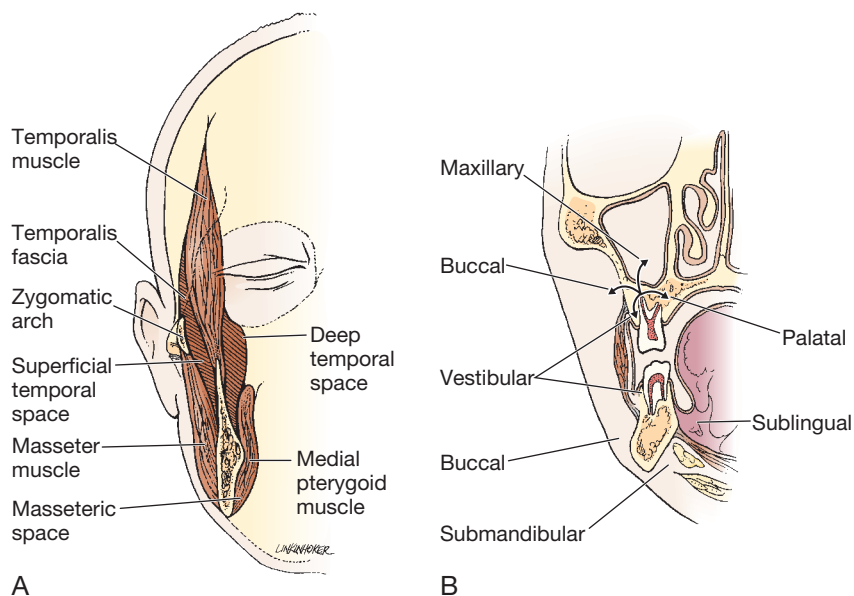

Figure 64.25 **A**, Location of temporal space abscesses. **B**, Route of infection into the buccal space, vestibular spaces, submandibular space, sublingual space, and palatal space. (From Eisele D, McQuone S, editors: *Emergencies of the head and neck*. St. Louis, 2000, Mosby.)

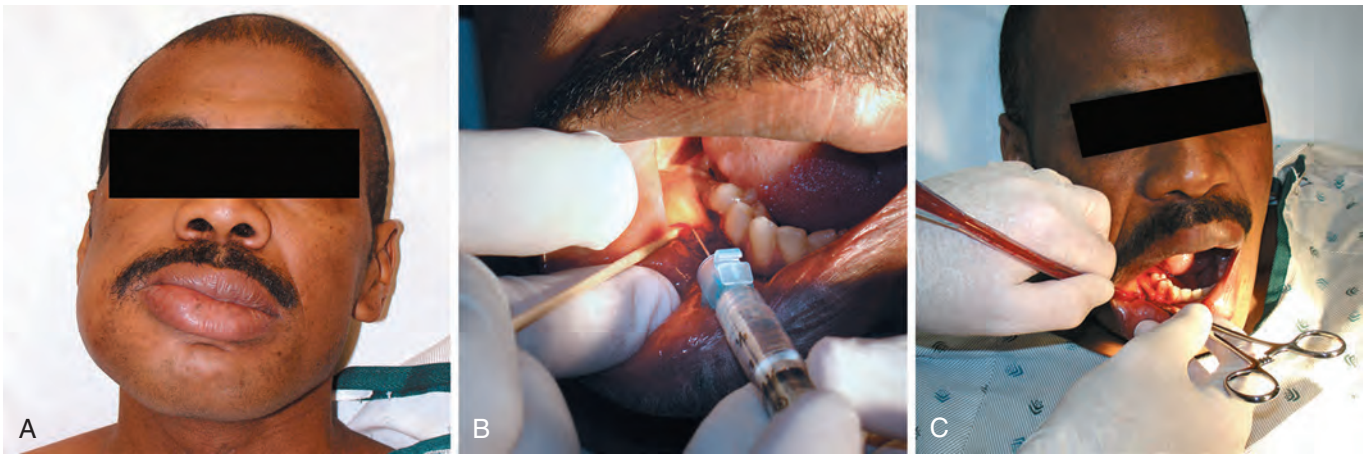

Figure 64.26 **A**, Advanced dental infection with characteristic facial swelling, probably involving the masseter space. **B**, Local anesthetic (lidocaine with epinephrine) is injected with a 27-gauge needle into an area of obvious fluctuance (shown by the probe). A mandibular nerve block is an alternative to local injection. **C**, After the site is punctured with a No. 11 blade, a hemostat is inserted into the cavity and spread. Copious pus is drained with a suction catheter. Initial intravenous antibiotics (clindamycin), oral antibiotics, and outpatient follow-up yielded good results. The offending tooth was extracted when the infection was controlled.

Figure 64.27 Ludwig's angina may initially appear to be benign. **A**, This patient's main complaint was dental pain. Tooth No. 27 (arrow) was noted to be decayed and a probable source of the infection. **B**, Physical examination revealed erythema and edema of the submandibular space, consistent with early Ludwig's angina. She was admitted to the hospital for intravenous antibiotics (clindamycin). A high index of suspicion and early treatment are mandated in such patients because this infection can progress rapidly. **C**, This patient had the beginnings of an infection as manifested by elevation of the tongue and swelling of the floor of the mouth, which characteristically raises the openings of the submandibular (Wharton's) ducts (arrow). **D**, The cause was a badly decayed lower tooth (arrow). **E**, Tenderness and induration can be palpated in the floor of the mouth.

Figure 64.28 Ludwig's angina may progress rapidly and compromise the airway in a few hours. Notice how the massive submandibular edema elevates the tongue in the oral cavity.

cover the anaerobe *Bacteroides fragilis*. Penicillin plus flagyl is another option. Clindamycin is an effective choice in patients who are allergic to penicillin. It should be used in combination with a cephalosporin, such as cefotetan or cefoxitin, to cover recently emerging resistant organisms. It is important to realize that in many of these infections, antibiotics are an adjunctive therapy and not a substitute for surgical intervention. Likewise, if the source of the infection is likely otogenic or rhinogenic, the antibiotic regimen should be adjusted.

DENTAL MATERIAL

As a general rule, EDs should have a well-stocked supply of basic dental material. Many commercially available products can be used interchangeably with many of the items listed here. These products can often be kept in a cart or in another appropriate location. The following is a basic list:

1. Packing gauze.
2. Dental roll gauze.
3. CaOH paste, glass ionomer cement, or zinc oxide cement.
4. Dry socket medicament or eugenol.
5. Topical anesthetic gel (20% benzocaine or 5% lidocaine).
6. Periodontal paste (Coe-Pak [GC America Inc.], others) or self-cure composite.
7. Articaine (Septocaine, SEPTODONT, Louisville, CO) cartridges with epinephrine.
8. Save-A-Tooth Tooth Preservation System (Phoenix Lazarus), EMT Toothsaver (Smart Practice, Inc., Phoenix, AZ), or fresh milk.
9. Zinc oxide/eugenol temporary cement (Temrex [Temrex Corp., Freeport, NY], others).
10. Ringed injection syringe.
11. Stainless steel spatula and mixing pads.
12. Oral surgery tray with arch bars and ligature wires.
13. Tongue blades and cotton-tipped applicators.
14. Gelfoam (Pharmacia and Upjohn Company), HemCon (Tricol Biomedical), Surgicel (Ethicon), or topical thrombin.

Figure 64.29 The Dental Box. This commercially available kit contains most of the items required for dental care in the emergency department. It is available at <https://www.thedentalbox.com>.

Regional dental supply houses are good sources for these items. The Dental Box is a commercially available kit that contains many of these items and is designed for ED use (Fig. 64.29). It is available at <https://www.thedentalbox.com>. Dentrauma is another dental emergency kit available to EDs.

INTRAORAL PIERCING

Dating back to antiquity, body piercing has been practiced in many countries and cultures as part of ceremonial and religious rites. In recent years, body and intraoral piercing has gained tremendous popularity throughout the world as a means of self-expression. In the ED, clinicians may see patients with piercings of the lips, tongue, and even uvula. Complications of oral piercing on the gums and teeth include pain, infection, bleeding, increased salivary flow, difficulty swallowing, gingival recession, gingival trauma, and chipped or fractured teeth. Repeated trauma from a metal tongue ball can be quite detrimental to teeth and cause microfractures and a sudden shattered tooth (Fig. 64.30). One study of 400 consecutive patients at a military dental office found that 20% of their

Figure 64.30 Tongue and lip piercing can cause dental and gingival problems. A metal tongue ball and other intraoral piercings can have significant detrimental effects on the teeth and gums. A tongue ball can cause microfractures leading to a suddenly shattered tooth. The longer the post, the greater the tooth damage.

patients had at least one type of oral piercing, with the tongue being the most common location.²¹ Of these patients, 14% had fractured teeth and 27% had recession of the gums. Another study assessed the impact of time and found that tooth chipping was found on molars and premolars in 47% of patients who had a tongue piercing for longer than 4 years.²²

CHAPTER 65

Procedures Pertaining to Hypothermia and Hyperthermia

Heather M. Prendergast and Timothy B. Erickson

PROCEDURES PERTAINING TO HYPOTHERMIA

With an increase in outdoor activities, changing weather patterns, and the growing epidemic of homelessness in our country, issues pertaining to hypothermia remain in the forefront. Hypothermia is not only a common diagnosis in rural areas but has also become more commonplace in urban centers across the nation secondary to inadequate housing or lack of preparation for cold weather changes.¹ It is also important to note that numerous cases of accidental hypothermia (AH) are reported each year in areas typically considered warm weather locales such as Florida, Texas, California, Alabama,^{2,3} and even the Sahara desert.⁴ Every year, many recreational and elite athletes participate in outdoor sporting events. The higher the environmental stress, the greater the potential for failure in performance and the development of hypothermia.⁵ The high-altitude expeditions on Mt. Denali in 2003, Mt. Hood in 2006, and Mt. Everest in 1996, 2014 and 2015, are reminders that even well-protected, acclimatized individuals can succumb to cold-related fatalities.

Neonates are at particular risk of hypothermia due to large surface area-to-mass ratio, deficient subcutaneous tissue and inefficient shivering. Neonates also lack behavioral defense mechanisms. Acute neonatal hypothermia is common after emergency delivery or resuscitation and has been reported in cases of infant abandonment.⁶ Optimal treatment of hypothermia remains controversial. It is a well-accepted practice to carry out resuscitation of these individuals for extended periods. The medical literature contains numerous anecdotal reports of profoundly hypothermic individuals who are successfully resuscitated and discharged neurologically intact,⁷⁻¹⁰ the longest being in cardiac arrest for 8 hours and 40 minutes.¹¹ Despite these spectacular reports of survival, both morbidity and mortality from hypothermia are common. Between 1972

and 2002, 16,555 deaths in the United States were attributed to hypothermia, which equates to 689 deaths per year.¹² The United States Centers for Disease Control and Prevention (CDC) reported that in the United States during the years of 1999–2011, there were an average of 1301 deaths from environmental cold exposure per year.¹³ The actual number of patients seen in emergency departments (EDs) with hypothermia is unknown. Poverty, homelessness, alcoholism, and psychiatric illnesses are commonly associated conditions. Ethanol intoxication is the most common cause of excessive heat loss in urban settings.¹⁴ This chapter critically reviews approaches and procedures appropriate to the management of several categories of hypothermic patients. The recommendations combine treatment efficacy with safety. Before describing procedures and making recommendations, essential terms are defined and the pathophysiology of hypothermia is briefly reviewed.

Definitions

Accidental hypothermia has been defined as an unintentional decrease in core (vital organ) temperature to below 35°C (< 95°F).⁷ Victims of hypothermia can be separated into the following categories: *mild hypothermia*, 35°C to 32°C (95°F to 90°F); *moderate hypothermia*, lower than 32°C to 30°C (< 90°F to 86°F); and *severe hypothermia*, colder than 30°C (< 86°F). Other factors that may be useful in separating groups of patients with AH include the presence of underlying illness,^{1,15-20} altered neurologic state on arrival at the ED, hypotension, and the need for prehospital cardiopulmonary resuscitation (CPR). Shivering has been observed down to 31°C and may not cease until 30°C. Additionally, there are case reports of patients being verbally responsive at 25°C and having signs of life at temperatures less than 24°C.²¹ A hypothermia outcome score has been developed that incorporates some of these factors and may permit comparison of outcomes in patient groups treated with different modalities.

Risk factors for the development of AH include burn injuries, extremes of age, ethanol intoxication, dehydration, major psychiatric illness, trauma, use of intoxicants, significant blood loss, sleep deprivation, malnutrition, and concomitant medical illnesses.²²⁻²⁴ Risk factors for the development of hypothermia indoors include advanced age, coexisting medical conditions, being alone at the time of illness, being found on the floor, and abnormal perception or regulation of temperature.¹⁸ Unlike healthy exposed outdoor enthusiasts, such as skiers or mountaineers,²⁵ hypothermia in urban populations is most often associated with conditions that impair either thermoregulation or the ability to seek shelter. In the majority of studies of urban hypothermia, death has been attributed to the severity of the underlying disease.¹

Because signs and symptoms may be vague and nonspecific, mild to moderate hypothermia may easily be overlooked in the ED. A common error is failure to routinely obtain an accurate core temperature in all patients at risk. The diagnosis is frequently delayed because of false reliance on standard oral temperatures. Symptoms such as confusion in the elderly and combativeness in intoxicated patients might not initially be recognized as symptoms of hypothermia. Hypothermic patients frequently will not feel cold or shiver, particularly the elderly population, who have impaired thermoregulatory responses because of their advanced age.²⁶⁻²⁸ Paradoxical undressing, a cold-induced psychiatric dysfunction, has been described in confused patients in whom a sensation of heat develops at lowered body temperatures. It occurs as a result of constricted blood vessels near the surface of the body that suddenly dilate. In many cases these patients are mislabeled as psychotic, thereby leading to further delays in appropriate treatment.²⁹

Measurement of Core Temperature

Because of the nonspecific nature of the symptoms of hypothermia, accurate assessment of temperature is a necessity when considering this diagnosis. It is of paramount importance not only for confirmation of the diagnosis but also for guidance in further diagnostic and therapeutic decisions. Any thermometer that does not record temperatures in the hypothermic range is *inappropriate* for evaluating significant hypothermia. Standard glass/mercury thermometers generally cannot record temperatures lower than 34°C (< 93.2°F), although some models are available that record temperatures as low as 24°C (75.2°F) (Dynamed, Inc., Carlsbad, CA). An electronic probe with accompanying calibrated thermometer is recommended when monitoring this vital sign. Examples of thermometers with accompanying accuracy at various temperature ranges are shown in Fig. 65.1.

NORMAL BODY TEMPERATURE RANGES

°F	0-2 years	3-10 years	11-65 years	>65 years
Oral	—	95.9 — 99.5	97.6 — 99.6	96.4 — 98.5
Rectal	97.9 — 100.4	97.9 — 100.4	98.6 — 100.6	97.1 — 99.2
Axillary	94.5 — 99.1	96.6 — 98.0	95.3 — 98.4	96.0 — 97.4
Ear	97.5 — 100.4	97.0 — 100.0	96.6 — 99.7	96.4 — 99.5
Core	97.5 — 100.0	97.5 — 100.0	98.2 — 100.2	96.6 — 98.8

Figure 65.1 Electronic thermometers provide accurate temperatures over various ranges. **A**, The Welch Allyn Model 692/690 SureTemp Plus (Skaneateles Falls, NY) (oral, axillary, rectal) is accurate from 80°F to 110°F. Note the various ranges for normal temperatures from various sites by age. *It is generally accepted that a rectal temperature higher than 100.3°F represents a fever and that oral readings can be misleading.* **B**, The IVAC electronic thermometer (Alaris CNA Medical, Royce City, TX) is also commonly used in the emergency department (accurate from 88°F to 108°F). For severe hypothermia or hyperthermia, it is important to know the accuracy of the thermometer being used. **C**, The graph demonstrates variations in normal body temperature by site and age. (A and B, Images courtesy WelchAllyn, Inc.)

Core temperature is traditionally estimated with a rectal probe, but due to large gradients within the body, rectal temperature often lags behind core temperature by up to 1 hour, reading higher than esophageal temperature during cooling and lower than esophageal temperature during rewarming.^{28,30} Esophageal probes may be used, although they may be affected by warm humidified air therapy. Other possible sites for measurement of temperature include the tympanic membrane, nasopharyngeal tract, and urinary bladder.^{1,31,32} Fresh urine temperature can closely approximate core temperature. “Deep forehead” temperatures measured with a Coretemp thermometer (Teramo, Tokyo) have also demonstrated excellent accuracy and approximation of core temperatures.³³ For continuous monitoring purposes, rectal or bladder probes are preferred. Infrared tympanic temperatures have demonstrated excellent correlation with core temperatures. However, studies show that although easier to use and faster, infrared tympanic temperatures can be inaccurate at extremes of temperature by underestimating higher temperatures and overestimating lower temperatures.³⁴ When a rectal probe is used, insert it at least 15 cm beyond the anal sphincter and verify its position frequently.⁸ One should remember that temperature gradients exist in the human body and therefore consistency of monitoring at one or more sites is mandatory. A chart and formula that convert centigrade to Fahrenheit temperatures will assist the clinician in assessing the severity of hypothermia (see Fig. 65.1C).

Pathophysiology

AH results from failure of the body’s thermoregulatory responses to generate enough heat to compensate for heat losses. These thermoregulatory responses include shivering, tachycardia, tachypnea, increased gluconeogenesis, peripheral vasoconstriction, and shunting of blood to central organs (Fig. 65.2).^{35,36} As core temperature drops despite these compensatory mechanisms, the patient becomes poikilothermic and cools to ambient temperature.

Four methods of heat loss affect the body: radiation, conduction, convection, and evaporation. *Radiation* involves transfer

of heat from a warmer body to a cooler environment and accounts for approximately 60% of heat loss in a normothermic individual. *Conduction* refers to loss of heat from direct contact with a cooler surface. These losses are most profound with immersion hypothermia. *Convection* occurs when cool air currents pass by the body and this accounts for 15% of heat loss, especially with a wind chill factor. *Evaporation* refers to significant loss of heat through sweating and insensible water loss.^{27,36} With hypothermia, the enzymatic rate of metabolism decreases twofold to threefold with each 10°C (18°F) drop, and cerebral blood flow decreases 6% to 7% per 1°C (1.8°F) drop. Signs and symptoms of hypothermia vary according to the core temperature. The overall functioning of all organ systems is impaired by the cold.³⁷ The greatest effects are seen in the cardiovascular, neurologic, and respiratory systems (Table 65.1). As core body temperature drops below 33°C (< 91.4°F), the patient becomes confused and ataxic.³⁸ The initiation of involuntary motor activity (shivering) prevents the reduction in core temperature.³⁹ Shivering thermogenesis in skeletal muscle operates on acute cold stress. In a malnourished patient, the mechanism may be rendered ineffective secondary to reduced muscle mass.⁴⁰ Shivering stops at approximately 32°C (89.6°F), and shivering artifact on an electrocardiogram has been associated with increased survival of individuals with severe hypothermia.⁴¹ Atrial fibrillation occurs frequently as the temperature continues to drop and the patient loses consciousness. A J wave on the electrocardiogram often appears before ventricular fibrillation (Fig. 65.3).^{42,43} Though classically considered pathognomonic for hypothermia, the J or “Osborne” wave has no prognostic or predictive value in cases of hypothermia. Studies have found that Osborne waves are present in 36% of AH survivors and in 38% of nonsurvivors.^{41,44} Ventricular fibrillation may occur below 29°C (< 84.2°F) and becomes common as the core temperature drops to 25°C (77°F).⁴⁵ The electroencephalogram flattens at 19°C to 20°C (65.2°F to 68°F).⁴⁶ Asystole commonly develops at 18°C (64.4°F) but has been seen at higher temperatures. Initial core temperature does not necessarily correlate with patient outcome. The lowest recorded temperature in a survivor of AH is 9°C (43.7°F).³⁶

TABLE 65.1 Signs and Symptoms of Hypothermia

CORE TEMPERATURE (°C)	CARDIOVASCULAR SYSTEM	RESPIRATORY SYSTEM	CENTRAL NERVOUS SYSTEM
30–34	Tachycardia Increased afterload Increased systemic blood pressure	Tachypnea Increased minute ventilation	Lethargy Mild confusion Loss of fine motor coordination
30–34	Progressive bradycardia Decreased cardiac output Hypotension Lengthening of cardiac conduction Atrial/ventricular dysrhythmias	Increased bronchial secretions Diminished gag reflex Depressed cough response	Delirium Slowed reflexes Muscle rigidity Abnormal EEG findings
< 30	Spontaneous ventricular fibrillation Osborne waves at 25°C	Respiratory rate decreased to 5 breaths/min	Areflexia Coma Fixed pupils Rigidity EEG silent at 19°C

EEG, Electroencephalogram.

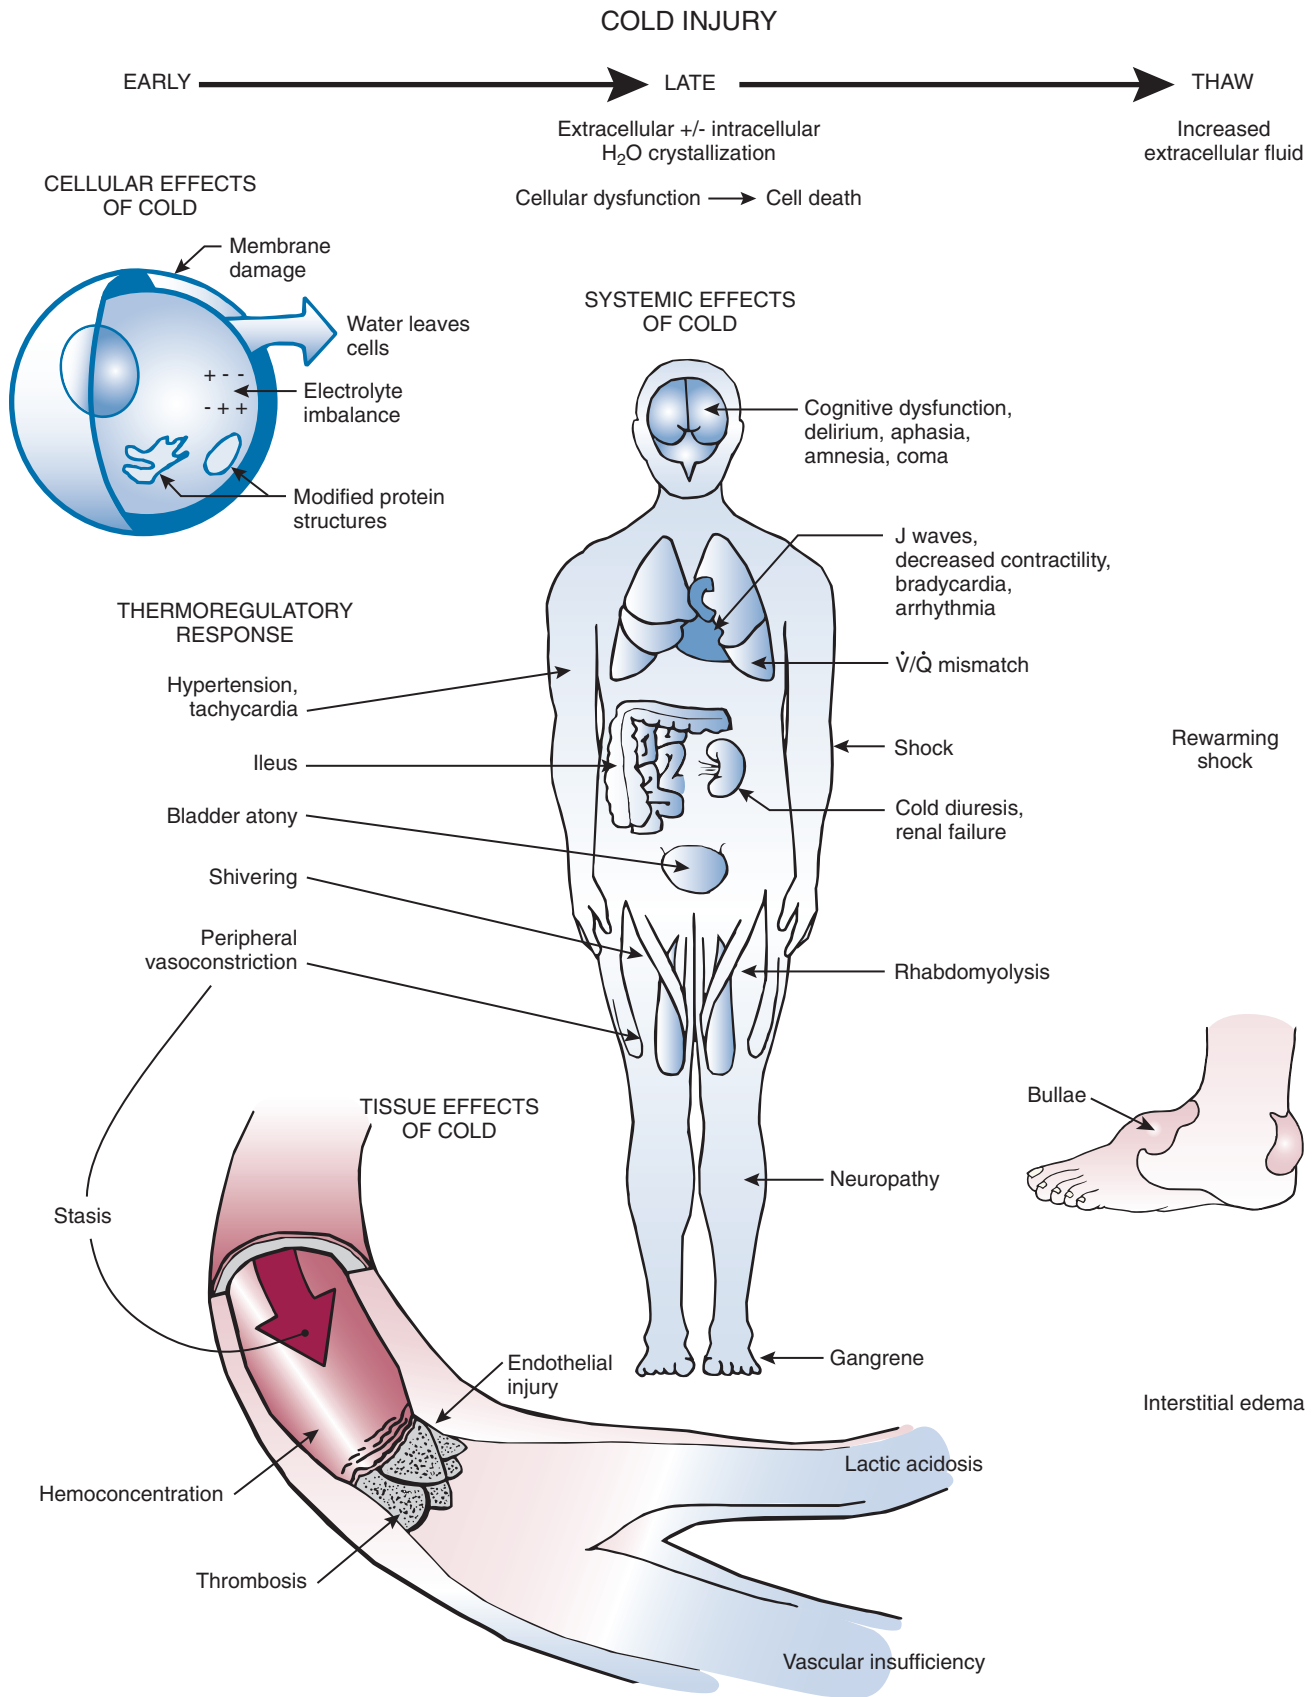

Figure 65.2 Cold-induced injuries such as hypothermia and frostbite lead to a thermoregulatory response (e.g., shivering and increased sympathetic activity), cellular and tissue effects (e.g., membrane damage, electrolyte imbalance, endothelial injury, and thrombosis), and systemic effects (e.g., shock, arrhythmia, and neuromuscular dysfunction). (From Coughlin MJ, Zumwalt R, Fallico F, editors: *Surgery of the foot and ankle*, ed 8, St. Louis, 2006, Mosby.)

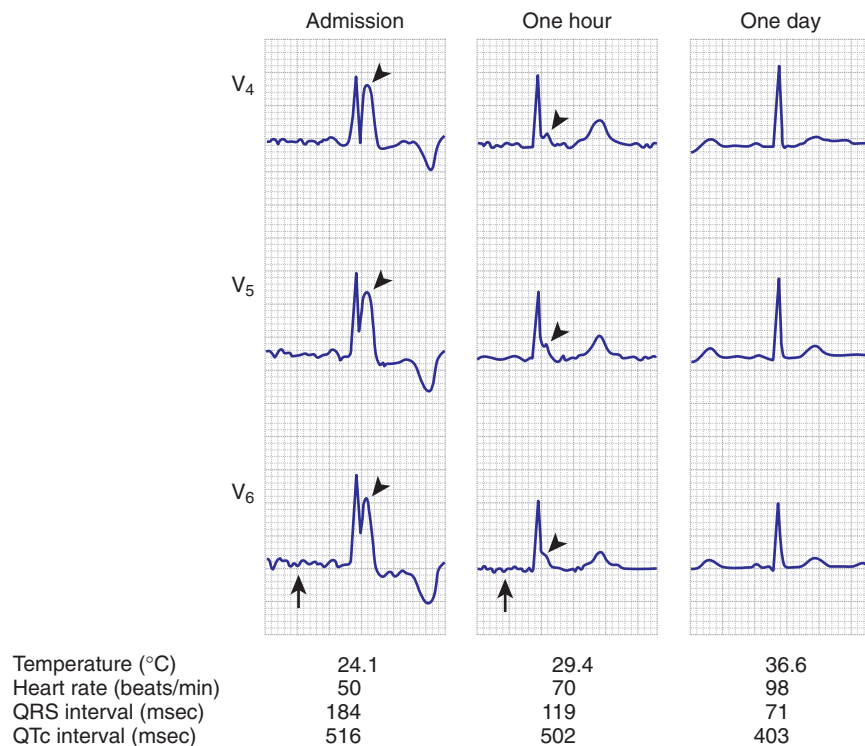

Figure 65.3 In severe hypothermia, the electrocardiogram (ECG) exhibits marked elevation of the J deflection, so-called Osborne waves (*arrowheads*). The height of the J wave is proportional to the degree of hypothermia, and this finding is usually most marked in the midprecordial leads. This ECG is from a patient with sinus bradycardia, but in approximately half the patients with a temperature below 32°C (89.6°F), slow atrial (*arrows*) fibrillation develops, a rhythm that usually converts spontaneously with rewarming. (Adapted from Krantz MJ, Lowery CM: Giant Osborne waves in hypothermia, *N Engl J Med* 352:184, 2005. Used with permission.)

Initial Evaluation and Stabilization of Hypothermic Patients

Several guidelines for the treatment of AH exist. The State of Alaska Cold Injuries Guidelines were last updated in 2014 and include a section on AH.⁴⁷ Additionally, in 2014, the Wilderness Medical Society developed practice guidelines for out-of-hospital care of AH.⁴⁸ Treatment of hypothermia can be divided into prehospital care and ED management.

Prehospital Care

In the prehospital setting, focus primarily on removing the patient from the current environment to prevent further decreases in core temperature. Studies have shown that oral temperatures are sufficiently accurate for field use; however, infrared tympanic thermometers may not be reliable in the prehospital setting. Handle these patients with special care and anticipate the presence of an irritable myocardium because aggressive measures can inadvertently trigger cardiac dysrhythmias. Hypovolemia and a large temperature gradient often exist between the periphery and the core in a hypothermic patient.⁸ Avoid aggressive field management and prolonged transport times.^{49,50} After removing the patient's wet clothing, wrap the patient in dry blankets or sleeping bags. *Field rewarming* is a misnomer because adding significant heat to a hypothermic patient in the field is extremely difficult. Studies have shown that for mild hypothermia, resistive heating (e.g., warming blankets) can be used safely in the prehospital setting. Resistive

heating augments thermal comfort, increases core temperature by approximately 0.8°C/hr (33.4°F/hr), and reduces patient pain and anxiety during transport.⁵¹ In one study, resistive heating more than doubled the rewarming rate when compared with passive insulation and did not produce an afterdrop.⁵² With longer transport times, use active rewarming methods limited to heated inhalation and truncal heat application. Place insulated hot water bottles near the patient's axilla or groin. The Res-Q-Air device (CF Electronics, Inc., Commack, NY) is lightweight, portable, and delivers heated humidified air or oxygen at temperatures ranging from 42°C to 44°C (107.6°F to 111.2°F) and down to ambient conditions of -20°C (-4°F). In more remote settings, another option is to use a modified forced-air warming system in the field. The Portable Rigid Forced-Air Cover is heated with a Bair Hugger heater/blower (Augustine Medical, Inc., Eden Prairie, MN). It covers the patient's trunk and thighs and can adapt to various transport vehicle power sources.⁸

Immobilize patients with potential traumatic injuries to the spine or extremities before transport. Pay continuous attention to airway maintenance. Initiate fluid resuscitation with intravenous (IV) crystalloid, preferably 5% dextrose in normal saline (D₅NS). Alternatively, give warmed oral glucose-containing drinks to a patient who is awake and alert. Most hypothermic patients are dehydrated because fluid intake is reduced and cold causes diuresis. Avoid using lactated Ringer's solution because it can theoretically decrease the metabolism of lactate by cold-induced hepatic dysfunction. If possible, use warmed

IV fluids because they are generally well tolerated.^{53,54} If available, use a flameless heater, which is currently being used by military medical units and provides an easy and expedient means of warming fluids in the prehospital setting.⁵⁵

Intubate unresponsive patients, but recognize that there is no universal agreement on when to intubate a hypothermic patient who has detectable vital signs. Pulse oximetry is not usually helpful because vasoconstriction limits blood flow to the periphery and readings may be inaccurate or not possible. Prehospital providers should assess for pulses and initiate CPR at a standard rate of 100 compressions per minute if no pulses are palpable after 1 minute. Delayed or intermittent CPR can be associated with good outcomes with neurologically intact survivors after prolonged chest compressions,⁵⁶ but should be used only if evacuation efforts necessitate.⁵⁷ Some authors suggest that pulseless victims with core temperatures below 32°C (<89.6°F) should be transported with continuous CPR.⁵³ Other authors believe that it is unnecessary to perform CPR on a patient who has any perfusing cardiac rhythm because it may precipitate ventricular fibrillation. There is no universally accepted standard for intubation or CPR in hypothermic patients with detectable vital signs.⁵⁸

Definitive prehospital determination of cardiac activity requires a cardiac monitor. Cardiac arrest is a common misdiagnosis because peripheral pulses are difficult to palpate when extreme bradycardia is present along with peripheral vasoconstriction. Some authors report that asystole is a more common rhythm than ventricular fibrillation. In the field, differentiating between ventricular fibrillation and asystole may be impractical. Successful defibrillation has been reported at 20°C but attempted defibrillation is often unsuccessful until the core temperature is above 30°C. If the defibrillation attempt is unsuccessful, initiate active rewarming while continuing CPR defibrillation. These attempts can be given occasionally during the rewarming process.⁵⁹

Transport cold, stiff, cyanotic patients with fixed and dilated pupils because the treatment dictum for prehospital personnel remains, “No one is dead until warm and dead.” Some patients are actually cold and dead. It is useful and humane if they can be safely identified. Because human physiologic responses are variable, it is difficult to predict outcome.⁶⁰ A succinct summary of the prehospital care of a hypothermic patient is rescue, examine, insulate, and transport.⁸ In the majority of cases, evacuation, resuscitation, and transport should be initiated, provided that doing so does not endanger prehospital responders.⁶¹

ED Management

There are no universally established standards of care regarding the use of specific techniques for rewarming a hypothermic patient or cooling a hyperthermic patient. This chapter describes all potentially useful modalities. Many are not applicable for general use in the ED, whereas others are safe, beneficial, and easily accomplished in the general ED setting. Some invasive procedures, however, such as cardiopulmonary bypass and irrigation of the peritoneal or thoracic cavity, may be overly aggressive or of anecdotal or theoretical benefit only. Exactly when to institute any given intervention is best determined by the resources available, the initial scenario, and clinical judgement individualized for each patient.

Treatment priorities in the ED setting are to prevent further decreases in core body temperature; establish a steady, safe rewarming rate; maintain stability of the cardiopulmonary

TABLE 65.2 Rewarming Techniques

system; and provide sufficient physiologic support. Adjust the rate of rewarming and the techniques used according to the degree of hypothermia and the severity of the patient's clinical condition (Table 65.2). Anticipate and prevent complications.

In a pulseless, apneic patient, initiate CPR and continue until the core temperature is above 34°C (> 93.2°F). Profound hypothermia results in coma, hyporeflexia, fixed and dilated pupils, severe bradycardia, and often an unobtainable blood pressure. With severe hypothermia, a pulse might not be palpable and measurement of blood pressure might require the use of a Doppler device. If available, use ultrasound to detect the presence of cardiac wall motion. Follow the heart rate and rhythm with electrocardiographic monitoring. In patients who have anything more than minimal impairment, perform arterial blood gas analysis frequently to determine oxygenation, ventilation, and acid-base status. If feasible, establish large-bore IV lines. Avoid central lines if possible because insertion of such lines may exacerbate the myocardial irritation. Give maintenance IV fluids. Warm all IV fluids to 40°C to 42°C (104°F to 107.6°F), but be aware that the usual volumes administered will not contribute significant heat calories. With long standard IV tubing, the heated IV fluids may actually cool to room temperature before entering the patient's IV site.

With a mild to moderate reduction in core temperature, the level of mentation correlates with the severity of the AH, associated illnesses, or both. Noteworthy exceptions are alcoholics and diabetics, who can be in a coma at higher core temperatures because of concomitant hypoglycemia. Perform bedside glucose measurements on patients when they arrive

TABLE 65.3 Warming Rates (°C/hr)

	PASSIVE EXTERNAL	ACTIVE EXTERNAL	INHALATION OF WARM AIR	PERITONEAL LAVAGE	BLADDER LAVAGE
1st hr	1.4	1.5	1.5	1.5	1.3
2nd hr	1.4	2.4	2.0	2.5	1.7
3rd hr	1.8	2.0	1.9	3.2	1.8

Note: Thoracic lavage had a median rewarming rate of 2.95°C/hr (see Plaisier⁵⁴).
From Danzl D, Pozos RS: Multicenter hypothermia study, *Ann Emerg Med* 16:1042, 1987.

in the ED. A high correlation exists between alcohol consumption and the development of hypothermia, especially in colder climates.¹ A review of 68 cases of hypothermic deaths in Jefferson County, Alabama, found that a significant number of cases involved middle-aged men who had consumed alcohol.³ In other urban cases of AH reviewed, the majority were alcoholics. This study noted glycosuria in patients, even when low serum glucose values were evident, and described a renal tubular glycosuria in patients with AH. Such glycosuria may worsen or cause hypoglycemia. Glycosuria in AH is no guarantee of an adequate serum glucose concentration. This supports the routine use of supplemental IV glucose unless a normal serum glucose value can be quickly ensured. Consider administering IV thiamine (100 mg) and a trial dose of 0.4 to 2 mg of IV naloxone (Narcan, Adapt Pharma, Inc. Radnor, PA) in a comatose patient. Although failure to rewarm spontaneously has been noted in victims with hypothyroidism and other endocrine deficiencies, reserve the use of thyroid hormones and corticosteroids for patients with suspected thyroid and adrenal insufficiency, respectively.

The thermoregulatory vasoconstriction caused by hypothermia significantly decreases subcutaneous oxygen tension.²⁷ Good correlation exists between the incidence of wound infection and subcutaneous oxygen tension. As core temperatures decrease from 41°C to 26°C (105.8°F to 78.8°F), neutrophil function is significantly impaired.²⁷ In animal models, hypothermia appears to decrease leukocyte sequestration within the brain parenchyma, thus offering some resistance to meningitis.⁶² Although antibiotics are not routinely indicated for victims of uncomplicated mild hypothermia, some authors advocate the routine empirical initiation of broad-spectrum antibiotic therapy on admission of severely hypothermic patients. In this setting, detection and treatment of the underlying cause, such as infection, may be more critical than treatment of the hypothermia.¹

Management Guidelines

Hypothermia affects virtually every organ system because of generalized slowing of the body (see Fig. 65.2). Management goals depend on the severity of the hypothermia, but in all cases the primary goal is to increase core temperature and prevent further loss. In a patient with mild hypothermia, a conservative approach to rewarming is generally advocated. Overly aggressive methods may be more harmful to the patient by causing worsening hypotension, a paradoxical decrease in core temperature, and cardiac dysrhythmias. Other complications may include bleeding and infection of surgical incisions.²⁷ The optimal rewarming rate remains unclear and varies with each case. Standard rewarming rates are a 0.5°C/hr to 2.0°C/

hr (0.9°F/hr to 3.6°F/hr) rise in temperature in an otherwise stable patient (Table 65.3). Carefully consider and individualize invasive therapy to the severity of the hypothermia and the condition of the patient. Avoid overtreating and overusing invasive techniques in an otherwise stable hypothermic patient. In patients with severe underlying problems such as hypoglycemia, hyperglycemia, sepsis, adrenal crisis, drug overdose, or hypothyroidism, treat these conditions appropriately in addition to treating the hypothermia. Long-term outcome may depend more on treatment of the underlying illness than on treating the hypothermia.^{1,63}

Passive External Rewarming

The cornerstone of the effectiveness of passive external rewarming relies on the body's ability to restore normal body temperature through its own mechanisms for heat production. Stop further heat loss with insulation and manipulation of the environment. Give warm fluids containing glucose to patients who are fully alert. For patients with mild AH, remove wet clothing and then provide passive external rewarming with blankets. The technique is simple, but the patient must be capable of generating enough body heat for this method to be successful. Give warmed IV fluids to counteract the cold-induced diuresis. Internal heat generation is required for rewarming, and this effect will be relatively slow. In an otherwise stable patient, aggressive intervention with drugs and invasive monitoring might be more harmful than beneficial. Patients who cannot shiver, those who are hypotensive, or those who are intoxicated or malnourished may not have this capability. Survival rates with passive external rewarming have ranged from 55% to 100%.⁶⁴⁻⁶⁷

For patients in the moderate or severe category of hypothermia, a more aggressive approach may be warranted. The options available are active external rewarming and active core rewarming. Active core rewarming techniques can be further divided into less invasive and more invasive techniques. The aggressiveness of therapy depends more on the patient's underlying health, hemodynamic status, and response to initial therapy than on the initial temperature.

Active External Rewarming

The application of heat to the skin of a hypothermic patient has been termed *active external rewarming*.

Indications

Although there is some suggestion that active external rewarming of profoundly hypothermic patients by immersion may be associated with an increase in mortality over other treatments, other studies suggest that this technique is highly effective for mild hypothermia.^{38,68} Use it selectively and limit it to the

trunk. Other forms of active external rewarming are increasingly being used in the ED as adjunctive care of moderately hypothermic, otherwise healthy individuals. Vasoconstriction limits the ability to increase core temperature with techniques that primarily warm the skin.

Active external rewarming is most beneficial when the heat supplied by the external source is greater than the loss of rewarming heat incurred by the cessation of shivering. In more remote wilderness settings where more aggressive warming techniques are precluded because of the lack of equipment or personnel, active external rewarming with body-to-body contact may be the only option. The rewarming contribution of body-to-body contact appears to be limited, however.

Equipment

Traditionally, immersion therapy has used a heated (40°C to 42°C [104.0°F to 107.6°F]) water tank of the type present in most burn units. Generally, immerse a hypothermic patient entirely except for the extremities and head, but immersion of the extremities may hasten rewarming. A major drawback is the inability to closely monitor patients undergoing immersion. Alternatively, use a warm water–filled heat exchange blanket (e.g., Blanketrol, Cincinnati Sub-Zero Products, Cincinnati, OH) for conduction warming. Intraoperative studies have demonstrated excellent results.⁶⁹ A forced warm air convection system (Bair Hugger, Augustine Medical, Eden Prairie, MN; Snuggle Warm Convective Warming System, Sims Level 1, Inc., Rockland, MA) has been used for postsurgical rewarming.⁶⁹ This approach has also been used successfully for ED-based AH therapy (Fig. 65.4). Rewarming by warm air convection permits continued monitoring in the ED and is better tolerated than immersion because of the less rapid development of vasodilation in peripheral tissues. As an alternative for noninvasive active external rewarming, there are case reports describing rewarming hypothermic patients with a device called Arctic Sun (Medivance, Inc., Artic Sun, Temperature Management System, Louisville, CO), a system also used to induce therapeutic hypothermia. The system circulates warm water through gel pads placed on areas of the body with large surface areas (e.g., the trunk and thighs). Case reports

Figure 65.4 Forced warm air convection systems, such as the Bair Hugger (Augustine Medical, Eden Prairie, MN) may be used for active external warming of accidental hypothermia victims.

exist showing rewarming rates from 0.63°C to 2.5°C per hour, with one patient rewarmed from an initial temperature of 22°C.⁷⁰

Technique

Because profound fluid shifts can occur with conduction warming, give the patient supplemental IV fluid warmed to 40°C (104.0°F; Hotline Fluid Warmer, Sims Level 1, Inc., Rockland, MA) at a rate sufficient to generate a urinary output of 0.5 to 1.0 mL/kg per hr. Give an initial fluid bolus of 500 mL of D₅NS. Note that blood pressure is not an accurate means of gauging fluid resuscitation because serious hypothermia is always accompanied by “physiologic” hypotension. Because patients requiring mechanical ventilation have rarely been subjected to tank immersion, it cannot be recommended for hypothermic patients who require intubation. Rewarming rates ranging from 0.9°C to 8.8°C (1.6°F to 15.8°F) per hour have been reported with immersion therapy.^{8,71}

A heat exchange blanket allows the patient to receive other treatments that may be difficult or impossible to carry out in a tub, such as defibrillation, CPR, or more invasive warming techniques. Place the heating blanket and overlying cloth sheet underneath the patient. Set the blanket temperature to 40°C to 42°C (104.0°F to 107.6°F), and initiate the measures described in the section on Passive Rewarming Techniques. Forced-air rewarming (convection) uses a blanket cradle to create an environment through which heated air is blown. Access to the patient is quite good with this system because the overlying blankets can be raised temporarily to evaluate the patient or perform procedures. Experience with mild immersion-induced hypothermia in volunteers suggests that the forced-air technique warms at a rate comparable to that of vigorous shivering, but with less metabolic stress and less afterdrop.⁷²

Arteriovenous Anastomoses Rewarming

Arteriovenous anastomoses rewarming (AVR) involves immersion of the distal end of the extremities (hands, forearms, feet, and lower part of the legs). Advantages include rapid rewarming rates. A study of AVR immersion at temperatures of 45°C and 42°C (113.0°F and 107.6°F) in healthy volunteers demonstrated rewarming rates of 9.9°C/hr ($\pm 3.2^\circ\text{C/hr}$) for the former and 6.1°C/hr ($\pm 1.2^\circ\text{C/hr}$) (43.0°F \pm 34.2°F/hr) for the latter.⁷³ There was also a decrease in postcooling afterdrop. AVR is well tolerated by patients because of the rapid rise in core temperature and the shortened period of shivering.⁷⁴

Complications

There is concern that surface warming with accompanying vasodilation may produce relative hypovolemia in a hypothermic patient. Other complications described with the active external rewarming method include core temperature afterdrop and rewarming acidosis. In *core temperature afterdrop*, colder peripheral blood is transported to the warmer core organs, thereby further reducing core temperature. In *rewarming acidosis*, colder blood and lactic acid return to the core organs and worsen the acidosis. To limit these complications in patients with moderate hypothermia, some authors advocate using active external warming only after active internal techniques have been initiated.⁷⁴ Others suggest that core afterdrop is inevitable regardless of the rewarming method, as temperature will temporarily decrease in any object with a warm core and cool periphery, due to conductive properties.⁷⁵

CPR and other advanced cardiac therapy and monitoring are impossible with immersion rewarming. Until studied further, active external rewarming should be considered only in a clinically monitored setting for mildly hypothermic patients who can protect their airways. When using a heating device, also monitor the potential for burns in areas that have the greatest contact with the heating source.

Active Core Rewarming

There is evidence that active core rewarming may decrease mortality from severe hypothermic exposure when compared with other techniques. In the face of circulatory failure, often the best chance of survival is treatment with extracorporeal circulation (ECC) and warming of the blood.⁷⁶ Several methods have been described, including the use of warm humidified air through an endotracheal (ET) tube or mask, peritoneal lavage, gastric or bladder lavage with warm fluid, thoracic tube lavage, cardiopulmonary bypass, AVR, peripheral vascular extracorporeal warming, hemodialysis, and thoracotomy with mediastinal lavage. These techniques transfer heat actively to the body core and achieve varying rewarming rates. The specific techniques and some of the advantages and disadvantages for each procedure follow.

Emergency Warming of Saline in a Microwave

Under ideal circumstances, keep saline in a standard warming device. When large amounts of saline are required for such procedures as peritoneal lavage, warm 1-L saline bags rapidly in a standard microwave oven (Fig. 65.5). Although devices vary, a 650 W microwave oven has been demonstrated to warm 1 L of room-temperature non-dextrose-containing saline from 21.1°C to 38.3°C (70°F to 101°F) in 120 seconds on the high setting. At midcycle (i.e., after 60 seconds), interrupt the heating with agitation, and repeat the agitation at the end of the cycle before infusion. Fluids containing dextrose should not be warmed in this manner, as glucose caramelizes at 60°C. Fluids in glass bottles and blood products are also not safe to be warmed with this method.⁷⁷

Inhalation of Heated Humidified Oxygen or Air

The use of warm humidified oxygen to treat hypothermia has been well established. Average rates of rewarming of 1°C/hr (33.8°F/hr) via mask and 1.5°C/hr to 2.0°C/hr (34.7°F/hr to 35.6°F/hr) via ET tube with heated aerosol at 40°C (104.0°F) can be obtained.^{8,38} Faster rewarming rates may be accomplished with a maximum safe aerosol temperature of 45°C (113°F). Core rewarming with this technique occurs through the following mechanisms. The warmed alveolar blood returns to the heart and warms the myocardium. The heated, humidified air delivered to the alveoli also warms contiguous structures in the mediastinum by conduction. Warming the inhaled air or oxygen eliminates a major source of heat loss.

Indications and Contraindications. The use of heated humidified air or oxygen is a simple technique that should be used routinely in all patients with hypothermia, regardless of severity. If the correct equipment is available, it can be used in the field and in the hospital.^{50,51} One must address the risk for burns during the inhalation of warm air in the field environment. Mouth-to-tube ventilation in an intubated hypothermic prehospital patient has the theoretical advantage of providing warm humidified air without special equipment. A ventilating rescuer can inhale oxygen and then expire it into the patient's

Figure 65.5 A, To rewarm hypothermic patients with intravenous heated saline, a standard 650 W microwave oven, on high for 120 seconds, will raise the temperature of a non-dextrose-containing liter of saline (in a plastic bag) to approximately 100°F. B, Agitate the bag halfway through the warming and again before infusion.

ET tube to provide air with increased oxygen content. There are no contraindications to or reported complications from the use of warm humidified air for hypothermia, and there is no afterdrop.⁷⁸

Technique. Use a heated cascade nebulizer with a mask for patients with spontaneous respirations. Use a volume ventilator for intubated patients. Monitor the inspired air to maintain a temperature of approximately 45°C (≈113.0°F). Temperatures higher than 50°C (122°F) may burn the mucosa, and temperatures lower than 45°C (< 113°F) do not deliver the maximum heat. Humidify the air or oxygen and note that the heater module may need modification because many units have feedback mechanisms that shut off at a given temperature. It may be difficult to deliver oxygen at the recommended temperature because of equipment limitations. In many cases the air temperature is only 30°C (86°F).

Summary. Inhalation of warm humidified air or oxygen results in gradual rewarming of the core and should be the

mainstay of all rewarming therapy. Studies have suggested that the rewarming rate of inhalation therapy is inferior to that of peritoneal lavage, thoracic lavage, and bath rewarming.⁸ Inhalation therapy can be combined with any and all other methods of rewarming and is relatively noninvasive and inexpensive. This therapy should be considered as the initial treatment of choice for hypothermic patients.

Peritoneal Dialysis (Lavage)

Peritoneal dialysis (lavage) is an attractive treatment for severe hypothermia because it is available in most hospitals and does not require any unusual equipment or training. Rewarming rates of 2°C to 3°C (3.6°F to 5.4°F) per hour, depending on the dialysis rate, can be achieved without sophisticated equipment that may delay therapy or require transfer of the patient to a tertiary care facility.⁷⁹ This technique can also be used to help correct electrolyte imbalances. Peritoneal lavage is useful primarily in severe cases in combination with other rewarming techniques for patients without spontaneous perfusion, but has also been used alone in patients undergoing CPR in whom ECC was felt to be contraindicated or not available.^{80,81}

Rewarming by peritoneal dialysis was first used successfully in a patient in ventricular fibrillation with a temperature of 21°C (69.8°F). Since that time, there have been reports of successful rewarming with peritoneal lavage in stable, severely hypothermic patients and unstable hypothermic patients in cardiac arrest.⁸² Peritoneal lavage works via transfer of heat from lavage fluid to the peritoneal cavity. The peritoneal great vessels and abdominal organs provide a large surface area for exchange of heat. The use of warmed peritoneal lavage fluid is an effective approach to rewarming. There have been reports in the literature of success with rapid high-volume peritoneal lavage in pediatric patients. The technique involves the use of an infraumbilical “mini-laparotomy” incision followed by placement of a large silicone peritoneal dialysis catheter. The catheter is connected to a rapid infusion device with delivery of 1 L of warmed normal saline every 90 seconds.

Indications and Contraindications. Peritoneal dialysis is appropriate therapy in a severely hypothermic patient. In practice, it is often omitted if other measures appear to be successful. There are no universally established criteria for performing peritoneal lavage in hypothermic patients who have detectable vital signs. Though theoretically less effective than other techniques that directly warm the thorax in the setting of cardiac arrest, it has been used successfully in that situation. It is theoretically useful in hypothermic patients who have overdosed with a dialyzable toxin. Other less invasive methods, such as gastric or bladder lavage or warm nebulized air or oxygen inhalation, may be preferred in stable patients with temperatures higher than 26°C to 28°C (> 78.7°F to 82.4°F). Peritoneal dialysis should not be performed on patients with previous abdominal surgery. It should be used with extreme caution in patients with a coagulopathy.

Equipment. We recommend using the Seldinger technique with a commercially available disposable kit (e.g., Arrow Peritoneal Lavage Kit, product no. AK-09000, Arrow International, Inc., Reading, PA) because of the ease of performance and minimal morbidity associated with this procedure.

Technique. In a noncritical patient, obtain a coagulation profile before the procedure, but in life-threatening situations,

initiate the procedure immediately before laboratory studies. Place the patient in the supine position with a Foley catheter and nasogastric tube in place. After infiltrating with lidocaine, make an infraumbilical stab incision with a No. 11 scalpel blade, and place an 18-gauge needle into the peritoneal cavity directed toward the pelvis at a 45-degree angle. Insert a standard flexible J wire through the needle, and then remove the needle. Pass the 8-Fr dialysis catheter over the wire with a twisting motion, and then remove the wire.

Lavage rates of 4 to 12 L/hr can be achieved with two catheters. Warm the fluid with a standard blood warmer to 40°C to 45°C (104.0°F to 113.0°F). Use a standard 1.5% dextrose dialysate solution. Add potassium (4 mmol/L) if the patient becomes hypokalemic. Saline has also been used successfully. The rate should be at least 6 L/hr and preferably 10 L/hr.

Complications. The Seldinger method has a complication rate of less than 1%. A “mini-lap” performed via direct dissection may also be used but might have a higher complication rate. Further discussion of potential complications is provided in [Chapter 43](#).

Summary. Peritoneal dialysis is a useful method because it entails readily available fluid and can be done with a self-contained disposable kit. If a hospital also treats trauma victims, the lavage kit can be the same as that used for evaluation of abdominal trauma. If this technique is combined with warm nebulized inhalation, warming rates of 4°C/hr (7.2°F/hr) can be achieved. Peritoneal lavage rewarms the liver and restores its synthetic and metabolic properties.⁷⁹

Gastrointestinal and Bladder Rewarming

Gastric or bladder irrigation offers some of the same advantages as peritoneal dialysis without invading the peritoneal cavity. Heat is delivered to structures in close proximity to the core. In the Multicenter Hypothermia Study, gastric/bladder/colon lavage had a first-hour rewarming rate of 1.0°C to 1.5°C/hr (33.8°F/hr to 34.7°F/hr) and a second-hour rewarming rate of 1.5°C/hr to 2.0°C/hr (34.7°F/hr to 35.6°F/hr) for severe hypothermia.⁸³ In a multifactorial analysis of the Multicenter Hypothermia Study there was a trend toward improved survival in patients treated in this manner.

Although the amount of heat delivered with gastric lavage appears to be less than that delivered with peritoneal dialysis, it is somewhat easier to use and less invasive. When combined with other methods, gastric or bladder lavage provides significant warming. Serum electrolyte levels should be monitored if large volumes of tap water are used because dilutional electrolyte disturbances may occur. Children and geriatric patients might be more susceptible to electrolyte changes with tap water irrigation.

Indications and Contraindications. Warmed gastric or bladder lavage may be used as adjunctive therapy for moderate or severe hypothermia. It can be combined with other warming techniques when rapid rewarming is needed. Patients who are obtunded and lack protective airway reflexes should undergo ET intubation before gastric lavage to prevent aspiration of gastric contents. Refer to the appropriate chapters concerning nasogastric tube placement (see [Chapter 40](#)), gastric lavage (see [Chapter 42](#)), and urethral catheterization for specific contraindications to these procedures.

Equipment. Use a large-diameter 32- to 40-Fr lavage tube with normal saline solution warmed to 40°C to 45°C (104.0°F to 113.0°F) in a microwave or blood warmer with verification of temperature before use. Although smaller tubes are easily passed nasally, use oral placement of the large lavage tubes. A modified Sengstaken tube with gastric and esophageal balloons may also be used.

Technique. Instill 200- to 300-mL aliquots of fluid into the stomach before removal by gravity drainage. For bladder irrigation the optimal volume is not known, but avoid distention of the bladder (100- to 200-mL aliquots should be sufficient). The amount of time that the irrigant should be left in place before removal is not known, but use of rapid exchanges with a dwell time of 1 to 2 minutes is suggested.

Complications. Complications of lavage include trauma to the nasal turbinates, gastric and esophageal perforation, dilutional hyponatremia, inadvertent placement of the tube in the lungs, and pulmonary aspiration, all of which can be minimized by careful, proper technique. Fluid overload and electrolyte disturbances when using tap water are potential complications in pediatric and geriatric patients.

Summary. Gastrointestinal and bladder lavage with heated fluids is easily performed with equipment and solutions available in any hospital. The stomach, colon, and bladder are poor sites for body cavity lavage as a result of the small surface area for heat exchange.⁷⁹ Because of its ease and availability, it can be started early in the resuscitation and be combined with any other rewarming method to significantly add heat,⁷² although its specific effect on morbidity and mortality is not known.

Thoracic Cavity Lavage

Thoracic cavity lavage can be performed either by *closed* means, through chest tubes placed in one hemithorax, or in *open* fashion, after resuscitative thoracotomy.⁸⁴ The former approach offers the advantages of being less invasive and is an effective form of treatment in hospitals not equipped for cardiopulmonary bypass. Furthermore, closed-chest CPR can be continued while this technique is used. The open thorax approach offers the theoretical advantage of direct warming of the heart and the option of open-chest cardiac massage. Rapid warming rates of 6°C to 7°C (42.8°F to 44.6°F) in 20 minutes have been described. Pleural irrigation results in cardiac rewarming and might be the method of choice, particularly in patients with an arrhythmia.⁷⁹

Indications and Contraindications. Thoracic cavity lavage should be considered for patients requiring rapid core rewarming in the setting of cardiac arrest or inadequate perfusion (e.g., shock, during CPR) when cardiac bypass is not available.⁸⁵ Open thoracic lavage should be considered in patients who will receive open-chest massage or thoracotomy for other reasons (e.g., hypothermic arrest with penetrating trauma). Thoracic lavage is not necessary for patients with mild or moderate hypothermia who can be rewarmed by other less invasive methods. Avoid the technique in patients with a coagulopathy unless required as a lifesaving measure.

Closed Thoracic Lavage. An alternative that is more practical in the ED is pleural rewarming by repeatedly using warmed

saline placed intermittently and then withdrawn through a chest tube. Place two large-bore thoracostomy tubes (e.g., 36- to 38-Fr in 70-kg adults) in one hemithorax. Infuse one chest tube with 3-L bags of heated normal saline (40°C to 41°C [104°F to 105.8°F]) via a high-flow fluid infuser (e.g., Level-1 Fluid Warmer, Technologies, Inc., Marshfield, MA). Collect the effluent with an autotransfusion thoracostomy drainage set (e.g., Pleur-evac, Deknatel A-5000-ATS, Fall River, MA). Empty the removable reservoir as needed. Alternatively, use a single-chest tube system with a Y-connector arrangement similar to that used for gastric lavage. Place aliquots of 200 to 300 mL with a 2-minute dwell time followed by suction drainage (at 20 cm H₂O).

Provide closed-chest massage until adequate spontaneous perfusion occurs. Perform closed-chest defibrillation if the patient is warmed to 30°C (86°F) and has persistent ventricular fibrillation. Continue thoracic lavage until the patient's temperature approaches 35°C (95°F).

Open Thoracic Lavage. Perform a left thoracotomy and pour saline warmed to 40°C to 41°C (104.0°F to 105.8°F) continuously into the thoracic cavity to bathe the heart while an assistant suctions the excess fluid from the lateral edge of the thoracotomy. Alternatively, add fluid to the thorax and mediastinum intermittently and suction after several minutes. Follow this with more warmed saline and repeat. This technique also allows direct monitoring of myocardial temperature. Perform direct cardiac massage until adequate spontaneous perfusion occurs. Perform direct cardiac defibrillation in a patient warmed to 30°C (86°F) with persistent ventricular fibrillation. When defibrillation is successful, continue direct myocardial warming until the patient's temperature approaches 35°C (95°F). If defibrillation is unsuccessful at a core temperature of 30°C (86°F), continue warming while oxygenation, perfusion, and other physiologic parameters are optimized before further attempts at defibrillation.

Summary. Thoracic lavage is an effective form of active core rewarming that is usually reserved for hypothermic arrest patients.⁸⁴ Thoracic lavage may be considered when vital signs are inadequate or unstable enough to severely limit perfusion. Precise indications have not been clarified beyond patients in cardiac arrest.

Cardiac Bypass

The use of cardiac bypass or an extracorporeal shunt through either the femoral artery–femoral vein or the aortocaval procedure can result in rapid rewarming but requires surgical expertise, the availability of appropriate equipment, and technical support.^{7,86} ECC usually refers to cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO).⁸⁷ ECMO appears to reduce the risk of intractable cardiorespiratory failure or severe pulmonary edema after rewarming.⁸⁸ This procedure has not been compared with other rewarming methods in a controlled fashion, and few centers have this modality available in a time frame that would affect survival rates. Its main advantages appear to be the rapid rate of warming that it produces and optimal patient oxygenation and perfusion. Femoral flow rates of 2 to 3 L/min with the warmer set at 38°C to 40°C (100.4°F to 104°F) will raise the core temperature 1°C to 2°C (33.8°F to 35.6°F) every 3 to 5 minutes.⁸ Drawbacks include potential delays in assembling the appropriate team and equipment, delays because of the time necessary to complete

the operation, complications from the operation, the expense of the procedure and bypass equipment, and the potential for infection. Its use in extreme situations that may include cardiac arrest should be based on individual characteristics of the patient, clinician team, and hospital resources. If readily available, it should be strongly considered in hypothermic patients with asystole or ventricular fibrillation.⁴⁷ If oxygenation is not a consideration, venovenous rewarming with an extracorporeal venovenous warmer can achieve rapid rewarming rates (2°C/hr to 3°C/hr [3.6°F/hr to 5.4°F/hr]), although they are slower than rates with cardiopulmonary bypass.^{73,74} Such a device is relatively easy to use, involves readily available technology, and probably does not require heparin. This equipment needs to be assembled before patients with hypothermia arrive.³¹ In severely hypothermic patients, extracorporeal rewarming using venovenous hemofiltration has also been reported to be successful.^{73,74} When compared with adults, children, especially smaller ones, require special consideration with regard to IV cannulation because drainage can be inadequate with femoral-femoral cannulation. In smaller hypothermic children, some sources recommend a more aggressive emergency median sternotomy for cardiopulmonary bypass.⁸⁹

Cardiopulmonary bypass is indicated in the following situations: (1) cardiac arrest or hemodynamic instability with a temperature lower than 32°C (< 89.6°F), (2) no response to less invasive techniques, (3) completely frozen extremities, or (4) rhabdomyolysis with severe hyperkalemia.² A 47% long-term survival rate was obtained in a Swiss study of 32 young, otherwise healthy individuals, including mountain climbers, hikers, and victims of suicide attempts. Cardiopulmonary bypass is unlikely to confer similar benefit in older, poorly conditioned populations with underlying chronic diseases.

Hemodialysis

Hemodialysis was first described for the management of AH in 1965.⁹⁰ It is a rapid and efficient modality for rapid internal rewarming of patients with moderate to severe AH,⁹¹ but it is uncommonly used in clinical practice. Temporary dialysis catheters are readily available and relatively easy to place.⁹² One study reported that 26 patients with AH combined with circulatory arrest or severe circulatory failure were rewarmed to normothermia with the use of ECC.⁹³ Core rewarming by hemodialysis has been achieved after placement of a dialysis catheter or with the use of an existing shunt. Some of the potential advantages and drawbacks of cardiac bypass also apply to this procedure, although slower warming rates have been reported. A range from 0.6°C/hr (33.1°F/hr) to rates as high as 4.5°C/hr (40.1°F/hr) have been achieved with fluid warmed to 40°C (104.0°F). For patients who have ingested a dialyzable toxin (such as barbiturates and toxic alcohols), hemodialysis can be used to both remove the toxin and rewarm the blood.⁹⁰ In such cases its use may be appropriate.

Experimental Techniques

Ultrasonic, radiowave, and low-frequency microwave diathermy rewarming appears to be a rapid, safe, noninvasive technique that has shown promise in animal studies. Frequencies of 13.6 to 40.7 MHz are typically used. In a volunteer study the technique seemed to be less effective than immersion therapy and equivalent to passive rewarming techniques.⁹⁴ Total liquid ventilation with warmed oxygenated perfluorocarbon is currently being studied in animals as a method of rapidly rewarming the core. Benefits include shorter rewarming times than with

warm humidified oxygen (1.98 ± 0.5 hours vs. 8.61 ± 1.6 hours; $P < 0.0001$), no afterdrop phenomenon, and no increase in lactate dehydrogenase and aspartate transaminase.⁷⁸

Very hot IV fluids (65°C [149°F]) have been used in animals with little vascular damage or hemolysis. Trials in humans undergoing burn débridement have been successful in preventing hypothermia during operative procedures. Saline heated to 60°C (140°F) with modified fluid warmers was infused through central venous access. There was no evidence of intravascular hemolysis or coagulopathy after the infusions. The role of hot IV fluids in the management of AH is currently undefined.

Special Situations

Cardiac Arrest

Cardiac arrest secondary to AH requires immediate treatment for the best chance of a successful outcome. Rapid rewarming and restoration of cardiac rhythm are essential for patients in cardiopulmonary arrest and can best be achieved with a combination of passive and multiple active core rewarming techniques. Because of numerous cases of survival from hypothermic cardiac arrest with prolonged external cardiac compression,^{7,95} thoracotomy is not mandatory. Thoracotomy does offer some theoretical advantages, however, such as increased cardiac output with open-chest massage, direct observation of cardiac activity, and direct warming of cardiac tissue with thoracic cavity lavage of warm fluid. Cardiopulmonary bypass is an effective technique for rapid rewarming. Blunt trauma and head trauma victims were previously not ideal candidates for cardiac bypass because of the anticoagulation requirement, but some authors have advocated this technique with heparin-bonded tubing even in the setting of known traumatic injury.⁷ A review of outcomes after hypothermic cardiac arrest from one institution found that the average time from thoracotomy to the development of a perfusing rhythm was 38 minutes (range, 10 to 90 minutes).⁵ The optimal rate of cardiac compressions in hypothermic patients is not known. Because of decreased oxygen consumption by vital organs, the rate required in hypothermic cardiac arrest is less than that recommended for normothermic cardiac arrest. Cardiac compressions should be initiated at half the normal rate in profoundly hypothermic patients. Guidelines developed by the American Heart Association and the Wilderness Medical Society recommend that CPR be initiated in patients with AH unless any of the following conditions exist: a “do-not-resuscitate” status is documented and verified, obvious lethal injuries are present, chest wall depression is impossible, no signs of life are present, or rescuers are endangered by delays in evacuation and altered triage conditions.⁸

The duration of CPR depends on the time required to raise the core temperature to a level at which defibrillation should be successful (i.e., > 30°C [> 86°F]). Previously, it was recommended that patients not receive a set of three countershocks until a core temperature above 30°C (> 86°F) could be attained. There have been reports of successful defibrillation in patients with profound hypothermia with core temperatures of 25.6°C (78.1°F).⁸³ The decision to terminate resuscitative efforts remains a clinical one, but there are certain poor prognostic factors. Certainly, survival is unlikely in patients who persist in asystole or go from ventricular fibrillation to asystole as they are warmed past 32°C (> 89.6°F). Some authors describe prognostic markers for patients with severe hypothermia and

cardiac arrest which have been proposed as contraindications to ED thoracotomy and cardiac bypass.⁷ Such markers include potassium levels elevated to above 10 mmol/L (mEq/L) and pH levels below 6.5. Nonetheless, there are reports of survival in patients with higher potassium levels and a pH as low as 6.29.⁸⁹ Presenting rhythm of asystole, advanced age, underlying illness (including infection) and elevated serum lactate may also be poor prognostic indicators. Multiple reviews have shown that asphyxia prior to hypothermia arrest (as seen in avalanche and drowning victims) is a poor prognostic factor.⁹⁶ Ultimately, the decision to continue resuscitative efforts should not be based solely on specific laboratory values or the initial core temperature.

Isolated reports of survival of hypothermic patients with prolonged CPR make extended efforts to resuscitate such patients reasonable. Children may be the best candidates for heroic measures. Under ideal conditions, hypothermic cardiac arrest patients may reasonably be admitted to an intensive care unit for a 4- to 5-hour trial of rewarming with CPR in progress. Manual CPR should be replaced by mechanical methods if the equipment is available. The oxygen-powered “thumper” has been successful during prolonged hypothermic resuscitation. Absence of responsiveness to treatment, in conjunction with a highly elevated potassium level, is an indication for termination of resuscitative efforts.

Airway Management

Maintain a secure functioning airway for hypothermic patients, just as in any critically ill patient. With mild hypothermia, deliver heated, humidified oxygen by face mask. Recognize that a hypothermic patient can be combative and uncooperative and may require arm restraints if a mask is used. Intubate patients with decreased sensorium who cannot reliably maintain their airway or hypothermic patients who may be hypoxic. ET intubation may be performed safely without the added risk of ventricular dysrhythmias.²⁰ The technique for ET intubation depends on the specific circumstances and the expertise of the operator. Once an ET tube has been placed and secured, use it to provide warm humidified oxygen. There is no evidence that tracheal intubation is detrimental in severely hypothermic patients, and it should be considered if indicated for ventilation, oxygenation, or airway protection.

Acid-Base Disturbances

Acid-base disturbances are variable and can lead to metabolic acidosis from carbon dioxide retention and to lactic acidosis or metabolic alkalosis from decreased carbon dioxide production or hyperventilation. Interpretation of arterial blood gases in a hypothermic patient has been the cause of some confusion. Previously, it was suggested that all blood gases be corrected for temperature with correlation factors. With a decrease in temperature of 1°C (33.8°F), pH rises 0.015, carbon dioxide pressure (PCO₂) drops by 4.4%, and oxygen pressure (PO₂) drops 7.2% relative to values that would be obtained with blood analyzed under normal conditions. Despite the conversion guide, optimal or normal values in hypothermia have not been well documented.³⁶ Other literature supports the use of uncorrected arterial blood gas values to guide therapy with bicarbonate or hyperventilation.³⁸ This approach appears appropriate to support optimal enzymatic function. Gradual correction of acid-base imbalance will allow increased efficiency of the bicarbonate buffering system as the body warms. Arterial pH did not correlate with patient death in the Multicenter

Hypothermia Study and should not be used as a prognostic guide to resuscitation.

Coagulopathies

Abnormal clotting occurs frequently in hypothermic patients, probably because cold inhibits the enzymatic coagulation cascade.⁹⁷⁻⁹⁹ Hypothermia-induced coagulopathy does not result from excessive clot lysis, but rather from impaired clot formation.²⁷ Platelet function is also impaired during hypothermia because production of thromboxane B₂ is inhibited. Hypothermia-induced platelet aggregation with or without neutrophil involvement has been associated with neurologic dysfunction in patients undergoing surgical procedures.⁸⁶ Hypercoagulability with a risk for thromboembolism may also occur, but the importance of cold-induced coagulopathy mainly involves patients with coincidental trauma. Such victims often have bleeding that is difficult to control. Replace appropriate clotting factors and use warm blood to limit further blood loss and worsening of the hypothermia.

Trauma and Hypothermia

Mortality is increased in trauma patients with temperatures below 32°C (< 89.6°F). It is not clear whether this increased mortality is actually a result of the hypothermia or whether the hypothermia is merely an indicator of severe injury and response to a massive transfusion of cold fluid.^{27,100} Patients with severe trauma are prone to hypothermia because their injuries often expose them to environmental heat loss. Patients with hemorrhagic shock are often acidotic and coagulopathic, leading to the “lethal triad” of acidosis, coagulopathy, and hypothermia. These patients are at extremely high risk for multisystem organ failure and death.¹⁰¹ Concurrent alcohol intoxication may add to the heat loss as a result of its vasodilatory effects on cutaneous vasculature and the prolonged cold exposure secondary to altered mental status. Victims of severe injury also lose heat because of exposure during resuscitation and rapid administration of cold fluids.

It is unknown to what degree correcting the hypothermia improves outcome. Nevertheless, devices to rapidly infuse warm fluids such as the Level 1 fluid warmer (Level 1 Technologies, Rockland, MA) and the Thermostat 900 (Arrow International, Reading, PA) are frequently used to warm large-volume fluid transfusions. Use of these devices seems reasonable to prevent the hypothermia associated with massive transfusions (see [Chapter 28](#)). Their use for hypothermia not associated with severe trauma is limited by the relatively low fluid requirements of patients with environmental exposure. Another Thermostat device (Aquarius Medical Corp., Phoenix, AZ) is used to accelerate recovery from hypothermia by mechanically distending blood vessels in the hand, thereby increasing transfer of exogenous heat to the body core.

Pharmacotherapy and Monitoring

Hypothermia alters the pharmacodynamics of various drugs. It markedly alters drug kinetics, but not enough is known about this phenomenon to define specific therapeutic guidelines. Administer drugs with caution to hypothermic patients ([Table 65.4](#)). Because of the negative effects of hypothermia on both hepatic and renal metabolism, toxic levels of medications can accumulate rapidly after repeated use.¹⁰² Avoid certain drugs, such as digitalis. Sinus bradycardia and most atrial arrhythmias do not require pharmacologic treatment because the majority

TABLE 65.4 Commonly Used Medications for Hypothermia

CLINICAL SITUATION	MEDICATION	DOSAGE
Hypoglycemia	D ₅₀ W	1 mg/kg IV
Alcoholic/ malnourished	Thiamine	100 mg IV
Altered mental status	Naloxone	0.4–2 mg IV
Ventricular fibrillation	Bretylium ^a Magnesium sulfate	5 mg/kg IV 100 mg/kg IV

^aThe role of more available antidysrhythmics such as amiodarone in patients with hypothermia remains to be determined.

D₅₀W, 50% dextrose in water; IV, intravenously.

resolve with rewarming. Transient ventricular dysrhythmias also do not require treatment. Bretylium is the preferred agent for patients requiring medication for ventricular dysrhythmias, but lidocaine, magnesium, isoproterenol, and amiodarone have also been used.^{36,103} For severe acidosis (pH < 7.1), IV sodium bicarbonate can be used with extreme caution. Vasopressors should be used with care, perhaps in much smaller doses than usual, because of the arrhythmogenic potential and the delayed metabolism of these agents. A review of intensive care unit admission of hypothermic patients found that treatment with vasoactive drugs was an independent risk factor for mortality, but this phenomenon remains poorly understood.⁴⁷ In animal studies, use of epinephrine impaired myocardial efficiency in cases of moderate hypothermia.¹⁰⁴ There was no advantage to repeated doses of epinephrine or high-dose epinephrine in hypothermic cardiac arrest animal models.¹⁰⁵ The use of inamrinone, formerly known as amrinone, has been investigated in cases of deliberate mild hypothermia. Initial results indicate that inamrinone accelerates the cooling rate of the core temperature, thereby potentially limiting its usefulness in the management of AH.¹⁰⁶

Administer IV fluids slowly to prevent fluid overload potentiated by the decreased cardiac output. Fluids should be started early because intravascular volume is depleted in most hypothermic patients. D₅NS has been advocated as the ideal initial resuscitation fluid.^{68,71} Avoid potassium until electrolytes are measured and normal renal function is confirmed. Check serum levels of creatine phosphokinase in hypothermic patients, which may indicate rhabdomyolysis. If elevated, carefully monitor renal function. Replace fluids aggressively because this may help prevent the development of renal failure. In severely hypothermic patients, consider placing a Swan-Ganz catheter and closely monitor urinary output to assist in fluid management. The risk of precipitating ventricular fibrillation should be weighed against the potential benefits of the Swan-Ganz catheter.

It should be emphasized that hypothermic patients exhibit a “classic physiologic response” that may be somewhat protective. This response depends on the severity of the decrease in core temperature and classically consists of hypotension, hypoventilation, depressed mental status, and bradycardia. This prohibits a precise recommendation of the indications and use of medications, intubation, CPR, and other resuscitative

interventions, which are better defined in normothermic patients. Hypothermic patients with a blood pressure, respiratory rate, or mental status that would prognosticate certain morbidity in normothermic patients may recover with minimal intervention on their normal pre-hypothermic state. Avoid aggressive therapies or medications aimed at providing hypothermic patients with vital signs that would be desirable in normothermic patients but may be supraphysiologic in hypothermic patients.

Frostbite

Hypothermic patients frequently suffer other forms of cold-related injuries in addition to their systemic hypothermia. The mildest form of frostbite is termed *frostnip*, a condition that involves only the skin and spares subcutaneous tissue. The skin is blanched and numb, but the injury is immediately reversible with no permanent sequelae if the area is quickly rewarmed. Rewarm rapidly in a water bath at 40°C to 42°C (104.0°F to 107.6°F). Frostnip occurs most frequently on the distal ends of the extremities, the nose, and the ears. Nonfreezing temperatures also produce *trench foot*, an intermediate step in the progression to true frostbite. Trench foot is the result of prolonged immersion in cold water. Rewarm patients and apply dry dressings.^{105,107}

In frostbite, the body parts most susceptible are those farthest away from the body’s core: the hands, feet, earlobes, and nose. Exposure of the fingers to severe cold leads to cold-induced vasodilation.^{108,109} Apical structures rich in arteriovenous anastomoses can shunt blood flow away from tissues. Freezing of the corneas has been reported to occur in individuals who keep their eyes open in highwind chill situations without protective goggles (e.g., snowmobilers and skiers).⁹⁴

The pathophysiology of frostbite includes three pathways of tissue freezing: (1) through the extracellular formation of ice crystals, (2) hypoxia as a result of cold-induced local vasoconstriction, and (3) release of inflammatory mediators. These pathways often occur simultaneously and intensify the tissue damage. At the early stages of frostbite the “hunting reaction” is observed whereby the body alternates between periods of vasoconstriction and periods of vasodilation. As the temperature continues to decrease, the reaction stops and vasoconstriction persists.^{105,110} Cold also increases blood viscosity, promotes vasospasm, and precipitates the formation of microthrombi. Release of the inflammatory mediators, prostaglandin F₂ and thromboxane A₂, causes further vasoconstriction leading to cell death. Release of these mediators peaks during rewarming, and cycles of recurrent freezing and rewarming only increase their tissue levels. Avoid rewarming until refreezing can be prevented.

The clinical signs and symptoms of frostbite vary according to the degree of injury. Though useful clinically, the degree classification does not predict the extent of further tissue damage.^{38,89,97} The appearance of the affected extremity depends on the extent of the frostbite. With superficial frostbite, the affected extremity appears pale, waxy, and numb. The limb has poor capillary refill and is very painful on rewarming. With deeper frostbite, the affected extremity is hard, solid, and blanched. Hemorrhagic blisters may be present (Fig. 65.6). Initially, there is no pain or feeling in the frostbitten extremity. After rewarming, severe edema and blistering develop in the affected areas, and victims eventually exhibit dry gangrene, mummification, and ultimately tissue sloughing.

Figure 65.6 Frostbite. Rapid rewarming is the treatment of choice; immersion in warm water (40°C to 42°C) for 15 to 30 minutes is a practical method. A conservative approach to frostbite débridement is suggested, with many alternatives acceptable. One approach is to débride white or clear blisters and leave hemorrhagic or dark blisters intact.

Favorable prognostic signs for frostbite include intact sensation, normal color, warm tissues, early appearance of clear blisters, and edema. Early intervention is critical in terms of the ultimate outcome. Delay in seeking medical care for more than 24 hours is associated with an 85% likelihood that surgical intervention will be required. Patients seen within the first 24 hours require surgery less than 30% of the time.^{2,107} The predictive value of the initial physical examination is limited, but the presence of nonblanching cyanosis, hemorrhagic blisters, and impaired sensation appears to indicate a poor prognosis.²

Based on early bone scans and retrospective studies, researchers from France proposed a new classification for predicting frostbite outcomes on day 0.¹¹¹ Four degrees of severity are defined. With *first degree*, there is complete recovery. *Second degree* often leads to soft tissue amputation. With *third degree*, bone amputation is needed, and with *fourth degree*, systemic effects occur.¹¹¹

It is critical to stabilize hypothermia and other life-threatening conditions before warming frostbitten extremities.^{112,113}

Rapid rewarming is the treatment of choice for frostbite.¹⁰⁵ The aim is to limit the length of time that the tissue remains in the frozen state. The most practical way to rewarm an

extremity is to totally immerse the area in warm water at 40°C to 42°C (104.0°F to 107.6°F) for 15 to 30 minutes. Carefully protect the affected area to ensure that the tissue is not additionally injured by contact with the sides or rim of the container. After thawing, meticulously protect the area from injury. Elevate the extremity and place cotton or gauze between the toes or fingers to limit maceration. At some point, necrotic tissue should be débrided, most often after the ED encounter has allowed identification of viable tissue; however, the ideal timing and best method or intervention have not been elucidated. A conservative approach is advocated. One method is to débride white or clear blisters. Leave hemorrhagic or dark blisters intact because disruption may theoretically cause damage to the vascular supply and viable tissue.

Use topical aloe vera, a thromboxane inhibitor, and administer systemic antiprostaglandins such as ibuprofen. Aspirin and ibuprofen inhibit the arachidonic and acid cascade, although there is no evidence of efficacy for either agent. Some prefer ibuprofen because it also produces fibrinolysis.¹¹³ The use of semioclusive dressings has shown promising results in the management of deep frostbite injuries of the fingertips.¹¹⁴ Provide tetanus prophylaxis. Adjuvant therapies involving the use of heparin or low-molecular-weight heparin, warfarin, vasodilators, corticosteroids, or immediate surgical sympathectomy have failed to improve outcomes.

The ideal intervention to ameliorate or limit tissue injury has not been proved, and it is uncertain if any protocol will prove effective. Mixed success has been achieved with the use of hyperbaric oxygen and thrombolytics.¹¹⁵ In a small study of frostbite victims, Twomey and coworkers suggested the following treatment algorithm for severe frostbite¹¹⁶: (1) rapid rewarming; (2) assessment of the patient's clinical appearance; (3) early-phase ^{99m}Tc scintiscan to assess the distal circulation; (4) administration of tissue plasminogen activator (t-PA), 0.15 mg/kg by IV bolus, followed by 0.15 mg/kg per hr to a maximum dose of 100 mg over a 4- to 6-hour period, for patients with digits or limbs showing no flow and an absence of contraindications; (5) therapeutic heparin for 3 to 5 days; (6) administration of warfarin to an international normalized ratio two times control for 4 weeks; (7) pain management as needed; (8) ibuprofen, 400 to 600 mg orally four times daily; (9) light dressings with topical antimicrobials; and (10) no ambulation on frostbitten feet.¹¹⁶ Bruen and colleagues,¹¹⁷ in a small retrospective study, reported that administration of t-PA within 24 hours of frostbite injury improved tissue perfusion and reduced amputations. The protocol included t-PA administered at an initial rate of 0.5 to 1.0 mg/hr into the extremity via a femoral or brachial arterial catheter sheath. Heparin was also administered at 500 Units/hr into the intraarterial catheter.¹¹⁷ Thrombolytic therapy for frostbite is encouraging, but the exact parameters for its use are still being investigated. Iloprost, a prostacyclin analogue, has vasodilatory properties that mimic a chemical sympathectomy. The risk of amputation was significantly lower in a controlled trial of patients with severe frostbite who received IV iloprost plus aspirin after thawing.¹¹⁸ Agents that can inhibit the formation of free radicals are also promising. Such agents include superoxide dismutase, prostaglandin E₁ analogues, and drugs containing antiplatelet activity such as pentoxifylline.^{105,110} The use of antibiotics is controversial, although some authors advocate agents effective against *Staphylococcus* and *Streptococcus* (e.g., cephalosporins, penicillins). Avoid débridement of tissue in the ED. Give analgesics (IV opioids) as needed.

Cold Water Immersion and Submersion

One of the leading causes of hypothermia remains cold water immersion or submersion.¹¹⁹ In a retrospective review of AH cases in a 3-year period, submersion hypothermia accounted for the greatest number of cases.¹²⁰ Unlike cases of AH caused by cold exposure, risk factors are harder to identify because of the high mortality from drowning.⁹⁷ Studies have shown that at cold water temperatures (8°C [46.4°F]), core cooling occurs at slower rates in persons with increased body mass and subcutaneous fat and at faster rates with increased voluntary activity (e.g., treading water). Risk factors for submersion hypothermia include impaired performance and the initial cardiorespiratory response to immersion. Studies have demonstrated that, in healthy volunteers, swimming efficiency and length of stroke decreased whereas the rate of stroke and swim angle increased as the water temperature dropped.

The body's response to cold water immersion (head out) has previously been described as occurring in three phases. The initial phase involves the "cold-shock response," which typically occurs within the first 4 to 6 minutes. Signs include peripheral vasoconstriction, gasp reflex, hyperventilation, and tachycardia. At this stage, there is a higher incidence of sudden death resulting from hypocapnia, inability to hold one's breath, and increased cardiac output. After the initial cold-shock response, the body undergoes profound cooling of the peripheral tissues. The peripheral cooling tends to be the greatest in the hands, which leads to incoordination and difficulty grasping. With prolonged immersion in cold water, heat is lost from the body quicker than it is produced, with the individual quickly progressing to hypothermia.^{121–123}

In cases of cold water submersion, researchers have found that rapid cooling is protective against neurologic impairment and increases the chance of survival.¹²⁴ There are numerous reports in the literature of survival in children after cold water submersion but very few reports in adults. There are also reports of survival after up to 66 minutes of cold water submersion.¹²⁵ Children tend to have a better prognosis because of the presence of the mammalian dive reflex and a greater body surface area-to-mass ratio, which allows more rapid cooling. A 2007 case was reported of a 2-year-old boy who suffered from severe hypothermia after falling into ice water.⁹ On discovery, cardiac arrest and asystole were present and the first measured temperature was 23.8°C (74.8°F). The patient was rewarmed by ECC with cardiopulmonary bypass and was discharged 9 days later without any sequelae. Five poor prognostic factors for near-drowning in pediatric patients include: (1) maximum submersion time longer than 5 minutes, (2) comatose on arrival at the ED, (3) arterial blood gas pH less than 7.10, (4) age younger than 3 years, and (5) resuscitation not attempted for at least 10 minutes after rescue. Adults tend to have higher mortality rates because of the following: (1) lack of the mammalian dive reflex and (2) slower rates of cooling secondary to lower body surface area-to-mass ratios than in children. Recent reports of hypothermia and drowning in commercial fishing deaths in Alaska noted a strong protective association with the use of personal floatation devices, particularly immersion suits, in surviving cold water-related events in adults.¹²⁶

Various mechanisms of brain and body cooling during submersion hypothermia have been described, including the mammalian dive reflex, cold-induced changes in release of neurotransmitters, and water ventilation. The mammalian dive reflex prevents or delays aspiration or ventilation until the

body has cooled to a point at which protection against hypothermia occurs. Much attention has focused on the theory of water ventilation as a key component of accelerated brain cooling. Animal studies comparing immersed (head out) and submersed dogs found that cooling rates were faster in submersed dogs than in immersed dogs. The submersed dogs cooled by convective heat exchange in the lungs, whereas the immersed dogs cooled by surface conduction only. Laboratory data obtained after the submersion indicates that there was indeed ventilation exchange in the water. The body also undergoes a relative bradycardia as another protective measure. Bradycardia is inversely proportional to the water temperature, with heart rates reaching 18 beats/min in water at 10°C (50°F). Many authors advocate therapies aimed at symptoms resulting from near-drowning rather than severe hypothermia because in fatal cases of submersion, death occurs too rapidly for hypothermia to be a significant contributor. Complications of near-drowning include pneumonia, lung edema, hemorrhagic pancreatitis, and skin edema.⁹⁷

Environmental Hypothermia Conclusion

Mortality rates from AH are decreasing, and this is linked to increased recognition and advanced therapy. Caution should be used when extrapolating published data obtained in adults to children.⁶⁴ With the exception of severe hypothermia, the prognosis correlates mostly with the presence or absence of underlying disease states. Studies have shown that the prognosis is excellent in patients in whom no hypoxic event precedes the hypothermia and no serious underlying disease states exist. Previously healthy individuals usually have full recovery with mortality rates lower than 5%, but patients with coexisting medical illnesses reportedly have mortality rates higher than 50%.⁵⁵

As a general guideline, take a conservative approach to rewarming stable hypothermic patients, with avoidance of overtreatment and selective and careful use of invasive monitoring. Evaluate a hypothermic patient's "physiologic" hypotension, hypoventilation, and bradycardia with regard to that expected for the given core temperature.

Because death is related more to underlying illnesses than to hypothermia, some sources do not believe that invasive rewarming modalities are useful for poikilothermic patients with severe underlying disease.¹

With moderate hypothermia, underlying problems should be sought, passive rewarming and basic support started, and less invasive core rewarming begun. This approach should include mask ventilation with warm humidified air or oxygen in conscious patients and intubation and ventilation in unconscious patients. In selected patients, gastric or peritoneal lavage with warm fluid may be considered. For severely hypothermic, *unstable* patients, cardiac bypass and thoracic lavage may offer additional benefits, including rapid warming rates and direct heart warming. The benefits should be weighed against the institutional capabilities, time, expense, and the danger for complications that these procedures entail. Although these patients often require tremendous time and resources, the literature is clear on one point: incredible recoveries are possible.¹²⁷

Targeted Temperature Management for Cardiac Arrest

In contrast to environmental hypothermia or AH, therapeutic hypothermia (TH, cooling to 32°C–34°C) or targeted

temperature management (TTM, cooling to 32°C–36°C) refers to the intentional lowering of temperature in patients for clinical benefit. Whereas lowered temperature may be protective for several diseases, particularly following an ischemic injury, the greatest benefit of active cooling has been demonstrated in the clinical context of out-of-hospital cardiac arrest (OHCA). Application of hypothermia as a therapeutic agent dates back to over 5000 years ago.¹²⁸ In 1700 the first systematic experimental studies were done on humans to determine the effects of cooling on the body.¹²⁸ However, it was not until 1958 that the first clinical trial of hypothermia on comatose cardiac arrest patients was conducted.¹²⁹ Since then TTM (a term that now encompasses TH) has proven to be one of the few treatment options for cardiac arrest patients that significantly improves neurologically intact survival.

Two landmark trials set the stage for TTM. In 2002, the Hypothermia After Cardiac Arrest (HACA) trial¹³⁰ and the Bernard and colleagues trial¹³¹ became the largest randomized trials at that time to report the effect of cooling to 32°C to 34°C within 6 hours for up to 24 hours following OHCA in patients with initial rhythms of ventricular fibrillation/tachycardia (VF/VT) on survival to discharge. Both trials showed that hypothermia improved neurological outcome. The HACA trial demonstrated significantly improved neurologically intact survival at 6 months after OHCA, with a number needed to treat of only six, suggesting a profound clinical benefit. Based on the evidence from these two prospective randomized trials, the International Liaison Committee on Resuscitation (ILCOR) incorporated TH into the post-cardiac arrest recommendations in 2003.¹³² In 2013, Neilsen and colleagues conducted a prospective randomized trial comparing active cooling to 33°C versus 36°C for 24 hours following OHCA, with further temperature control to prevent fever of less than 37.5°C for an additional 72 hours. Both groups demonstrated a similar mortality and neurological benefit at 180 days comparable to that seen in the HACA trial.¹³³ However, the Nielsen study enrolled patients who survived to the ICU (vs. ED in the HACA trial), and who had the benefit of higher rates of bystander CPR and higher rates of ST-elevation myocardial infarction that could be treated by percutaneous intervention. Nielsen patients overall appeared less injured than HACA patients as demonstrated by lower rates of hypotension. Thus, the use of TTM (32°C–36°C) for OHCA patients in the most recent ILCOR treatment guidelines¹³⁴ allows for a wider range of target temperatures that can be based upon level of injury and whether patient characteristics are more comparable to those seen in the HACA or Nielsen studies. Although the Nielsen study has been cited to suggest that cooling after OHCA is no longer necessary, it is important to emphasize that active cooling was needed to attain a target temperature of 36°C.

In conjunction with the Nielsen landmark study, a similar study was conducted for pediatric patients through the Therapeutic Hypothermia After Pediatric Cardiac Arrests Out of Hospital (THAPCA-OH) to evaluate for the efficacy of TH (TTM to 33) versus therapeutic normothermia (TTM to 36.8).¹³⁵ Primary outcome of good neurological outcome at 12 months resulted in no significant difference between the groups. It must be noted that there are grave differences in the pediatric patients; the leading cause of arrest in pediatric patients was respiratory (72%) and the proportion of patients with shockable rhythms was only 8% versus 80% in the Nielsen study. Therefore, a potentially important clinical benefit cannot be ruled out. Many unanswered questions remain about the

depth (higher temperature vs. lower temperature), duration (longer vs. shorter), and timing of TTM in pediatric patients. However, as of 2015, the American Heart Association national recommendations conclude that for comatose children who achieve return of spontaneous circulation (ROSC), temperature should be monitored closely and fever treated aggressively (see [Table 65.5](#) for specific recommendations for OHCA).¹³⁶

The clinical implementation of TTM for OHCA occurs within hours after a patient has had ROSC and is generally maintained for 24 hours. An opportunity to expand the application of cooling during CPR prior to ROSC has been highlighted in the ILCOR systematic review by Donnino and colleagues.¹³⁷ Although it remains clinically challenging to implement, there is mounting evidence that such intra-arrest therapeutic hypothermia (IATH) could have a profound benefit that exceeds TTM alone. Animal studies have shown that cooling to 32°C during CPR is highly protective of heart and brain function^{138,139} and that survival protection is lost if active cooling is delayed by even 20 mins.¹⁴⁰ This suggests that an important therapeutic window exists for cooling during CPR. Furthermore, a systematic review of the literature by Scolletta concludes that IATH improves survival and neurological outcome compared to normothermia and conventional hypothermia in experimental models.¹⁴¹

In summary, the role of environmental hypothermia and hyperthermia in causing human injury is well known and treatment strategies have advanced. In parallel, interest in intentional cooling and fever control for preventing the human injury of disease has a long history in medicine, with tremendous advances made in its application to OHCA patients. The time-sensitive care of patients that involves achieving optimal temperature for protection from injury remains a unique aspect of emergency medicine, with great potential to save the lives of some of our sickest patients.

A concise overview of all the recent TTM recommendations for adult,¹⁴² pediatric,⁹ and neonatal¹⁴³ guidelines for OHCA are listed in [Table 65.5](#).

PROCEDURES PERTAINING TO HYPERTHERMIA

As a result of global climate change, it is projected that worldwide there will be a significant increase in the number and intensity of heat waves with resultant deaths from hyperthermia and heat-related illness.¹²⁸ Temperature extremes and variability will remain important determinants of overall health, especially in the vulnerable populations of the elderly, children, and those with chronic illness. The mortality associated with heatstroke accounts for more than 200 deaths per year in the United States.^{144,145} In the United States from 1999 to 2003, a total of 3442 deaths were attributed to extreme heat exposure.¹⁴⁶ During the heat wave of 2003, France reported 15,000 excess deaths.¹⁴⁷ The morbidity associated with heat-related illness is on the rise. Nationally, an estimated 54,983 patients were evaluated in US EDs for exertional heat-related illness from 1997 to 2006.¹⁴⁸ This represents a 133% increase over the 10-year period.¹⁴⁸ Lack of heat acclimatization during extreme environmental conditions is responsible for the increasing percentage of heat-related illness, particularly in younger populations and agricultural workers.¹⁴⁹

Other important causes of hyperthermia include malignant hyperthermia (MH) and neuroleptic malignant syndrome

TABLE 65.5 AHA TTM Guidelines and 2015 Updates

AHA TTM Guidelines	2015 Updates
Initial TTM	All comatose (i.e., lacking meaningful response to verbal commands) adult patients with ROSC after cardiac arrest should have TTM, with a target temperature between 32°C and 36°C selected and achieved, then maintained constantly for at least 24 hours.
Beyond 24 hours	Actively preventing fever in comatose patients after TTM is reasonable.
Neuroprognostication	The earliest time to prognosticate a poor neurologic outcome using clinical examination in patients not treated with TTM is 72 hours after cardiac arrest, but this time can be even longer after cardiac arrest if the residual effect of sedation or paralysis is suspected to confound the clinical examination.
Prehospital cooling	The routine prehospital cooling of patients with rapid infusion of cold IV fluids after ROSC is not recommended.
Pediatric TTM	For comatose children resuscitated from OHCA, it is reasonable for caretakers to maintain either 5 days of normothermia (36°C to 37.5°C) or 2 days of initial continuous hypothermia (32°C to 34°C) followed by 3 days of normothermia.
Neonatal TTM (resource-limited setting)	Evidence suggests that use of therapeutic hypothermia in resource-limited settings (i.e., lack of qualified staff, inadequate equipment, etc.) may be considered and offered under clearly defined protocols similar to those used in published clinical trials and in facilities with the capabilities for multidisciplinary care and longitudinal follow-up.
Neonatal TTM (resource-abundant setting)	It is recommended that infants born at more than 36 weeks of gestation with evolving moderate-to-severe hypoxic-ischemic encephalopathy should be offered therapeutic hypothermia under clearly defined protocols similar to those used in published clinical trials and in facilities with the capabilities for multidisciplinary care and longitudinal follow-up.

(NMS). Both MH and NMS are largely iatrogenic and are mostly triggered by modern pharmacologic therapy.¹⁵⁰ There is evidence that MH involves a dose-dependent response, but the minimum dose is unknown.¹⁵⁰ The incidence of hyperthermic conditions induced by psychostimulant drugs of abuse, such as morphine and amphetamine derivatives, continues to increase.¹⁵¹

As with hypothermia, it is important to use the proper thermometer capable of detecting a wide range of body temperatures. Heatstroke remains a common clinical problem with significant morbidity and mortality. A variety of cooling techniques have been advocated since World War II. Although some cooling techniques have been compared in controlled human and animal models of heatstroke, our practice decisions are not based solely on the theoretical rate of cooling. Other important factors include the ease of use, rapidity of initiation, and safety.

Before considering the various cooling techniques, it is essential that the underlying disorders of hyperthermia be clearly understood. Heat illness represents a broad spectrum of disease ranging from mild heat exhaustion to severe heatstroke. The latter includes disorders such as MH and NMS. Treatment of this spectrum of disease requires a discriminating approach, including supportive care only for heat exhaustion and rapid cooling for heatstroke. MH requires specific pharmacologic therapy (e.g., dantrolene), in addition to cooling measures. A brief discussion of hyperthermic disorders is necessary before describing cooling techniques.

Normal Thermoregulation

Body temperature typically follows a diurnal pattern, with an increase from approximately 36°C (96.8°F) in the early morning to 37.5°C (99.5°F) in the late afternoon, and is normally tightly regulated by an effective thermoregulatory system.¹⁵² Heat is produced as a by-product of metabolic processes and when ambient temperature exceeds body temperature. Body temperature increases when the rate of heat production exceeds the rate of heat dissipation. The brain's thermal center is located in the preoptic nucleus of the anterior hypothalamus. In response to rising core temperature, this thermal center activates efferent fibers of the autonomic nervous system to produce vasodilation and increase the rate of sweating. Vasodilation dissipates heat by convection, and sweat dissipates heat by evaporation.

Hyperthermia occurs when the thermoregulatory mechanisms are overwhelmed by excessive metabolic production of heat, excessive environmental heat, or impaired heat dissipation. Different age-related thermoregulation strategies are used when dealing with heat stress. Children have a greater surface area-to-mass ratio and a lower sweating rate and rely more on "dry" heat exchange to dissipate heat. On the contrary, adults use evaporative heat loss as the primary heat dissipation technique. With primary aging, the reflex cutaneous vasoconstriction and vasodilation capabilities are impaired, thereby allowing increased susceptibility to complications from heat-related exposure.¹⁵³ Fever occurs when the hypothalamic

set-point is increased by the action of circulating pyrogenic cytokines, which cause peripheral mechanisms to conserve and generate heat until the body temperature rises to the elevated set-point. Hyperthermia and fever cannot be differentiated clinically on the basis of the magnitude of temperature or on the pattern of its changes.^{154,155}

Types of Hyperthermia

Mild Heat Illness

Heat cramps and heat exhaustion are induced by a hot environment.¹⁵⁶ The body's heat dissipation mechanisms are generally able to keep up with heat production and absorption in these disorders. Symptoms are largely due to the mechanisms used by the body to dissipate heat, and body temperatures remain at or near normal. Rapid cooling techniques are *not* required, and supportive care and hydration in a cool environment are usually adequate therapy.

Heat cramps are intensely painful but generally benign involuntary skeletal muscle spasms. The pain most often occurs in the calf, hamstring, or quadriceps muscles but may also involve the arms and back. The cramps may be severe and prolonged but only rarely lead to rhabdomyolysis. Heat cramps occur after strenuous exercise or heavy labor in a hot environment. Heat cramps were previously thought to be the result of dehydration associated with significant loss of sodium chloride, but some clinical observations have proved that heat cramps can occur at rest or during exercise under any environmental conditions.¹⁵⁷ Resting in a cool environment plus vigorous oral fluid replacement with isotonic solutions is usually adequate therapy, but in some cases IV saline is required.¹⁵⁷ The benefits of oral rehydration over IV hydration directly relate to oropharyngeal stimulation, which influences the release of antidiuretic hormone (arginine vasopressin), cutaneous vasodilation, thirst sensation, and mean arterial pressure.¹⁵⁸ A common mistake is to rely on thirst to indicate dehydration. The pain of severe cramping may be resistant to narcotics in the absence of adequate fluid replacement.

Heat exhaustion, commonly referred to as heat syncope, is a poorly defined syndrome with nonspecific symptoms that occur after heat exposure.¹⁵⁹ Many have suggested replacing the current terminology of heat exhaustion with the term exercise-associated collapse.¹⁶⁰ Malaise, flulike symptoms, orthostasis, dehydration, nausea, headache, and collapse may all occur. Previously it was believed that heat exhaustion is the result of dehydration-induced heat retention that is not severe enough to cause heatstroke.¹⁶¹ There is modern evidence that postural hypotension developing after exercise is the result of exercise-induced changes in blood pressure regulation. These changes involve recalibration of the arterial baroreflex to lower pressures after exercise, impaired sympathetic vascular regulation, and H₁ and H₂ receptor-mediated vasodilation.¹⁶¹ When compared with the more severe heat disorder of heatstroke, mental status is normal and body temperature is normal or mildly elevated with heat exhaustion. There does not appear to be any thermoregulatory failure in persons with heat exhaustion. Rehydration, rest, and supportive care in a cool environment are adequate therapy for heat exhaustion.^{156,157,160} Some authors advocate cooling and placing the patient either in the supine position with the legs elevated or seated with the head between the knees to decrease skin blood flow and increase venous blood flow to the heart.¹⁶¹ Recovery is usually evident within a few minutes to hours. Occasionally, heat exhaustion

is accompanied by heat cramps, thus presenting a confusing scenario if the diagnosis is not suspected. Rapid cooling techniques, IV hydration, and advanced therapies are not usually required, but patients should be observed for progression to heatstroke because heat exhaustion and heatstroke are a continuum of one disease process.^{158,161}

Heatstroke

When the body's normal heat dissipation mechanisms are overwhelmed, core temperature elevation and heatstroke develop rapidly. Heatstroke is a state of thermoregulatory failure.¹⁶¹ Previously, the morbidity and mortality associated with heatstroke were attributed to the magnitude of the hyperthermic response.¹⁶¹ Recent literature has described a more complex interaction between cytokines, coagulation, and the systemic inflammatory response syndrome (SIRS), with endotoxin and cytokines being implicated as key mediators of heat-induced SIRS.¹⁶² Two forms of heatstroke are described in the literature. *Classic (nonexertional) heatstroke* usually occurs during summer heat waves. The poor, urban elderly, infants, homeless, and persons with impaired mobility are at greatest risk.^{163,164} Dehydration, lack of air-conditioning, obesity, neurologic disorders, hyperthyroidism, cardiovascular disease, impaired mentation, and medications that interfere with heat dissipation (e.g., phenothiazines, diuretics, and anticholinergics) predispose this population to heatstroke.^{163,164} *Exertional heatstroke*, a consequence of strenuous physical activity, usually afflicts a younger segment of the population. Highly motivated, poorly acclimatized, or unconditioned athletes and overweight military recruits are common victims, as are individuals who perform heavy physical labor in hot, humid conditions (Fig. 65.7).¹⁶⁵⁻¹⁶⁷ With exertional heatstroke, the risk appears to

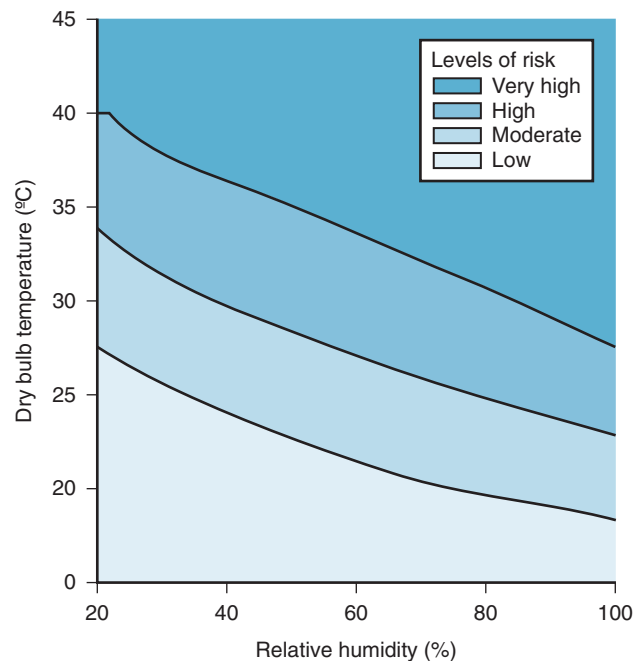

Figure 65.7 Risk for heat exhaustion or heatstroke during intense work in the heat (adjusted to the American College of Sports Medicine position stand: prevention of thermal injuries during distance running²). (Adapted from Epstein Y, Moran D: Environmental aspects of travel medicine. In Keystone JS, Kozarsky P, Freedman DO, et al, editors: *Travel medicine*, ed 3, Philadelphia, 2013, Saunders.)

be greatest in individuals performing high-intensity exercise for relatively short durations.¹⁶⁷ A retrospective review of long-distance cyclists participating in the California AIDS (acquired immunodeficiency disease) Ride found that as the number of chronic medical illnesses increased, so did the risk for development of an exertional heat-related illness. Human immunodeficiency virus seropositivity alone was not associated with an increased risk for exertional heat-related illness.¹⁶⁷

The degree of hyperthermia necessary to produce heatstroke in humans is unknown. In tissue culture cells, thermal injury is observed with temperatures in the range of 40°C to 45°C (104°F to 113°F). Studies of hyperthermia in patients undergoing cancer therapy have revealed that tissue sensitivity to heat is increased by relative hypoxia, ischemia, and acidosis.¹⁶⁸

The key clinical findings in the diagnosis of heatstroke are (1) a history of heat stress or exposure, (2) a rectal temperature higher than 40°C (> 104°F), and (3) central nervous system (CNS) dysfunction (altered mental status, disorientation, stupor, seizures, or coma). The cerebellum is very sensitive to heat, and ataxia may be an early clue. Although anhidrosis is described as a classic sign of heatstroke, investigations have demonstrated that cessation of sweating may be a late finding. Failure to consider the diagnosis of heatstroke in a diaphoretic patient with changes in mental status could prove disastrous.¹⁶⁹

The sequelae of heatstroke are caused by thermal damage to multiple organ systems.¹⁷⁰ Whole-body hyperthermia decreases pulmonary capillary wedge pressure and cerebral vascular conductance and causes an inotropic shift in the Frank-Starling curve.¹⁷¹ After a hyperthermic event, tissue injury continues.^{169,170} Delirium, seizures, and coma can result from the direct effects of heat on the CNS. Autopsies show profound brain edema after hyperthermic insults. Researchers suggest that in cases of instant death, brain edema from the increased permeability of the blood-brain barrier causes raised intracranial pressure and papilledema, followed by vascular infarction and brain herniation.¹⁷² Cardiovascular collapse results from dehydration, maximal cutaneous vasodilation, and direct heat-induced myocardial depression. Coagulopathies and liver dysfunction (elevated levels of bilirubin and transaminases) occur as a consequence of thermal breakdown, consumption of serum proteins, and direct heat damage to hepatic cells. Children often demonstrate diarrhea. Reduced intestinal blood flow causes barrier dysfunction and endotoxemia.^{173,174} Development of an acute abdomen, bloody diarrhea, dilated loops of bowel on radiographic studies, and unexplained shock should raise suspicion for colonic ischemia and pending colonic perforation.¹⁷⁵ Renal failure can result from myoglobinuria (related to rhabdomyolysis) and acute tubular necrosis.¹⁷⁵ Metabolic acidosis is the primary acid-base alteration observed in patients with heatstroke, with the prevalence increasing with the degree of hyperthermia.¹⁷⁶

Treatment of these sequelae of acute heatstroke does not differ from that of other heat-related disorders, with the sole exception that rapid cooling is necessary to prevent further damage and reverse the heat stress. The more rapidly that rectal temperature is reduced to 38°C (100.4°F), the better the prognosis.¹⁶³ The human body tolerates hyperthermia poorly. Unlike patients with hypothermia, in whom slow, gentle rewarming and supportive care often result in a favorable outcome, victims of severe heatstroke must be treated aggressively with measures designed to rapidly lower core temperature. Studies investigating precooling techniques to avoid heatstroke have been relatively unsuccessful in attenuating increases in

core body temperature, and such techniques are not recommended.¹⁷⁷ In contrast, whole-body precooling increases overall exercise endurance.¹⁷⁸

Malignant Hypertension (MH)

MH is a pharmacogenetic disease attributable to a medication that triggers a life-threatening, hypermetabolic syndrome.¹⁷⁹ It results from a rare inherited autosomal dominant abnormality in the skeletal muscle membrane and has an incidence of 1 in 50,000 in adults.¹⁵¹ In response to certain stresses or drugs (Box 65.1), patients with this disorder sustain a potentially lethal hypermetabolic reaction with massive efflux of calcium from the skeletal muscle sarcoplasmic reticulum. This results in contraction of the sarcomeres, skeletal muscle rigidity, increased skeletal muscle metabolism, elevated serum creatine kinase levels, heat production, and finally, systemic hyperthermia.^{180,181} Hyperthermia is a late development and occurs after rigidity has been present for some time and the body's normal heat dissipation mechanisms are overwhelmed. The earliest signs of MH are increased carbon dioxide production, muscle rigidity, and tachycardia.¹⁸² Cardiac output and cutaneous blood flow also increase to maximize the heat loss. Diagnosis of MH is based on the clinical triad of (1) exposure to an agent or stress known to trigger the condition, (2) skeletal muscle rigidity, and (3) hyperthermia.

MH is usually encountered in the operating room while patients are undergoing general anesthesia, particularly with halogenated inhalational agents and depolarizing muscle relaxants. Heat production in anesthetized patients can be profound with as much as a fivefold increase in oxygen consumption.¹⁸¹ Cases of MH may be encountered anywhere that general anesthetics or neuromuscular blocking agents are used.^{181,182} A massive increase in creatine kinase is a strong indicator of an MH reaction.¹⁷⁹

As with heatstroke, treatment of MH requires rapid cooling and supportive care for the sequelae described previously. Unlike heatstroke, MH requires specific pharmacologic therapy to stop excessive heat production by skeletal muscle. Dantrolene sodium induces muscle relaxation in patients with MH by blocking release of calcium from the muscle cell sarcoplasmic reticulum.¹⁸³ In all cases of MH, the inciting stimulus should be discontinued immediately and dantrolene therapy administered. A dantrolene bolus of 2.5 mg/kg should be started and repeated at 5-min intervals until normalization of the hypermetabolic state is achieved and all MH symptoms disappear.¹⁸³

BOX 65.1 Triggers of MH

DRUGS

Halothane
Methoxyflurane
Enflurane

Chloroform
Gallamine
Nitrous oxide

CONDITIONS

Heat stress
Vigorous exercise
Emotional stress

MH, Malignant hyperthermia.

Procainamide has been used successfully when dantrolene is unavailable.¹⁸³

It has been suggested that dantrolene administration speeds cooling of heatstroke victims by reducing skeletal muscle heat production.¹⁸³ A randomized, controlled trial of the use of dantrolene for heatstroke found no difference between the treatment and placebo groups in terms of cooling time, complications, or length of stay.¹⁸⁴ In 2005, a meta-analysis concluded that there was no role for the use of dantrolene in the management of heatstroke.¹⁸⁵ Currently, dantrolene administration is best reserved for patients with clinical muscle rigidity or suspected MH. Routine use of this drug in heatstroke patients is not recommended.¹⁸⁵ New and promising treatments of MH are being investigated. Researchers have discovered mutations in the gene coding for the ryanodine receptor calcium release channel (RyR1) in families with MH, which may be the functional basis for MH. Some studies have examined the effects of MH mutations on the sensitivity of the RyR1 to drugs and endogenous channel effectors, including Ca^{2+} and calmodulin.¹⁸⁶

Neuroleptic Malignant Syndrome (NMS)

First described in the late 1960s, NMS is characterized by hyperthermia, muscle rigidity, altered level of consciousness, and autonomic instability.¹⁸⁷ Mortality from NMS is estimated to be 20% in patients in whom the condition develops.^{187,188} This idiosyncratic disorder follows the therapeutic use of neuroleptic drugs, including phenothiazines, butyrophenones, thioxanthenes, lithium, and tricyclic antidepressants. The reaction is triggered by blockage of dopaminergic receptors and results in skeletal muscle spasticity, which generates excessive heat and impairs hypothalamic thermoregulation and heat dissipation.¹⁸⁸ Muscle rigidity, described as “lead pipe” rigidity in its most severe form,¹⁸⁸ can be manifested as oculogyric crisis, dyskinesia, akinesia, dysphagia, dysarthria, or opisthotonos. NMS occurs in 0.2% of patients who take neuroleptic agents either chronically or acutely. Haloperidol and depot fluphenazine appear to be the most common offending agents.¹⁸⁷ Temperatures can exceed 42°C (107.6°F). The initial agitation often progresses to stupor and coma. Catatonia and mutism may also be present. Autonomic instability is manifested as tachycardia, labile blood pressure, sweating, and incontinence. Ventilations are impaired by the chest wall rigidity.

This syndrome is more likely to occur at the initiation of or after an increase in neuroleptic dosage. Researchers suggest that NMS typically occurs over a period of several days (average in patients taking neuroleptic agents). It may also occur if the use of antiparkinsonian drugs is suddenly discontinued.¹⁸⁸⁻¹⁹¹ NMS resembles MH but usually lasts longer (5 to 10 days) after use of the inciting drug is discontinued. The syndrome may be misinterpreted as worsening of an underlying psychiatric disorder, drug intoxication (e.g., cocaine and amphetamines), a severe dystonic reaction, tetanus, or a variety of CNS infections. In addition to agents with increased dopaminergic blocking activity, other risk factors for NMS include dehydration, previous history of dystonia, catatonia, agitation, and iron deficiency.¹⁹¹ The mortality rate is high, and respiratory failure, renal failure, cardiovascular collapse, or thromboembolic disease usually causes death.¹⁹²

Treatment of severe NMS (i.e., hypotension, hyperthermia, marked rigidity) closely follows that of MH, except that therapy must be maintained for several days until the symptoms resolve. Therapy for NMS involves discontinuation of the triggering

agent; rapid cooling; benzodiazepines; a combination of a central dopamine agonist, bromocriptine, or levodopa; dantrolene; and supportive treatment of the ensuing organ failure.¹⁹¹ Although the effects are not immediate, pharmaceutical therapy is directed at overriding the dopaminergic blockade caused by the offending neuroleptic agent or the dopamine depletion resulting from the cessation of antiparkinsonian medications. There are reports of successful treatment of NMS with subcutaneous apomorphine monotherapy or high-dose lorazepam and diazepam.^{192,193} As with MH, dantrolene (2.5 mg/kg) can be given to treat NMS-induced muscle rigidity.¹⁸⁹ The beneficial response stems not only from effects at the sarcoplasmic reticulum of skeletal muscle but also from central dopamine metabolism of calcium in the CNS. Bromocriptine, a central dopamine agonist, is reported to be efficacious in treating NMS at doses of 2.5 to 10 mg three times a day.¹⁹³ Although both these agents have been noted to reduce the duration of hyperthermia, there have been mixed results with the use of bromocriptine and dantrolene.^{190,193}

A more recently described disorder often confused with NMS is *serotonin syndrome*.¹⁹⁴ This syndrome involves the newer antidepressants fluoxetine, paroxetine, citalopram, fluvoxamine, venlafaxine, and sertraline,¹⁹⁴ which are selective serotonin reuptake inhibitors. These drugs can adversely react with other stronger serotonin receptor agents such as monoamine oxidase inhibitors and nonselective serotonin reuptake inhibitors (clomipramine and tricyclic antidepressants) to induce a clinical picture similar to that of NMS, only milder. Serotonin syndrome classically occurs when two or more drugs that interfere with serotonin metabolism act synergistically on the 5-HT_{1A} receptor and lead to overstimulation.^{190,194} Drugs that act at any of the other serotonin receptors are not likely to produce the syndrome.¹⁹⁴ The range of symptoms varies from mild gastrointestinal upset, insomnia, and agitation to more severe symptoms that include muscle spasms, seizures, ataxia, rhabdomyolysis, and autonomic instability. Treatment is primarily supportive in milder cases and consists of prompt recognition and withdrawal of the offending agent. Adequate sedation, usually with benzodiazepines, is essential in controlling serotonin syndrome. Most cases resolve spontaneously within 24 hours. For the most severe cases, aggressive intensive care unit management is warranted to prevent renal failure and death.

The drug cyproheptadine (Periactin, TEVA Pharmaceuticals USA, Sellersville, PA) has shown promise in managing the agitation often seen in severe cases.^{190,194} Cyproheptadine is an antihistamine with antiserotonergic properties. Cyproheptadine is available in 4-mg tablets or 2-mg/5 mL syrup. When administered as an antidote for serotonin syndrome, an initial dose of 12 mg is recommended, followed by 2 mg every 2 hours until clinical response is seen. Cyproheptadine is only available in an oral form, but it may be crushed and given through a nasogastric or orogastric tube. There has been limited success with benzodiazepines and β -blockers to treat agitation in these patients.¹⁹⁴ In cases in which serotonin syndrome and NMS cannot be differentiated, benzodiazepines represent the safest therapeutic option.¹⁹⁰ Further study of the newer antipsychotic drugs, such as ziprasidone, a powerful 5-HT_{1A} receptor blocker, may delineate other possible benefits.¹⁹⁴

Hyperthermia and Psychostimulant Overdose

As mentioned previously, the recognized incidence of hyperthermia induced by sympathomimetic psychostimulant drugs of abuse is on the rise. The offending agents most commonly described are

cocaine, phencyclidine, amphetamine, and amphetamine derivatives such as 3,4-methylenedioxy-*N*-methamphetamine (MDMA) (“ecstasy”) and 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA) (“Eve”).^{195,196} A number of studies have looked specifically at the club drug MDMA and its impairment of heat dissipation.^{195,196} Animal studies in rats suggest that MDMA-induced hyperthermia results not from MDMA-induced release of 5-HT but from increased release of dopamine acting at D₁ receptors, thus suggesting a future role for the use of dopamine antagonists in clinical treatment.¹⁹⁷

Hyperthermia is a common feature of these potentially severe to lethal poisonings with sympathomimetic psychostimulant drugs and may be the primary cause of fatality or MDMA-induced neurotoxicity.¹⁹⁶ Because of the nonlinear pharmacokinetics of MDMA and γ -hydroxybutyrate, it is difficult to estimate a dose-response relationship.¹⁹⁶ Some have applied a pathophysiologic model of exertional heatstroke or NMS to profound cocaine intoxication.¹⁹⁷ In addition to profound hyperthermia (> 42°C [$> 107.6^\circ\text{F}$]), acute rhabdomyolysis, disseminated intravascular coagulation, psychiatric and cognitive dysfunction, renal failure, coma, seizures, and death have been described in these patients.^{198–201} As demonstrated by Roberts and associates,²⁰⁰ even a patient with a core temperature of 45.5°C (114°F) because of acute cocaine intoxication may survive with aggressive cooling methods. Treatment requires prompt recognition, maintenance of adequate hydration, rapid cooling, and the aggressive use of sedatives or paralyzing agents (or both) to control agitation. Importantly, the longer that psychostimulant-overdosed patients remain hyperthermic, the higher their morbidity and mortality rates. Agitation and seizures must be chemically controlled because they lead to continued generation of heat and muscle injury. Therefore liberal doses of benzodiazepines are recommended.²⁰⁰ Some have advocated the use of bromocriptine and dantrolene as for MH and NMS, but their efficacy in the setting of drug-associated hyperthermia remains controversial.^{201,202}

Hemorrhagic Shock and Encephalopathy Syndrome

The condition of hemorrhagic shock and encephalopathy syndrome in children (mainly infants, but some older children also) resembles heatstroke in adults. The full-blown syndrome includes hyperthermia, coagulopathy, encephalopathy, and renal and hepatic dysfunction.²⁰³ Although there may be an association with concurrent viral illness, the condition generally follows an elevation in temperature, which may be triggered by “bundling” of a child with a low-grade fever. Therapy is largely supportive and includes volume replacement with rapid cooling of the hyperthermic child while sources of bacterial infection are sought and treated.

Cooling Techniques

General Considerations

Heatstroke mortality is proportional to the magnitude and duration of thermal stress measured in degree-minutes.²⁰⁴ Delay in cooling may be the single most important factor leading to death or residual disability in those who survive.¹⁵⁶ In addition, advanced age and underlying disease states are significant contributing factors.^{157,158,163,164}

Many exertional heatstroke victims are volume-depleted and may exhibit hypotension. Initial stabilization with cooled (room-temperature) IV fluids and correction of electrolyte abnormalities are valuable in hypotensive patients. Traditional

sources recommend a rate of 1200 mL over the first 4 hours.²⁰⁵ Others advise a 2-L bolus over the first hour, with an additional 1 L/hr for the following 3 hours.²⁰⁶ Seraj and coworkers challenged this more aggressive recommendation.²⁰⁷ In their study of pilgrims who suffered heatstroke, 65% had normal or above normal central venous pressure (CVP) on arrival. These authors found that an average of 1 L of saline was sufficient to normalize CVP during the cooling period in their patients, who had a mean age of 55 years (range, 31 to 80 years). In older patients, fluid resuscitation should be monitored carefully to avoid pulmonary edema. Regarding antipyretics, there is no indication for either salicylates or acetaminophen in the setting of heatstroke because their efficacy depends on a normally functioning hypothalamus. Overzealous use of acetaminophen could potentiate hepatic damage, and salicylates may promote bleeding tendencies.²⁰⁸ A study comparing acetaminophen and physical cooling methods found that in patients treated with antipyretics only, mean body temperature increased by 0.2°C (32.4°F) on average.²⁰⁹

Given that rapid cooling is accepted as the cornerstone of effective heatstroke therapy, the clinician must choose which cooling technique to use. Studies in animal models are based on the assumption that the fastest cooling technique is the best. In clinical patient care, other factors also influence the choice of technique. Patient access, monitoring, safety, ease of use, availability, and speed are all considerations.²¹⁰ A technique that may not be the most rapid but allows easy patient access and is readily available may be preferable to more cumbersome (albeit more rapid once established) cooling techniques in some clinical settings.

The cooling rates achieved in various human and animal studies of heatstroke are summarized in [Table 65.6](#).^{211–225} The advantages and disadvantages of various cooling techniques are outlined in [Table 65.7](#).

In addition to the cooling procedures outlined, it is imperative that the clinician institute the judicious use of sedation, muscle paralysis, or both to control agitation, suppress shivering, reduce energy expenditure, and make the patient receptive to sometimes unpleasant therapies.²²⁶ In general, IV benzodiazepines are the easiest and safest first-line drugs used for sedation.

Indications for Rapid Cooling

Rapid cooling should be instituted as soon as the diagnosis of heatstroke (rectal temperature > 40°C [104°F], altered mental status, history of heat stress or exposure) is made. Rapid cooling is also indicated for the treatment of MH and NMS but should be instituted concurrently with discontinuation of the triggering agent or drug and administration of dantrolene. Because studies show that the degree of organ damage correlates with the degree and duration of temperature elevation above 40°C (>104°F), a reasonable clinical goal is to reduce the temperature to below 40°C (< 104°F) within 30 minutes to an hour after the start of therapy.^{157,226}

Contraindications to Rapid Cooling

Rapid cooling is never contraindicated in patients with heatstroke. Immersion cooling is relatively contraindicated when cardiac monitoring of an unstable patient is required or when limited personnel make constant patient supervision impossible. Iced gastric lavage is contraindicated in patients with depressed airway reflexes unless the airway is protected by ET intubation. Gastric lavage is also contraindicated by conditions that preclude

placement of an orogastric or nasogastric tube. Cold peritoneal lavage is relatively contraindicated when multiple previous abdominal surgeries make placement of a lavage catheter risky.

Evaporative Cooling

Evaporating water is thermodynamically a much more effective cooling medium than melting ice, given an appropriate water-vapor gradient. Evaporating 1 g of water requires 540 kcal. Melting 1 g of ice requires only 80 kcal. In theory, evaporative cooling should be approximately seven times more efficient than ice packing. In practice, evaporative cooling is more efficient. In separate human studies, Weiner and Khogali and Wyndham and colleagues found that evaporative cooling rates were substantially greater than cooling rates with water immersion at 14.4°C (57.9°F).^{212,214} Studies in primate models demonstrated faster cooling rates with evaporative cooling as an adjunct to ice bag placement.²²⁷ Methods using convection and evaporation were more effective than those involving conduction for the treatment of hyperthermia. In clinical practice, ice water immersion or ice packing causes heat loss by conduction and heat consumption by the phase change of melting ice. In healthy volunteers, evaporative cooling techniques (e.g., facial fanning) were associated with decreased thermal sensation and improved thermal comfort.²²⁷

Despite the continued enthusiasm of some clinicians for ice water immersion, evaporative cooling has been an effective noninvasive cooling technique in human studies.^{226,228} To maximize evaporative cooling rates, several factors must be optimized. Airflow rates must be high and therefore large fans are required. The air must be warm but *not* humid because evaporation is decreased at lower temperatures. The entire body surface must be exposed to airflow and continuously moistened with water. Ideally, the patient is suspended in a mesh sling to expose the back to airflow and moisture. Finally, the temperature of the water used to moisten the skin must be tepid (15°C [59°F]). Warm forced air is essential for effective evaporation. It maintains good peripheral perfusion and prevents shivering by warming the skin.²²⁸ If the water is ice cold, evaporation will be slowed. Conversely, if it is hot, conductive heat gain may occur. Studies conducted in heat-stressed laying hens demonstrated superior cooling rates with ventral cooling regimes over dorsal cooling.²²⁹

Weiner and Khogali constructed a sophisticated “body cooling unit” (BCU) to maximize evaporative cooling.²¹² Patients in the BCU are suspended in a mesh net. High airflow rates (30 m/min) at a temperature of 45°C (113°F) are maintained both anterior and posterior to the mesh net. Atomized water at 15°C (59°F) is continuously sprayed on all body surfaces.

TABLE 65.7 Advantages and Disadvantages of Various Cooling Techniques

TECHNIQUE	ADVANTAGES	DISADVANTAGES
Evaporative	Simple Readily available Noninvasive Easy monitoring and patient access Relatively fast	Constant moistening of skin required
Immersion	Noninvasive Relatively fast Low mortality rates	Cumbersome Patient access and monitoring difficult Shivering Poorly tolerated by conscious patients
Ice packing	Noninvasive Readily available	Shivering Poorly tolerated by conscious patients
Strategic ice packs	Noninvasive Readily available Can be combined with other techniques	Relatively slower cooling Shivering Poorly tolerated by conscious patients
Cold gastric lavage	Can be combined with other techniques	Relatively slower cooling Invasive Requires airway control Human experience limited
Cold peritoneal lavage	Rapid cooling	Invasive Human experience limited

For EDs without access to a BCU,²³⁰ temporary units can be set up with shower sprays and fans, provided that the ambient temperature in the ED is relatively cool. An alternative less expensive, portable device developed at King Saud University involves covering the patient with a gauze sheet soaked in water at 20°C (68°F) while two fans direct room air over the patient.²³¹ Cooling rates obtained with this device (0.087°C/min [32.2°F/min]) were nearly double the cooling rates achieved with the original BCU developed by Weiner and Khogali.²¹²

The realities of clinical practice make these conditions hard to reproduce. Half the body surface, the back, will usually be unavailable for evaporative cooling. Airflow rates and temperatures are usually limited by the ambient temperature in the treatment facility and by the size and power of the fan available. These realities are reflected by the slower cooling rates achieved with evaporative cooling in a clinical setting.

Procedure

For evaporative cooling, undress the patient completely. Position a fan at the foot of the bed or stretcher, as close to the patient as possible. Then sponge or mist the patient's skin with tepid water (15°C [59°F]). Spray water continuously over the skin to create a warm microclimate around the skin and to promote water evaporation.²³² A single care provider can continue the technique and monitor the patient once cooling has been initiated. It is important to keep as much of the body surface area as moist as possible and exposed to airflow. Do not cover with sheets or clothing because this will impede skin evaporation and cooling. Studies of evaporative cooling in heatstroke patients show cooling rates of 0.046°C/min to 0.34°C/min (32.1°F/min to 32.6°F/min).^{228,232}

Complications

Complications of evaporative cooling are rare and more often a result of the underlying disorder than the cooling technique. Wet skin may interfere with electrocardiographic monitoring, but this can usually be avoided by placing electrodes on the patient's back. Shivering occurs infrequently with this technique when compared with other cooling methods because the water is relatively lukewarm.²³³ Because rectal temperature lags behind core (esophageal) temperature, evaporative cooling should be discontinued when rectal temperature reaches 39°C (102.2°F). In cases of mild hyperthermia, tympanic temperature also accurately reflects core temperature and can be useful in this setting.²³³ Continued cooling beyond this temperature may lead to subsequent "overshoot hypothermia" as a result of a continued drop in core temperature after active evaporative cooling is discontinued. Shivering indicates that core temperature has decreased to 37°C (89.6°F) or below.²³³

Immersion Cooling

It would seem obvious that the fastest way to cool a heatstroke patient would be immersion in ice water. In a case series of exertional heatstroke patients, iced water immersion cooled patients to lower than 39°C (< 102.2°F) within 19.2 minutes.²²⁶ A 2010 study found that cold water immersion for 9 minutes in a 2.0°C circulated water bath until a rectal temperature of 38.6°C was achieved avoided any risk associated with overcooling.²³⁴ Some contemporary sources recommend ice water immersion as the cooling technique of choice for heatstroke.^{226,235} Plattner and associates demonstrated cooling rates with ice water immersion that were six times faster than rates seen with forced air or circulating water.²³⁶

Costrini reported no fatalities in 252 consecutive young marine recruits with exertional heatstroke who were treated by ice water immersion within 20 minutes of diagnosis.²¹⁸ He regarded ice water immersion as superior to other conventional methods described in the literature in reducing mortality rates.

In clinical trials, cold water immersion remains one of the fastest noninvasive cooling techniques available (see Table 65.6). Cold water immersion takes advantage of the high-conductance property of water, which is 25 times that of air.²³⁵ When an adequate evaporative cooling system is not available, immersion may be the cooling technique of choice. Several factors are important in maximizing the rate of immersion cooling. Conductive heat loss depends on cutaneous blood flow to maintain a heat gradient from skin to water. Theoretically, contact with ice water causes skin and subcutaneous vasoconstriction, which blocks heat exchange and turns these structures into insulators.²³⁷ Intense cutaneous vasoconstriction will impede conductive heat loss. Mekjavic and coworkers reported that motion sickness actually potentiates core cooling during immersion by attenuating the vasoconstrictor response to skin and core cooling, thereby augmenting heat loss and the magnitude of the decrease in deep body temperature.²³⁸ Careful monitoring is required because this may predispose patients to hypothermia.

Researchers have suggested that ice water immersion may be superior to cold water immersion because of the establishment of a steeper thermal gradient between the skin and the environment.²³⁷ A study comparing the cooling capacity of ice water immersion (5.2°C [41.4°F]), tepid water immersion (14°C [57.2°F]), and passive cooling in experienced distance runners with body temperatures of 39.3°C to 39.6°C (102.7°F to 103.3°F) found comparable cooling rates with ice water and cold water immersion. Both techniques were superior to passive cooling techniques.²³⁷ The optimal water temperature for cooling human heatstroke patients has not been defined. Aggressive skin cooling may stimulate shivering and peripheral vasoconstriction, thus hindering cooling efficacy. Investigators suggest the inclusion of skin massage as a crucial component of immersion cooling techniques.²³⁹

Regardless of the water temperature, it is clear that increasing surface area increases conductive heat loss. Maximizing the body's surface area in contact with water will increase cooling rates with immersion cooling. In clinical practice, this means that complete immersion of the trunk and extremities will cool the patient faster than partial immersion of the trunk (back only) with the extremities extended out of the bath.

Procedure

For immersion cooling, undress the patient completely and transfer the patient to a tub of water with a depth sufficient to cover the torso and extremities. Various water containers may be used. A regular bathtub can be used. Most clinical reports describe tubs that can be moved to the emergency treatment area when needed. A child's plastic wading pool and a decontamination tub or stretcher with waterproof sides and drainage capability are examples of the latter approach. Support the patient's head out of the tub at all times. When tubs are unavailable, place patients on water-impermeable sheets and in a sling apparatus while ice and water are poured into the sling. Securely attach temperature and electrocardiogram leads to the patient if monitoring is to be continued during immersion. Remove the patient from the bath when rectal temperature reaches 39°C (102.2°F) because core temperature

will continue to drop for a short period even after the patient is removed. If available, use an electronic temperature monitor with a long flexible rectal probe for continuous monitoring of temperature during immersion. Studies show cooling rates with ice water immersion (1°C–5°C [33.8°F–41.0°F]) in heatstroke patients of 0.15°C/min to 0.23°C/min (32.3°F/min to 32.4°F/min).^{218,235,239}

Complications

The common complications of immersion cooling are shivering, cutaneous vasoconstriction, discomfort, and loss of monitoring capability. Shivering generates considerable heat through muscle metabolism. Cutaneous vasoconstriction impedes conductive heat loss. If significant shivering does occur, it can be reduced with benzodiazepines. A 2009 study found that high-dose IV diazepam facilitates core cooling during cold saline infusion in healthy volunteers. Subjects were randomized to receive high-dose (20-mg) or low-dose (10-mg) diazepam or placebo during cold saline infusion. Administration of high-dose diazepam decreased the shivering threshold without compromising respiratory or cardiovascular status.²⁴⁰ The use of phenothiazines such as chlorpromazine has been advocated for shivering in the past. They are currently discouraged because administration of these agents may impair heat loss through anticholinergic effects on sweat glands, contribute to hypotension via α -adrenergic blockade, lower the seizure threshold, and cause dystonic reactions. In addition, phenothiazines possess central dopamine-blocking effects, which may exacerbate symptoms of NMS.¹⁸⁷ Benzodiazepines are also valuable if the patient is hyperthermic secondary to sympathomimetic agents such as cocaine. Patient monitoring is a problem under water. Electrodes can be used on the nonimmersed upper part of the shoulders, but electrocardiographic artifact often becomes a major problem during vigorous shivering. Immersion cooling is not recommended for patients with unstable cardiac rhythms or those at risk for the development of these rhythms. A significant change in cardiac rhythm might go undetected during the labor-intensive process of immersion cooling.

Patient access for resuscitative procedures is also a major problem when using this technique. Should ventricular fibrillation develop, the patient must be removed from the bath and dried before defibrillation. Invasive and diagnostic procedures (e.g., IV access and radiography) cannot be performed during the cooling period. Care must be taken to avoid displacement of IV lines during placement into and removal from the bath.

As body temperature drops, mental status will improve in many heatstroke victims. When awake, most people find ice water immersion difficult to tolerate. IV sedation may be required. Finally, this technique is labor-intensive. Several caregivers must be present throughout the process. The patient's head must be maintained out of the bath. If massage is used, one or more individuals will need to immerse their own hands in water to continuously massage the patient. Medications should be given intravenously, and constant attention to temperature and electrocardiogram monitors is also necessary. This cooling technique should be used only if adequate personnel are available.

Whole-Body Ice Packing

Packing a heatstroke victim in ice may enhance conductive heat loss without the attendant logistic problems caused by water immersion (Figs. 65.8 and 65.9). Constant attendance,

Figure 65.8 It is essential to rapidly lower the core temperature of a severely hyperthermic patient by instituting cooling techniques as soon as possible. Evaporative cooling (see text) is usually quite effective and technically easy. Note the fan for additional cooling. Many such patients require sedation, paralysis, and mechanical ventilation. An alternative aggressive method shown here, in a patient with a rectal temperature of 110°F, is to literally pack the patient in ice. As is often the case, this older patient did not survive.

Figure 65.9 A body bag or plastic sheets may keep water from flooding the floor when packing the patient in ice.

as required for skin moistening with evaporative cooling and as described for immersion cooling, may not be necessary with ice packing. Kielblock and associates demonstrated in a human study of mild, exercise-induced hyperthermia that whole-body ice packing cooled just as fast as evaporative cooling did (see [Table 65.6](#)).²¹³

Procedure

For whole-body ice packing, undress the patient completely and then cover the extremities and torso with crushed ice. A fan blown over the patient may increase cooling. As with any cooling technique, monitor the patient's temperature constantly with an electric thermometer and a long, flexible rectal probe. A large supply of crushed ice will be needed whenever this technique is used. Logistically, ice packing may be problematic. Whole-body ice packing can usually be performed on an ED stretcher without additional equipment. Ideally, the patient is placed in a container that facilitates contact of ice with the skin and prevents water from dripping onto the floor. A body

bag makes an ideal device. Iced cooling may also be accomplished by placing the patient in a child's lightweight plastic pool, available in toy stores. Lacking this equipment, plastic cloths or trash bags may be placed under the patient with the edges curled up to form a slinglike apparatus. As with immersion cooling, electrocardiographic monitoring can potentially be difficult because of shivering artifact and displacement of electrodes. If the patient is alert and cannot tolerate the ice packing, use IV sedation or restraint. Treat excessive shivering with benzodiazepines if needed. Once rectal temperature reaches 39°C (102.2°F), remove the ice and dry the patient off. Studies show cooling rates of 0.34°C/min (32.6°F/min) in heatstroke patients with whole-body ice packing.^{213,235}

Strategic Ice Packs

Noakes suggested that strategic placement of ice packs over areas of the body where large blood vessels run close to the skin may be an effective cooling technique.²⁴¹ Cooling in these areas occurs despite cutaneous vasoconstriction because of direct conductive heat loss from blood within the vessel and across the vessel wall, subcutaneous tissue, and skin to ice. The most common areas used for strategic ice packing are the anterior aspect of the neck (carotid and jugular vessels), the axilla (axillary artery and vein), and the groin (femoral vessels). There have been numerous reports of successful cooling using ice packs as primary or adjunctive therapy (see [Table 65.6](#)).^{241,242} In addition, application of ice packs, though easier to perform than immersion or total-body ice packing, limits the conductive cooling offered by the latter two procedures. A study in pigtail monkeys demonstrated that a combination of strategic ice packs with evaporative cooling results in faster cooling than either technique alone, although the relative increase achieved by adding ice packs to evaporative cooling was small.²⁴³

In unconscious patients or in awake patients who can tolerate ice packs without excessive shivering, this technique could be added to evaporative cooling. Kielblock and associates found that the combination of strategic ice packs and evaporative cooling yielded higher cooling rates than did either method individually (0.036°C/min vs. 0.027°C/min and 0.034°C/min).²¹³ The clinical value of strategic ice packs alone or in combination with other techniques remains to be determined. Anecdotally, during the Chicago heat wave of 1995, the majority of heatstroke patients who went to EDs survived after being effectively cooled with the evaporation method accompanied by strategic placement of ice packs.²⁴⁴

Procedure

Place large plastic bags filled with crushed ice or an ice and water mixture in both axillae and over both femoral triangles. If the neck is used, place the packs laterally so that they do not compress the trachea or apply excessive weight over the carotid arteries. Do not pack the neck if the patient has carotid bruits or a history of cerebrovascular disease. Some sources advocate rubbing the body surface briskly with plastic bags containing ice after the body has been wet down with water. This is effective, provided that it is combined with evaporation therapy. Studies show ranges of cooling rates of 0.028°C/min to 0.087°C/min (32.0°F/min to 32.2°F/min) in heatstroke patients with strategic ice packs.²⁴⁵

Complications

Complications of strategic ice packing are limited to shivering and patient discomfort, as described previously for whole-body

ice packing. The ice packs are removed when rectal temperature reaches 39°C (102.2°F) to avoid an excessive drop in core temperature.

External Versus Core Cooling

All the external cooling techniques described previously are noninvasive and involve heat loss by evaporation or conduction across the skin as the primary cooling mechanism. With each of these techniques, central temperature will continue to drop even after the technique is discontinued and the skin is dried. This is due to a delay in establishment of an equilibrium between the cold skin and the core. The amount of “core afterdrop” can exceed 2°C (> 35.6°F).^{228,230,245} For this reason, cooling is discontinued when the core temperature reaches 39°C (102.2°F).

Because the sites of significant cell damage with heatstroke are centrally located (e.g., liver, kidney, heart), central cooling techniques are theoretically preferable to external techniques. Core cooling techniques studied in both animal and human models include iced gastric lavage, intravascular cooling, bladder lavage, and peritoneal lavage.^{220–222,224,246,247} Central venous cooling is effective in rapidly decreasing core temperatures.²⁴⁶ Studies conducted in healthy volunteers have demonstrated that reductions in core temperature vary according to the temperature of the infused fluid. Subjects receiving 30-minute infusions of fluid at 4°C (39.2°F) experienced decreases in core temperature of 2.5°C ± 0.4°C (36.5°F ± 32.7°F). Subjects receiving 30-minute infusions of fluid at 20°C (68°F) experienced decreases of 1.4°C (±0.2°C [34.5°F ± 32.4°F]).²⁴⁶ Clinical trials investigating this method showed that cooling via the respiratory tract had no significant impact on temperature changes when used exclusively but did demonstrate effectiveness as an adjunctive measure to other external cooling techniques.²³⁵ Cool air (10°C [50°F]) was administered via a hood or mask. Cooling via the respiratory tract has been studied in animals but not investigated clinically.^{248–250} Central cooling techniques are necessarily more invasive than external techniques and have the potential for more significant complications.

Cold Gastric Lavage

The stomach lies in close proximity to the liver, great vessels, kidneys, and heart. The gastric mucosa is not subject to the intense vasoconstriction observed on exposure of the skin to ice water.²²⁰ For these reasons, lavage of the stomach might be expected to be an effective central cooling method. Studies of cold gastric lavage in a canine model produced cooling rates five times greater than in controls exposed to ambient air at room temperature (0.15°C/min vs. 0.03°C/min).²²¹ Human heatstroke victims have been cooled successfully with gastric lavage, but only in combination with external techniques.²²² Cold gastric lavage seems to be best suited for use in patients with severe hyperthermia who are cooled at a slow rate with external techniques alone. The presence of an ET tube and passage of a large-bore gastric tube make rapid lavage without aspiration possible. This technique should be reserved for patients whose airway is protected by ET intubation and who do not have a contraindication to gastric tube placement.

Procedure

For cold gastric lavage, instill 10 mL/kg of iced tap water into the stomach as rapidly as possible (usually over a 30- to

60-second period). After a 30- to 60-second dwell time, remove the water by suction or gravity.²²⁵ Cooling will theoretically be faster if a high temperature gradient is maintained in the stomach. A faster lavage rate can be maintained if suction is used to withdraw the instilled fluid. A large container of ice-temperature water maintained 1 to 1.5 m above the patient's body will facilitate the instillation of fluid. Connect this container directly to the lavage tubing and ideally allow passage of water but not ice, which may occlude the tube. Because large volumes of water are needed, it is helpful if additional ice can be added to the container without interrupting the lavage. A large syringe can be used as an alternative to gravity instillation, but this is usually slower.

A simple system that accomplishes this procedure can be devised from equipment readily available in most EDs. Use a standard lavage setup (for use in drug overdoses) and a large-bore gastric tube. Cut the lavage bag open at the top to allow water and ice to be added. Suspend this bag above the patient's body and connect it to the orogastric tube by Y tubing with clamps. Connect the other arm of the Y tubing to suction. Using the clamps, intermittently instill ice water by gravity and withdraw it by suction.

Complications

A major potential complication of cold gastric lavage is pulmonary aspiration. Use of a cuffed ET tube minimizes the incidence of this complication. Because of the large volume of water used and the frequent depression of airway reflexes seen with severe heatstroke, this technique should rarely be used in a patient who is not endotracheally intubated.

If tap water is used, water intoxication, hyponatremia, and other electrolyte disturbances are *potential* complications, particularly in pediatric or geriatric patients. Water is absorbed from the stomach and, with large-volume lavage, may pass the pylorus into the small intestine. In canine studies, large-volume gastric lavage with tap water did not cause electrolyte abnormalities.²²⁰ The actual incidence of these potential complications in human heatstroke has not been determined. Use of normal saline instead of tap water would eliminate this potential problem.

Theoretically, passage of cold water through the esophagus, located directly behind the heart, has the potential to induce cardiac dysrhythmias. Dysrhythmias have not been observed in canine studies or in case reports of human heatstroke victims cooled with this technique.^{224,247}

Cold Peritoneal Lavage

The surface area and blood flow of the peritoneum greatly exceed those of the stomach. Peritoneal lavage is expected to exchange heat much faster than possible with gastric lavage. Peritoneal lavage achieves some of the fastest cooling rates ever reported in large animal or human studies (see [Table 65.6](#)). A case report of cooling via cold peritoneal lavage for hyperthermia after the ingestion of ecstasy demonstrated rapid cooling.²⁴⁷ As with gastric lavage, this central cooling technique offers the advantage of directly cooling the core organs that are most susceptible to thermal damage. Unlike gastric lavage, ET intubation is not required. Peritoneal lavage is used extensively to treat hyperthermia under various conditions and typically decreases core temperatures 5°C/hr to 10°C/hr (41°F/hr to 50°F/hr).^{222,247}

Peritoneal lavage is a more invasive cooling technique. Because heat exchange is more efficient across the peritoneum,

smaller volumes of fluid can be used. Surgical placement of the lavage catheter is necessary. This cooling technique is relatively contraindicated by conditions that preclude placement of a lavage catheter (e.g., multiple abdominal surgical scars).

Peritoneal lavage is the most rapid central cooling technique. It can theoretically be combined with other techniques to speed cooling of heatstroke patients with refractory hyperthermia. As the most invasive cooling technique, it requires time, proper equipment, and surgical expertise to institute. Its use is probably best suited to situations in which heatstroke patients are not responding to external cooling and adequate equipment and personnel are readily available.²²⁸

Procedure

To institute cooling by peritoneal lavage, immerse 2 to 8 L of sterile saline in an ice water bath to cool while the catheter is being placed. Place a standard peritoneal lavage catheter (as for diagnostic use in trauma patients) via any of the techniques described in [Chapter 43](#). Standard contraindications apply. Use of a larger peritoneal dialysis catheter may speed instillation and withdrawal of fluid. Actual lavage volumes and rates have not been established, however. One approach is to instill and withdraw 500 to 1000 mL every 10 minutes until adequate cooling is achieved. Rectal temperature may be falsely low during lavage because of the presence of cold water around the rectum at the level of the rectal temperature probe. It may be preferable to monitor temperature in the tympanic membrane or esophagus when using this technique. Stop the lavage when core temperature reaches 39°C (102.2°F) to avoid excessive core temperature afterdrop.

Complications

The potential complications of peritoneal lavage cooling are primarily related to placement of the catheter and include bowel or bladder perforation and placement into the rectus sheath rather than the peritoneum.

Other Cooling Techniques

“Rewarming” techniques are used to minimize ongoing heat loss via the respiratory tract in hypothermic patients.⁷² Although high-frequency jet ventilation (HFJV) achieves core cooling in critically ill patients,²⁴⁸ efforts to use the respiratory tract to cool heatstroke victims have been unsuccessful. In a canine model of heatstroke, HFJV was shown to be a relatively ineffective cooling technique.²⁴⁹ Heat loss by convection (air transfer) is relatively inefficient when compared with the conductive heat loss mechanism used by other cooling techniques. The use of dry, hot air to maximize evaporative heat loss from the lungs might cause respiratory complications.²⁴²

In human trials, ice water lavage of the bladder (300 mL of iced Ringer’s solution every 10 minutes) provided only minimal cooling at rates of 0.8°C/hr ($\pm 0.3^\circ\text{C/hr}$ [$33.4^\circ\text{F/hr} \pm 32.5^\circ\text{F/hr}$]).²¹³ Iced water lavage of the rectum would theoretically provide faster cooling rates secondary to the increased surface area and better perfusion, but it has not been investigated in human trials.

Hemodialysis or partial cardiopulmonary bypass could theoretically be used to cool heatstroke patients. Before the availability of dantrolene in 1979, partial cardiopulmonary bypass was one of the treatments of MH.¹⁸⁵ Drawbacks include the need for technical expertise and preparation time for the procedure. A 2005 case report described successful treatment

of a heatstroke patient with multiple-organ failure refractory to conventional cooling techniques with cold hemodialysis initially at 30°C (86°F) and later at 35°C (95°F), followed by continuous hemodiafiltration with cold dialysate (35°C [95°F]) at a high flow rate of 18,000 mL/hr. Within 3 hours of starting this particular technique, the patient’s body temperature was below 38°C ($< 100.4^\circ\text{F}$).²⁵⁰

Cyclic lung lavage with cold perfluorochemicals is currently under investigation in animal models. Benefits include rapid cooling rates of 0.5°C/min (32.9°F/min) and minimally invasive nature in already mechanically ventilated subjects.^{225,251}

Intravascular cooling catheters have demonstrated efficiency as cooling devices. They circulate temperature-controlled sterile saline placed in the bladder or inferior vena cava. Although these devices have not been used in heatstroke patients, studies have found the cooling catheters to be very effective for neurologic conditions in both human and animal models.^{252,253}

Another promising cooling technique involves the use of a hypothermic retrograde jugular vein flush (HRJVF) for heatstroke. HRJVF has been studied only in animal models thus far. This technique involves the infusion of 4°C (39.2°F) isotonic sodium chloride solution through the external jugular vein (1.7 mL/100 g of body weight over a 5-minute period). Use of HRJVF was found to increase survival rates during heatstroke by attenuating cerebral oxidative stress, tissue ischemia or injury, systemic inflammation, and activated coagulation.²⁵⁴

Pharmacologic agents have demonstrated merit as adjunctive agents in the management of hyperthermia. There are anecdotal reports of enhanced reduction in temperature with IV ketorolac. Cienki and colleagues demonstrated enhanced decreases in temperature with the administration of ketorolac, 30 mg intravenously.²⁵⁵ All patients received standard hyperthermia treatment (e.g., ice packs, iced lavage, circulating air). Patients were randomized to receive ketorolac versus saline. In the group receiving ketorolac, the average rectal temperature after 90 minutes was two times lower than in those receiving placebo saline (3.7°C vs. 1.6°C [38.7°F versus 34.9°F]).

Conclusion

Rapid cooling is the key step in the emergency management of heatstroke patients. Survival rates approach 90% when elevated temperatures are lowered in a timely fashion.^{169,239} Evaporative cooling appears to be the technique of choice. It combines the advantages of simplicity and noninvasiveness with the most rapid cooling rates achieved with any external technique. It is also logistically easier to institute, maintain, and monitor evaporative cooling measures than with any other cooling technique. If a patient is not cooling rapidly with evaporative cooling, other techniques can be added. Strategic ice packs can be used. If the patient is endotracheally intubated, gastric lavage can be instituted. If facilities and personnel are available, peritoneal lavage cooling can be used as a rapid central cooling technique. If muscle rigidity is present or MH is suspected, dantrolene sodium should be administered. In addition, the clinician should have a heightened index of suspicion for NMS and toxicity from sympathomimetic drugs. Regardless of the cause, a reasonable clinical goal is to reduce rectal temperature to 40°C (104°F) or below within 30 minutes of instituting therapy.^{169,239}

Immersion cooling is best limited to centers with the proper equipment and skilled medical personnel experienced in

managing hyperthermic patients. This method may also be effective in conditions in which electric power for evaporative cooling is unavailable (e.g., in wilderness settings where bodies of cool water are available nearby and the victim is far from more sophisticated medical care). Central venous cooling with iced saline is a promising technique for rapid cooling of patients with severe hyperthermia. Other cooling techniques require further study before a clear recommendation regarding their efficacy can be made.

Ultrasound

Christine Butts

Bedside ultrasound has become an indispensable tool in the emergency department (ED). It has enabled physicians to make a rapid diagnosis at the bedside and formulate a plan of care. Perhaps most importantly, ultrasound has revolutionized procedures performed in the ED. Use of ultrasound gives the physician the advantage of viewing the anatomy and directly imaging the procedure while it is being performed. Procedures that had previously been performed “blindly” can now be performed with the added assurance of monitoring the procedure while it is in progress. This has resulted in greater safety in both common and uncommon procedures.^{1,2}

▶ Ultrasound is now routinely applied to procedures in the ED ranging from the common, such as incision and drainage of an abscess, to the rare, such as drainage of a pericardial effusion (Videos 66.1-66.15). Use of ultrasound to facilitate each procedure is covered in detail in individual chapters. This chapter covers the basic principles of ultrasound that can be applied to any procedure. Ultrasound applications for specific procedures can be found in the appropriate procedure chapter.

PHYSICS

Ultrasound operates on the *pulse echo principle*. Electrical energy created by the ultrasound machine causes crystals in the tip of the transducer to vibrate, also known as the *piezoelectric effect*. This vibration emits high-frequency sound waves that travel into the body. The sound waves are reflected back to the transducer at varying intensities and speeds, depending on the nature of the object that they encounter. The ultrasound machine is able to interpret this information and plot an image on the screen.

Objects in the body that are liquid or water-like, such as a full bladder, reflect very few sound waves and allow most of the energy to pass through them. These objects are presented on-screen as black by ultrasound and are described as *anechoic* (i.e., without echoes) (Fig. 66.1). Conversely, objects that are dense and have very little water content, such as bones, reflect almost all the sound waves back. These objects are presented on-screen as white by ultrasound and are described as *hyperechoic* (i.e., producing a lot of echoes) (Fig. 66.2). Objects that lie between these two extremes present as varying shades of gray, depending on the water content of the object. For example, the liver contains a large amount of blood, a water-like substance, and is not completely liquid, appearing on-screen as dark gray (Fig. 66.3). An object that contains less water and is not completely solid would appear as a lighter shade of gray.

These properties of objects also account for two important artifacts. *Acoustic shadowing* is an artifact that is encountered when dealing with hyperechoic objects. These objects reflect almost all the sound waves back to the transducer. As a result,

the ultrasound machine “senses” an absence of information deep to the hyperechoic object. The absence of information is represented by a strong, dark vertical line emanating deep to the object (Fig. 66.4). This type of shadowing is referred to as a *clean shadow*. This shadow can be frustrating to the sonographer when attempting to obtain the best image possible, classically, when imaging over the ribs. Alternatively, it can also be helpful in identifying hyperechoic objects, such as gallstones or foreign bodies.

In contrast to a clean shadow, the presence of air may create a phenomenon known as *dirty shadowing* (Fig. 66.5). Air causes the ultrasound beam to scatter and creates a hazy, gray appearance on the image. This can be an anticipated finding, such as when viewing bowel gas within the abdomen, or an indication of an abnormality, such as when viewing gas within subcutaneous tissue.

Acoustic enhancement, or an *acoustic window*, is the artifact created by an anechoic object. As noted earlier, sound waves pass through anechoic objects well and therefore lose less of their energy. This enables more ultrasonic energy to be available when the sound reaches the object on the other side of the fluid. This results in a brighter, clearer image immediately behind the fluid-filled object. As an example, a full bladder enables a clearer image of the pelvic organs (Fig. 66.6).

INDICATIONS AND CONTRAINDICATIONS

Although vascular access was one of the first uses of ultrasound for ED procedures, the list of procedures that can be facilitated by ultrasound is growing rapidly and continuously (Box 66.1). Even when a procedure cannot be directly observed with ultrasound, bedside ultrasound can frequently be used to diagnose the abnormality and to plan the approach for the procedure.

Ultrasound is a very safe modality for imaging at the bedside. It can be used in a variety of populations (pediatrics, pregnancy), without concern for excessive radiation exposure. The only absolute contraindication to using bedside ultrasound for procedural guidance is lack of training or experience in its use. Lack of adequate training or experience may result in an incorrect diagnosis and erroneous evaluation of the anatomy. This may result in harm and unnecessary complications in patients.

EQUIPMENT

The nature of the image obtained depends on the type of transducer used. In general, transducers fall into two categories: high frequency and low frequency, referring to the type of ultrasound waves generated by the transducer.

High-frequency sound waves do not penetrate very far into the tissue but provide excellent resolution. A linear or vascular transducer and an intracavitary transducer are examples of specific types of high-frequency transducers (Figs. 66.7 and 66.8). Examples of examinations that are best evaluated with a high-frequency transducer are central or peripheral vascular access, evaluation of the pleura for pneumothorax, and evaluation of soft tissue for an abscess or foreign body. These examinations rely on a high degree of resolution (Fig. 66.9).

Low-frequency sound waves penetrate farther into tissues and do not provide as much resolution as high frequency does.

Figure 66.1 This image demonstrates a fluid-filled bladder, which appears black, or anechoic, when viewed with ultrasound.

Figure 66.4 Acoustic shadowing (*arrow*) occurs when ultrasound encounters a hyperechoic, or hard, object. All the sound waves are returned to the transducer, which results in absence of information behind the hyperechoic object.

Figure 66.2 This image demonstrates the cortex of a bone (*arrow*), which appears white, or hyperechoic, when viewed with ultrasound.

Figure 66.5 In contrast to clean shadowing, the presence of air causes a dirty shadow (*arrow*).

Figure 66.3 The liver (*arrow*) contains a large amount of blood (a water-like substance) but is not completely liquid and appears on-screen as dark gray. Note the kidney adjacent to the liver. Fluid in the abdomen (blood, ascites) will often collect in the space between the liver and kidney, and appear as a black collection (see Fig. 66.24).

Figure 66.6 The presence of a fluid-filled object (in this case a full bladder) creates an acoustic window effect (*arrow*). This effect allows objects behind, or deep to the window to be seen more clearly.

Curvilinear, phased-array, and microconvex transducers are examples of specific types of low-frequency transducers (Figs. 66.10 and 66.11). They are distinguished from each other by the shape of the footprint of the transducer, the part that directly touches the patient, and by the layout of crystals in the tip of the transducer. Examples of the types of examinations

that are best evaluated with a low-frequency transducer are evaluation of the pleural or peritoneal cavities for fluid drainage, evaluation of the bladder for aspiration or suprapubic catheter placement, and evaluation of the pericardium for pericardiocentesis. These examinations are not as dependent on resolution and typically require greater penetration (Fig. 66.12).

BOX 66.1 Examples of Procedures Performed With Ultrasound Guidance

Abscess incision and drainage
 Arterial line placement
 Arterial puncture
 Arthrocentesis
 Central venous catheter placement
 Foreign body localization and removal
 Nerve block
 Paracentesis
 Pericardiocentesis
 Suprapubic catheter placement
 Thoracentesis
 Transvenous pacemaker insertion

Figure 66.9 An example of an image as seen with a high-frequency transducer. In this case soft tissue and tendon (*arrowhead*) can be seen overlying the ankle joint (*arrow*).

Figure 66.7 Linear, or vascular, transducer.

Figure 66.8 Intracavitary transducer.

Figure 66.11 Phased-array transducer.

The growing use of ultrasound for procedures has prompted the development of echogenic needles and needle guidance systems. Both these advances are designed to improve the ease and accuracy of ultrasound-guided procedures, but this depends on the operator's familiarity with their properties and the correct use.

Additionally, many procedures require sterile conditions. Commercially designed sterile transducer covers are available and allow the operator to completely cover both the transducer and the cord. In the absence of these covers, the transducer can be placed inside a sterile glove. To further protect the field, a sterile drape can be wrapped around the cord.

Figure 66.12 Example of an image as seen with a low-frequency transducer. In this case the liver and kidney can be seen in the right upper quadrant.

Figure 66.14 Indicator on-screen (*arrow*), which corresponds to the indicator on the side of the transducer.

Figure 66.13 Indicator on the transducer (*arrow*).

GENERAL APPROACH

Although each procedure has unique techniques, there are several general principles that apply when using ultrasound. Selection of the correct transducer is of the upmost importance for adequate visualization of the anatomy and pathology. This process is described in the preceding section, and in general the degree of resolution and depth of penetration should guide selection of the transducer.

Once the correct transducer has been selected, evaluate the area of interest. This step is key when evaluating the nature of the pathology. For example, understanding the size and position of a subcutaneous abscess and the surrounding anatomy is essential. Determining the correct orientation of objects on the screen can be challenging, and it is crucial for success with ultrasound-guided procedures. All transducers have a dot or mark on one side (Fig. 66.13). This mark corresponds to an indicator on the left-hand side of the screen (Fig. 66.14). When the indicator on the transducer is pointing toward the patient's right side, a transverse image will be generated (Fig. 66.15). Objects on the right of the screen are closer to the patient's left side and objects on the left side, near the on-screen indicator, are closer to the patient's right side. Objects near the top of the screen are closer to the skin and objects near the bottom of the screen are deeper in the body. When the indicator is

Figure 66.15 Relationships in the transverse orientation. As the indicator points toward the patient's right, objects on the left side of the screen are toward the patient's right (toward the indicator). Objects on the right side of the screen are toward the patient's left (away from the indicator). As in all images, objects closer to the top of the image are closer to the surface, whereas objects at the bottom of the image are deeper in the body.

turned toward the patient's head, a longitudinal image is generated (Fig. 66.16). Objects on the right side of the screen are closer to the patient's feet and objects on the left side of the screen (near the on-screen indicator) are closer to the patient's head. As with the transverse image, objects near the top of the screen are closer to the skin surface and objects at the bottom of the screen are deeper in the body.

Once the initial evaluation has been completed, make a decision whether to use ultrasound to directly guide the procedure or to simply “mark the spot” beforehand. Some procedures, such as paracentesis of large fluid collections, may not require direct guidance. In this case, ultrasound can be used to locate the most optimal puncture site, away from important structures. Once that site has been marked, proceed with the procedure in the usual fashion. For other procedures, such as central line placement, direct visualization throughout the entire procedure may be more important.

When direct visualization is desired, the orientation of the needle to the transducer must be considered. When the needle is introduced at the midpoint of the transducer in the transverse

Figure 66.16 Relationships in the longitudinal, or sagittal, orientation. As the indicator on the transducer points toward the patient's head, objects on the left side of the screen are toward the patient's head. Objects on the right side of the screen are toward the patient's feet. As in all images, objects closer to the top of the image are closer to the surface, whereas objects at the bottom of the image are deeper in the body.

Figure 66.17 Inserting a needle in the transverse approach. In this technique the needle is inserted at the midpoint of the transducer. This image is for demonstration purposes only and does not demonstrate sterile technique.

approach, the tip of the needle may be difficult to visualize (Fig. 66.17). In this orientation the operator may have difficulty following the tip of the needle because only a small portion of the needle intersects the ultrasound beam at any given time (Figs. 66.18 and 66.19). Conversely, when the needle is introduced from either end of the transducer, the needle can be visualized in its entirety (Figs. 66.20 and 66.21). Slight movement of the transducer may result in losing the view of the needle. Consider each potential approach in the context of the particular procedure.

The oblique approach is a combination of the transverse and longitudinal approaches. Primarily, this has been described for central venous access and can also be applied to other procedures.³ In this method, place the transducer on an oblique axis to the target object (Fig. 66.22). This allows an oblique view of the target object while enabling the operator to introduce the needle along the long axis of the transducer (Fig. 66.23).

Figure 66.18 As the needle is advanced the transducer can be seen to transect only a small portion of the needle. The tip of the needle is now away from the transducer and will not appear on-screen.

Figure 66.19 Real-time image of the needle as it approaches the vein. The needle (*arrow*) is seen as a hyperechoic object with strong shadowing extending behind it. The portion of the needle seen will correspond to the portion of the needle that is underlying the transducer, as shown in Fig. 66.18.

Figure 66.20 Inserting a needle in the longitudinal approach. In this technique the needle is inserted at the end of the transducer. This image is for demonstration purposes only and does not demonstrate sterile technique.

Figure 66.21 Real-time image of the needle as it approaches the vein. The needle (*arrow*) can be identified as a hyperechoic object with reverberation artifact. In this orientation it can be seen in its entirety as it progresses toward the vein.

Figure 66.22 Inserting a needle in the oblique approach. In this technique the needle is inserted at the end of the transducer. This is similar to the longitudinal approach, with the exception that the vessel is viewed from an oblique angle rather than from a longitudinal orientation. This image is for demonstration purposes only and does not demonstrate sterile technique.

Figure 66.23 Real-time imaging of the needle approaching the vein. The needle (*arrow*) can be identified as a hyperechoic object with a reverberation artifact. It can be seen in its entirety as it advances toward the vein.

COMPLICATIONS

In general, the incidence of complications should be reduced with the use of ultrasound, but complications may occur even when performed by an experienced sonographer. Complications may be related to one of several factors. To maximize success, obtain an optimal image of the structure in question. Evaluate the anatomic relationships to ensure that the target object (e.g., the femoral vein versus the femoral artery) is correctly identified and pursued. Once the procedure begins, pay constant attention to the orientation and location of the needle. Errors, including inadvertent arterial puncture, can occur when the position of the tip of the needle is not closely followed.^{4,5} Techniques to minimize these errors are addressed in the individual chapters.

FAST, E-FAST, AND RUSH EXAMS

No discussion about bedside ultrasound would be complete without a reference to the FAST, E-FAST, and RUSH exams.

The FAST (**F**ocused **A**ssessment with **S**onography for **T**rauma) exam was one of the first applications of ultrasound at the bedside, performed by non-radiology physicians. The FAST exam was first developed in the 1970s outside of the United States and spread to the United States in the 1980s, with rapid growth thereafter.^{6,7} The FAST exam was first developed as an alternative to diagnostic peritoneal lavage (DPL) in patients with blunt trauma. In contrast to DPL, FAST is noninvasive, repeatable, and can be performed on any patient, from infants to pregnant women. Due to these advantages, FAST has not only largely replaced DPL for evaluation of hemorrhage following blunt trauma, but has been adapted for use in other scenarios, such as penetrating trauma and nontrauma situations (such as in the case of a ruptured ectopic pregnancy). The E-FAST (**E**xtended **F**ocused **A**ssessment with **S**onography for **T**rauma) exam builds upon the traditional thoracoabdominal views of the FAST to include evaluation of the pleura and lung.

The effectiveness of the FAST and E-FAST exams as diagnostic tools varies depending on the scenario in which they are used. The expertise and experience of the examiner plays a significant role and although the basic exam appears to be easily mastered, examiners with more experience are more capable of diagnosing small free-fluid collections.⁸ FAST appears to be most sensitive when evaluating hypotensive blunt trauma patients.^{9,10} Multiple studies have determined that the sensitivity for detecting free fluid in these patients approaches 100%.¹¹⁻¹³ In patients who are normotensive following blunt trauma, the sensitivity and specificity for FAST is more questionable, with most studies finding between 42% to 86% and 98% to 99%, respectively.¹⁴⁻¹⁶ The FAST exam in penetrating trauma can also be helpful, although the sensitivity is not as high as in blunt trauma patients.¹⁷ In an unstable penetrating trauma patient, a quick FAST exam to evaluate the pericardium can yield important information to help aid the operating room course.¹⁸ Ultrasound for pneumothorax has shown to be extremely sensitive, particularly in comparison to traditional supine chest radiography.¹⁹ Supine x-rays have sensitivities ranging from 47% to 75%, even with moderately sized pneumothoraces.^{20,21} Ultrasound conveys the advantage of quickly identifying even a small pneumothorax. Ultrasound is also reliable for identifying pleural fluid.²² Identifying a

Figure 66.24 Free fluid (black) seen surrounding the inferior tip of the liver (arrow).

Figure 66.26 Pericardial effusion seen surrounding the heart in the subxiphoid view (arrow).

Figure 66.25 Large amount of free fluid seen deep to the bladder (arrow).

hemothorax can be difficult in the supine patient, as fluid can layer on chest x-ray, making rapid diagnosis challenging. Ultrasound at the costophrenic angles can quickly identify as little as 10 cc of fluid.²³

The basis of the FAST exam relies on the principle that intraperitoneal free fluid will settle into dependent areas within the peritoneum when the patient is supine. These dependent areas form the foundation of a basic FAST exam. The right and left upper quadrants, as well as the pelvis, are evaluated for free fluid. The pericardium is easily viewed from either the subxiphoid region or from the anterior chest wall, identifying pericardial effusions. This view is helpful in determining if cardiac motion is present, particularly when deciding whether to continue resuscitation. Quick views of the pleura from the anterior chest and the costophrenic angles can be added to evaluate for pneumothorax and hemothorax.

A full description of the FAST and E-FAST exams is outside of the scope of this text, but the dependent areas of the abdomen should be evaluated for the presence of free fluid, which will typically appear anechoic or black (Figs. 66.24 and 66.25). A low-frequency transducer (2 to 5 mHz) is usually optimal for

BOX 66.2 Components of the RUSH Exam

FAST, *Focused Assessment with Sonography for Trauma*; RUSH, *Rapid Ultrasound in Shock*.

evaluation of the abdomen. A curvilinear or phased-array transducer can be used, depending on availability and examiner preference. For evaluation of the pleura, a high-frequency transducer (6 to 13 mHz) is optimal for maximum resolution, although a low-frequency transducer will suffice if no high-frequency transducer is available. The pericardium can be assessed for effusion from either the subxiphoid region of the chest or from the left anterior chest wall (Fig. 66.26). In the supine patient, a pneumothorax will rise and be best seen on the anterior-medial aspect of the chest wall. A more detailed description of components of this exam can be found within this text:

- Evaluating the dependent portions of the abdomen in trauma is similar to evaluating dependent portions of the abdomen for ascites and paracentesis; see [Chapter 43](#).
- Evaluating the pericardium for effusion following trauma is similar to evaluating effusions in anticipation of pericardiocentesis; see [Chapter 16](#).
- Evaluating the pleura for evidence of a pneumothorax is covered in [Chapter 10](#).

The RUSH (Rapid Ultrasound in SHock) exam was developed as a means to quickly assess a hypotensive patient at the bedside, utilizing ultrasound. The goals of the RUSH exam are to attempt to identify treatable causes of shock, such as pericardial tamponade, and also to attempt to classify the type of shock present.²⁴ Distinguishing between cardiogenic, obstructive, distributive, and hypovolemic shock is important, as the treatment strategies can vary widely. For example, determining that cardiogenic shock is present early in the evaluation of a hypotensive patient can assist the physician in narrowing the

BOX 66.3 Findings Sought in Each Component of the RUSH Exam

Pump	Tank	Pipes
Estimate contractility of the heart to evaluate for cardiogenic shock and to determine ability to tolerate volume resuscitation	Determine the size and collapsibility of the inferior vena cava as a marker of volume status	Evaluate the thoracic and abdominal aorta for the presence of either an aneurysm (AAA) or dissection
Identify the presence of pericardial effusion and tamponade	Assess for the presence of free fluid in the peritoneum to indicate hypovolemic shock	Study the deep veins of the lower extremities to identify thrombus (DVT) when PE is a consideration
Evaluate for signs of right heart strain to indicate possible PE	Identify the presence of pneumothorax/tension pneumothorax Evaluate the lung parenchyma for evidence of pulmonary edema associated with cardiogenic shock Assess the costophrenic angles for evidence of pleural effusion/hemothorax

differential diagnosis and in avoiding unnecessary (and potentially harmful) initial treatments such as large fluid boluses. The RUSH exam is divided into components: the “pump”, the “tank”, and the “pipes” and should be evaluated in a step-wise fashion (Box 66.2). Each component of the RUSH exam should be evaluated for specific findings to guide management

(Box 66.3). A detailed overview of the technique is outside of the scope of this text. Box 66.4 lists the specific views that can be used to evaluate each component.

Bedside Laboratory and Microbiologic Procedures

Anthony J. Dean and David C. Lee

ASSESSMENT OF URINE

Obtaining a Urine Specimen

Several methods are available for obtaining a urine specimen. They can be found in [Table 67.1](#) and are listed in order of increasingly precise collection techniques. They come at the cost of increasing difficulty, patient discomfort, or both.

General Considerations Regarding Urine Collection

The advantages and disadvantages of each of the techniques listed in [Table 67.1](#) can be determined only by the purpose of the urine test and the clinical context. The clinical context influences interpretation of the results. For the great majority of clinical scenarios, the basic dichotomy is between specimens obtained for infectious versus noninfectious reasons. With the exception of testing for red blood cells (RBCs) and white blood cells (WBCs), most of the noninfectious tests (e.g., ketones, glucose, bilirubin, protein) are not affected by the collection method. Urine specimens collected to diagnose infection can be contaminated in a number of ways, and the clinical scenario intricately influences the choice and interpretation of tests.

Urinary tract infections (UTIs) are either symptomatic or asymptomatic, and the symptoms determine which collection method is required ([Fig. 67.1](#)). Symptomatic female patients without potential complications who present for the first time require no further urine testing, and should be treated empirically based on local patterns of susceptibility for urinary pathogens. However, in symptomatic patients who have failed a course of therapy or have potential complicating factors, testing is recommended and extremely low levels of bacteriuria (10^2 colony-forming units [CFUs]/mL) and pyuria are of clinical significance.^{1,2} This may be obscured in some clinicians' minds by an alternative, more widely promulgated fact: In asymptomatic patients the threshold for "significant bacteriuria" is 1000-fold higher at greater than 10^5 CFUs/mL.^{3,4} Symptomatic patients constitute a clinically distinct group who require a urine test that is much more sensitive and thus will render a false-positive result with much lower levels of contaminants. Although many studies do not show a statistically significant increase in contamination rates with less stringent urine collection techniques, most show increased accuracy with more meticulous or invasive collection methods.⁵⁻⁸ Because it takes only marginally longer, it makes sense to always strive for the highest-quality urine specimen available, especially in view of the delays, repeated testing, and additional cost entailed by false-positive results. A frequent misconception is that contaminated specimens are characterized by the isolation of

multiple pathogens, but in fact, up to 50% of symptomatic women may have polymicrobial infections.^{1,9}

The issue of whether a patient is symptomatic might appear trivial, but the clinical practice of checking for UTI in most patients with any type of abdominal pain has important implications. Studies of urine collection and testing in symptomatic patients focus on the classic signs and symptoms of UTI (e.g., urgency, frequency, dysuria, flank pain, costovertebral angle tenderness) and do not include patients with nonspecific abdominal pain. Whether undifferentiated abdominal pain or fever constitutes a symptom of UTI has never been studied, and how to apply the results of studies done on patients with classic symptoms to those with nonspecific symptoms is unclear.¹⁰ Patients with classic symptoms need the most careful urine collection method because they have the most riding on the outcome of the test. This group of patients should include those with systemic signs of infection (e.g., fever and chills) who are unable to accurately report their symptoms and patients in whom failure to diagnose asymptomatic bacteriuria would be potentially dangerous (e.g., the immunocompromised, neonates and infants, pregnant patients, diabetics) or for whom urine cultures are going to be necessary because of a history of relapsing, recurrent, complicated, or childhood UTI.^{10,11}

In cooperative, motivated males and females with symptoms of uncomplicated lower UTI or pyelonephritis who are capable of diligently performing the necessary maneuvers, a midstream clean catch (MSCC) specimen is as accurate as a catheterized specimen, especially when the possibility of urethral or prostatic trauma and patient discomfort are considered.¹² Lower resource utilization and avoidance of urethral or prostatic trauma and patient discomfort are additional advantages to an MSCC specimen. In patients who are unable to provide an MSCC specimen, or in children in whom thorough cleansing is more difficult, the increased accuracy afforded by a catheterized specimen is usually warranted.¹³

If no symptoms of UTI are present, the urine examination can be considered a screening test. In asymptomatic patients, routine screening for bacteriuria is unwarranted in all but two clinical situations: pregnant women and all patients scheduled for urologic surgery.^{14,15} If only a urine culture is to be performed, some would argue that any spontaneously voided specimen would suffice because the diagnosis of asymptomatic bacteriuria depends on 10^5 or more CFUs of a single pathogen per milliliter of urine. With such criteria, contaminants are usually easily identified.⁸ Because performing cultures on all such patients is prohibitively costly, dipstick testing, urinalysis (UA), or both are commonly used for screening.^{16,17} With these tests, contamination by bacteria, leukocytes, or erythrocytes results in diagnostic confusion. The advantages of a less-contaminated specimen are worth the minimal, extra effort of asking the patient to provide an MSCC sample. The approach in [Fig. 67.1](#) covers the vast majority of situations. A few circumstances and techniques deserve special mention.

Bladder Percussion and the Midstream Specimen in Infants

The emergency clinician is familiar with how frequently a urine stream is generated in infants confronted by the alarming emergency department (ED) environment and a cold stethoscope. Rather than wasting a potentially perfect MSCC specimen on a laboratory coat with an ensuing delay in obtaining urine, the clinician can exploit the situation by approaching an infant with an open sterile urine container in hand in case

TABLE 67.1 Urine Collection Methods Listed in Order of Increasing Precision

METHOD	DESCRIPTION AND COMMENTS
Random voided	Any specimen provided by the patient.
Midstream voided	No skin preparation, container placed in the urinary stream 2–3 sec after initiation of micturition.
Clean catch	Same as above, plus antiseptic cleansing of the urethral area. This is performed by retraction of the prepuce in males and the labia in females and then cleansing the meatus in an anterior-to-posterior direction. Use three swabs soaked in povidone-iodine (or some other antiseptic solution). For female patients who are physically capable, the ideal position is sitting astride a toilet, facing backward. This helps separate the labia and position the cup for collection of the specimen.
Midstream clean catch	Cleansing as for clean catch, with midstream collection as for midstream voided.
Catheterized	Obtained from a newly placed catheter after cleansing of the meatus.
Suprapubic aspiration	See Chapter 55.

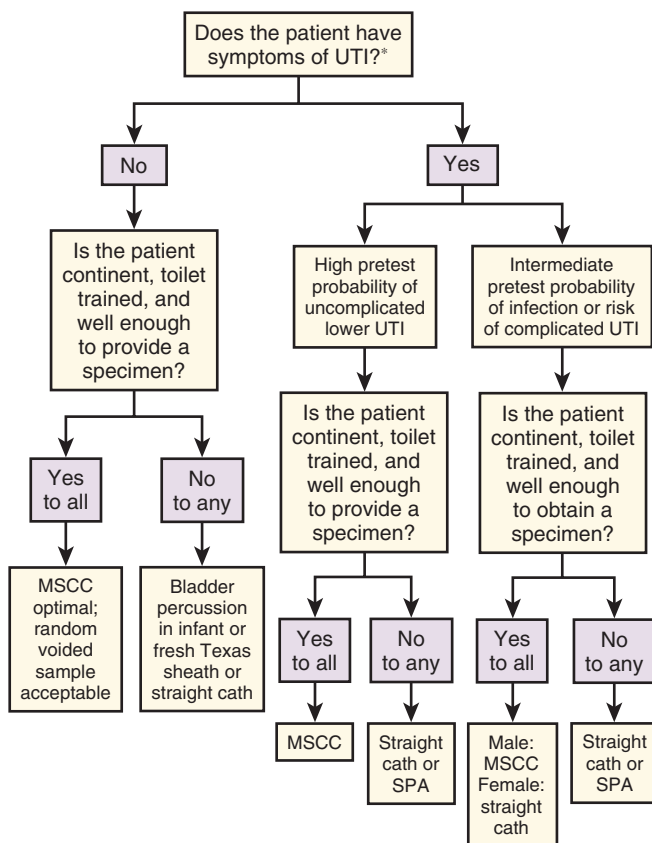

Figure 67.1 Algorithm for deciding method of obtaining urine specimen for evaluation of possible urinary tract infection. For initial presentation with symptoms in otherwise healthy females: no urine testing indicated; see text. *MSCC*, Midstream clean catch; *SPA*, suprapubic aspiration; *UTI*, urinary tract infection.

the urine stream is spontaneously forthcoming. The process is facilitated by the application of cold povidone-iodine to the genitalia. Such an approach has been shown to generate a urine sample in a median time of 10 minutes.¹⁸ This is less than the typical time needed for straight catheterization or suprapubic aspiration (SPA), and it can be performed concomitantly with the history and physical examination and thereby circumvent an invasive procedure. If the urine specimen

is not immediately forthcoming, a parent can be equipped with a sterile container and be instructed on collection of an ensuing specimen to free up ED staff for other tasks. Two techniques to actively induce voiding in infants have been described. The first, which is useful in newborns, exploits the Perez reflex.¹⁹ After cleansing the genitalia, hold the infant in one hand while stroking the paraspinal muscles in a cephalad to caudad direction. This causes extension of the back and flexion of the hips and induces micturition in less than 5 minutes in most cases.¹⁹ The second technique is known as “bladder tapping.” After urethral cleansing, if there is still no urine, use two fingers to tap on the suprapubic area at a rate of approximately once per second for a full minute, followed by a minute’s rest. Repeat the cycle until urine is produced. The mean time before the production of a urine sample is approximately 5 minutes. This technique, though not practicable for the staff in a busy ED, can provide an infant’s parents with a task that invests them in the clinical process. This clinical pearl may expeditiously furnish a specimen with significantly less investment of staff time than required for more invasive techniques.²⁰ A combined method using finger-tap for 30 seconds alternating with lumbar stimulation with a light circular motion for 30 seconds after oral hydration achieved success in 86% of infants younger than 30 days old in less than 2 minutes.²¹

Bag Collection in Non-Toilet-Trained Children

The incidence of unsuspected UTI in a febrile neonate or infant is approximately 5%.²² Similar rates are found in asymptomatic children less than 5 years of age who present to the ED with nonspecific symptoms of acute illness.²³ A true UTI in an infant or child requires subsequent evaluation for urinary tract pathology, and the disease may produce significant morbidity (e.g., hypertension, renal disease). One must be certain of the presence or absence of infection in this subgroup. The costs of overdiagnosis with a false-positive UA are significant and include bacterial resistance that leads to the use of increasingly expensive antibiotic medications.²⁴ Numerous studies have demonstrated the disutility of urine specimens obtained for culture from a collection bag stuck to an infant’s perineum.^{19,20,25–27} Bag specimens may be more sensitive than catheter specimens when used for UA or microscopy to identify infection in children at low or moderate risk for UTI.²⁸ In this group it is acceptable to perform screening UA, microscopy, or both on a bag specimen.^{29,30} If negative, UTI is ruled out.

If positive (leukocyte esterase or nitrite present, more than 5 WBCs/high-power field [HPF] on spun urine, or bacteria on an unspun Gram-stained specimen), it is followed by catheterization and culture, with treatment usually pending the results of culture.^{25,29-31} If a urine specimen is needed solely for chemical analysis (e.g., glucose, ketones, specific gravity), a bag specimen will suffice.

Urine Specimens From Patients With Chronic Urinary Drainage Systems

Urine obtained from any part of a chronic urinary drainage system is highly inaccurate for bacteriologic purposes. If UTI is suspected, insert a new catheter and obtain a fresh bladder urine specimen.³² A small study advocating replacement of a chronically applied Texas sheath catheter with a fresh one was performed on patients who did not have symptoms of UTI.³³ Such a method might be sufficiently accurate for screening asymptomatic patients, but chronic asymptomatic bacteriuria is very common in such patients, and treatment is not recommended.³⁴ In most cases, a Foley catheter should be used to obtain urine from patients with sheath catheters who have signs or symptoms of acute UTI and are unable to provide an MSCC specimen.

Catheterization and SPA

The low levels of bacteriuria found in 2% to 8% of patients after straight catheterization are generally below the threshold that defines the presence of UTI.³⁵ Catheterization can cause minor local injury, as reflected by low-level hematuria in 15% of patients.^{35,36} SPA continues to be advocated by some for neonates in cases in which accurate diagnosis is essential and the risk for infection must be minimized. Both SPA (see [Chapter 55](#)) and catheterization have an approximately 25% failure rate as a result of an empty bladder.³⁷ This problem and associated complications can be avoided by performing bedside ultrasound before the procedure.³⁷⁻³⁹ SPA may spuriously lower leukocyte or bacterial colony counts because of the necessity of filling the bladder before performing the procedure.⁴⁰ A study in infants demonstrated that the discomfort associated with SPA is greater than that with catheterization.⁴¹ Surprisingly, however, older men who underwent both catheterization and SPA strongly preferred SPA.⁵

Urine Dipstick

Urine dipstick tests are available to test 10 separate parameters. The unassuming appearance and commonplace use of the urine dipstick might lead one to mistakenly underestimate its technical sophistication. Each colored square on a urine dipstick involves a biochemically complex assay, and therefore it is essential to meticulously follow the manufacturer's instructions for storage and use.⁴² Even with optimal storage and testing conditions, the false-negative and false-positive rates of these tests are problematic. In addition, most of the tests are susceptible to interference from a variety of substances ([Table 67.2](#)).

Method

Test urine specimens as soon as possible after they are collected. If the urine has been standing, stir or shake the specimen well because cells sink rapidly in a container. Immerse the test strip completely for 1 second or less. Draw the edge of the strip along the rim of the specimen container and lightly tap it to remove excess urine, thus avoiding mixing the reagents between

different test patches. Next, hold the strip horizontally or place it on a clean gauze pad until the recommended time has elapsed. Most strips are designed so that all the test results can be read together after 1 to 2 minutes ([Fig. 67.2](#)).

Interpretation Glucose

The urine glucose test is normally negative. Urine glucose testing has limited usefulness in quantitative testing because the serum glucose level at which spillage occurs varies (although in most patients it starts at between 180 and 200 mg/dL).⁴³ Changes in urine glucose lag behind changes in blood glucose by approximately half the interval between voids.⁴⁴ Glycosuria in the absence of hyperglycemia suggests renal tubular dysfunction. Glycosuria may occur in hypothermic patients in the absence of hyperglycemia and indeed may actually occur with hypoglycemia in such patients.⁴⁵

Ketones

Ketones are found in the urine of patients with starvation, inadequate carbohydrate intake, diabetic and alcoholic ketoacidosis, isopropyl alcohol poisoning, or glycogen storage disease. Tests for urine ketones are 5 to 10 times more sensitive to acetoacetate than to acetone, similar to the serum tests. Dipsticks do not detect 5-hydroxybutyrate, which accounts for 80% to 95% of the three ketone bodies and is the predominant form in the setting of ketoacidosis. Urine ketone testing is significantly more sensitive than serum ketone testing.⁴⁶ There is generally no need to obtain serum acetones to diagnose or manage diabetic ketoacidosis when urine ketone monitoring is coupled with blood gas and anion gap analysis.

Leukocyte Esterase

This portion of the dipstick test is designed to detect enzymes from the azurophilic granules in neutrophils. Normally the test is negative. Studies report a wide and clinically important range of thresholds for the sensitivity of dipstick testing, from 10 to 100 WBCs/ μ L urine.^{16,17} Studies suggest that the test is between 50% and 96% sensitive in detecting infection.^{2,47,48} Its specificity for the presence of WBCs is between 91% and 99%. The most common cause of a false-positive leukocyte test is vaginal contamination.

Nitrites

Normally, urine does not contain nitrites. Nitrites are specific ($\approx 95\%$), but not sensitive ($\approx 45\%$) indicators of UTI.^{14,49,50} Urinary nitrates are converted to nitrites most strongly by enteric coliform bacteria, thus explaining the nitrite test's 90% sensitivity in detecting UTI caused by *Escherichia coli*. *Enterococcus*, a moderately frequent urinary pathogen, *Pseudomonas* species, and *Acinetobacter* lack the reductase enzyme and are not detected by nitrite testing. False-negative results also occur because of the lack of dietary nitrate, frequent voiding, and diuresis. Early morning-voided specimens are ideal because they allow time for conversion of nitrate to nitrite, but they are rarely available in the ED. If possible, a specimen obtained more than 4 hours after the last voiding is preferred.

Protein

Proteins with a molecular weight below 50,000 to 60,000 daltons can pass through the glomerulus to be reabsorbed in the proximal tubule. Normal passage of protein in urine is less

TABLE 67.2 Overview of Urine Dipstick Tests

SOURCES OF ERROR AND ARTIFACT		COMMENTS
Glucose	False positive with peroxide, hypochlorite, ketonuria, levodopa, and the dipstick exposed to air False negative with ascorbate, ketones, uric acid, and high specific gravity	Hypothermia may cause glycosuria despite hypoglycemia Glycosuria without hyperglycemia suggests renal tubular dysfunction
Ketones	False positive with ascorbate, low pH urine, high specific gravity, levodopa, valproate, phenazopyridine, <i>N</i> -acetylcysteine, high-protein diet, phenylketonuria, phthalein compounds	Very susceptible to deterioration with humidity and delay in analysis, which can cause false-negative results
Nitrites	False positive with phenazopyridine False-negative with high specific gravity, frequent urination, ascorbate, high urine pH, and urine standing in the specimen cup >2 hr	75% false-negative rate when exposed to air for 15 days Does not detect reductase-negative bacteria
Protein	False positive with pH >7 and chlorhexidine False negative with low pH, very dilute urine	Only reliable for albumin (glomerular proteinuria) Does not detect Bence-Jones protein Positive with pyuria, rarely with hematuria
Blood	False positive with povidone-iodine, certain (peroxidase-producing) bacteria, hypochlorite False negative with high specific gravity and high concentrations of urinary nitrites, ascorbate, or captopril	Positive test with speckles or dots implies nonhemolyzed blood Positive test with a diffuse pattern implies hemolyzed red blood cells or high levels of myoglobin
Bilirubin	False positive with iodine, stool contamination, chlorpromazine, mefenamic acid False negative after prolonged standing	Hard to read with agents causing marked urine discoloration
Urobilinogen	False positive with phenazopyridine, sulfisoxazole, sulfonamides, porphyrin, methyl dopa, procaine, aminosalicic acid, 5-hydroxyindolacetic acid False negative with sulfisoxazole and phenazopyridine	Use a fresh specimen: rapidly broken down by light and in acidic urine
Leukocyte Esterase	False positive with vaginal contamination, oxidizing agents, eosinophils in urine, <i>Trichomonas</i> False negative with high glucose, ketones, protein (especially albumin), pH, and specific gravity, as well as with cephalexin, tetracycline, oxalates, ascorbic acid, neutropenia	Sterile pyuria seen with tuberculosis, nephrolithiasis, interstitial nephritis
pH	Urea-splitting bacteria elevate pH Runoff from the protein strip can falsely lower pH	Use a fresh specimen: standing raises pH by loss of CO ₂
Specific Gravity	Overestimates specific gravity with low pH, ketoacidosis, and protein Underestimates specific gravity with glucose, urea, or pH >7	Not reliable at specific gravity >1.025 Elevated with use of dextran, intravenous contrast material, proteinuria

than 150 mg/24 hours, or approximately 10 mg/dL of urine. Approximately 10% to 33% of urinary protein is albumin, 33% is Tamm-Horsfall glycoprotein (secreted by renal tubular cells), and the balance is made up of a variety of immunoglobulins and other proteins. Proteinuria is a finding noted in approximately 5% of routine urine screens in men.⁵¹ This may represent a normal variant as 3% to 5% of healthy adults have postural proteinuria (proteinuria when standing but not when recumbent).⁴³ Proteinuria is rarely clinically significant unless 3+ or greater is seen on the dipstick, although lower levels are

still indicative of some degree of renal dysfunction (see later). The dipstick detects negatively charged proteins more strongly than positively charged ones; it is therefore most sensitive to albumin. A study of ED patients with severe acute hypertension identified renal dysfunction, defined as elevated serum creatinine, with 100% sensitivity when using urine dipstick detection of 1+ proteinuria or hematuria.⁵² Along similar lines, in patients being considered for radiographic contrast-enhanced studies who do not have a serum creatinine measurement, a negative dipstick test for protein or blood combined with the absence

Figure 67.2 Urine dipstick testing. **A**, Totally immerse the dipstick in urine for a few seconds. **B**, Place it on its side on a paper towel to allow drainage of urine and limit cross-contamination of the individual testing squares. Note that the bottle of test strips should be closed immediately because prolonged exposure to air can produce false results. **C**, Formal reading of the test strip is accomplished electronically rather than only by the naked eye for quality assurance and a permanent record. **D**, Myoglobinuria: strongly positive for blood on the dipstick with no red blood cells on microscopy.

of prior renal disease, hypertension, diabetes, congestive heart failure, and age younger than 60 years effectively excludes renal insufficiency.⁵³ The urine dipstick test is positive for protein with pyuria of greater than 6 WBCs/HPF.⁵⁴ This is a false-positive finding for protein but is helpful when the urine dipstick is being used to screen for UTI because the threshold for leukocyte esterase is often significantly higher. Hematuria only slightly elevates urine protein levels.

In assessing a patient with proteinuria, it is helpful to divide the list of causes into those that are and those that are not associated with hematuria. These are listed in [Box 67.1](#). Elevated urinary protein is more commonly due to renal than systemic causes. The source is either glomerular, with passage of normally unfiltered proteins, or tubular, with failure to reabsorb physiologically filtered, low-molecular-weight globulins. The former condition causes albuminuria. Renal tubular proteinuria is characterized by low levels of urinary albumin and is therefore more likely to be missed.

Blood

The blood section of the urine dipstick is positive if exposed to RBCs, hemoglobin (Hb), or myoglobin. Urine in healthy volunteers contains fewer than 7 RBCs/mL. Studies have shown that the urine dipstick is very sensitive to 10 RBCs/mL. False-negative results are confined to clinically insignificant hematuria.⁵⁵ The dipstick pad should be inspected for discrete positive “dots,” indicative of nonhemolyzed RBCs. Moderate intravascular hemolysis does not cause hemoglobinuria because Hb is tightly bound to haptoglobin and is therefore not filtered. Massive intravascular hemolysis gives rise to free plasma Hb

with a molecular weight of 32,000 daltons, which easily passes through the glomerulus. Myoglobin has a molecular weight of 17,000 daltons, which also allows easy glomerular passage, but the dipstick has been shown to have a sensitivity of only 14% with heat-induced rhabdomyolysis, as reflected by serum creatine phosphokinase levels of up to 1000 U/L.⁵⁶ Guidelines for distinguishing hematuria, hemoglobinuria, and myoglobinuria are outlined in [Table 67.3](#). In asymptomatic men older than 50 years, significant disease can be signaled by intermittent hematuria, thus mandating follow-up of patients with this incidental finding.⁵⁷

Dipsticks are vitiated by humidity and air, which can cause false-negative results after improper storage.⁵⁸ Because RBCs may lyse rapidly, delays in performing UA may misleadingly suggest myoglobinuria or hemoglobinuria. Microscopy or dipstick testing of a freshly obtained specimen can clarify this issue. Conversely, high specific gravity or low pH can inhibit lysis of erythrocytes, which is necessary for the dipstick chemical reaction to occur, thus causing false-negative results.⁵⁹ A study reproducing clinical conditions has demonstrated that povidone-iodine does not cause false-positive results on the dipstick.⁶⁰ Iatrogenically caused trace positive results may occur after catheterization in 15% of cases.³⁶

Urine Bilirubin

Urine bilirubin represents the filtered, soluble, conjugated form of bilirubin. Unconjugated bilirubin is bound to protein and does not pass through the glomerulus. Bilirubinuria is therefore due to intrahepatic or extrahepatic cholestasis. Bilirubinuria will be detected significantly earlier than clinical jaundice.

BOX 67.1 Proteinuria**PROTEINURIA USUALLY WITH HEMATURIA**

Usually indicates glomerular disease
Most etiologies in early stages can present without hematuria

INFECTIOUS DISEASES

Post-streptococcal glomerulonephritis, pneumococcal pneumonia,
bacterial endocarditis, meningococcemia, secondary syphilis,
hepatitis B, severe viral infections, malaria, toxoplasmosis,
Guillain-Barré

MULTISYSTEM DISEASES

Vasculitides: Henoch-Schönlein purpura, polyarteritis nodosa,
Wegener's granulomatosis, Kawasaki disease, etc.
Connective tissue diseases (lupus, rheumatoid arthritis, scleroderma)
Neoplasia
Rhabdomyolysis (artificial hematuria)
Goodpasture's syndrome
Cryoglobulinemias
Toxemia of pregnancy
Serum sickness

PRIMARY GLOMERULAR DISEASES**PROTEINURIA USUALLY WITHOUT HEMATURIA**

Generally indicates tubular/interstitial disease, or high serum levels
causing "overflow"
In advanced disease, can develop hematuria

SYSTEMIC CONDITIONS

Physiological: postexercise, postural (with standing)
Pathological: fever, shock states, severe hypovolemia, dehydration,
congestive heart failure
Diabetes
Amyloidosis
Sarcoidosis
"Overflow states": multiple myeloma, lymphoma, leukemia,
rhabdomyolysis
Renovascular hypertension

MEDICATIONS, DRUGS, AND TOXINS

Nonsteroidal antiinflammatory drugs, gold, penicillamine, probenidic,
captopril, lithium, cyclosporin
Heroin
Heavy metal nephropathy: lead, mercury, or cadmium

RENAL DISEASES

Chronic pyelonephritis
Interstitial nephritis
Fanconi's syndrome

TABLE 67.3 Aids in Distinguishing Hematuria, Intravascular Hemolysis, and Myoglobinuria

	HEMATURIA	MYOGLOBINURIA	INTRAVASCULAR HEMOLYSIS
Serum Findings	Color: clear	Color: clear Haptoglobin: normal	Color: pink Haptoglobin: low
Urine Appearance	Color: clear to brown; clears with centrifugation	Color: clear to red/brown; no clearing with centrifugation	Color: clear to brown; no clearing with centrifugation
Urine Microscopy	RBCs, RBC casts, and protein: glomerular source RBCs, no RBC casts, tubular cells, small protein: nephron source RBCs alone: source distal to the nephron (e.g., ureterolithiasis)	Possible occasional RBCs and tubular cells secondary to rhabdomyolysis-induced renal damage	Usually unremarkable

RBC, Red blood cell.

Urinary bilirubin excretion is enhanced by alkalosis. A fresh sample of urine should be tested because bilirubin glucuronide is hydrolyzed when exposed to light. Ascorbic acid and high levels of urinary nitrites decrease the sensitivity of the test to bilirubin.

Urobilinogen

In a healthy person, conjugated bilirubin is excreted in bile. In the colon it is broken down into a number of compounds, including urobilinogen. Most of these compounds are excreted in stool, which is the source of its characteristic color. A small amount of urobilinogen is absorbed from the colon, and if it is not taken up on the first pass through the liver, it enters the circulation. Ultimately, some of this urobilinogen may enter

the urine, so it is normal to have zero to moderate levels of urinary urobilinogen on dipstick testing. Most diseases that cause hepatocyte dysfunction (hepatitis, cirrhosis, passive liver congestion, etc.) increase urinary urobilinogen excretion by impairing hepatic uptake of urobilinogen. As a qualitative test with a wide range of normal values it is rarely helpful, but in evaluating a patient with jaundice it can have diagnostic significance (Table 67.4).

pH

The average daily excretion of 50 to 100 mmol of H⁺ in urine gives rise to a typical urine pH of approximately 6 with a range from 4.5 to 8. Dietary protein lowers urinary pH, whereas fruit (especially citrus) and vegetables tend to raise it. The significance

TABLE 67.4 Relationship Between Urinary Bilirubin, Urobilinogen, and Stool Color in Jaundiced Patients

	HEALTHY NORMAL	COMPLETE BILIARY OBSTRUCTION	INTRAVASCULAR HEMOLYSIS	HEPATOCELLULAR DISEASE
Urinary Bilirubin	None	Elevated	None	Elevated
Urinary Urobilinogen	None or present	None	Present, sometimes large	Normal early, increased late
Stool Color	Normal	Acholic	Normal	Normal

of pH testing is in the assessment of normal renal function. In most states of alkalosis and acidosis, healthy kidneys maintain homeostasis by conserving or excreting H^+ . Failure to do so suggests renal disease, especially renal tubular acidosis. An exception is the *paradoxical aciduria* of hypokalemic alkalosis secondary to volume contraction, hypercorticism, or diuretics, where the highest priority of the renal tubule is to conserve sodium. pH is elevated by the action of urea-splitting bacteria, especially *Proteus* species. This can occur with stasis of urine, either in the bladder or in specimen cups. A persistently alkaline urine is seen in patients with struvite (triple phosphate) urolithiasis.

Specific Gravity

The dipstick test for urine specific gravity assays for the primary urinary cations, sodium and potassium. True specific gravity, which is also dependent on anions, albumin, proteins, urea, and glucose, is therefore not measured. Artificially low specific gravity readings are obtained with alkaline urine, whereas acidic urine and albumin falsely elevate the specific gravity reading. Consequently, some investigators believe that these strips on the dipstick test are of marginal clinical utility.⁶¹ Other clinical indicators of a patient's hydration status are probably more reliable. If necessary, a refractive specific gravimeter or a hygrometer should be used.

Microscopic UA

Microscopic UA is performed to identify cells, bacteria, and other microbes, as well as formed elements such as casts and crystals (Fig. 67.3). The following discussion focuses on the findings of significance in diagnosing UTI: WBCs, bacteria, and WBC casts. The presence of WBCs with bacteria distinguishes infection from colonization (bacteriuria without pyuria). Some authorities state that significant infection without pyuria occurs in less than 5% of cases, thus making pyuria alone a sensitive marker of infection.^{58,62} Other studies do not support reliance on pyuria by itself as an indicator of infection.^{2,3,5,31} The presence of WBC casts distinguishes pyelonephritis ("upper UTI") from cystitis ("lower UTI").

Microscopic UA is performed by one of five methods. Traditionally, the most common technique has been examination of unstained centrifuged urine. It has the advantage of concentrating formed elements that might otherwise be missed. Its disadvantage is that the presence and quantity of elements in a specimen will depend on many uncontrolled factors: the volume of the specimen, the duration and speed of centrifugation, the fragility of the formed elements, the volume of the "drop" in which the pellet is resuspended, and the size of the microscope's HPF.^{15,63,64}

1. Examination of unspun urine in a hemocytometer counting chamber. A hemocytometer is a precisely milled slide etched

with measured squares, which allows exact enumeration of the cells in each square. Because the distance between the etched surface and the coverslip is known exactly, it is possible to determine the number of cells per unit volume of specimen. Enough fresh unspun urine is placed on the slide to fully cover the counting area, and the cells are counted. There should usually be less than 1 WBC/ μ L, although more than 10 WBCs/ μ L and more than 5 RBCs/ μ L are unequivocally abnormal.⁶⁵ The threshold for diagnosing UTI is usually set at 8 or more WBCs/ μ L.^{9,26,63,66,67} Bacteria do not sink to the surface of the hemocytometer, so counting them through the many focal planes of the chamber is not possible, although methods to estimate the bacterial count per unit volume have been described.⁶⁴ The hemocytometer is accurate, fast (time need not be spent on staining or centrifugation), and relatively easy to master. Its major drawbacks are cost (approximately \$150 for the slide and cover slip) and fragility (easily destroyed if dropped). These characteristics are problematic given the conditions and resources in many EDs, although their use has been advocated by some.⁶⁸ Formed elements other than WBCs and RBCs (e.g., casts) occur in such low concentrations that they are encountered in the hemocytometer only by chance, and therefore microscopy of spun urine is needed for their identification.

2. Examination of unspun, unstained urine placed on a regular microscope slide. This qualitative method is sometimes used for the diagnosis of UTI. Using 1 organism/HPF as a positive result, the sensitivity and specificity of detecting 10^5 CFUs/mL are between 60% and 90%.⁶⁹ This method identifies only 1 WBC/HPF with the highly pyuric state of 250 WBCs/ μ L,⁶⁷ which has led some to advocate the use of more than 1 WBC per low-power field as a criterion for infection.⁶⁵
3. Examination of unstained, centrifuged urine. With this method, 10 mL of urine is centrifuged at approximately 450g (1000 to 4000 rpm) for 3 to 5 minutes. Roughly 9 mL of supernatant is poured off and the pellet is resuspended in the remaining fluid. This suspension is placed on a slide with a coverslip and examined. The larger formed elements, especially casts, tend to migrate to the edge of the coverslip, and they can be seen with low magnification. One or two casts, depending on the clinical context, may be normal; more are not. The morphology of the more commonly encountered formed elements of urine sediment is shown in Fig. 67.3. The significance of each is beyond the scope of this text, but this information can be found in a standard textbook of clinical laboratory procedures and diagnostic testing.^{43,44} When examining centrifuged urine, more than 5 WBCs/HPF in the middle of the coverslip has traditionally been taken as being indicative of abnormal pyuria. Most authors have estimated that 10 WBCs/ μ L is equivalent to

Figure 67.3 Microscopic urinalysis. **A**, Neutrophils. **B**, Fine granular cast. **C**, Red blood cell cast (the distinct and uniformly spherical shape of the erythrocyte is visible). **D**, White blood cell cast (seen with intrinsic renal diseases such as pyelonephritis and glomerulonephritis; note the discernible nuclei and cell boundaries). **E**, Uric acid crystals. **F**, Calcium oxalate crystals. **G**, Calcium phosphate crystals. **H**, Cysteine crystal (indicative of cystinuria). **I**, Bacteria and leukocytes. **J**, *Candida*, budding yeast. **K**, *Candida*, pseudohyphae. **L**, *Trichomonas vaginalis*. (A–K, From McPherson RA, Pincus MR, editors: Henry's clinical diagnosis and management by laboratory methods, ed 22, Philadelphia, 2011, Saunders; L, From Bieber EJ, Sanfilippo JS, Horowitz IR, editors: Clinical gynecology. Philadelphia, 2006, Churchill Livingstone.)

approximately 1 WBC/HPF; thus, this oft-cited threshold for diagnosing UTI is actually equivalent to 50 WBCs/ μ L in unspun urine.^{63,65,66} As the gold standard for the diagnosis of UTI is more than 8 WBCs/ μ L of unspun urine, many infections will escape detection with this method. Various numbers of bacteria per HPF have been used as criteria for the diagnosis of UTI. A threshold of 10 to 20 organisms/HPF has been recommended to rule out bacteriuria at the 10^5 -CFU/mL level.⁶⁹ As noted previously, this threshold would not exclude infection in symptomatic patients.

4. Examination of Gram-stained, uncentrifuged urine. Also a semiquantitative measurement, it is estimated that 1 bacterium/HPF is equivalent to 10^5 CFUs/mL in bacterial culture.^{43,69} A drop of urine is placed on the slide, allowed to air-dry, and then heat-fixed and Gram-stained.
5. Examination of Gram-stained, centrifuged urine. This method is probably the optimal technique, short of culture, for the assessment of bacteriuria. It is more than 95% sensitive and more than 60% specific at 10^4 CFUs/mL, a concentration of bacteriuria that is an order of magnitude lower than the previously described methods.⁷⁰ Detection of 1 organism per oil-immersion field constitutes a positive result. Specificity is increased to 95% if 5 organisms/HPF are seen.⁶⁹

Summary of Tests Used in the Diagnosis of UTI

The three tests commonly used to evaluate a patient for the presence or absence of UTI are urine dipstick, microscopic UA, and urine culture. Each represents an increasing degree

of expense, delay, and resources.⁷¹ A brief discussion of their relative strengths and weaknesses ensues.

Urine Dipstick

Dipstick testing of urine is faster than microscopic UA, is less labor-intensive, cheaper, and circumvents multiple sources of potential and proven error. Is it sufficiently accurate to replace UA; however, if either leukocyte esterase or nitrites are used to indicate infection, the dipstick is only 50% to 90% sensitive for culture-proven infection.^{16,48,49,70,72} This is not adequate to rule out infection in symptomatic patients, in whom the prevalence of disease is high, but may be acceptable in asymptomatic patients, in whom the test has a serviceably high negative predictive value of 95% to 99%. A large retrospective series demonstrated laboratory-performed UA (with microscopy) in children to be 8% more sensitive than dipstick testing in the ED, with similar specificity of approximately 80% for both tests.²⁴ In symptomatic men, sensitivity is enhanced by taking a positive result in any one (or more) of either leukocyte esterase, nitrites, protein, or blood as an indication of UTI.^{16,73–75} This process can be augmented by allowing extra time before reading the strip. For women with classic symptoms of UTI, empirical treatment is recommended because no test can rule out infection.⁷¹ A negative dipstick test in a patient with a high pretest probability of UTI should prompt a search for an alternative source of the patient's symptoms. Maneuvers to enhance dipstick sensitivity diminish its specificity, which may be as low as 26%.¹⁰ This has led some to advocate microscopic UA on all urine specimens that are found to be abnormal by dipstick,⁷⁴ but this probably adds little to a carefully performed dipstick test.

Microscopic UA

If the urine dipstick has such poor specificity when it is used as a test with adequate sensitivity, should it be discarded altogether and microscopic UA be relied on instead? Apart from the hemocytometer, the most reliable method for identifying significant bacteriuria is oil-immersion microscopy of Gram-stained, centrifuged urine.⁶⁹ Nonetheless, the practice in most hospital laboratories is to examine a resuspended pellet of unstained, centrifuged urine. The problems with this method have been discussed. In various studies a range between 1 and 10 organisms/HPF or 5 WBCs/HPF has been considered a “positive” test (as the threshold number rises, so does specificity, at the price of sensitivity). In aggregate, the accuracy of microscopy in the diagnosis of UTI is similar to that of the dipstick alone, with 22% false-positive and 23% false-negative rates when compared with culture.^{58,64,71} Microscopic UA, like the dipstick, cannot rule out infection in symptomatic patients. The specificity of pyuria is improved when viewed as a marker of all genitourinary infections, including urethritis, prostatitis, epididymitis, vaginitis, and cervicitis. These diagnoses should always be entertained in patients with urinary symptoms, especially those with sterile pyuria.

Urine Culture

Cultures are indicated for any potentially complicated UTI, including infections in children; men; women with recurrences or relapses; immunocompromised individuals; patients with urinary tract pathology, including stones and possible pyelonephritis; and pregnant patients. Cultures are usually recommended at approximately the 16th week of gestation. Every effort should be made to obtain a high-quality specimen because of the difficulty in distinguishing contamination from significant low-count bacteriuria in symptomatic patients and in view of the expense of cultures and treatment if the culture is positive.

The Bottom Line

It is well established that female patients with symptoms of uncomplicated lower UTI can be treated without culture because the prevalence of disease is 50% or greater in women with classic urinary symptoms.^{15,50,76,77} Treatment is generally benign, and 95% of urine cultures that are positive will yield a limited number of organisms with predictable antibiotic susceptibilities. Some authors recommend dipstick or microscopic UA (or both) because a negative test might prompt more careful consideration of alternative diagnoses in this group, with a high incidence of sexually transmitted disease.^{15,50} If none is found, such patients can be treated empirically.

Fluoroquinolone antibiotics are no longer recommended as empiric treatment for uncomplicated UTI. Traditional choices have included trimethoprim-sulfamethoxazole or macrodantin, but both of these agents have high resistance rates in many locations, so choices should be based on local microbial susceptibility patterns, if available.^{78,79}

Urine testing is more likely to influence clinical management in patients with an intermediate pretest probability of infection.¹⁰ Urine microscopy may also help in distinguishing pyelonephritis (WBC casts), vaginitis (absence of pyuria or hematuria in a meticulous MSCC or catheterized specimen), and urethritis (pyuria, rarely hematuria) from cystitis (pyuria and often hematuria).^{15,50} In the ED, the ease of performing a dipstick test argues for its use without UA because it is equally sensitive

unless formed elements such as casts, crystals, *Trichomonas*, or other parasites are suspected. In patients with pyelonephritis, urine cultures are warranted because they alter therapy in approximately 5% of cases.⁸⁰ In most asymptomatic patients, a negative dipstick or UA result has sufficient negative predictive value to rule out disease unless the patient is pregnant or undergoing urologic surgery. Special clinical considerations in some patients (e.g., the immunocompromised, diabetic females at high risk for UTI) may mandate adjustments to this approach.¹⁶ Recommendations vary regarding infants. Cultures are recommended for all febrile infants younger than 2 months and for children who appear sick or have a high pretest probability of infection.^{25,27} In a 2009 study, combined microscopic and dipstick UA was only 64% sensitive (and 91% specific) for culture-proven UTI in febrile infants younger than 24 months, thus suggesting the use of culture unless an alternative source of infection is clear.⁸¹

TESTING FOR PREGNANCY

Some investigators have found female patients reliable in determining their own pregnancy status.^{82,83} Others have not.⁸⁴ With respect to ordering radiographic studies on women of childbearing age, clinicians should determine from their own practice experience the reliability of patient history in this regard. If in doubt and with the potentially lethal outcome of an ectopic pregnancy, it might be prudent to use an objective test. Pregnancy tests are based on the detection of β -human chorionic gonadotropin (β -hCG) in serum or urine. β -hCG is secreted by trophoblastic cells of the placenta starting from the time of implantation of the blastocyst. Qualitative serum and urine tests can detect β -hCG levels of between 15 and 25 mIU/mL (Fig. 67.4).⁸⁵ The concentration of β -hCG is usually lower in urine than in serum, which accounts for the slight advantage of serum tests in detecting early pregnancy. Optimal results on urine pregnancy tests are obtained with first-voided, concentrated morning specimens. It has recently been established that whole blood is a reliable specimen for the bedside dipstick tests used in most EDs.^{86,87} The same volume of blood is placed in the testing well(s) as when performed with urine. This alternative may be lifesaving in timely recognition of an ectopic pregnancy in a hypotensive female with pelvic complaints and unknown pregnancy status when a urine specimen is unavailable or results in significant delay.

If fertilization has occurred, β -hCG levels of 5 to 8 mIU/mL (the threshold of the quantitative serum test) correspond to the 9th to 11th day after ovulation (23 to 25 days after the first day of the last normal menstrual period). In a viable intrauterine pregnancy (IUP), the β -hCG level doubles approximately every 2.5 days during the first 4 weeks of gestation and reaches a serum level of greater than 25 mIU/mL, which is detectable by virtually all pregnancy tests on the first day of the missed menstrual period. The doubling rate declines to every third day thereafter.^{88,89} β -hCG reaches a peak of between 100,000 and 200,000 mIU/mL between the 10th and 14th gestational weeks and declines to 10,000 to 20,000 mIU/mL for the rest of the pregnancy (Table 67.5). There is a wide range of β -hCG levels in different women at the same stage of gestation, thus making definite clinical determination on the basis of a single quantitative test impossible.^{90,91} False-positive test results have been described in association with molar pregnancy, choriocarcinoma, teratoma, occasional

Figure 67.4 Urine β -human chorionic gonadotropin (β -hCG) testing. **A**, The concentration of β -hCG is usually lower in urine than in serum, thus making the urine test slightly less sensitive for the detection of early pregnancy. Whole blood specimens can also be used in these kits (see text). **B**, This test is positive, as indicated by the dark stripe in both the test (T) and control (C) positions (*arrows*).

malignancies outside the genitourinary tract, and very high levels of proteinuria. There is one report of a positive urine β -hCG finding (but normal serum β -hCG) associated with a tuboovarian abscess.⁹²

Although a previous quantitative β -hCG level is rarely available to the emergency clinician, doubling rates are an important part of the assessment of a healthy first-trimester pregnancy. Fetal nonviability, ectopic pregnancy, and intra-uterine demise are signaled by abnormalities in the predicted rise in quantitative β -hCG.^{93,94} A serum quantitative β -hCG level that does not increase by 66% every 48 hours has a 75% chance of being a nonviable pregnancy.^{94,95} β -hCG levels in a healthy IUP and associated sonographic findings are listed in [Table 67.5](#).

The rate of decline in quantitative β -hCG after gestation depends on the reason for the conclusion of the pregnancy. After a term delivery, β -hCG falls to zero in 2 weeks; after surgery for an ectopic pregnancy, the range is 1 to 31 days, with a median of 8.5 days; after a first-trimester spontaneous abortion, the range is 9 to 35 days (median, 19 days); and after a first-trimester elective abortion, the range is 16 to 60 days (median, 30 days).⁴³

The association between β -hCG levels and gestational dates has led to the concept of the “discriminatory zone.” In a normal pregnancy, a quantitative β -hCG level of 1000 to 2000 mIU/mL should be reflected by the presence of a double decidual sac (at the least) on transvaginal ultrasound (and on transabdominal ultrasound with levels higher than 6500 mIU/mL).⁹⁶ The clinician should beware of several potential pitfalls in applying this concept. First, it applies only to the double decidual sign, itself subject to interobserver variation among sonographers. The discriminatory zone cannot be extrapolated to the expected levels at which any of the more definitive sonographic signs of IUP such as yolk sac, fetal pole, or cardiac motion should be seen. Second, although it is true that if the double decidual sign is absent at these thresholds, the pregnancy is almost certainly abnormal with a significant possibility of

TABLE 67.5 Relationship Between Gestational Age, Q β -hCG Levels, and Ultrasound Findings

TIME ELAPSED FROM THE FIRST DAY OF THE LAST NORMAL MENSTRUAL PERIOD	Q β -hCG LEVEL (mIU/mL) USING THE IRP	ULTRASOUND FINDINGS
< 28 days	5–50	
4–5 wk	50–500	From approx. 4.5 wk and Q β -hCG level of 1000–1500 EVU can show a nonspecific intrauterine sac
5–6 wk	100–10,000	Definitely abnormal if no DDS seen on TVU with a Q β -hCG level >2000 or by TAU with a Q β -hCG level >6500 Abnormal if no YS with an MSD >10 mm
6–7 wk	1000–30,000	FP, cardiac activity 5.5–7 wk, Q β -hCG level >10,000 Abnormal if no FP with an MSD >18 mm
7–8 wk	3500–115,000	
8–14 wk	12,000–270,000	
>10 wk	270,000–15,000	

DDS, Double decidual sac; EVU, endovaginal ultrasound; FP, fetal pole; IRP, international reference preparation; MSD, mean sac diameter; Q β -hCG, quantitative β -human chorionic gonadotropin; TAU, transabdominal ultrasound; TVU, transvaginal ultrasound; YS, yolk sac.

being ectopic, the converse—that it is pointless to perform ultrasonography if the quantitative β -hCG level is lower than 1000 mIU/mL—is not true. This is because the discriminatory zone does not preclude the possibility of identifying an ectopic pregnancy (or an IUP) before the quantitative β -hCG level reaches 1500 mIU/mL. Ectopic gestational sacs are pathological and therefore do not display β -hCG levels according to nomograms established for normal IUPs, and advanced ectopic pregnancies may have low β -hCG levels. One percent of ectopic pregnancies have a quantitative β -hCG level of less than 10 mIU/mL, and approximately a third of ectopic pregnancies are diagnosed in patients with a quantitative β -hCG level lower than 1000 mIU/mL.^{97–100} Even if no definitive diagnosis can be made, the clinician should be aware that pregnant ED patients with pelvic complaints and a β -hCG level of 1000 mIU/mL or lower have a fourfold increased risk for ectopic pregnancy in comparison to those with the same symptoms and a β -hCG level higher than 1000 mIU/mL.¹⁰¹

In summary, the discriminatory zone provides a basis for interpreting the ultrasound image, but not a basis for deciding whether to perform it.^{96,98,102} Although the percentage of patients below the discriminatory zone who will receive a definitive diagnosis by ultrasound is much lower than the percentage in those above the discriminatory zone (25% vs. 90%), even a 25% diagnosis rate would seem to merit pursuit for a potentially lethal condition, especially as follow-up for patients whose evaluation is indeterminate on their ED visit is time-consuming and resource-intensive.^{98,103}

BLOOD CULTURES IN THE ED

Indications

Blood cultures are indicated when the clinical findings suggest an otherwise unidentifiable bacteremic state (Box 67.2). Twenty-five percent of patients with documented bacteremia have periods without fever.¹⁰⁴ In the elderly the proportion is even higher, with 50% of bacteremic patients older than 65 having a temperature between 97.1°F (36.2°C) and 100.9°F (38.3°C)

BOX 67.2 Summary of Indications for Obtaining Blood Cultures

PATIENTS WITH FEVER AND ANY OF THE FOLLOWING:

- Unexplained alterations in mental status, functional status, or autonomic status in a previously healthy patient between the ages of 5 and 65
- No source found and younger than 2 years, older than 65, or immunocompromised
- Age younger than 2 months

PATIENTS WITH OR WITHOUT FEVER AND ANY OF THE FOLLOWING:

- Rigors
- Toxic or “septic” appearance (e.g., unexplained hypotension, altered mental status, shock)
- Suspicion of infectious endocarditis
- Serious focal infections (e.g., meningitis, septic arthritis, osteomyelitis)

and at least 13% with no documented temperature higher than 99.1°F (37.3°C) at any time.^{105–108} In the elderly, increasing age, vomiting, altered mental status, urinary incontinence, presence of a Foley catheter, or greater than 6% band forms is predictive of a positive blood culture.^{106,109} The subjective impression of “having fever” in adults is not a reliable indicator of the presence of fever, although the subjective impression of “no fever” is much more likely to be accurate.¹¹⁰ Prediction models to optimize the use of this costly test have been explored but are cumbersome, add little to educated clinical judgment, and lack widespread validation or acceptance.^{111–113} Many studies have shown that blood cultures in patients with uncomplicated pneumonia or pyelonephritis are of very limited clinical value,^{114–125} although a 2010 prospective investigation of patients with upper UTI found that malignancy, an indwelling urinary catheter, and ongoing antimicrobial treatment were clinical conditions that made it significantly more likely that blood cultures would be discordant with urine cultures and that they would reveal clinically important additional information.¹²⁶ Blood cultures are obtained during 2.8% of all ED visits in the United States, and in a single 3-year period this rate increased by 33%.¹²⁷ As disease prevalence is unlikely to have changed so rapidly, this increase is probably due to changes in practice. These changes have been coincident with regulatory agency-mandated blood cultures in patients being evaluated for pneumonia and have led to calls for more stringent criteria for obtaining blood cultures.

In children, the traditional teaching that blood cultures are indicated for all patients younger than 2 years with fever higher than 38.6°C (>101.5°F) and without an obvious source is being modified by the widespread use of pneumococcal conjugate (PC) and *Haemophilus influenzae* type b (HIB) vaccines.^{128,129} In the post-PC and post-HIB vaccine era, the incidence of occult bacteremia in otherwise well-appearing febrile children is probably lower than 1%, thus making the false-positive rate at least four times as high.^{128–130} It seems reasonable to withhold blood cultures and empirical antibiotic coverage in otherwise well-appearing febrile children with reliable parents. The risk for bacteremia in a child is positively correlated with the degree of fever, WBC count, and rapidity of onset of the illness. It is inversely proportional to the patient's age.^{131–134} In infants younger than 2 months with temperatures higher than 38°C (>100.5°F), some authorities would recommend blood cultures regardless of the presence or absence of a source, although this approach is subject to modification by experienced clinicians based on the patient's age and clinical setting. A child with a normal temperature in the ED and a history from the parents of a tactile fever needs to be approached in the same way as a patient with fever documented on physical examination. Parents' tactile impression of fever is reliable, and bacteremic children, like adults, have intermittent fever, with up to 50% afebrile rates in children with demonstrated bacteremia.^{135,136}

The Controversy Regarding Outpatient Blood Cultures

There is a long-standing debate regarding the utility of outpatient blood cultures (i.e., blood cultures on patients who are discharged from the ED pending results). Arguments for and against outpatient blood cultures are summarized in Box 67.3. Opponents cite medicolegal issues, problems with follow-up, high contamination rates, low rates of positive cultures, and

BOX 67.3 Summary of Arguments for and Against the Performance of Outpatient Blood Cultures

ARGUMENTS AGAINST OUTPATIENT BLOOD CULTURES

- Low true-positive rates
- True positives are rarely clinically significant.
- False positives are expensive and time-consuming for both the patient and the health care system.
- Unreliability of emergency department follow-up makes positive results a medicolegal liability.

ARGUMENTS FOR OUTPATIENT BLOOD CULTURES

- Permits outpatient evaluation and management of patients with a low probability of disease (especially infectious endocarditis).
- Patients: financial, psychological, and nosocomial cost savings from spared admissions
- Society: financial and nosocomial cost savings from spared admissions
- Allows initiation of antibiotics for possible alternative infectious diagnoses without irrevocable loss of the opportunity for blood cultures

even lower rates of frequency in patients in whom therapy is changed because of culture results.¹³⁷⁻¹⁴⁰ Proponents also cite medicolegal concerns, positive rates similar to those seen with inpatient blood cultures, cost savings, and the benefit of diagnosing significant, yet subtle bacteremic states (such as endocarditis).¹⁴¹⁻¹⁴³ Patients discharged with occult bacteremia generally have a benign clinical course.^{143,144} It should be noted that “occult” may be something of a misnomer in this setting, because some aspect of the patient’s clinical state prompted the decision to obtain blood cultures. Proponents of outpatient blood cultures also point out that the high false-positive rates seen in many ED series should be an indictment of poor technique, not of the test itself.

On the basis of current data, it seems fiscally extravagant to admit all patients in whom a bacteremic state is possible and injudicious to deny blood cultures solely on the basis of a patient not appearing “toxic enough” to warrant admission. Societal and economic pressures to avoid hospital admission buttress these clinical considerations. Outpatient blood cultures, with due attention to collection technique, patient selection, and arrangements for follow-up, have a place in emergency practice. This approach is reflected by the fact that fully half of ED blood cultures are obtained from patients who are not admitted to the hospital.¹²⁷

Technique for Obtaining Blood for Culture

False-positive blood cultures obtained in the ED can result in up to \$8800 in additional costs, with an average increase in hospital length of stay of 1 day per patient.¹⁴⁵ Studies have demonstrated sources of contamination at every stage of the process of performing and processing blood cultures. In addition to obvious sources of contamination from the patient’s and phlebotomist’s skin, antiseptic agents and gloves have been implicated.^{146,147} Some authorities have argued that the primary source of contamination is in the laboratory processing of

specimens.¹⁴⁸ The consensus is that the most common source of contamination is the process of phlebotomy and inoculation of blood culture bottles.^{145,149,150} Obviously, this is the single step over which emergency clinicians have control, either directly or via protocols of technique for blood culture phlebotomy. Contamination rates are typically between 1.5% and 3%,^{128,151,152} although many ED series show much higher rates.^{139,145,153} Conversely, settings in which there are rigorous protocols for obtaining blood cultures have contamination rates as low as 1%.¹⁵⁰

A high degree of sensitivity is required for blood cultures. Many significant bacteremic illnesses have been documented with as little as 1 CFU/10 mL of blood.^{154,155} In a cadaver study, human skin has been shown to have a bacterial concentration of between 10³ and 10⁶ CFUs/mL on the forearm and groin, respectively.¹⁵⁶ Designed to detect vanishingly low concentrations of bacteria, the test is clearly susceptible to false-positive results (impaired specificity) when blood must necessarily be obtained by passing a needle through the skin. Eighty percent of the skin flora is transient, superficial, and removable; 20% inhabit the sebaceous ducts and hair follicles and cannot be removed without destroying the skin.^{156,157} The former group consists of predominantly gram-positive and gram-negative aerobes and is the target of skin disinfectants.

The primary agents for skin disinfection are iodine compounds, alcohols, chlorhexidine, and hexachlorophene. Iodine solution remains a gold standard and kills bacteria, fungi, protozoa, and viruses but has been replaced in many institutions because of concern about skin burns and allergic reactions. Reports of the former were probably due to the use of 7% solution. The risk for a burn or an allergic reaction is thought to be negligible with the currently available 2% preparation.¹⁴⁹ The most effective cleansing agent is tincture of iodine, which is a mixture of 2% iodine solution and 70% alcohol.^{158,159} Povidone-iodine 10% solution (Betadine, Purdue Pharma L.P., Stamford, CT) has a much lower free-iodine concentration than iodine solution and is therefore less potent. Iodine is superior to hexachlorophene and chlorhexidine in killing gram-negative bacteria. Iodine, like other antiseptic agents, is inhibited by the presence of organic matter and thus requires thorough skin cleansing before the application of any skin disinfectant.

Ethyl or isopropyl alcohol should be used in a 60% to 80% solution. Alcohol prep pads, which generally contain 70% isopropanol, have solved traditional concerns regarding evaporation of alcohol from cotton balls stored in jars. Alcohol is a less powerful germicide than iodine *in vitro* and kills only 90% of surface bacteria after a full 2 minutes with reapplication to prevent drying.¹⁶⁰ Alcohol foam applicators can avoid premature drying. Alcohol is inactive against fungi, spores, and viruses, but *in vivo* studies of blood culture contamination rates have shown it to compare favorably with iodine.^{158,161} Because iodine solution is often not available and iodophor solutions are less potent, alcohol still has an important place in skin antiseptics. In addition, alcohol is an excellent solvent, so alcohol pads may assist in skin preparation by removing dirt- and microbe-laden skin oils before the application of iodine compounds.

Chlorhexidine (Hibiclens, Mölnlycke Health Care, Norcross, GA) and hexachlorophene (pHisohex, Aspen Pharmacare Australia Pty Ltd) are antiseptics that are more effective against gram-positive than gram-negative bacteria. Both agents are absorbed intradermally, thereby offering prolonged antimicrobial activity, which is the basis of their popularity as surgical

BOX 67.4 Skin Preparation and Technique for Drawing Blood for Culture

Cleanse the skin with alcohol swabs three times or until the swabs appear entirely free of surface dirt.

Allow to dry.

Apply 10% povidone-iodine or (preferably) 2% iodine solution or (ideally) 2% tincture of iodine in 70% alcohol three times in centrifugal circles from the anticipated site of venipuncture.

After the third swab, allow to dry for at least 60 seconds.

During this period:

- Remove the covers and sterilize the rubber stoppers of blood culture bottles with iodine, alcohol, or both.
- Lay out sterile gloves.
- Use a paper glove wrapper as a sterile field for the needle and syringe (not necessary if using a Vacutainer system).

Wipe off dry iodine at the venipuncture site with alcohol.

Substitute chlorhexidine if placing an indwelling catheter.

Obtain at least 20 mL of blood to place in two bottles.

- If short, use at least 10 mL for an aerobic bottle.
- If more than 20 mL, use additional aerobic bottles. Place no more than 10 mL of blood per bottle.

Inoculate bottles without changing needles between bottles.

However many bottles are filled, this is one set of blood cultures. Another set cannot be obtained from this site, regardless of how many bottles are filled.

scrub and operative site preparations. This also makes them preferable agents when indwelling lines, especially central lines, are being placed.¹⁶² For routine blood culture phlebotomy, they are not as effective as alcohol and iodine combinations, although they are superior to povidone-iodine solution.¹⁵² Most studies show chlorhexidine to be more potent than hexachlorophene, and it has not been associated with induction of seizures in infants.

Box 67.4 presents a skin preparation protocol. Optimal results seem to be obtained with alcohol-iodine mixtures.^{156,159,163,164} The most important concept in skin disinfection is that bacteria do not die at the instant of contact with disinfectant agents. Iodine (2%), which is twice as potent as 10% povidone-iodine, requires at least 90 seconds in contact with the skin to kill 90% of surface bacteria.¹⁶⁰ In many ED patients it will be necessary to use alcohol prep pads to remove gross dirt and debris from phlebotomy sites before initiating the steps of formal skin preparation.

Special Considerations in Obtaining Blood for Culture

Changing the Needle After Phlebotomy

In considering this issue it is important to emphasize the distinction between needle changing and needle recapping.¹⁶⁵ The latter is a well-established risk to health care workers. It contravenes standard recommendations for universal precautions and should not be performed. Needle replacement using the standard needle removal device on sharps containers is an unquantified risk, but clearly much less dangerous than recapping.

Based on little scientific data it was long considered essential to change the phlebotomy needle before inoculating blood

culture bottles. With increasing awareness of the risks associated with needlestick injuries, this practice has come under scrutiny. Studies generally show trends toward lower contamination rates with needle change, but without reaching statistical significance.¹⁶⁶⁻¹⁶⁸ Thus, not changing needles before inoculation of blood culture bottles is acceptable practice for routinely obtaining blood for culture. In situations in which the results of blood cultures are of paramount importance (e.g., suspected infectious endocarditis, where empirical antibiotics are to be started immediately), needles can be changed before inoculation of culture bottles (without recapping).

Special Access Sites

Most studies show that newly placed intravenous (IV) catheters are an acceptable source of blood specimens for culture, provided that the usual measures are taken in skin preparation.^{151,168} Chronically placed lines either trend toward or show statistically significant increases in contamination rates.¹⁶⁹⁻¹⁷² An exception can be made for carefully tended central venous access ports in cancer patients. These cultures may have increased sensitivity in identifying bacteremia, possibly because the catheters themselves are often a source of bacteremia in these patients.¹⁷³

Heel Stick in Neonates

This technique resulted in recovery rates of bacteria equivalent to those with phlebotomy in two studies.^{174,175} As approximately 25% of bacteremic infants have fewer than 5 CFUs/mL of blood, this proportion (25%) will be missed if less than 0.2 mL is obtained for culture. For this reason, heel stick should be considered a source of last resort for blood culture.

Intraosseous Specimens

This technique may also be used when phlebotomy is impossible.¹⁷⁶

Timing of Blood Cultures

In most circumstances the timing of blood cultures is moot in the ED. Patients are sick enough to warrant the initiation of empirical antibiotics or are well enough for discharge, so two or more sets of blood need to be drawn immediately. The timing of blood cultures might become a consideration in a patient requiring admission but in whom the diagnosis of bacteremia is in doubt such that empirical antibiotic therapy is withheld. Contrary to medical lore, true-positive blood cultures are more likely if blood is drawn in the 12 hours before a fever spike.^{177,178} Furthermore, except for infectious endocarditis, most clinically significant bacteremia is thought to be intermittent, so multiple sets of specimens obtained at one time for culture would heighten the risk for missing the period of bacteremia.¹⁷⁹ For patients admitted to the hospital with the tentative diagnosis of sepsis, it is theoretically advantageous to draw the three sets of blood for culture over the first 12 to 24 hours of admission.¹⁸⁰ If immediate administration of antibiotics is indicated, the two or three sets of blood for culture should be obtained before initiation of antibiotic therapy.

Blood Culture Volumes

Volumes in Adults

A large number of studies almost uniformly demonstrate that the sensitivity of blood cultures is directly related to the volume

of blood cultured.^{181–186} In a representative study, Ilstrup and Washington showed that 20 mL and 30 mL of blood yielded, respectively, 38% and 62% more true-positive results than 10 mL did.¹⁸³ Mermel and Maki showed that each additional milliliter of blood yields an average of 3% more true-positive results.¹⁸⁶ This finding is also consistent with the fact that 40% of adults with bacteremia have less than 1 CFU/mL of blood and that 20% have less than 1 CFU/10 mL.¹⁸⁷ Alternatively expressed, if 10 mL of blood is obtained for culture, 20% of patients with continuous bacteremia will be missed. As most bacteremia is intermittent and endogenous factors in blood will cause some inhibition of bacterial growth even with modern lysis and filtration centrifugation techniques, the false-negative rate in clinical practice will always be significantly higher. On purely mathematical grounds, 10 mL per set of blood cultures is a bare minimum for culture. In adults, most authorities recommend at least 30 mL of blood per culture site or set.^{188–190} To ensure dilution of the blood's antibacterial properties (e.g., immunoglobulins, complement, WBCs), culture bottles should contain a concentration of blood of less than 1 part blood to 10 parts medium.¹⁹⁰ If 30 mL of blood is obtained from one site, it should be divided equally into three of the usual 100-mL broth bottles.

Volumes in Children

A blood volume of 30 mL from a 70-kg adult is equivalent to 0.5 mL of blood from a 3.5-kg neonate. Fortunately (for the utility of blood cultures), levels of bacteremia are typically 10-fold higher in neonates than in adults.¹⁹¹ The sicker the child, the greater the likelihood of a high level of bacteremia.^{191,192} As the immune system matures during infancy, levels of bacteremia might be expected to fall toward those seen in adults, so small culture volumes are at increased risk for false-negative results.^{193–195} As a rule of thumb, a similar volume of blood with respect to body mass should be drawn from children as is drawn from adults: approximately 1 mL/2.5 kg, or 4 mL blood per 10-kg body mass.^{196,197}

How Many Sets of Blood Cultures Are Needed?

A set of blood cultures is the sample obtained from a single site. A 1-mL specimen from a neonate placed in an aerobic bottle and a 30-mL specimen from an adult divided between fungal, aerobic, and anaerobic bottles are both a single set of blood cultures (Fig. 67.5). Two or more sets of blood cultures make up a series.¹⁸⁰ The information derived from the blood culture sets is pooled in such a way to make both the sensitivity and specificity of the series greater than that of the component sets. Sensitivity is enhanced because, as discussed earlier, an individual set is typically not more than 80% sensitive.¹⁹⁸ Specificity is improved for microbes that can act as both pathogens and contaminants by determining whether they appear in all sets (pathogen) or in only some (more likely a contaminant).

Although this conceptual process is applied to all blood culture series, the focus of inquiry depends on the infectious process being ruled in or out. For example, in an elderly patient with sepsis and a chronic indwelling Foley catheter, it is extremely unlikely that the causative organism is a typical skin contaminant. The usual causes of false-positive blood cultures will therefore be easily recognized, thus lowering the false-positive rate for the series and yielding a test with intrinsically

Figure 67.5 These two blood culture bottles (anaerobic and aerobic) represent a single set of blood cultures, provided that they are filled with a sample from a single site. Two or more sets of blood culture bottles (each obtained from a different site) represent a series of cultures.

higher specificity. At the same time, with the typical pathogens in this clinical context being nonfastidious organisms, sensitivity is typically at approximately 99% with two sets consisting of 20 mL of blood per set.¹⁸⁹ Conversely, in a patient with a prosthetic heart valve, fever, and signs of septic emboli, many probable pathogens are also skin contaminants, thereby lowering the specificity of each individual blood culture set. Thus, at least two sets of cultures must be positive with such organisms before the overall test (i.e., the series) is considered positive. At the same time, this clinical picture makes the pretest probability of disease very high (diminishing the negative predictive value of a negative set), so an extremely sensitive overall test (i.e., series) will be needed to adequately rule out disease. In this setting, most authorities would recommend four sets of blood culture bottles, with good volumes in each.^{179,198} Except in infants, single sets of blood for culture are of insufficient sensitivity or specificity to be of any utility and should not be drawn.^{178,179,198–200} The recommended numbers of sets of blood cultures as they relate to the pretest probability of disease and causative organism are summarized in [Table 67.6](#).

Aerobic Versus Anaerobic Versus Other Bottles

Anaerobic infections tend to occur in poorly perfused tissues or locations and frequently evolve into abscesses. Both characteristics mean that these infections tend to be isolated or separated from the bloodstream, thereby decreasing the likelihood of bacteremia and detection by blood culture. For these reasons it is not surprising that anaerobic isolates account for 0.5% to 12% of positive blood cultures.^{179,201–203} Blood cultures in general have a typical true-positive rate of approximately 5%; with 5% or less of positive blood cultures being anaerobic, more than 400 patients need to have a complete series of blood drawn for culture to detect one case of anaerobic bacteremia.^{204–208} If more than 50% of anaerobic infections are clinically evident before culture, at least 800 blood culture series are needed to generate a single anaerobic result that would alter clinical management. Anaerobic cultures may also have the unintended consequence of compromising the sensitivity of aerobic cultures in situations in which less than the ideal 20 mL of blood is

TABLE 67.6 Numbers of Blood Culture Sets to Be Obtained in Various Clinical Situations in Adults

NUMBER OF SETS (MINIMUM)	CLINICAL CONTEXT
Two sets	A true positive is likely to be easily distinguished from contaminants and pretest probability of bacteremia is low to moderate.
Three sets	Skin contaminants are possible causes of the infectious process, the pretest probability of bacteremia is high, or infectious endocarditis is a consideration, but with a low to moderate pretest probability.
Four sets	Infectious endocarditis AND either a moderate to a high pretest probability or the patient has recently been taking antibiotics.

TABLE 67.7 Blood Culture Types to Be Used in Various Clinical Settings

CLINICAL SITUATION	BOTTLES TO BE OBTAINED
Children <12 yr	Aerobic bottles only unless the patient has peritonitis or fasciitis (in which case draw blood for standard aerobic and anaerobic culture).
Adults and children >12 yr	Anaerobic infection unlikely, immunocompetent patient: aerobic bottles only. Anaerobic infection unlikely, immunocompromised patient: aerobic bottle, one bottle for fungal culture (usually effective in aerobic bottles; consult the laboratory for guidance). Possibility of anaerobic infection: one aerobic and one anaerobic bottle per set.

drawn for a blood culture set.^{186,203} Allocation of blood to anaerobic bottles will also diminish the likelihood of detecting fungal infections, which are increasingly common in the rising population of immunocompromised patients.²⁰⁹ In addition to these pathophysiologic considerations, there was a widely reported decrease in the positive anaerobic blood culture rate in the 1980s and 1990s, although some authors have recently suggested a resurgence of anaerobic bacteremia rates.^{201–203,205,207,210} At the current time, the arguments for selective use of anaerobic blood cultures are compelling, especially if working in an institution where there is a low rate of anaerobic bacteremia. Based on a review of this topic, [Table 67.7](#) suggests a possible approach to the allocation of blood specimens to various blood culture media after phlebotomy.^{209–213} Clinical features that place a patient at high risk for anaerobic bacteremia are listed in [Box 67.5](#).

BOX 67.5 Clinical Settings at Higher Risk for Anaerobic Bacteremia**INFECTIOUS FOCI**

Abdominal or pelvic infections
Soft tissue or wound infections (e.g., myofasciitis)
Sepsis with decubitus ulcers or necrotic tissue
Aspiration pneumonia
Odontogenic head and neck infections

PREDISPOSING CLINICAL FEATURES

Malignancy
Immunosuppressive medications
Recent abdominal or pelvic surgery
Diabetes

BOX 67.6 Features Suggestive of Contaminant (False-Positive) Blood Culture Results

Coagulase-negative staphylococci (*Staphylococcus epidermidis*) and *Staphylococcus viridans* in a single bottle in patients not suspected of having infectious endocarditis and without chronic indwelling intravenous access catheters are usually contaminants.

Corynebacteria (previously known as diphtheroids), *Propionibacterium acnes*, and *Bacillus* species are usually contaminants but can be pathogenic in the immunocompromised.

Multiple organisms in a series suggest contamination.

Species that grow after prolonged culture have a higher likelihood of being contaminants. Conversely, early-growing bacteria have a much higher likelihood of being pathogens.

The patient's symptoms have resolved or are inconsistent with sepsis (beware with infectious endocarditis, which can have an indolent course).

A primary source (e.g., sputum or urine) has a different pathogen isolated.

Identifying Contaminants

The emergency clinician may receive calls from the laboratory about the results of positive blood cultures obtained on previous shifts. These may be true positives as a result of true contamination or may be caused by the intermittent bacteremia that occurs in normal, healthy people. This situation has been complicated by the increasingly common identification of *Staphylococcus epidermidis*, *Streptococcus viridans*, and fungi as real pathogens in blood culture series.^{214–217} The expense associated with false-positive blood cultures has been noted earlier. These costs emphasize the importance of good technique in obtaining blood for culture.^{218,219} Distinguishing contaminants from clinically significant bacteremia is based on both microbiologic information and the patient's clinical condition. Features of false-positive blood culture results are listed in [Box 67.6](#).^{189,198,220} It would be prudent to contact discharged patients with positive blood cultures, even when contamination is suspected on a microbiologic basis, to ensure that their condition is improving.

Fungal Cultures

Generally, fungi are difficult to isolate in blood cultures, and it may take 4 to 6 weeks to obtain a positive yield. If fungemia is suspected, it is best to discuss culture media and technique with the laboratory before blood is taken for culture. Cultures of bone marrow are occasionally positive for mycoses when blood cultures are negative.

PRINCIPLES AND PITFALLS IN PHLEBOTOMY FOR BLOOD TESTING

A number of blood tests are ordered as a part of emergency practice, but by far the most common are the complete blood count (CBC) and serum chemistries. Many medications, substances, and diseases have been identified as causes of hematologic abnormalities besides the familiar categories of infectious, inflammatory, stress-related, neoplastic, and hematopoietic processes. These include antibiotics (especially sulfonamides), antineoplastic and therapeutic drugs, immunosuppressives, and toxins (mercury and black widow spider envenomation causing leukocytosis and arsenicals causing leukopenia). There are also substances and disease processes that cause purely artifactual errors by interfering with the equipment or procedures used to perform the tests. Examples include *in vivo* and *in vitro* hemolysis, cellular clumping, and markedly elevated platelet, leukocyte, or triglyceride levels, all of which can perturb proper functioning of the machinery used to perform blood assays. The less common causes of laboratory abnormalities (both pathophysiologic and artifactual) are legion. It is necessary for most clinicians, when encountering a confirmed laboratory abnormality, to resort to standard reference texts or online sources to review potential causes or sources of error. Some of the analytical causes of false laboratory values on the CBC are listed in Table 67.8.

Before checking for obscure or uncommon causes of laboratory abnormalities, one should bear in mind that the most common source of error in laboratory blood tests is in the preanalytical phase.^{221–224} This is the part of the laboratory

process that actively involves the practicing clinician. Preanalytical errors have been broken down into problems with specimen loss and handling, clotting, hemolysis, inadequate volume, and patient identity.²²³ In one series, more than 90% of these errors related to specimen collection.²²⁵ These key components and their most common pitfalls are as follows:

1. Preparation of the site. The importance of aseptic technique in the preparation of a site to draw blood for culture has been discussed. For hematologic and serum analysis, enough time should be allowed for drying of the alcohol because trace amounts can cause hemolysis. Povidone-iodine can cause errors in several chemistry assays. When used, it should be cleaned off with alcohol, as described in the section on blood cultures.
2. Venous occlusion. Both intracellular and chemical changes start occurring in blood as soon as a tourniquet is applied, not, as is often thought, only after it has passed through a needle into a specimen container. Serum potassium levels may increase by 6% in a vessel that has been occluded for only 3 minutes.²²⁴ Venous access sites, if visually identifiable, should be prepared before placement of a tourniquet. After tourniquet application, phlebotomy and sample acquisition should proceed as rapidly as possible, ideally within 30 seconds.²²⁶ Pumping the fist should be avoided if possible because it increases serum concentrations of potassium, lactate, and phosphate.²²⁴
3. Routine phlebotomy. Smaller-gauge needles and higher suction pressure are associated with hemolysis. Overexuberant application of suction on a syringe is doubly counterproductive because in addition to causing hemolysis, the needle is likely to be occluded by the wall of the vein. This increases the likelihood of unsuccessful phlebotomy and iatrogenic injury to the patient. When applying negative or positive pressure to a syringe, a given amount of force on the plunger causes higher pressure within the chamber of a smaller-diameter syringe (pressure is proportional to $1/\text{radius}^2$). Blood drawn into either a standard Vacutainer or a syringe via a butterfly needle and tubing causes similar hemolysis rates (Fig. 67.6).²²⁶ If a phlebotomy site is tenuous, specimens are obtained in order of clinical priority. In most cases, tubes should be filled in the following order to avoid cross-contamination of chemicals: blood cultures, red, blue, speckled red, green, lavender, gray.²²⁴ Consistent with experience, the perception of difficult access or phlebotomy is associated with higher hemolysis rates.^{227,228}

TABLE 67.8 Artifactual Causes of False Values of the CBC^a

	ARTIFACTUAL INCREASE	ARTIFACTUAL DECREASE
White Blood Cell Count	Nucleated red blood cells	Multiple myeloma and other monoclonal gammopathies
Hemoglobin and Hematocrit	Severe leukocytosis (> 30,000), hyperlipemic serum, giant platelets, cryoproteins	<i>In vitro</i> hemolysis Microcytic anemia will demonstrate true low values despite normal RBC count

^aImproper collection techniques are the most common cause of errors in all categories.

CBC, Complete blood count; RBC, red blood cell.

Figure 67.6 Phlebotomy using a butterfly needle and Vacutainer system.

4. Phlebotomy through a freshly placed IV catheter. Routine phlebotomy typically causes a hemolysis rate of less than 2%.²²³ Reported hemolysis rates in ED patients are often 7% to 15%.^{228–230} This may be due to any or all of the reasons considered here, but one contributing factor is the number of blood specimens drawn in the ED through a catheter being placed for therapeutic use (Fig. 67.7). Several studies have shown that this arrangement significantly increases rates of hemolysis.^{228,230,231} The popularity of this technique in emergency care is most probably due to limitations of personnel and temporal resources and an attempt to enhance patient comfort by avoiding an extra needlestick. As tourniquet times are probably longer with catheter placement than with simple phlebotomy, it is likely that this contributes to hemolysis, although it has never been experimentally verified. Perceived ease of blood aspiration, larger-bore catheters, and small aliquots drawn through the catheter are associated with lower rates of hemolysis.^{230,231} Laboratory results of specimens obtained in this manner are accurate within clinically acceptable margins of error.
5. Phlebotomy through an established IV catheter. An established IV line appears to be a reliable source of blood for analysis, although success rates are lower and hemolysis rates are higher than for phlebotomy from a fresh site.^{232,233} Box 67.7 lists common blood tests that are accurate when drawn through an established IV line.^{233,234} As with the use

Figure 67.7 Phlebotomy via a freshly placed intravenous catheter and Vacutainer system.

BOX 67.7 Accurate Values Using Venous Blood Obtained From an Indwelling Intravenous Catheter or Saline Lock

CBC	Serum Chemistry	Other
Hemoglobin	Sodium	Creatine phosphokinase
Hematocrit	Potassium	Troponin I
	Bicarbonate	
	Chloride	
	Glucose	

CBC, Complete blood count.

These laboratory values will be accurate when the procedures outlined in the text are followed.

of a freshly placed catheter, results are accurate within clinical tolerances.^{232,235} If fluids are being administered through the catheter, it should be turned off for at least 3 minutes before the application of a tourniquet for phlebotomy. A typical 18-gauge 30-mm-long plastic IV catheter without a heparin well has a volume of 0.07 mL. The heparin well adds a volume of 0.05 mL to make a combined volume of 0.12 mL. Thus, when using a syringe directly attached to the heparin well (IV tubing detached), just 1 mL of aspirated fluid should have replaced the entire volume of the heparin well at least six times. This is demonstrated in a 2013 study that showed consistent and accurate results with aspiration and discarding of 1 mL of blood through a catheter that was also attached to a 6-inch extension tube.²³⁶ For a catheter that is being used for active infusion, a volume of 1.6 mL should be discarded.²³⁵ This suggests that the standard practice of discarding 3 mL to 5 mL is wasteful and a potential cause of iatrogenic anemia. These studies do not support the use of a “push-pull” technique (aspirating a small volume into the syringe and reinjecting prior to drawing blood to be discarded, out of concern for sequestered pockets of fluid).²³⁷ Use of the standard distal port of the IV tubing (usually 25 cm from the end) is not recommended. The IV tubing has a volume (combined with the heparin well and catheter) of approximately 1.6 mL, thus making it necessary to discard large volumes of blood, in addition to the risk of contamination from IV fluids entrained in the specimen from the main IV line during aspiration through the port.

6. Disposition of the specimen after phlebotomy. If blood has been drawn into a syringe, it should be promptly decanted into the appropriate containers for the laboratory. If it has already started to clot, it should not be forced because this can cause hemolysis of the specimen. As cells and platelets are fragile, specimens requiring agitation (all except red and speckled red-topped tubes) should be rocked gently, not shaken. If specimens are sent to the laboratory in pneumatic tubes, they should be surrounded by shock-absorbing material. Artifacts increases in measured HCO_3^- occur fairly rapidly at room temperature.²³² Progressive hemolysis of blood occurs with prolonged standing, and it is likely that specimens are of little utility after more than 2 to 3 hours of typical ED storage conditions. One study showed that unrefrigerated, nonagitated samples were reliable for up to 8 hours.²³⁸

BEDSIDE TESTS FOR GASTROINTESTINAL HEMORRHAGE

Detection of Blood in Stool

Beside fecal blood tests make use of the peroxidase-like activity of Hb. The test card is impregnated with a dye that exhibits a blue color reaction when oxidized. The developer contains 5% hydrogen peroxide and 75% alcohol. The original test used guaiac, but current tests use more sensitive and more reliable quinolone compounds. The addition of hydrogen peroxide developer solution will oxidize the dye to a blue color in the presence of a peroxidase (e.g., Hb).

Testing for occult blood in stool is associated with false-positive and false-negative results, but in its primary role in emergency medical practice, the test is usually reliable in

Figure 67.8 **A**, Hemoccult testing (see text). Two areas of stool can be tested. Add a drop of water to dry specimens. The positive and negative control areas (*arrows*) demonstrate that the test is working properly. Color change should occur on the paper under the stool sample. Brand instructions should be followed regarding time allowed before calling a negative test (positive results usually occur rapidly). Any blue color is a positive test. **B**, Although Hemoccult may also detect gastric blood, the Gastrocult card/developer performs better on gastric specimens (see text). **C**, Iron- and bismuth-containing products (such as Pepto-Bismol [Procter & Gamble Co., Cincinnati, OH] or Kaopectate [Chattem, Chattanooga, TN]) cause a black stool but not a reaction on the Hemoccult test. Do not attribute a positive test for blood in stool to iron therapy.

detecting significant acute gastrointestinal (GI) hemorrhage (Fig. 67.8).⁴⁴ Low pH, heat, dry stools, reducing substances (including antioxidants such as vitamin C), and antacids can cause false-negative findings.^{239–241} Slow bleeding in the upper GI tract, during which heme can be converted (denatured) to porphyrin during transit through the gut, may not be identified by stool testing. False-positive results have been attributed to the ingestion of partly cooked or large quantities of meat (dietary sources of myoglobin and Hb) and peroxidase-rich food.^{241,242} Most vegetables contain peroxidase, including (in decreasing order) broccoli, turnips, cantaloupe, red radishes, horseradish, cauliflower, parsnips, Jerusalem artichokes, bean sprouts, beans, lemon rind, mushrooms, parsley, and zucchini.²⁴² A simple in vivo study convincingly called into question the possibility of peroxidase passing through the stomach without being denatured.²⁴³ False-positive tests resulting from exposure to povidone-iodine were reported in the 1970s and 1980s, but this substance is not usually a potential contaminant in a rectal exam.^{244,245} If in doubt, the practitioner should determine the effects of povidone-iodine on the product used in his or her institution prior to performing the test on the patient's stool. A positive test should be considered evidence of the presence of blood until proved otherwise. Routine iron supplementation does cause black stool but does not cause a positive Hemoccult test result despite early in vitro studies to the contrary.^{246,247}

Normal GI blood loss is limited to less than 2.5 mL/day, which translates to less than 2 mg of Hb per gram of stool (0.2% by weight).²⁴⁸ The sensitivity of the Hemoccult test varies both with the concentration of Hb present in stool and with the extent of Hb exposure to the proteolytic effects of the digestive tract. The Hemoccult test is 37% sensitive to stool containing 2.5 mg Hb/g of stool but 95% sensitive when the concentration is 20 mg Hb/g of stool, thus indicating that low to moderate levels of blood may be missed.⁴³ The test is much more likely to detect lower GI hemorrhage than an identical rate of upper GI bleeding because of the 100-fold diminution in the peroxidase activity of blood during transition through the GI tract.⁷⁸ Impaired detection of Hb may also occur as a result of dilution because of diarrheal illness.^{43,44,249} Regulatory attempts in the United States to improve quality control in bedside occult blood testing seem to have had the unintended consequence of discouraging digital rectal examination in patients for whom they are indicated.^{250,251} In the event of a trace positive Hemoccult test that is not the source of an emergency illness, notification to the patient and advice regarding further outpatient evaluation should not be overlooked.²⁴⁰

Method

Smear the stool specimen onto the reagent area on the card and add a drop of developer. Because the reaction must occur

in an aqueous medium, add a drop of water to very dry specimens and allow it to moisten the specimen before adding the developer. Adding water increases the false-positive rate.^{240,241} Formation of a blue color on the paper anywhere around or under the specimen within 60 seconds should be considered a positive result.

Testing for Gastric Blood

Heme tests designed for use on stool specimens can be unreliable when applied to gastric juices, with increasing inaccuracies being reported as the pH decreases.^{252,253} Although a positive test of gastric contents with a fecal Hemocult card is likely to be accurate, a negative result with the fecal Hemocult card does not rule out the presence of blood. The Gastrocult card uses a modified guaiac developer containing buffers to neutralize gastric acid, thereby facilitating accurate detection of Hb. The test works on the same basis as the fecal guaiac test in that it uses the properties of Hb as a peroxidase. In product testing, the Gastrocult card was 100% sensitive in detecting specimens with greater than 500 ppm of blood by volume, equivalent to 0.05% or 0.25 mL of blood in 500 mL of gastric contents.

Method

Apply a drop of gastric aspirate onto the test area and two drops of developer onto the sample. Look for the formation of a blue color within 1 minute. Do not use fecal blood test developer. In a specimen that is already a bilious green, the test is considered positive only if new blue color is formed. The Gastrocult card also contains a pH testing strip located close to the occult blood testing area, which might be useful in testing emesis after an acidic or alkaline ingestion. Inaccurate results might be anticipated in the presence of the same substances that can confound the Hemocult test: meats, peroxidase-rich foods, and reducing substances such as ascorbic acid. The accuracy of Gastrocult should not be affected by the presence of cimetidine or sucralfate.

BLOOD GLUCOSE METERS

Bedside testing of capillary blood for glucose levels is a common procedure performed in the ED and is generally an excellent substitute for venous blood testing. A variety of meters are available and they are reasonably accurate ($\pm 10\%$) when a small drop of blood is electronically analyzed (Fig. 67.9). In patients with poor tissue perfusion, the accuracy of determining hypoglycemia is less precise and may vary up to approximately 5% from venous blood. In the setting of hypoperfusion, bedside measurement of whole blood is preferable. Bedside testing is also less accurate in patients with extreme hypoglycemia or hyperglycemia, but readings are sufficiently accurate to alert the clinician to very high or very low glucose levels. Fingertip capillary blood is the preferred specimen for bedside glucose meter testing. Blood from alternative sites, such as the skin of the forearm, may give slightly lower results than those taken at the fingertips as they may sample venous blood rather than capillary blood. When blood glucose concentrations are rising rapidly or falling rapidly (such as a hypoglycemic response secondary to rapidly acting insulin), blood glucose results from alternative sites may yield significantly delayed results (up to 30 minutes) when compared with finger stick readings, which are generally accurate at all time points.

Figure 67.9 Bedside glucose meters analyze capillary blood samples and are generally an excellent substitute for venous blood testing. Errors may occur in patients with poor tissue perfusion or in cases of extreme hypoglycemia or hyperglycemia. Additional errors may be due to the operator, including improper calibration, dirty meters, and improper storage of test strips.

Older glucose meters reported whole blood glucose values, which made it difficult to compare finger stick results with those from venous blood testing by the laboratory, which measures plasma glucose. Plasma glucose levels are 10% to 15% higher than whole blood glucose levels. The majority of glucose meters now available provide plasma-equivalent values rather than whole blood glucose values, so glucose meters and the results from venous blood analyzed in hospital laboratories should be comparable.

Most errors in bedside glucose testing are, however, due to operator error, including improper calibration, dirty meters, and improperly stored test strips. Meters should be calibrated frequently to ensure quality readings. Glucose strips have batch-to-batch variation. A common error in testing is due to leaving the lid off glucose strips for prolonged periods because inaccuracies on test strips can result from exposure to heat, moisture, and humidity.

DIAGNOSTIC AND THERAPEUTIC TOXICOLOGIC BEDSIDE PROCEDURES

Management of patients with altered mental status can be challenging, especially if the clinician suspects a drug overdose or poisoning. These patients often have no available history or provide an inaccurate history. Clinicians must rely heavily on the findings on physical examination and other sources of information to diagnose or confirm their clinical suspicion of poisoning or overdose. The hospital-based toxicology laboratory can be valuable in select cases. Screening tests for commonly ingested mind-altering substances are available but limited in scope. Determining concentrations of specific drugs (e.g., acetaminophen, lithium, digoxin, phenytoin) tend to be more

useful in guiding management. However, hospital-based laboratories are not equipped to perform timely analytical procedures for the thousands of possible drugs or toxins. In fact, the screening panels for drugs of abuse that most hospitals use have been shown to rarely influence medical management of adult patients in the ED. Use of these drug screens in selected pediatric patients may have more of an impact on medical management.

Diagnostic bedside testing (point-of-care testing) for specific poisons or toxins may have the advantage of being cost-effective and timely. When applied appropriately, certain bedside tests provide immediate information to the clinician and can significantly influence medical management in a timely manner. Unfortunately, with establishment of the Clinical Laboratory Improvement Amendments of 1988 (CLIA), bedside laboratory testing has undergone stricter oversight. This federal regulation has jurisdiction on any laboratory tests performed on humans, or specimens obtained from humans, and has added a layer of complexity to bedside testing. Tests that are not performed on humans, such as the Meixner test or mothball testing, are not covered by the CLIA act. This section discusses bedside diagnostic and therapeutic toxicologic procedures.

Noninvasive Diagnostic Procedures

Amatoxin: Meixner Test

Ingestion of several types of mushrooms (e.g., *Amanita phalloides*) can be fatal. The most poisonous of these mushrooms contain amatoxins. Patients who have ingested amatoxins often complain of GI symptoms consisting of nausea, vomiting, diarrhea, and abdominal cramping beginning 6 to 8 hours after ingestion. They often bring in specimens of the mushrooms chopped, crushed, cooked, or mixed with stool or gastric contents. Standard hospital laboratories cannot confirm or exclude the diagnosis of amatoxin poisoning; therefore treatment decisions are based on clinical grounds.

A simple colorimetric test for detecting amatoxins (the Meixner test) has been developed, and can be used on gastric contents, stool, or actual mushroom samples. The basis of this test is the acid-catalyzed color reaction of amatoxins with lignin, a complex organic compound found in wood pulp (Fig. 67.10). Cheaper grades of paper (e.g., newsprint or the whiter pages of a telephone book) contain high amounts of lignin. Although there have been no extensive reports of *in vivo* studies, *in vitro* tests have shown this method to be somewhat sensitive and relatively specific for amatoxins, but it should be considered an adjunctive test only. Psilocybin-containing mushrooms can cause false-positive results for amatoxin.²⁵⁴

The procedure for the qualitative detection of amatoxin consists of squeezing a drop of liquid from a fresh mushroom sample or squashing a piece of fresh mushroom onto a piece of newspaper. If stool or gastric samples are the only specimens available, mix the sample with reagent-grade methanol (99.8%) to extract the amatoxin. If the samples are mixed with methanol, centrifuge and filter them. Then place a drop of the liquid extract on newspaper. Gently air-dry all specimens at room temperature and avoid direct sunlight. Add two to three drops of concentrated hydrochloric acid (37%) to the dried specimen. Use an adjacent area for control. High amounts of amatoxin in the dried samples produce a blue color in 1 to 2 minutes. Small amounts of amatoxin yield a blue color in the sampled area in 10 to 20 minutes. This procedure has not been proved

Figure 67.10 The Meixner test is a crude assay for amatoxins. Place portions of the unknown dried mushroom on low-grade newsprint and add 10-N hydrochloric acid. The dried-up mushroom (left) is *Galerina marginata*, which yields a blue reaction (positive, probably deadly poisonous); the little brown mushroom (right) does not (negative, toxicity uncertain). This test is the only one readily available but has varying accuracy and depends on the paper being used (regular newsprint is shown here). (Courtesy Kathie T. Hodge and Kent Loeffler [photographer], Cornell University. Available at <http://blog.mycology.cornell.edu>.)

to be effective with other bodily secretions, such as blood or urine.²⁵⁴

Mothball Identification

At present, commercial mothballs are composed of either nontoxic paradichlorobenzene or possibly toxic naphthalene. Naphthalene can cause a hemolytic reaction in neonates and patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.²⁵⁵ In the past, mothballs have also been produced from camphor, which can cause central nervous system depression and seizures. Fortunately, camphor mothballs are no longer commercially available in the United States, although they may still exist in older households and may be obtained in other countries. Rapid differentiation between these groups of mothballs can expedite patient management and disposition. Several bedside tests have been reported to facilitate this.

1. Paradichlorobenzene is heavier than naphthalene. In turn, naphthalene is heavier than camphor. In lukewarm tap water, camphor will float and naphthalene and paradichlorobenzene will sink. In a solution of 3 tbsp of table salt thoroughly dissolved in 4 oz of lukewarm water, camphor and naphthalene will float and paradichlorobenzene will sink.
2. Paradichlorobenzene has a lower melting point than naphthalene does. Paradichlorobenzene mothballs will melt in a water bath at 53°C, whereas naphthalene requires a water bath hotter than 80°C.

3. Paradichlorobenzene is described as wet and oily, whereas naphthalene is described as having a dry appearance. Paradichlorobenzene is familiar to many people as a cake of disinfectant used in urinals and diaper pails.

Body Secretion Analysis

Careful analysis of bodily secretions, the odor emanating from poisoned patients, and the color of their urine can help identify certain toxins. Some characteristic smells and urine colors are listed in [Table 67.9](#) and [Box 67.8](#).

Bedside Toxicologic Tests on Urine

Ethylene Glycol

Evaluation of the urine of patients who may have ingested ethylene glycol can be helpful. Urine should be tested for fluorescence (an additive in many commercial antifreeze products) under an ultraviolet light and for the presence of calcium oxalate crystals (a metabolic by-product of ethylene glycol metabolism).

The presence of calcium oxalate crystals (either envelope-shaped calcium dihydrate or needle-shaped calcium monohydrate) in urine on microscopic inspection is indicative of high oxalate levels in serum ([Fig. 67.11](#); see also [Fig. 67.3F](#)). Calcium monohydrate crystals can easily be confused with sodium urate crystals; therefore the presence of the dihydrate crystal tends to be more specific for ethylene glycol ingestion. Lack of these crystals does not rule out significant ethylene glycol ingestion because excretion of these crystals may occur late in the ingestion (> 6 hours) and occasionally does not occur at all.^{256,257}

Visual inspection of urine under a Wood lamp or ultraviolet light to ascertain fluorescence may also be helpful in the diagnosis of ethylene glycol exposure. Antifreeze is the most common source of ingested ethylene glycol. Fluorescein, the actual fluorescing material, is often placed in commercially available antifreeze to enable mechanics to detect radiator leaks with a Wood lamp or other ultraviolet light source. Fluorescein is a nontoxic, inert vegetable dye that is eliminated unchanged in urine. Therefore high levels of fluorescein in urine suggest

significant ethylene glycol ingestion. However, lack of fluorescein does not rule out a significant exposure because not all antifreezes contain fluorescein or high concentrations of fluorescein in relation to ethylene glycol. False-positive findings can occur if certain plastic urine containers are used.²⁵⁸

To perform this procedure, place the test urine sample and control samples into separate glass test tubes. Inspect for fluorescence under a Wood lamp in a dark room. Always perform this test with controls that include urine that does not contain fluorescein and urine that does contain fluorescein. The use of controls may increase the sensitivity and specificity from 49% and 75%, respectively, to a sensitivity and specificity of 100%.²⁵⁹ Fluorescein is readily available because fluorescein-containing strips are commonly used in ophthalmologic procedures (see [Chapter 62](#)).

Salicylates

Several bedside tests have been developed to qualitatively detect salicylates in urine, including 10% ferric chloride solution, Trinder's solution, and Phenistix reagent strips. All are rapid, inexpensive, sensitive tests that give a qualitative rather than a quantitative result.

Ferric chloride and Trinder's solution both have sensitivities of 100% with serum salicylate levels of 5 mg/dL. False positives can occur with both tests. Acetoacetic acid, acetone, and phenylpyruvic acid will cause false-positive results. Thus, this test may be falsely positive in patients with diabetic, alcoholic, or starvation ketoacidosis. Phenol-containing drugs such as diflunisal, sulfasalazine, and salicylamide may also produce false positives. Any positive result requires a confirmatory quantitative serum salicylate assay.²⁶⁰

The ferric chloride test is a commonly used rapid, qualitative, urinary screening procedure. To perform this test, add several drops of 10% ferric chloride to 1 or 2 mL of urine that has been collected in a test tube. The immediate appearance of a bluish-purple color signifies that salicylates are present in the urine ([Fig. 67.12](#)). This test is very sensitive, and just one aspirin tablet taken within 12 to 24 hours will give a positive

Figure 67.11 A, Monohydrate (needle- or prism-shaped) and dihydrate (envelope- or tent-shaped) calcium oxalate crystals from a patient poisoned with ethylene glycol. The dihydrate form is more specific for ethylene glycol toxicity because the monohydrate form can easily be confused with urate crystals. B, Calcium dihydrate crystal (*arrow*) and a pseudocast of a crystal.

TABLE 67.9 Diagnostic Odors

CHARACTERISTIC ODOR	RESPONSIBLE DRUG OR TOXIN
Acetone (sweet, fruity; pearlike)	Lacquer, ethanol, isopropyl alcohol, chloroform, diabetic ketoacidosis, alcoholic ketoacidosis, trichloroethane, paraldehyde, chloral hydrate, methylbromide, <i>Pseudomonas</i> infection
Alcohols	Ethanol (congeners), isopropyl alcohol
Ammonia-like	Uremia
Automobile exhaust	Carbon monoxide (odorless, but associated with exhaust)
Beer (stale)	Scrofula
Bitter almond	Cyanide
Carrots	Cicutoxin (or water hemlock)
Coal gas (stove gas)	Carbon monoxide (odorless, but associated with coal gas)
Disinfectants	Phenol, creosote
Eggs (rotten)	Hydrogen sulfide, carbon disulfide, mercaptans, disulfiram, <i>N</i> -acetylcysteine
Feculent	Intestinal obstruction
Fish or raw liver (musty)	Hepatic failure, zinc phosphide, hypermethioninemia, trimethylaminuria
Fruitlike	Nitrites (e.g., amyl, butyl), ethanol (congeners), isopropyl alcohol
Garlic	Phosphorus, tellurium, arsenic, parathion, malathion, selenium, dimethyl sulfoxide, thallium
Halitosis	Acute illness, poor oral hygiene
Hay	Phosgene
Mothballs	Naphthalene, <i>p</i> -dichlorobenzene, camphor
Peanuts	<i>N</i> -3-pyridyl-methyl- <i>N</i> - <i>p</i> -nitrophenyl urea (Vacor)
Pepper-like	O-chlorobenzylidene malonitrile
Putrid	Anaerobic infections, esophageal diverticulum, lung abscess, scurvy
Rope (burned)	Marijuana, opium
Shoe polish	Nitrobenzene
Sweating feet	Isovaleric acid acidemia
Tobacco	Nicotine
Vinegar	Acetic acid
Vinyl-like	Ethchlorvynol (Placidyl)
Violets	Turpentine (metabolites excreted in urine)
Wintergreen	Methyl salicylate

From Chiang WK: Otolaryngologic principles. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al, editors: *Goldfrank's toxicologic emergencies*, ed 5, East Norwalk, CT, 1994, Appleton & Lange, p 374.

result. It will require 60 to 120 minutes from the time of ingestion for this reaction to become positive in patients with normal renal function, so early test results may be misleading.

The Trinder test uses a mixture of mercuric chloride and ferric nitrate in deionized water. To perform this test, mix 1 mL of urine with 1 mL of Trinder's solution. A violet or purple color signifies the presence of salicylates. Acetoacetic acid and high levels of phenothiazines may give false-positive results.

Phenistix reagent strips were originally developed to detect phenylketonuria. However, Phenistix strips also turn brown in the presence of salicylates. False-positive findings for salicylates can occur if phenothiazines are present.

Bedside Toxicologic Tests on Oral Secretions and Breath: Ethyl Alcohol

Several bedside devices have been developed to measure alcohol concentrations in body fluids. Measurements of the alcohol

concentration in expired air or saliva have been shown to correlate well with blood alcohol concentrations in the appropriate settings.

Breath alcohol analyzers have been developed since the 1950s and are currently used in law enforcement. These devices typically use infrared spectral analysis to determine the concentration of alcohol in expired air. Almost all the alcohol found in expired air at the level of the mouth is secondary to alcohol diffused from the bronchial system rather than the alveolar system.²⁶¹ Minor alterations in breathing patterns can cause large variations in readings. Thus, uncooperative patients who do not exhale properly will cause an inaccurate reading. Other causes of inaccurate readings include the recent ingestion of alcohol-containing products, belching or vomiting, use of inhalers, poor technique, or restrictive pulmonary pathology.

Alcohol concentrations in saliva have been shown to correlate with serum concentrations. Bedside measurement of salivary alcohol concentrations can also be obtained with a dipstick-like device. These devices use an enzymatic reaction involving alcohol dehydrogenase to measure alcohol concentrations.²⁶² Patients who are dehydrated (a common occurrence in alcohol-intoxicated patients) are often unable to provide adequate saliva samples, and inaccurate readings have occurred in patients with high blood alcohol concentrations.^{263,264}

Bedside Toxicologic Tests on Blood: Methemoglobinemia

Patients with methemoglobinemia will often have a normal partial pressure of oxygen on routine arterial blood gas analysis, a normal calculated Hb saturation, a nondiagnostic pulse

Figure 67.12 Adding ferric chloride (10%) to a few milliliters of urine immediately turns it a deep purple color in the presence of very small quantities of aspirin. Beware of other changes in color, such as gray or brown, which are not positive tests. This test is also positive in ketoacidotic states such as diabetic ketoacidosis.

oximeter reading, and a cyanosis that does not clear with O₂ administration. Newer models of CO-oximeters are able to reliably measure methemoglobin levels. Bedside visual inspection of venous or arterial blood may be helpful in the diagnosis of methemoglobinemia. Methemoglobinemia occurs when normal Hb is exposed to an oxidant stress (Fe²⁺ converted to Fe³⁺). If the erythrocytes are not able to handle such stress, such as in the presence of G6PD deficiency, Hb remains in an oxidized state (methemoglobin), which causes a color change in the molecule.

To evaluate for methemoglobinemia, place a drop of sample blood on a white background (a white coffee filter is appropriate) in a well-lit environment. Next to this, place a drop of normal blood as a comparison control sample. Blood with methemoglobinemia appears darker or chocolate brown.²⁶⁵ This method relies on the ability of the examiner to distinguish changes in color and may therefore have a degree of interobserver variance. Methemoglobin levels of less than 10% may alter the color of blood only slightly and thereby cause a false-negative finding. Methemoglobin levels of between 12% and 14% may cause a false-negative reading 50% of the time. Methemoglobin levels greater than 15% are reported to cause a cyanotic appearance in patients. With levels of 35% or greater, identification of methemoglobinemia by visual inspection of the color of blood is quite accurate.²⁶⁵ At this level, almost all patients are obviously cyanotic and symptomatic.

Invasive Diagnostic Procedures

Several invasive diagnostic bedside procedures can be useful in the assessment of possible drug overdoses. The basic premise of these procedures is that patients who have been exposed to a certain drug or poison will respond in a particular fashion if given a diagnostic challenge dose of another particular drug or true antidote.

Naloxone

Naloxone hydrochloride (Narcan, Adapt Pharma, Inc., Radnor, PA) is a μ -opioid receptor antagonist. A diagnostic challenge with IV naloxone has been recommended for all patients with central nervous system depression.²⁶⁶ Certain clinical findings

such as miosis, decreased respiratory rate, and evidence of illicit drug use can predict many patients who will respond to a challenge dose of naloxone.²⁶⁷ If a patient's mental status improves significantly after a dose of naloxone, the patient should be considered to have been exposed to an opioid-like substance. This is true even if a laboratory drug screen is negative for opioids. Furthermore, the routinely used immunoassay drug screen may not detect many of the synthetic opiates, such as fentanyl and fentanyl derivatives, tramadol, meperidine, methadone, and buprenorphine. Although cases have been reported of patients with nonopioid overdoses (such as alcohol or phencyclidine) responding to naloxone, these single observations have not been confirmed in controlled animal or human studies.

The traditional challenge dose of naloxone in an adult or child is 2 mg every 2 minutes intravenously until a response is achieved or 10 mg is given.²⁶⁸ Some clinicians prefer to use much smaller doses (0.1 to 0.2 mg) and titrate to effect. This may partially reverse the opioid overdose-related symptoms and confirm the diagnosis without precipitating a withdrawal syndrome in patients with opioid dependency. Most patients with an opioid overdose will exhibit some response to 1 to 4 mg of naloxone, but some massive overdoses might require larger doses. A patient who does not respond at all to 10 mg of naloxone probably does not have a pure opioid overdose. High doses of naloxone may be needed to reverse many synthetic opiates, such as buprenorphine and methadone. Lower doses can be given (0.4 to 0.8 mg in adults or 0.01 mg/kg in children) to reverse known opioid-induced respiratory depression without reversing the analgesia. Because naloxone has a half-life of between 30 and 60 minutes, a continuous drip of naloxone can be used to avoid resedation. A reasonable choice is to use two-thirds of the initial bolus dose that achieved the desired reversal effect as the hourly IV dose. For example, a patient who satisfactorily responded to 1.5 mg of naloxone might receive a naloxone solution of 10 mg of naloxone in 500 mL of normal saline at a rate of 1 mg (50 mL) per hour intravenously. Nalmefene, a long-acting opioid receptor antagonist that has a terminal half-life of roughly 11 hours, can also be given to patients with suspected overdose. Theoretically, a single dose of nalmefene will be effective longer than the effects of heroin or most abused opiate substances. The initial recommended dose is 1.0 to 1.5 mg intravenously.

Naloxone and nalmefene have minimal significant side effects, but they can precipitate withdrawal in patients addicted to opioids. Unlike alcohol withdrawal, naloxone-induced opioid withdrawal in adults is short-lived and not usually life-threatening. Withdrawal can be avoided if lower initial doses of naloxone or nalmefene are given and then slowly titrated upward to the desired effect.

Resedation may occur if the ingested drug (e.g., methadone, oxycodone [OxyContin, Purdue Pharma L.P.], morphine sulfate [MS Contin, Purdue Pharma L.P.]) has a clinical effect longer than that of naloxone. Reported drug half-lives may have significant variability in the clinical setting. If no narcotic effect is evident in 60 to 120 minutes after standard doses of naloxone (common with heroin, for example), no clinically significant resedation is expected. Larger naloxone doses may prolong the expected antidote effect of naloxone, and longer observation is required. All timing and dose recommendations are guidelines, and all clinical decisions with regard to resedation should be individualized.

Flumazenil

Flumazenil (Romazicon, Roche Pharmaceuticals, Nutley, NJ) is a competitive benzodiazepine receptor antagonist that has the ability to reverse the central nervous system depression caused by all currently commercially available benzodiazepines. However, flumazenil is no longer recommended as empiric treatment (part of the coma cocktail) of all sedated patients. The most supported use of flumazenil is to reverse excessive physician-initiated conscious sedation with benzodiazepines and for children with suspected benzodiazepine overdose. Its routine use in the setting of possible benzodiazepine overdose is controversial but is supported as a diagnostic and therapeutic agent in selected cases. Unlike naloxone, flumazenil can have significant side effects, but only in certain subsets of patients.²⁶⁷ Complications include precipitation of seizures or a withdrawal syndrome in benzodiazepine-dependent patients. To minimize the chance of seizures, flumazenil should be avoided in known benzodiazepine-dependent patients and those who may have ingested epileptogenic drugs (e.g., cyclic antidepressants, cocaine, theophylline, or isoniazid).

In suspected benzodiazepine overdoses in which patients are obtunded and have no history of seizures or suspicion of involvement of epileptogenic agents, flumazenil can be administered intravenously at a dose of 0.2 to 0.5 mg/min. Most benzodiazepine-overdosed patients show improvement in mental status with 1 mg of flumazenil and almost all respond to 3 to 5 mg. Small, escalating doses given slowly (maximally, 0.5 mg/min) have been recommended. Larger doses can be given at one time as a bolus, although this increases such side effects as anxiety, agitation, and emotional lability; it also increases the chances of precipitating withdrawal in benzodiazepine-dependent patients. Fortunately, seizures that occur after flumazenil use are usually transient. In rare cases, higher doses of benzodiazepines, barbiturates, and phenytoin might be required.

If a patient responds to flumazenil with an improvement in depressed mental status, this suggests only that the patient is under the influence of a benzodiazepine. Flumazenil can partially reverse the effects of many of the newer nonbenzodiazepine sleeping agents that affect the γ -aminobutyric acid pathway, such as zolpidem, zopiclone, and eszopiclone. Flumazenil can improve mental status in patients with hepatic encephalopathy.²⁶⁹⁻²⁷¹ It does not have any significant effect on alcohol, barbiturates, and other nonbenzodiazepine sedative-hypnotics.

Resedation is possible if the ingested drug has a clinical duration longer than that of flumazenil. If no resedation has occurred 60 to 90 minutes after standard doses of flumazenil, clinically significant resedation is not expected. If higher flumazenil doses have been used, additional observation may be warranted. All timing and dose recommendations are guidelines, and all clinical decisions with regard to resedation should be individualized.

Physostigmine

Physostigmine is an acetylcholinesterase inhibitor that can penetrate into the central nervous system and thus can reverse both the central and peripheral effects of anticholinergic agents. In the majority of patients with anticholinergic toxicity, no laboratory tests are available to rapidly confirm the diagnosis, and testing for specific drugs is limited or unavailable. A clinical picture that may consist of mydriasis, dry and flushed skin, dry mucous membranes, urinary incontinence, absent bowel

sounds, tachycardia, hyperthermia, hallucinations, agitation, and seizures suggests an anticholinergic syndrome. In some cases (low-dose antihistamines and others), only a central nervous system syndrome characterized by hallucinations, agitation, and confusion exists. A dramatic response to physostigmine frequently confirms a diagnosis of anticholinergic toxicity. In these patients, physostigmine often decreases the degree of agitation and confusion.²⁷²⁻²⁷⁴ The use of physostigmine as a diagnostic challenge can be helpful in selected situations, but similar to flumazenil, routine use of physostigmine as a diagnostic bedside challenge in all obtunded patients, especially in those without anticholinergic findings, should be discouraged. In some cases the agitation produced by potent anticholinergics, such as scopolamine, can be resistant to benzodiazepines. Judicious use of physostigmine is warranted to avoid excessive sedation, chemical paralysis, or impaired ventilation.

As a diagnostic challenge or therapeutic intervention, physostigmine can be administered intravenously under constant cardiac monitoring at a dose of 1 to 2 mg in adults and 0.02 mg/kg in children over a 3- to 5-minute period. It will take 3 to 6 minutes for the central nervous system effect to become apparent. Some clinicians empirically pretreat with a benzodiazepine to prevent possible seizures. Because the half-life of physostigmine is 30 to 60 minutes, a repeated dose of 0.5 to 2 mg can also be given as clinically indicated.

Similar to flumazenil, physostigmine has been reported to interact detrimentally with cyclic antidepressants. In this setting, physostigmine has been associated with life-threatening dysrhythmias. Physostigmine can also cause an excess of acetylcholine and a resultant cholinergic crisis. This syndrome includes salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, and seizures. For this reason, 1 mg of atropine intravenously should be readily available to reverse potential cholinergic excess when using physostigmine.

Deferoxamine

Deferoxamine is an organic compound derived from the bacterium *Streptomyces pilosus* and can chelate iron. It can be used as a therapy or as a diagnostic challenge in patients with iron overdoses. Patients who have unstable vital signs or significant GI or central nervous system symptoms usually require therapeutic doses of deferoxamine. Asymptomatic patients with a history of iron overdose typically require supportive care only. Patients with persistent but mild symptoms, such as vomiting and diarrhea, may be given a diagnostic challenge dose of deferoxamine. A diagnostic challenge is preferential over ancillary laboratory testing because tests such as iron levels and total iron-binding capacity in the setting of iron overdose can be inaccurate, misleading, and time-consuming.²⁷⁵

A diagnostic challenge dose of deferoxamine is administered intramuscularly or intravenously over a 45-minute period at doses of 40 to 90 mg/kg up to a maximum of 1 g in children and 2 g in adults. Deferoxamine can also be administered intravenously as a constant infusion of 15 mg/kg per hour. A positive result occurs when chelated iron in the form of ferrioxamine appears in the urine. This usually causes the urine to turn a reddish orange or "vin rose" color in 2 to 3 hours after the initiation of treatment. The change in color is qualitative only and has no prognostic significance. The color change caused by ferrioxamine is dependent on pH and concentration, and false-negative test results can occur.

Chronically administered deferoxamine has been reported to have multiple adverse effects, such as acute respiratory distress

syndrome, visual defects, and enhancement of *Yersinia enterocolitica* infection. In the setting of a single challenge dose, flushing, erythema, tachycardia, urticaria, and hypotension caused by rapid administration of deferoxamine are the most serious side effects.

Invasive Therapeutic Procedures

The indications and rationale for the use of certain therapeutic procedures in toxicology are often misunderstood.

Alkalinization of Urine and Blood

Alkalinization of urine consists of manipulating the pH of urine to enhance the excretion of certain drugs (Box 67.9). Weak acids remain in ionic form in a basic milieu. The ionic form often prevents reabsorption of that drug in the proximal tubule, and urinary alkalinization can therefore promote elimination in urine. For certain drugs this can play a significant role in their elimination. For example, salicylate elimination increases proportionately to the urinary flow rate, but it increases

exponentially with increases in urinary pH. The increased serum clearance attributed to alkalinization does not correlate well with outcome or length of hospitalization.

Recommendations differ on the actual method or formula to achieve urinary alkalinization. No body of literature supports one method of urinary alkalinization over another. In general, this procedure should be titrated to the patient's fluid and

^aIf a 5% ethanol solution is used, double the volume of the loading dose.

^bEquivalent to a 40-proof solution.

^cIf a 5% ethanol solution is used, double the volume rate; monitor closely for potential volume overload.

^dSerum ethanol levels should be monitored closely.

^eAt higher infusion rates it may be necessary to administer by volume rather than by milliliters per hour.

^fFor a 30% concentration, divide the amount by 1.5.

^gRounded off to the nearest milliliter.

Note: Concentrations higher than 10% are not recommended for intravenous administration. Concentrations higher than 30% are not recommended for oral administration. The dose schedule is based on the premise that the patient initially has a zero-ethanol level. The aim of therapy is to maintain a serum ethanol level of 100 to 150 mg/dL, but constant monitoring of the ethanol level is required because of wide variations in endogenous metabolic capacity. Ethanol is removed by dialysis, and the infusion rate of ethanol must be increased during dialysis. Prolonged ethanol administration may lead to hypoglycemia. Note that 10% ethanol for infusion may be difficult to find in the hospital pharmacy. To formulate 10% ethanol for infusion, (1) remove 50 mL from a 1-L bottle of 5% ethanol/5% dextrose in water (D₅W) and replace it with 50 mL of 100% ethanol, or (2) remove 100 mL from a 1-L bottle of D₅W and replace it with 100 mL of 100% ethanol.

acid-base status to achieve a urinary pH of 7.5 to 8.0. One method uses a constant infusion of a relatively isotonic solution consisting of three ampules of sodium bicarbonate (44 mmol/ampule) added to 1 L of 5% dextrose in water (D₅W). Another formula is to begin with a bolus of two ampules of IV sodium bicarbonate or 1 to 2 mmol/kg of body weight. The bolus is followed with a constant infusion of three ampules of sodium bicarbonate in 1 L of D₅W solution with 20 to 40 mmol of potassium infused at a rate of 100 to 300 mL/hr. These formulas assume that the patient has normal renal function. Repetitive boluses of sodium bicarbonate ampules can also be used, but this may increase the chance of hypernatremia, hypokalemia, relative hypocalcemia, fluid overload, and alkalemia. All of these are potential adverse effects of aggressive urinary alkalization. The actual amount of fluids and bicarbonate administered requires titration to the patient's clinical condition, and careful monitoring of electrolyte, pH, and fluid status is encouraged.

Urinary alkalization can sometimes be difficult to achieve or maintain. Hypovolemia is probably the leading cause of an inability to achieve alkaline urine. Other theoretical causes are hypokalemia, hypomagnesemia, and hypochloremia. Several authors have suggested that in patients with severe salicylate poisoning, urinary alkalization may be difficult, if not impossible to achieve.²⁷⁶ Some will empirically add potassium and magnesium to the diuresis fluid.

Ethanol Infusion

Fomepizole (4-methylpyrazole) has been approved by the US Food and Drug Administration for the treatment of ethylene glycol poisoning. It has also been used successfully in treating methanol poisoning.^{277,278} When compared with the traditional treatment of toxic alcohol poisoning, namely, ethanol, fomepizole has the advantages of ease of use, fewer side effects (specifically hypoglycemia), and ability to maintain therapeutic levels.^{277,279} Fomepizole is considered the antidote of choice; however, because of the cost and the logistics of stocking this antidote, many hospitals do not have this drug readily available.

Ethanol can be used as a therapeutic intervention in patients with methanol or ethylene glycol poisoning because of ethanol's much greater affinity for alcohol dehydrogenases. These enzymes metabolize methanol and ethylene glycol to toxic by-products. However, with serum ethanol levels of 100 mg/dL, minimal amounts of ethylene glycol or methanol are metabolized by alcohol dehydrogenases.^{123,125} Ethanol infusions are not useful in the treatment of isopropyl alcohol poisoning.

Ethanol can be administered orally or intravenously (Table 67.10). IV ethanol has the advantages of achieving therapeutic levels rapidly, ensuring complete absorption, limiting the chance of aspiration, and avoiding gastritis. A 5% concentration of ethanol, which can be given in a peripheral vein, requires the use of large fluid volumes. In a 70-kg patient, a loading dose

requires 1.4 L of a 5% solution, with a maintenance dose of 700 mL/hr. If IV ethanol is given, maintain careful attention to cardiopulmonary status. In contrast, oral loading can be achieved with much lower volumes. However, oral loading can be difficult in an uncooperative or unconscious patient or if vomiting or GI hemorrhage is present. A therapeutic level is reached more slowly with oral loading.

Ethanol metabolism can vary widely, and ethanol is dialyzable. Therefore it may be difficult to maintain appropriate

ethanol levels during dialysis therapy for ethylene glycol or methanol poisoning. Frequent measurements of ethanol should be obtained and the infusion adjusted accordingly. When patients are given ethanol infusions, central nervous system depression, hypothermia, hypotension, hypoglycemia, and phlebitis are common adverse effects, especially in children. Serial levels of ethanol and glucose should be obtained.

Standard Precautions and Infectious Exposure Management

Peter E. Sokolove and Aimee Moulin

Contamination of health care workers (HCWs) with body fluids is a frequent occurrence in the emergency department (ED). A survey of ED and trauma staff found that almost half reported a needlestick injury within the preceding year.¹ Body fluids often contain various transmissible infectious diseases, and the prevalence of human immunodeficiency virus (HIV) infection, hepatitis, and other communicable diseases has been shown to be high in ED patient populations.^{2,3}

Routine opt-out HIV screening of ED patients identifies approximately 1% of patients with previously undiagnosed HIV infections.^{2,4} Of such patients, many (20%) have no identifiable HIV risk factors, making it more difficult to identify patients who pose a risk to HCWs.⁵ This makes widespread use of standard precautions in the ED essential. However, compliance with standard precautions, formerly known as universal precautions, is far from universal.^{6–8} In a video-taped review of pediatric trauma resuscitations, compliance with barrier precautions was 81.3%.⁸ Similarly, ED staff have low observed compliance rates with standard precautions during cardiopulmonary resuscitation, with the lowest rates for wearing gowns (20%) and highest for wearing masks (90%).⁹

In 1985, the combination of high-risk illness with low-compliance barrier use prompted the Centers for Disease Control and Prevention (CDC) to recommend guidelines for the protection of HCWs.¹⁰ In 1991, these recommendations were enacted into law by mandate of the Occupational Safety and Health Administration (OSHA).¹¹ The primary focus of the CDC guidelines is to reduce mucocutaneous exposure to body fluids by encouraging hand washing and barrier protection. These measures do little to protect from percutaneous exposure, which is the most efficient method of transmission of hepatitis and HIV.^{12,13} The current strategy for risk reduction in the ED includes immunization against hepatitis B virus (HBV), use of standard precautions (including reengineered safety products), and prompt initiation of postexposure prophylaxis (PEP) when appropriate.

GUIDELINES FOR STANDARD PRECAUTIONS

Appropriate precautions for all patient contact must be viewed as a consistent practice or “way of life” in the ED. The following guidelines, based on CDC recommendations, should be used when there is any possibility of contact with body fluids.

Barrier Precautions

1. Use gloves for any patient contact with a risk for exposure to body fluids (Fig. 68.1). Both cutaneous and percutaneous

exposure can be reduced by the use of gloves. Gloves have been shown to reduce disease transmission in needlestick injuries, with greater reduction seen with double-gloving in animal models and in a case crossover study of HCWs.¹³

A systematic review looking at the practice of wearing multiple layers of gloves found moderate-quality evidence that double-gloving reduces perforations and blood stains on the skin, indicating a decrease in percutaneous exposure incidents.¹⁴

2. Wear a mask and protective eyewear when exposure to body fluid aerosols is possible (e.g., wound irrigation, traumatic chest wound) (Fig. 68.2).
3. Wear a gown and shoe covers when there is a risk for large volumes of splashed body fluids (e.g., chest tube, thoracotomy) (Fig. 68.3).

Respiratory Hygiene/Cough Etiquette

In 2007 the CDC included new elements to its standard precautions in response to outbreak investigations. The elements of “Respiratory Hygiene/Cough Etiquette” include: (1) education of health care facility staff, patients, and visitors; (2) posted signs, in language(s) appropriate to the population served, with instructions to patients and accompanying family members or friends; (3) source control measures (e.g., covering the mouth/nose with a tissue when coughing and prompt disposal of used tissues, using surgical masks on the coughing person when tolerated and appropriate); (4) hand hygiene after contact with respiratory secretions; and (5) spatial separation, ideally > 3 feet, of persons with respiratory infections in common waiting areas when possible.¹⁵

Safe Injection Practices

Most importantly, sharps precautions mean no recapping, bending, or breaking of needles. If needle recapping is deemed necessary, use a single-handed technique (Fig. 68.4). A safer alternative is to immediately dispose of the needle in an approved sharps container without recapping. In an observational study of ED employees, the rate of needle recapping was 34%, with most practitioners incorrectly using a two-handed technique.¹⁶ Various reengineered products are available for use in the ED, including retracting scalpels, auto-capping needles, and needleless intravenous systems (Fig. 68.5). Reviews of studies looking at these safety devices have found they are associated with a reduction in needlestick injuries.^{17,18} US federal law now requires the use of safety-engineered sharps devices to protect HCWs. The Needlestick Safety and Prevention Act of 2000 required the use of safety-engineered sharps devices to protect HCWs from needlestick injuries.¹⁹ A review of data from the Exposure Prevention Information Network (EPINet) sharps injury surveillance program estimated that needlestick injuries have decreased by 34% overall, with a 51% decline in nurses since the implementation of federal legislation.²⁰ To further prevent transmission of blood-borne infections, whenever possible use single-dose vials with a single-use disposable needle and syringe for each injection.¹⁵

Respiratory Precautions

ED patients commonly present with respiratory syndromes that require respiratory precautions in addition to standard precautions (Table 68.1).¹⁵ For example, patients with suspected

Figure 68.1 Gloves are mandatory for any patient contact with a risk for exposure to body fluids. Double-gloving may confer additional protection and should be considered in high-risk situations.

or confirmed pulmonary tuberculosis (TB), rubeola virus (measles), severe acute respiratory syndrome virus (SARS), or avian influenza should be isolated with airborne precautions, plus contact precautions with eye/face protections during any aerosol-generating procedures or if any contact with respiratory secretions is anticipated.¹⁵ During contact with patients who require airborne precautions, wear a National Institute for Occupational Safety and Health (NIOSH)-approved N-95 particulate respirator (Fig. 68.6). These masks are designed to efficiently filter 1- to 5- μ m particles and are less costly and more comfortable than high-efficiency particulate air

Figure 68.2 A mask and protective eyewear are mandatory when exposure to body fluid aerosols is possible. A gown is also suggested. This patient vomited profusely during intubation, which may have led to an exposure if proper protective gear had not been worn.

Figure 68.3 Full protective gear (eye protection, face mask, impervious gown, gloves, and shoe covers) should be worn when there is a risk for large volumes of splashed bodily fluids (e.g., emergency thoracotomy).

Figure 68.4 **A**, Recapping a needle by holding the cap in the hand is the most common way to sustain a needle puncture and should never be done! **B**, It is best to discard the needle/syringe without recapping, but if deemed absolutely necessary, use a single-handed technique to partially recap without holding the needle cap. **C**, Make sure that at least 80% of the needle is covered before completing the recapping with the second hand (by holding the base of the needle cap).

Figure 68.5 Using safety systems such as auto-recapping needles and retracting scalpels dramatically reduces percutaneous injuries to health care workers, and US federal law now mandates their use.

Figure 68.6 Respiratory precautions. Surgical masks are appropriate to protect against pathogens that are larger than 5 μm, such as influenza and *Neisseria meningitidis*. N-95 respirators are required for pathogens smaller than 5 μm, such as tuberculosis.

TABLE 68.1 Respiratory Syndromes That Require Respiratory Precautions in Addition to Standard Precautions^a

CLINICAL SYNDROME OR CONDITION ^b	POTENTIAL PATHOGENS ^c	EMPIRIC PRECAUTIONS (ALWAYS INCLUDES STANDARD PRECAUTIONS)
Respiratory Infections		
Cough/fever/upper lobe pulmonary infiltrate in an HIV-negative patient or a patient at low risk for HIV infection.	<i>Mycobacterium tuberculosis</i> , respiratory viruses, <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> (MSSA or MRSA).	Airborne precautions plus contact precautions.
Cough/fever/pulmonary infiltrate in any lung location in an HIV-infected patient or a patient at high risk for HIV infection.	<i>M. tuberculosis</i> , respiratory viruses, <i>S. pneumoniae</i> , <i>S. aureus</i> (MSSA or MRSA).	Airborne precautions plus contact precautions. Use eye/face protection if aerosol-generating procedure performed or contact with respiratory secretions anticipated. If tuberculosis is unlikely and there are no AIIRs and/or respirators available, use droplet precautions instead of airborne precautions. Tuberculosis more likely in HIV-infected individual than in HIV-negative individual.
Cough/fever/pulmonary infiltrate in any lung location in a patient with a history of recent travel (10–21 days) to countries with active outbreaks of SARS, avian influenza.	<i>M. tuberculosis</i> , SARS-CoV, avian influenza	Airborne plus contact precautions plus eye protection. If SARS and tuberculosis unlikely, use droplet precautions instead of airborne precautions.
Respiratory infections, particularly bronchiolitis and pneumonia, in infants and young children.	Respiratory syncytial virus, parainfluenza virus, adenovirus, influenza virus, human metapneumovirus.	Contact plus droplet precautions; droplet precautions may be discontinued when adenovirus and influenza have been ruled out.

^aInfection control professionals should modify or adapt this table according to local conditions. To ensure that appropriate empiric precautions are always implemented, hospitals must have systems in place to evaluate patients routinely according to these criteria as part of their preadmission and admission care.
^bPatients with the syndromes or conditions listed below may present with atypical signs or symptoms (e.g., neonates and adults with pertussis may not have paroxysmal or severe cough). The clinician’s index of suspicion should be guided by the prevalence of specific conditions in the community, as well as clinical judgment.
^cThe organisms listed under the column “Potential Pathogens” are not intended to represent the complete, or even most likely diagnosis, but rather possible etiologic agents that require additional precautions beyond the standard precautions until they can be ruled out.
 AIIR, Airborne infection isolation room; HIV, human immunodeficiency virus; CoV, coronavirus; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-sensitive *S. aureus*; SARS, severe acute respiratory syndrome.
 From Siegel JD, Rhinehart E, Jackson M, et al: 2007 Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings. *Am J Infect Control* 35(10 Suppl 2):S65–164, 2007. <https://www.cdc.gov/infectioncontrol/pdf/guidelines/isolation-guidelines.pdf>.

(HEPA)-filtered masks. In addition, place such patients in a respiratory isolation room with negative pressure, high circulation (optimally at least 12 air changes per hour), and external exhaust. When performing aerosol-generating procedures (such as intubation or sputum induction) that result in increased release of infectious droplets, add extra face/eye protection.¹⁵ However, even during outbreaks, adherence to isolation precautions is variable. A survey of medical students and residents at a Washington, DC, hospital (November–December 2009) showed that only 13% of medical students and 21% of residents would wear an N-95 respirator when caring for a patient with influenza symptoms.^{21,22}

For patients with respiratory infections such as suspected or confirmed respiratory syncytial virus (RSV), parainfluenza virus, adenovirus, or human metapneumovirus, the CDC recommends droplet precautions (see Table 68.1). Droplet precautions consist of placing the patient in a private room or a special separation of > 3 feet. HCWs should don a mask on entering the patient's room.¹⁵ If transport or movement is necessary, such as to radiology, instruct the patient to wear a mask and follow Respiratory Hygiene/Cough Etiquette.¹⁵

Personal Protective Equipment

Isolation gowns are worn in combination with gloves only if contact with blood or body fluid is anticipated. The need for and the type of isolation gown selected is based on the nature of the patient interaction, including the anticipated degree of contact with infectious material and the potential for blood and body fluid penetration of the barrier.¹⁵ The CDC updated its personal protective equipment (PPE) guidelines when contacting haemorrhagic fever viruses in response to new data gained during an outbreak of the Ebola virus in several West African nations. CDC guidance emphasizes the importance of training, practice, competence, and observation of HCWs in correct donning and doffing of PPE.²³ Procedures recommended by the CDC for donning and doffing PPE are aimed at preventing skin or clothing contamination and are shown in Figs. 68.7 and 68.8.²³

Contamination during removal of PPE occurs frequently, thus training and practice are important to reduce the risk of contamination during PPE removal.²⁴

The CDC recommends the following sequence for donning and doffing PPE when evaluating persons under investigation for Ebola.²³

Donning PPE (See Fig. 68.7)

This donning procedure applies to PPE recommended for evaluating and managing persons under investigation, who are clinically stable and do not have bleeding, vomiting, or diarrhea. There is a lower risk of splashes and contamination in these situations. An established protocol, combined with proper training of the HCW, helps to facilitate compliance with PPE guidance.

1. Remove personal clothing and items. The HCW should wear surgical scrubs. No personal items (e.g., jewelry [including rings], watches, cell phones, pagers, pens) should be worn under PPE or brought into the patient room. Long hair should be tied back. Eyeglasses should be secured with a tie.
2. Inspect PPE prior to donning. Visually inspect the PPE ensemble to ensure that it is in serviceable condition (e.g., not torn or ripped), that all required PPE and supplies

are available, and that the sizes selected are correct for the HCW.

3. Perform hand hygiene. Perform hand hygiene with alcohol-based hand rub (ABHR). When using ABHR, allow hands to dry before moving to the next step.
4. Put on inner gloves. Put on first pair of gloves.
5. Put on gown or coverall. Ensure gown or coverall is large enough to allow unrestricted movement. Ensure cuffs of inner gloves are tucked under the sleeve of the gown or coverall.
6. Put on face mask.
7. Put on outer gloves. Put on second pair of gloves (with extended cuffs). Ensure the cuffs are pulled over the sleeves of the gown or coverall.
8. Put on face shield. Put on full face shield over the surgical face mask to protect the eyes, as well as the front and sides of the face.
9. Verify. After completing the donning process, the integrity of the ensemble should be verified by the HCW (e.g., there should be no cuts or tears in the PPE). The HCW should be comfortable and able to extend the arms, bend at the waist, and go through a range of motions to ensure there is sufficient range of movement while all areas of the body remain covered. A mirror in the room can be useful for the HCW while donning PPE.

Doffing PPE

1. PPE is doffed in the designated PPE removal area in the health care facility. As with all PPE doffing, meticulous care should be taken to avoid self-contamination. Place all PPE waste in a leak-proof infectious waste container.
2. Inspect. Inspect the PPE for visible contamination, cuts, or tears before starting to remove. If any PPE is visibly contaminated, disinfect by using an Environmental Protection Agency (EPA)-registered disinfectant wipe. If the facility conditions permit and appropriate regulations are followed, an EPA-registered disinfectant spray can be used, particularly on contaminated areas.
3. Disinfect and remove outer gloves. Disinfect outer-gloved hands with either an EPA-registered disinfectant wipe or ABHR. Remove and discard outer gloves, taking care not to contaminate inner gloves when removing the outer gloves. Dispose of outer gloves into the designated leak-proof infectious waste container.
4. Inspect and disinfect inner gloves. Inspect the inner gloves' outer surfaces for visible contamination, cuts, or tears. If an inner glove is visibly soiled, disinfect the glove with either an EPA-registered disinfectant wipe or ABHR, remove the inner gloves, perform hand hygiene with ABHR on bare hands, and don a new pair of gloves. If a cut or tear is seen on an inner glove, immediately review occupational exposure risk per hospital protocol. If there is no visible contamination and no cuts or tears on the inner gloves, then disinfect the inner-gloved hands with either an EPA-registered disinfectant wipe or ABHR.
5. Remove face shield. Remove the full face shield by tilting the head slightly forward, grabbing the rear strap and pulling it over the head, gently allowing the face shield to fall forward. Avoid touching the front surface of the face shield. Discard the face shield into the designated leak-proof infectious waste container.

Donning Personnel Protective Equipment

1 Change into scrubs, and remove all personal items such as jewelry and watches.

2 Visually inspect the PPE prior to donning to confirm correct sizing and ensure its structural integrity.

3 Perform hand hygiene and allow hands to dry. Alcohol-based hand rub is preferred if available.

4 Put on the gown or coveralls. Ensure the gown is large enough to allow unrestricted movement.

5 Apply the face mask or respirator. This should fit snug to the face and below the chin.

6 Apply gloves. Inner standard gloves and outer long-cuff nitrile gloves should be worn.

7 Put on full face shield over the surgical face mask to protect the eyes and front and sides of the face.

8 Have an assistant check the PPE to assure that all body areas are properly protected.

Figure 68.7 Donning personal protective equipment. A trained safety observer should be present to help apply and inspect the equipment. *PPE*, Personal protective equipment.

Doffing Personal Protective Equipment

1 Inspect the PPE for visible contamination, cuts, or tears before starting to remove.

2 Disinfect outer-gloved hands with either a disinfectant wipe or ABHR, and then remove.

3 Inspect and disinfect the inner gloves. Replace them with a new pair if visibly soiled.

4 Remove the outer gown, avoiding contact with the outer surface. Disinfect and replace gloves.

5 Remove the face mask and discard. Disinfect hands and replace gloves after face mask removal.

6 Remove the surgical or respiratory mask. Hold it by the straps and avoid touching the front of the mask.

7 Disinfect and remove the inner gloves.

8 Perform hand hygiene with ABHR, and have your safety observer inspect your scrubs for contamination.

Figure 68.8 Doffing personal protective equipment. *ABHR*, Alcohol-based hand rub; *PPE*, personal protective equipment.

6. Disinfect inner gloves. Disinfect inner gloves with either an EPA-registered disinfectant wipe or ABHR.
7. Remove gown or coverall. Remove and discard.
 - a. Depending on the gown design and location of fasteners, the HCW can either untie or gently break fasteners. Avoid contact of scrubs or disposable garments with the outer surface of the gown during removal. Pull the gown away from the body, rolling it inside out and touching only the inside of the gown.
 - b. To remove the coverall, tilt the head back to reach zipper or fasteners. Unzip or unfasten the coverall completely before rolling down while turning inside out. Avoid contact of scrubs with outer surface of coverall during removal, touching only the inside of the coverall. Dispose of gown or coverall into the designated leak-proof infectious waste container.
8. Disinfect and change inner gloves. Disinfect inner gloves with either an EPA-registered disinfectant wipe or ABHR.
 - a. Remove and discard gloves, taking care not to contaminate bare hands during the removal process.
 - b. Perform hand hygiene with ABHR.
 - c. Don a new pair of inner gloves.
9. Remove surgical face mask. Remove the surgical face mask by tilting the head slightly forward, grasping first the bottom tie or elastic strap, then the top tie or elastic strap, and remove the front of the surgical face mask without touching it. Discard the surgical face mask into the designated leak-proof infectious waste container.
10. Disinfect and remove inner gloves. Disinfect inner-gloved hands with either an EPA-registered disinfectant wipe or ABHR. Remove and discard gloves, taking care not to contaminate bare hands during the removal process. Dispose of inner gloves into the designated leak-proof infectious waste container.
11. Perform hand hygiene. Perform hand hygiene with ABHR.
12. Inspect. The HCW should inspect for any contamination of the surgical scrubs or disposable garments. If there is contamination, shower immediately, and then immediately inform the infection preventionist, occupational safety and health coordinator, or their designee.

Hand Hygiene

Immediately wash any skin surface coming in contact with body fluids with soap and water. If performed properly, both soap and water and alcohol-based products are generally efficacious in removing bacteria and preventing the spread of communicable diseases.^{25,26} Alcohol-based formulations have shown both bactericidal and virucidal activity.^{27,28} However, soap and water perform better in removing *Clostridium difficile* spores.²⁹ Hand hygiene adherence is frequently low in emergency settings.³⁰⁻³²

OCCUPATIONAL DISEASE EXPOSURE

Occupationally acquired infections cause considerable morbidity and mortality among HCWs, despite OSHA requirements for precautions. Given the often occult manifestation of disease in the ED patient population, emergency HCWs are at high risk for exposure to infectious diseases. There is a high prevalence of HIV, HBV, hepatitis C virus (HCV), and pulmonary TB in ED patients, as well as associated high morbidity and

mortality. This chapter focuses on these particular diseases and provider risks.

HBV

Transmission

HBV is a well-recognized occupational risk for health care providers, and multiple studies have documented the high prevalence of hepatitis in ED patients.^{33,34} Despite the attention focused on transmission of HIV, the infectivity of HBV is significantly higher. HBV is a more virulent organism and requires a relatively small inoculum for transmission.³⁵ Percutaneous injuries are the most efficient mode of HBV transmission, and many infected HCWs do not recall a specific injury.³⁶ Many body fluids other than blood contain hepatitis B surface antigen (HBsAg), and levels of infectious HBV particles in blood-free body fluids are 100 to 1000 times lower than in blood itself. Implementation of the CDC's standard precautions, along with the OSHA regulations for barrier protection and preexposure vaccination, has led to a decrease in the incidence of HBV transmission.³⁷

To understand the risk of HBV transmission resulting from occupational exposure, an understanding of a few key serologic markers for HBV is essential. HBsAg is a marker of active infection in the source patient. From a practical standpoint, HBV can be transmitted when HBsAg is present, and it is not generally transmissible when this marker is absent. Hepatitis B surface antibody is a protective antibody against HBV. In vaccinating HCWs, the goal is to stimulate the immune system prior to accidental exposure, to produce a sufficient quantity of this antibody to protect the individual if exposed to the virus. Hepatitis B e antigen (HBeAg) can be found in the bloodstream of HBV-infected individuals during times of peak virus replication. The risk for clinical hepatitis is approximately 2% (range, 1% to 6%) if HBeAg is absent, as opposed to a risk of 22% to 31% if HBeAg is present.³⁸ Yet testing occupational exposure-source patients for HBeAg is not recommended.³⁸

Postexposure Management

PEP following exposure to an HBsAg-positive source may require hepatitis B vaccine, hepatitis B immunoglobulin (HBIG), both, or neither (Table 68.2). This depends on the vaccination and antibody response status of the exposed HCW. HBIG is derived from pooled human plasma and provides passive immunization for nonimmune exposed individuals. This preparation is very safe and not known to transmit disease.^{37,38} When HBIG is used for PEP, give it ideally within 24 hours after exposure, and note that it is of questionable value beyond 7 days.³⁸ PEP for HBV is remarkably effective, and infection is unlikely to develop in individuals who receive PEP.³⁸ Hepatitis B vaccine may also be given with PEP. Individuals who have not previously been vaccinated or who have not demonstrated an adequate response should receive the hepatitis B vaccine. Adverse reactions to the hepatitis B vaccine are generally quite mild, and it is safe to give during pregnancy. For primary immunization, give an initial intramuscular injection, followed by subsequent intramuscular vaccinations at 1 and 6 months. There is no need to provide vaccination or to check titers in individuals who have previously had an adequate titer.³⁷ PEP with these agents is not contraindicated during pregnancy or lactation. HCWs who have previously been infected with HBV are immune to reinfection, so PEP is not indicated.

TABLE 68.2 Postexposure Management of Health Care Personnel After Occupational Percutaneous and Mucosal Exposure to Blood and Body Fluids, by Health Care Personnel: HepB Vaccination and Response Status

HCP STATUS	Postexposure Testing		Postexposure Prophylaxis		POSTVACCINATION SEROLOGIC TESTING ^b
	SOURCE PATIENT (HBSAG)	HCP TESTING (ANTI-HBS)	HBIG ^a	VACCINATION	
Documented responder ^c after complete series (≥ 3 doses)	No action needed				
Documented nonresponder ^d after 6 doses	Positive/unknown	— ^e	HBIG × 2 separated by 1 month	—	No
	Negative	No action needed			
Response unknown after 3 doses	Positive/unknown	< 10 mIU/mL ^e	HBIG × 1	Initiate revaccination	Yes
	Negative	< 10 mIU/mL	None		
	Any result	≥ 10 mIU/mL	No action needed		
Unvaccinated, incompletely vaccinated, or vaccine refusers	Positive/unknown	— ^e	HBIG × 1	Complete vaccination	Yes
	Negative	—	None	Complete vaccination	Yes

^aHBIG should be administered intramuscularly as soon as possible after exposure when indicated. The effectiveness of HBIG when administered > 7 days after percutaneous, mucosal, or nonintact skin exposures is unknown. HBIG dosage is 0.06 mL/kg.

^bShould be performed 1–2 months after the last dose of the HepB vaccine series (and 4–6 months after administration of HBIG to avoid detection of passively administered anti-HBs) using a quantitative method that allows detection of the protective concentration of anti-HBs (≥ 10 mIU/mL).

^cA responder is defined as a person with anti-HBs ≥ 10 mIU/mL after ≥ 3 doses of HepB vaccine.

^dA nonresponder is defined as a person with anti-HBs < 10 mIU/mL after ≥ 6 doses of HepB vaccine.

^eHCP who have anti-HBs < 10 mIU/mL, or who are unvaccinated or incompletely vaccinated, and sustain an exposure to a source patient who is HBsAg-positive or has unknown HBsAg status, should undergo baseline testing for HBV infection as soon as possible after exposure, and follow-up testing approximately 6 months later. Initial baseline tests consist of total anti-HBc; testing at approximately 6 months consists of HBsAg and total anti-HBc.

Anti-HBc, Hepatitis B core antibodies; *anti-HBs*, antibody to hepatitis B surface antigen; *HBIG*, hepatitis B immune globulin; *HBsAg*, hepatitis B surface antigen; *HCP*, health care personnel.

HCV

Transmission

The estimate of the number of US residents with HCV is at least 4.6 million,³⁹ and many individuals are unaware of their infection. ED patients have a high prevalence of HCV.³ HCV is often acquired from injection drug use. It was once commonly transmitted by blood transfusion, but fortunately, with modern screening, this is now rare. Although HCV can be transmitted sexually, this is a minor route. Mucous membrane transmission of HCV is possible but much less common. Percutaneous transmission is the most efficient route. The incidence of seroconversion after an HCV-positive needlestick is approximately 1.8% (estimates range from 0% to 7%).^{40,41} It is useful to remember that the risk for transmission of HCV after a needlestick injury is similar to that for transmission of HBV when the source is HBeAg negative. When seroconversion does occur, 80% of patients will demonstrate antibodies at 15 weeks and 97% at 6 months after exposure. Although the clinical course of HCV is often asymptomatic or mild, cirrhosis develops in 10% to 20%, and in those patients the annual risk of hepatocellular carcinoma is 1% to 5%.⁴²

Postexposure Management

Currently, PEP for HCV exposure is not recommended.⁴⁰ The HCV exhibits a high degree of genetic heterogeneity and a very rapid mutation rate, making the development of a vaccine challenging but work is ongoing.^{43,44} Recently effective treatment regimens for HCV have been identified.⁴⁴

HIV

Transmission

The number of occupational exposures to HIV reported to the CDC have steadily decreased. As of December 2013, 58 confirmed occupational transmissions of HIV have been reported.⁴⁵ In 2010 one case of occupational HIV transmission was reported to the CDC.⁴⁶ The risk for contracting HIV from working in the ED depends on the prevalence of HIV in the local patient population. The overall risk for HIV seroconversion is approximately 0.23% after a needlestick injury and 0.03% for mucocutaneous transmission. The risk of HIV infection associated with intact skin is too low to be detected.⁴⁷ Cardo and colleagues⁴⁸ demonstrated that the risk for HIV seroconversion after needlestick injuries is not uniform. Seroconversion was found to be more likely for deep injuries

(odds ratio [OR] = 15), if blood was visible on the device (OR = 6.2), if the needle had been used in a source patient's artery or vein (OR = 4.3), or if the source patient suffered from terminal acquired immunodeficiency syndrome (OR = 5.6). It is essential to gather information regarding the nature of the injury to risk-stratify the exposure.

When seroconversion occurs, HIV antibodies can be detected as early as 3 weeks after exposure and are almost always present by 6 months. Acute retroviral syndrome is a clinical manifestation of HIV seroconversion that occurs in approximately 80% of newly infected individuals at a median of 25 days after exposure. The signs and symptoms of acute retroviral syndrome are similar to those of mononucleosis and consist of fever, lymphadenopathy, and rash.

Postexposure Management⁴⁹ Evidence Supporting PEP

In 1998 the US Public Health Service recommended using PEP for selected HIV exposures.⁵⁰ These recommendations were based on a single case-control study.⁴⁸ Currently, a large placebo-controlled trial would be considered unethical. The CDC-sponsored case-control study, undertaken in the United States, France, the United Kingdom, and Italy, compared 33 HCWs who seroconverted after exposure to HIV with 665 control HCWs who did not seroconvert after exposure to HIV. Approximately 90% of the patients in this study were exposed via hollow-bore needles.⁴⁸ When postexposure zidovudine (azidothymidine) was used, the risk for HIV infection was reduced by 81% (95% confidence interval, 48% to 94%).

Selecting Patients for PEP

In 2013 the US Public Health Service published updated recommendations regarding the use of HIV PEP.⁴⁹ In general, the decision to use PEP depends on the type of exposure and the source's HIV status. The first step in determining whether PEP is indicated is to assess the severity of exposure. Percutaneous exposure can be categorized as "less severe" or "more severe." A less severe exposure involves a solid needle, a superficial injury, and no blood visible on the device. All other percutaneous injuries are categorized as more severe. Exposure to mucous membranes and nonintact skin is categorized as either "small volume" (a few drops of blood) or "large volume" (a major blood splash). There are no reported cases of HIV seroconversion after exposure of intact skin to blood.^{37,48,49} After assessing the severity of exposure, determine the potential infectivity of the source. The US Public Health Service emphasizes the importance of determining the HIV status of the exposure source.⁴⁹ Consider PEP only for exposure to blood and body fluids from a source known or likely to be HIV positive. Exposure from an HIV-negative source does not require PEP. Do not test sharp instruments for HIV because this is not reliable or recommended. Note that drug development is ongoing and recommendations change rapidly. The clinician is urged to periodically check for updates. The most reliable source is the CDC website or the *Morbidity and Mortality Weekly Report* journals, most easily found via an Internet search under various topics.

A number of special circumstances may arise when determining the need for HIV PEP. When a source is known but an individual's HIV status is pending, decide about the use of PEP on a case-by-case basis. When the source is high risk, initiate PEP and then stop or modify it later once the HIV status of the source is determined. When a source can be

identified but the HIV status of the source is unknown and will not become available, PEP is not generally recommended. However, if it is unknown whether the source constitutes a significant risk and consultation is not available within a few hours; it is recommended to begin PEP and obtain consultation later.⁴⁹

Choice of PEP Medications

The US Public Health Service recommends that PEP medication regimens begin as soon as possible after the exposure and should be continued for 4 weeks. When HIV PEP is administered, a minimum of three drugs is recommended.⁴⁹ The current preferred three-drug HIV PEP regimen includes raltegravir, tenofovir, and emtricitabine (Table 68.3).

A number of second-line and alternative agents may be chosen for HIV PEP. Expert consultation is recommended, especially if antiretroviral (ARV) resistance is suspected. Pregnancy and breastfeeding are not contraindications to taking ARV agents and PEP is recommended.^{49,51,52} Consult an infectious diseases or occupational health specialist when treating pregnant and lactating patients, as alternative regimens may be considered. Enter all pregnant women starting ARVs in the Antiretroviral Pregnancy Registry, a database designed to collect information on the outcomes of ARV-exposed pregnancies regardless of HIV status: <http://www.apregistry.com>. ARV

TABLE 68.3 HIV PEP Regimens

Preferred HIV PEP regimen	Raltegravir (Isentress; RAL) 400 mg po bid Plus Tenofovir DF (Viread; TDF) 300 mg po qd plus Emtricitabine (Emtriva; FTC) 200 mg po qd
Alternative agents for use with expert consultation	Abacavir (Ziagen; ABC) Efavirenz (Sustiva; EFV) Efuvirtide (Fuzeon; T20) Fosamprenavir (Lexiva; FOSAPV) Maraviroc (Selzentry; MVC) Saquinavir (Invirase; SQV) Stavudine (Zerit; d4T)
Agents generally not recommended for use as PEP	Didanosine (Videx EC; ddI) Nelfinavir (Viracept; NFV) Tipranavir (Aptivus; TPV)
Agents contraindicated as PEP	Nevirapine (Viramune; NVP)

HIV, human immunodeficiency virus; PEP, postexposure prophylaxis.
Note: for consultation or assistance with HIV PEP contact the National Clinicians' Post-Exposure Prophylaxis Hotline at telephone number 888-448-4911 or visit its website at <http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>.
Data from Kuhar DT, Henderson DK, Struble KA, et al: Updated US Public Health Service guidelines for the management of occupational exposures to human immunodeficiency virus and recommendations for postexposure prophylaxis, *Infect Control Hosp Epidemiol* 34(9):875–892, 2013.

Figure 68.9 Prepackaged human immunodeficiency virus postexposure prophylaxis kits are ideal for use in the emergency department. These kits contain a 3-day supply of medications that can be started immediately while follow-up with an infectious disease specialist is arranged. Both basic and expanded regimens are available. The expanded regimen shown here is a three-drug combination: Truvada (emtricitabine plus tenofovir, which are reverse transcriptase inhibitors) and Kaletra (lopinavir/ritonavir, which is a protease inhibitor). Basic regimens do not include a protease inhibitor. (Courtesy AccessPak, Cardinal Health, Dublin OH.)

agents can be used in pediatric patients for occupational and nonoccupational exposure, however consultation is recommended.^{53,54} For consultation or assistance with HIV PEP, contact the National Clinicians' Post-Exposure Prophylaxis Hotline, telephone number 888-448-4911 or visit its website at <http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>.

Timing, Duration, and Side Effects of PEP

HIV exposure should be considered a true emergency. Administer PEP as soon as possible after exposure, ideally within 1 hour. Animal studies indicate that the efficacy of PEP diminishes with a delay in initiation.^{55,56} HIV PEP regimens consist of a 4-week course of therapy. In the ED, patients can be prescribed the first 3 days of medications, and outpatient follow-up should be arranged within 72 hours (Fig. 68.9).⁴⁹ Side effects from the medications used for HIV PEP are not insignificant. However, the current recommended three-drug regimen is better tolerated than earlier zidovudine-containing regimens.⁵⁷ Depending on the choice of PEP medications, patients should also be prescribed antiemetics and antidiarrheal agents when PEP is initiated.

TB

Transmission

During the mid-1980s the United States experienced a resurgence in TB, especially among HIV-positive patients. Although the incidence of TB cases in the United States has continued to decline, more than 9000 cases were reported in 2014.⁵⁸ TB continues to pose a serious risk to both public health and HCWs. Baussano and colleagues estimated that the annual risk for TB infection in HCWs, attributable to occupational exposure, is between 3.8% and 8.4% depending on local

prevalence.⁵⁹ TB is transmitted by infectious droplets 1 to 5 μm in size. Primary infection occurs when one to three organisms are inhaled into the alveoli, where they begin to replicate. Host defenses usually stop infection within 2 to 10 weeks, and the patient enters the latent period. During this time, patients are asymptomatic and not contagious. Reactivation occurs when cell-mediated immunity wanes, and patients are again contagious. This can be due to advancing age, HIV infection, steroid use, malignancy, malnutrition, or other causes of suppression of the immune system. The lifetime risk for reactivation is 5% to 10%, with approximately half this risk occurring in the first few years after primary infection. Patients with increased infectivity include those with pulmonary or laryngeal TB, an active cough, positive sputum smears for acid-fast bacilli, cavitory lesions on chest radiographs, and inadequate therapy. Overall, children are less contagious than adults, but can still transmit the disease. Extrapulmonary TB is contagious only in cases of an open skin lesion or involvement of the oral cavity.⁶⁰

Depending on the patient population and geographic location, ED personnel can be at high risk for occupational TB infection. In a 1993 study at a county hospital in Los Angeles it was reported that 31% of ED workers became positive for purified protein derivative (PPD) during their employment, including 20% of attendings, 32% of nurses, and 33% of residents.⁶¹ The risk for PPD conversion was found to be 6% after 1 year of ED employment, 14% after 2 years, and 27% after 4 years. EDs typically care for higher-risk patients: those who are homeless, foreign born, recently incarcerated, or chronically debilitated. Overcrowding can lead to extended waiting periods and delays in admission. The clinical manifestation of TB in ED patients is often atypical, which can lead to a delay in diagnosis.^{62,63} Delayed ED diagnosis of pulmonary TB is associated with factors such as recent antibiotics, older age, renal insufficiency, preexisting chronic lung disease, HIV, homelessness, or substance abuse.⁶⁴⁻⁶⁷ A 14-year review of the US National Tuberculosis Surveillance System showed that rates of advanced pulmonary TB are on the rise, especially in populations without traditional risk factors.⁶⁸ These data suggest that substantial delays in diagnosis and misdiagnosis of pulmonary TB may be increasing.

Preventing exposure to TB requires a multifaceted approach.⁶⁰ Proper ED ventilation plays a key role; inadequate ventilation has been a contributing factor in many nosocomial outbreaks. Ideally, install single-pass airflow from waiting rooms to the outside. Within the ED, make sure that air flows from clean areas to less clean areas, not vice versa. If patients with TB are seen frequently, provide at least one true respiratory isolation room in the ED. Make sure that such rooms have at least 12 air changes per hour and that they are “negative pressure” rooms in which air flows into the room from other ED areas. Other engineering approaches for control of TB infection include using HEPA filters and upper-room ultraviolet light irradiation.

Familiarize all ED personnel with the appropriate use of respiratory protection against TB. Provide surgical masks (e.g., string-tie masks) for source control. Place these masks on potentially contagious patients to decrease the passage of infectious droplets into the air. Because air can leak around such masks, they are not optimal for protection of HCWs. In late 1995, NIOSH certified a new class of masks known as N-95 particulate respirators.^{69,70} These masks filter particles 1 μm in size with at least 95% efficiency and are generally the

Figure 68.10 N-95 particulate respirators are the preferred mask for health care workers caring for patients who potentially have tuberculosis.

preferred mask for HCWs (Fig. 68.10). In some circumstances, such as when patients are undergoing cough-inducing or aerosol-generating procedures, HCWs need better protection. N-95 masks are usually the appropriate choice for ED use, but these masks should be thought of as the minimum required level of respiratory protection against TB.⁶⁰

Initiate early respiratory isolation of patients with suspected pulmonary TB as soon as possible in the ED, ideally at triage. Screening protocols at triage can detect patients with more classic signs and symptoms of TB, but reported protocols are only moderately sensitive and somewhat cumbersome.^{62,63} Consider immediate respiratory isolation for patients with high-risk chief complaints and those with hemoptysis, weight loss, or a prolonged cough. Also be aware of patients with HIV, with a history of TB, or from high-risk populations who have a cough or fever.⁶⁰ The best guideline is to initiate respiratory isolation as soon as TB is considered to be a possible diagnosis. Place masks on such patients before obtaining chest radiographs. Consider isolating patients with chest radiograph

findings of an apical infiltrate, cavitary lesions, extensive hilar or mediastinal lymphadenopathy, pleural disease, or a miliary pattern.⁷¹⁻⁷⁴

Postexposure Management

If HCWs are exposed to patients with active pulmonary TB, refer them to either employee health care or their primary care clinician for follow-up testing and treatment. To establish a HCW's baseline PPD status, perform skin testing within days after exposure. If the baseline test is negative, perform a follow-up skin test 8 to 10 weeks later to determine whether PPD conversion has occurred. A positive baseline test (≥ 10 -mm induration) indicates previous exposure or infection. A positive test consists of 5-mm induration after a negative baseline test or an increase to at least 10-mm induration after a baseline test of 1- to 9-mm induration.

HCWs in whom PPD converts to positive after an exposure should undergo chest radiography to screen for active pulmonary TB.⁶⁰ If active disease is present, initiate treatment with at least four antituberculous medications. In PPD converters who do not have active disease, consider chemoprophylaxis. When deciding whether to initiate chemoprophylaxis, balance the potential benefit of TB prevention with the risk for medication-associated hepatitis. In general, give chemoprophylaxis in the case of a recent (≤ 2 years) PPD conversion, a known TB contact, a patient who is medically predisposed to TB, HIV-infected patients, intravenous drug users, or those younger than 35 years. For occupationally exposed HCWs who are PPD converters, the preferred regimen for HIV-negative persons is daily isoniazid (INH) for 9 months, although acceptable alternative regimens can be considered.⁷⁵ Some HCWs may become exposed to strains of TB that are resistant to INH because of the continued emergence of multidrug-resistant and extensively drug-resistant strains of TB.⁵⁸ For exposure to multidrug-resistant TB, consult an expert when selecting an individualized chemoprophylaxis regimen. Baseline and serial liver function testing is not necessary for administration of chemoprophylaxis in most cases, but monitor closely for clinical symptoms suggestive of hepatotoxicity.

Physical and Chemical Restraint

J. Michael Kowalski

Emergency clinicians often face the challenge of caring for agitated, uncooperative, combative, and violent patients who are unable to participate in their care, make rational health care decisions, and/or are a danger to themselves and others.^{1,2} Psychiatric illness, acute chemical intoxication or withdrawal, delirium, medical illness, uncontrolled rage, hypoxia, and rarely, central nervous system infection are causes of agitated or violent behavior in the emergency department (ED).¹

BACKGROUND

Patients more likely to exhibit severe uncontrolled agitation are those who abuse alcohol; sympathomimetic agents such as cocaine or methamphetamines or designer drugs such as ecstasy (MDMA), mephedrone, or methylone (bath salts); and hallucinogenic drugs such as phencyclidine (PCP). Patients can also experience toxicity after accidental and intentional ingestion of medications. Drug-associated delirium may be related to anticholinergic toxicity, serotonin syndrome, or intoxication with sympathomimetics. Alcohol withdrawal may progress to delirium tremens, a condition typified by excessive agitation and confusion.

Patients with agitated delirium are often the most difficult to manage and at high risk for significant morbidity and mortality. This is especially true for patients with excited delirium syndrome (ExDS), a variant of and the extreme form of agitated delirium (see later section on ExDS).³ Causes of agitated delirium include manic-depressive disorder, psychosis, chronic schizophrenia, intoxication with sympathomimetics or anticholinergics, cocaine intoxication, alcohol or benzodiazepine withdrawal, hypoglycemia, the postictal state, or head trauma. Some causes are idiopathic, but many are due to a combination of underlying psychiatric illness and stimulant drugs or alcohol (or both). Because of the variety of causes, management of agitated and combative patients requires a systematic approach (Fig. 69.1).

Schizophrenia, schizoaffective disorder, and the manic phase of bipolar disorder can all lead to an impaired perception of reality. Paranoid delusions, hallucinations, and hostile moods that can easily lead to severe agitation often develop in patients with these disorders.

Any medical condition that leads to brain dysfunction may also result in agitated, combative, or violent behavior (Box 69.1). Well-documented examples include hypoglycemia, hypoxia, medication intoxication, encephalitis, meningitis, intracranial hemorrhage, thyrotoxicosis, traumatic brain injury, febrile illnesses in the elderly, and dementia.⁴

It is essential to achieve control of an agitated patient as quickly as possible. Goals of management include preventing

patients from harming themselves and others, identifying the underlying cause, and initiating medical treatment. Early intervention allows caregivers to implement appropriate monitoring, perform a physical examination, initiate diagnostic testing, and institute timely treatment. Successfully achieving these goals often necessitates physical and chemical restraint.

During the late 1980s and early 1990s, reports of restraint-associated deaths in psychiatric and extended care facilities⁵ led lawmakers to pass legislation establishing regulations for the use of restraint.⁶ Since then, the Joint Commission for Accreditation of Healthcare Organizations (TJC) and the Center for Medicare and Medicaid Services (CMS) have created standards governing the use of restraint in a variety of health care settings, including EDs and tertiary care facilities (Box 69.2).^{7,8} The aforementioned standards allow the use of physical restraint for a limited period. A licensed practitioner must evaluate the patient and determine that less restrictive interventions have been ineffective and physical restraint is required to ensure the patient's well-being. The standards also include requirements for written policies and procedures governing the use of restraint that must address indications, staff training and education, patient assessment and reevaluation, appropriate documentation, and patient-focused issues such as maintaining dignity and respect. Hospitals and extended care facilities are required by law to report any death or adverse event related to the use of restraint.⁸

Some authors have advocated "restraint-free" environments in nursing homes, extended care facilities, and acute care hospitals.⁹ Although this concept is laudable, mandating a restraint-free ED is impractical and potentially dangerous. Clinicians should recognize the risks associated with restraining a patient; however, they should not be deterred from using either physical or chemical restraint when patients demonstrate dangerous behavior toward themselves or others. Indeed, the American College of Emergency Physicians (ACEP) recently revised and approved their policy statement in 2014 by supporting the careful and appropriate use of physical restraints or seclusion.¹⁰

EXCITED DELIRIUM SYNDROME (EXDS)

In September 2009, a task force of the ACEP published a multi-authored White Paper Report on ExDS. This was a landmark report because it legitimized a heretofore poorly defined serious medical scenario that was familiar to law enforcement, emergency medical services, and emergency physicians. In addition, it supported the aggressive and potentially lifesaving use of chemical sedation.

It was the consensus of the task force that ExDS is a unique syndrome that may be identified by the presence of a distinctive group of clinical and behavioral characteristics that can be recognized in the premortem state. ExDS, though potentially fatal, may be amenable to early therapeutic intervention in some cases.

The task force defined the existence of excited delirium as a true disease entity; described the signs, symptoms, and risk for death; and reviewed current and emerging methods of control and treatment. Before this report, agitated delirium and various poorly defined related terms were used to describe a serious form of agitated delirium that could culminate in death. Such deaths were often high-profile news events that

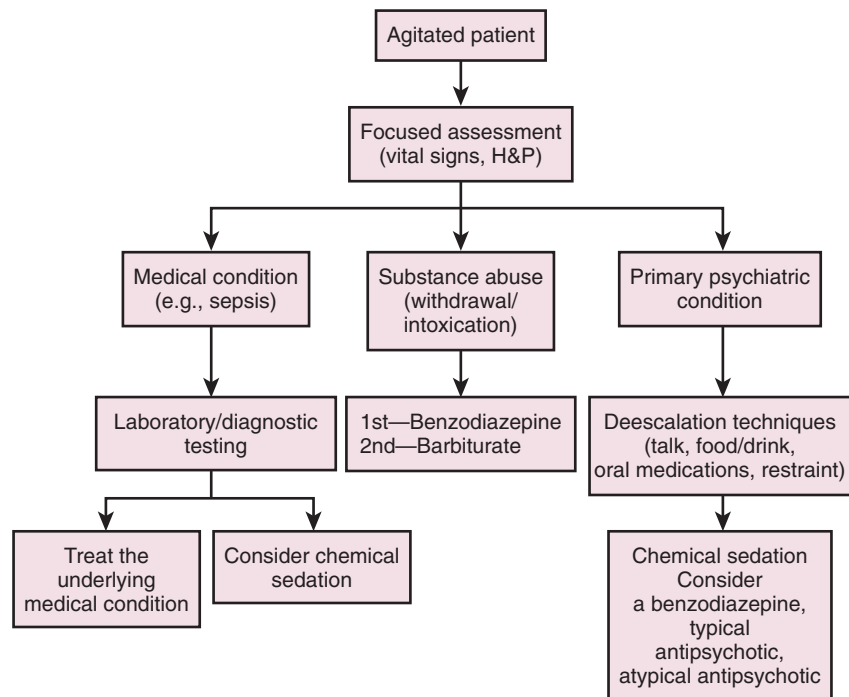

Figure 69.1 Approach to undifferentiated delirium in the emergency department. Intramuscular benzodiazepines and antipsychotic agents (alone or in combination), and IM/IV ketamine are used for the treatment of acute agitation or violence in the emergency department. *H&P*, history and physical examination. (Adapted from Rund DA, Ewing JD, Mitzel K, et al: The use of intramuscular benzodiazepines and antipsychotic agents in the treatment of acute agitation or violence in the emergency department, *J Emerg Med* 31:317–324, 2006.)

BOX 69.1 Conditions That May Cause Agitated and Violent Behavior

ENDOCRINE

Hypoglycemia
Hyperglycemia
Thyrotoxicosis, thyroid storm
Myxedema

INFECTIOUS

Meningitis
Encephalitis
Sepsis
Urinary tract infection

TOXICOLOGIC

Acute alcohol intoxication
Sympathomimetic intoxication
Anticholinergic intoxication
Delirium tremens
Alcohol withdrawal
Benzodiazepine withdrawal
Narcotic withdrawal

TRAUMATIC

Intracranial hemorrhage
Diffuse axonal injury
Hypoxia
Low-flow states secondary to
systemic hemorrhage

METABOLIC

Hypoxia
Hypercapnia
Hyponatremia
Hypernatremia

NEUROLOGIC

Status epilepticus
Postictal states
Acute delirium
Subarachnoid hemorrhage
Cerebral vascular accident

inexplicably occurred in seemingly healthy young males and often involved interactions with seriously deranged and violent individuals and law enforcement officers.

The majority of affected individuals are young males. Features of ExDS include uncontrolled aggression and agitation, tremendous pain tolerance, tachypnea, tachycardia, sweating, tactile hyperthermia, pacing, grunting, noncompliance with police orders, unusual and untiring strength, being inappropriately clothed, extreme paranoia, and having an attraction to mirror or glass. Individuals are unable to engage in rational discussion or understand or deescalate their abnormal aggressive, violent, and threatening behavior. A common fatal scenario is

characterized by a period of extreme delirium, increasing agitation, and inability to reason or comply with efforts to control their agitated state, followed by a struggle with law enforcement that involves vigorous physical restraint (choke holds, hog-tying, prone positioning, knee to the throat), and noxious chemicals. The actual role of physical restraint is unproven. The use of the TASER device (TASER International, Inc., Scottsdale, AZ) to control violent and markedly agitated individuals has been temporally related to death, but the role of this device in causing death is also unproven. Intervention may be followed by a sudden cessation of struggling that may herald death by cardiopulmonary arrest.

BOX 69.2 TJC Requirements for Patient Restraint Protocols and Documentation

RESTRAINT PROTOCOLS SHOULD INCLUDE

- Guidelines for assessing the patient
- Criteria for applying restraint
- Criteria for monitoring the patient and reassessing the need for restraint
- Monitoring at least every 2 hours or sooner based on patient needs
- Criteria for terminating restraint

DOCUMENTATION SHOULD INCLUDE

- Relevant orders for use
- Results of patient monitoring
- Reassessment
- Significant changes in the patient's condition

TJC, *The Joint Commission*.

The exact cause of death in ExDS cannot be identified at autopsy. Death may be related to underlying but unknown pathology (such as cardiomyopathy, conduction abnormalities, and metabolic disturbances). Lack of complete prior medical information, especially underlying cardiac abnormalities, hampers ascertainment of the actual cause of death when only the autopsy results are interpreted. Unfortunately, law enforcement may be blamed for using excessive force when no autopsy proven cause of death is forthcoming.

Stimulant drug use, including cocaine, methamphetamine, and PCP, has a well-established association with ExDS and is usually implicated as being closely linked to if not causative of death from ExDS. Persons with psychiatric illnesses represent the second largest, but distinctly smaller cohort of ExDS cases. The combination of drugs, alcohol, and psychiatric illness is well recognized. Some deaths are temporally related to the application of a conducted electrical weapon (CEW; e.g., a TASER), but there are well-documented cases of ExDS-associated deaths with minimal restraint such as handcuffs without TASER use.

No definitive diagnostic tests are available for ExDS. Currently, it must be identified by clinical features, which renders it very difficult to ascertain the true incidence. Though not universally fatal, it is clear that a proportion of individuals with ExDS progress to cardiac arrest and death regardless of medical intervention.

Although the specific precipitants of fatal ExDS remain unclear, epidemiologic and clinical reports provide some understanding of the underlying pathophysiology. The clinical picture is one of an agitated and delirious state with severe autonomic dysregulation. When available, cardiac rhythm analysis demonstrates bradycardic asystole; ventricular dysrhythmias are rare and have occurred in only a single patient in one study. Severe acidosis and hyperthermia appear to play a prominent role in lethal ExDS-associated cardiovascular collapse. One potential cause is thought to be excessive central dopamine stimulation.

Based on the available evidence, it was the consensus of the task force that ExDS is a real syndrome of uncertain etiology. It was also the consensus of the panel that rapid and appropriate,

albeit limited, physical restraint measures and immediate administration of benzodiazepines intravenously, ketamine intravenously, or midazolam intranasally may be lifesaving.

Importantly, insufficient data were available to the task force to determine whether fatal ExDS is preventable or whether there is a point of no return after which the patient will die regardless of advanced life support interventions.

MEDICOLEGAL CONCERNS

Emergency clinicians need to be cognizant of the potential legal ramifications stemming from physically restraining patients. The risk for litigation may be mitigated by strict adherence to written institutional and departmental policies regarding the use of restraint and medications. Unfortunately, no one-size-fits-all protocol is realistic, and each case must be individualized by a clinician at the bedside, often with little data or background on which to base a specific intervention. Emphasis should be placed on timely and comprehensive assessment before restraint, regular patient reevaluation, limitations on the time spent in restraint, and detailed documentation in the ED record. Furthermore, clinicians need to recognize that *competent patients* do have the legal right to refuse medical treatment even if the result of their refusal is death or serious bodily harm. Competence, however, may be difficult to evaluate or ascertain in the time frame required to make important clinical decisions. There are many gray areas that cannot simply be solved by attempting to obtain a formal psychiatric consultation. In fact, there are no data proving that a psychiatrist is any better than an emergency physician in determining competence in an ED patient within the time frame of the ED evaluation, when important decisions must be made. Individuals with true ExDS are clearly mentally incompetent, but coercive measures, including physical restraint or the threat of physical restraint, should not be used simply because a competent patient refuses treatment or as retaliation for perceived disruptive behavior.¹¹

PATIENT ASSESSMENT

Emergency clinicians must avoid ascribing agitated or abusive behavior to drug or alcohol intoxication or underlying psychiatric disease before considering severe, life-threatening diagnoses (see Box 69.1). Every attempt should be made to obtain a detailed history of issues related to the patient's condition, as well as the patient's past medical and psychiatric history, including medications, drug and alcohol use, and previous similar events. In reality, such information is rarely available or accurate, thus leaving only the clinician's clinical judgment to guide therapy.

Five groups of patients have been identified as being at increased risk for an underlying medical problem: the elderly, those with a history of substance abuse, patients without a previous psychiatric disorder, those with preexisting or new medical complaints, and individuals from lower socioeconomic groups.^{12,13} Of these, patients with new psychiatric symptoms are especially worrisome and require careful evaluation for underlying medical illness.¹⁴

Physical examination should be aimed at identifying organic causes of the patient's behavior such as trauma, infection, and metabolic derangements. Rapid bedside serum glucose

BOX 69.3 Recommended Areas to Assess During Reevaluation of Restrained Patients

Neurologic Status	• Respiratory rate
• Level of alertness	• Oxygen saturation
• Degree of agitation	• Temperature
• Pupillary examination	Patient Comfort
• Motor examination	• Skin under and around the restraints
• Sensory examination	• Hydration
Vascular Status	• Personal hygiene
• Capillary refill	• Toileting needs
• Distal pulses	Assessment for Restraint Removal
Vital Signs	
• Blood pressure	
• Heart rate	

determination should be performed on any patient with agitated or combative behavior. Temperature measurements, preferably rectal, should be obtained as soon as possible because hyperthermia may be indicative of an underlying central nervous system infection or drug-induced toxidrome. Evidence of head trauma in a patient who appears intoxicated warrants further evaluation to exclude traumatic brain injury.

Once a patient has been restrained, frequent periodic reevaluation is paramount to the patient's safety and is required by TJC (see [Box 69.2](#)).¹⁵ Reevaluation of restrained patients should include a reassessment of vital signs, neurologic status, respiratory status, skin condition, and perfusion of the extremities ([Box 69.3](#)). Physical restraints should be removed as soon as the clinician has determined that patients are no longer a risk to themselves or others.

DE-ESCALATION TECHNIQUES

Coburn and Mycyk described three phases of escalating violence: anxiety, defensiveness, and finally, physical aggression.¹⁶ Recognition of this somewhat predictable pattern may help in defusing a difficult situation before physical or chemical restraint is necessary. Indeed, several de-escalation techniques have been shown to assist in quelling agitated and violent patients.²

One simple, yet effective technique is verbally engaging the patient by asking, "how can we help you?" This display of compassion on the part of the treating clinician and staff may calm the patient. Similarly, offering food and drink will often soothe an agitated patient. Along with these displays of caring and empathy, it is important to impress on the patient that violent behavior will not be tolerated and will be dealt with quickly and firmly.² If the patient continues to demonstrate agitated or violent behavior, enlist the aid of a family member or a specially trained individual, such as a social worker, psychiatric counselor, or member of the clergy.

If these conservative measures fail, summon hospital security to ensure the safety of the patient and staff. In these situations, security staff should not rush to the patient's bedside but instead should gather outside the door or close by, within eye contact of the patient's room. A strong show of force may calm a potentially violent patient without the need for restraint.

TYPES OF PATIENT RESTRAINT

Seclusion

The utility of seclusion in psychiatric evaluation units and inpatient hospital wards is well documented in both adult and pediatric populations.^{17–20} In the mid-1980s, seclusion was commonly used to calm combative and violent ED patients, but its popularity has declined since then.^{1,21,22} Reasons for this decline are unclear but probably include lack of adequate space and concerns regarding provision of medical care and compliance with regulatory agencies.²² Nevertheless, at institutions with adequate physical space and well-designed policies and procedures, experience has shown that seclusion is an effective ED practice for selected patients.^{22,23}

Seclusion involves placing agitated and violent patients in an isolated space and confining them to dedicated hospital stretchers or beds that are secured in place to prevent injury. Seclusion is often used in conjunction with chemical sedation, physical restraint, or both.²² The seclusion room should be located near ED staff to allow continuous patient observation. Regularly reassess patients who are placed in seclusion, similar to physically restrained patients (see [Box 69.3](#)).

Physical Restraint

Research regarding the application of physical restraint in the ED is limited. In one prospective study of restraint-associated complications in 298 ED patients, minor complications occurred in only 7% of patients, and there were no serious complications or deaths.²⁴ The author of this study concluded that the dangers of ED patient restraint promulgated by professional organizations and health care regulators may be overstated.²⁴ Moreover, this study supports the safe use of restraint by emergency clinicians, who by virtue of their training and experience are experts in recognizing signs of deterioration and skilled in airway management and resuscitation. It should also be noted that TJC sentinel event tracking has demonstrated a decreased rate of complications when patients are restrained on their sides.^{16,25}

Although the actual prevalence of patient restraint in EDs is unknown, it has been estimated that 25% of teaching hospitals physically restrain at least one person per day.¹

Restraint Devices

Limb Holders (Restraints)

Restraining a patient's extremities is the primary method of physical restraint used in the ED. Limb restraints are constructed from a variety of materials, including leather, synthetic leather, cotton, and single-use foam material. These materials provide restraint that differs in strength, ease of removal, and cleaning.

Hard leather and synthetic leather limb holders are virtually impossible to break or tear but are difficult to sterilize if they become soiled with blood or body fluids ([Fig. 69.2](#)). They are more rigid than soft restraints, which also makes them somewhat more difficult and time-consuming to apply. More importantly, most leather limb holders require a key to unlock and, as a result, might take longer to remove after an adverse event such as vomiting or respiratory arrest. Leather limb holders are generally used to restrain combative and violent patients in whom the need for indestructible secure restraints outweighs the more time-consuming application and removal process.

Figure 69.2 Leather extremity restraint. (Courtesy Posey Company, Inc., Arcadia, CA.)

Figure 69.3 Cotton extremity restraint. (Courtesy Posey Company, Inc., Arcadia, CA.)

Soft limb restraints are usually made from cotton or foam material, or both (Fig. 69.3). They are single-use devices, which obviates the need for cleaning and sterilization. Soft limb restraints are less rigid than leather limb restraints, which makes them easier to apply. In addition, because they are fastened without the use of a key, soft limb restraints are more easily removed. Soft restraints are typically used for agitated but less combative patients because they are not as secure as leather limb holders.

Belts/Fifth-Point Restraint

A fifth-point restraint is a belt apparatus used to supplement the use of four limb restraints by holding down the thighs, chest, or pelvis (Fig. 69.4). A fifth-point restraint is used on patients who continue to be at risk for harming themselves despite adequate limb restraint and whose continued combative behavior interferes with diagnostic or therapeutic interventions. When patients are restrained across the thighs, chest, or pelvis, they may not be able to sit up or turn onto their sides, thus placing them at higher risk for aspiration should vomiting occur. Keep the side rails of the stretcher in the upright position at all times and place the belt snugly enough to prevent the

Figure 69.4 Fifth-point restraint. (Courtesy Posey Company, Inc., Arcadia, CA.)

Figure 69.5 Restraint vest. (Courtesy Posey Company, Inc., Arcadia, CA.)

patient from slipping under the device and thereby increasing the risk for accidental suffocation. Fifth-point restraints are usually made of synthetic material and are available with both quick-release and key-release locks.

Jackets and Vests

Jackets and vests are generally used on inpatient wards and extended care facilities for the prevention of falls; they have little utility in the ED (Fig. 69.5). Moreover, these products have been implicated in a number of restraint-associated deaths secondary to choking and suffocation. The use of restraint jackets and vests in the ED is not recommended.

Hobble Leg Restraints

Hobble leg restraints limit movement by securing the patient's ankles with connecting locking cuffs (Fig. 69.6). Hobble leg restraints are commonly used by law enforcement agencies because they impede running and kicking, which makes them

Figure 69.6 Hobble leg restraint. (Courtesy Posey Company, Inc., Arcadia, CA.)

Figure 69.7 *Not to be used:* The “hog-tie” method of restraint. The combination of prone positioning, hobble leg restraints, and binding a patient’s hands behind the back is commonly referred to as a hog tie. Although this was a common method of restraining prisoners and violent psychiatric patients in the past, the hog tie is no longer recommended. The exact physiologic and metabolic derangements from this position by itself are probably minimal, but the practice is strongly discouraged.

an effective method of transporting potentially violent patients and those who pose a risk for flight. Hobble leg restraints are seldom used in the ED, but their use by law enforcement agencies and prison authorities means that most emergency clinicians will encounter patients placed in these devices. The combination of prone positioning, hobble leg restraints, and binding a patient’s hands behind the back, commonly referred to as *hog-tying*, was a common method of restraining prisoners and violent psychiatric patients (Fig. 69.7). However, this practice is no longer widely used because of the risk for suffocation (see later section on [Positional Asphyxia](#)).

Indications

Use limb restraints to prevent agitated, combative, or violent patients from harming themselves or others. Frequently, the use of restraints can be delayed while verbal de-escalation techniques are attempted (see earlier section on [De-escalation Techniques](#)). However, if a patient is deemed an immediate threat to himself/herself or others, restrain him/her without delay. Patients with altered mental status may require limb restraints so that diagnostic testing can be completed or appropriate treatment rendered, or both. Use limb restraints also to prevent patients from interfering with devices, such as endotracheal tubes, cardiac monitors, and indwelling intravenous (IV) lines and catheters.

Contraindications

When appropriate, delay physical restraint in favor of trying verbal de-escalation techniques. Do not place limb restraints

Figure 69.8 Show of force. A minimum of five well-trained individuals should be available to restrain a patient. This show of force may help discourage the patient from resisting and is an important part of the restraint process.

on extremities with fractures, open wounds, or acute skin and soft tissue infections. Use caution to avoid ischemia in patients who exhibit tenuous perfusion of extremities, such as those with peripheral vascular disease or previous arterial injury or surgery.

Avoid fifth-point restraint of the abdomen and pelvic region in patients with pelvic fractures, suprapubic tubes, ostomies, and percutaneous feeding tubes. In addition, it is important to note that patients with underlying pulmonary or cardiac disease may not tolerate restraint of their thorax.

Procedure

Use a minimum of five people, all trained in restraint techniques and patient safety, to restrain the patient if possible (Fig. 69.8). This show of force may help discourage the patient from resisting and is an important part of the restraint process. The individuals making up the restraint team may include clinicians, nurses, technicians, and police or hospital security. When possible, undress and place the patient in a hospital gown before attempting to apply physical restraint. When this is not practical, restrain the patient, but promptly search for weapons and potentially harmful belongings. Confiscate these items and account for them in accordance with institutional policies.

Always restrain patients in the supine rather than the prone position because the prone position increases the risk for suffocation. Assign one person to hold each limb firmly against the stretcher by applying direct pressure proximal to the elbows and knees. The fifth member of the team places restraints around the wrists and ankles (Fig. 69.9). Control above the elbows and knees reduces the risk for injury to these joints and concentrates force closer to the patient’s center of gravity for better control.

Apply the limb holders snugly enough to control movement and prevent escape, but not so tight that they cause pain or impair circulation. If necessary, place a fifth-point restraint across the patient’s thighs, pelvis, or chest to further limit motion. Place a surgical mask temporarily over the patient’s mouth to prevent the patient from spitting at members of the restraint team or ED staff. If leather restraints are used, keep

Figure 69.9 Technique to physically restrain a violent patient. Adequate chemical restraint should be used early in the ED course, either before or after physical restraints, to limit acidosis, rhabdomyolysis, and hyperthermia. **A**, Patients should always be restrained in the supine position. One person is assigned to each limb, which is held firmly against the stretcher by applying direct pressure proximal to the elbows and knees. **B**, The fifth member of the team places restraints around the wrists and ankles. The limb holders should be applied snugly enough to control movement and prevent escape, but not so tight that they cause pain or impair circulation. If necessary, a fifth-point restraint may be placed across the patient's thighs, pelvis, or chest to further limit motion.

a restraint key readily available in the event that the restraints need to be removed urgently.

▶ If four-point (Video 69.1) rather than five-point restraints are applied (i.e., use of extremity restraints only), consider placing one arm up alongside the head and the opposite arm down along the side of the body. In this position, it is less likely the patient will be able to overturn the stretcher.¹⁶

Once the patient has been safely restrained, frequently assess pulses, capillary refill, skin color and temperature, and motor and sensory function. Reevaluate frequently in accordance with your institution's policies and procedures because this is key to preventing complications. In general, restraints should have well-defined time limits and should be removed as soon as the patient's condition has changed sufficiently that the patient is no longer a threat to self or others. For further details regarding rules, regulations, and recommendations for restraint procedures and patient assessment, the reader is referred to the TJC website at <https://www.jointcommission.org>.

Complications

Increased Agitation

For some patients, placement in physical restraints is so emotionally disturbing that it actually increases agitation and combative behavior. Patients who continue to struggle despite restraints are at risk for a number of potentially serious adverse events, including skin damage, ischemia, metabolic acidosis, rhabdomyolysis, hyperthermia, and even death (see later section on **Other Complications**). In these patients, the addition of chemical sedation is highly recommended (see later section on **Chemical Restraint**). In contrast, the use of extremity restraints alone is often effective in an alcohol-intoxicated patient because the natural progression of alcohol intoxication is sedation and sleep. Intoxicated patients may benefit from a brief period of observation before a decision is made to administer chemical sedation. Most of these patients will fall asleep, thereby obviating the need for sedation and the accompanying risks.

Local Skin

Restraints may cause skin irritation or breakdown. Risk factors include restraints that are too tight and those that have been left on for prolonged periods. Leather restraints are more likely than soft restraints to cause skin damage, particularly in patients who continue to struggle despite being placed in restraints. To help prevent skin complications, use soft restraints whenever possible, avoid overly tight restraints, limit restraint time, and reevaluate the patient frequently. In addition, use chemical restraint judiciously to help avoid skin damage in patients who continue to struggle. It is important to not ignore a patient's complaints of restraint pain without first evaluating the possibility of an adverse event.

Vascular Compromise

Restraints have the rare potential to impede blood flow to the hands and feet. In extreme cases, this could result in ischemia of the distal end of the extremity. Ischemia is more likely to occur in patients whose restraints are placed too tightly and in those in whom swelling develops as a result of an occult injury. Struggling against the restraints may further increase this risk. A thorough search for occult injuries, attention to proper fit, and limited restraint time will help avoid ischemia. Frequent assessment of pulses, capillary refill, skin color and temperature, and motor and sensory function is also extremely important. As mentioned previously, it is also important to not ignore a restrained patient's complaints regarding extremity pain without first evaluating for the possibility of ischemia.

Respiratory Compromise

Restraints may impair respiratory mechanics in some patients. This is more likely to occur in patients restrained in the prone or hog-tied positions and in those with underlying pulmonary disease.²⁶⁻³⁰ Patients with chronic obstructive pulmonary disease (COPD) may not tolerate a fifth-point restraint across the chest. Avoid respiratory complications by not restraining patients in the prone or hog-tied position. In addition, use adequate chemical sedation to help negate the need for a supplemental restraint belt in patients with underlying COPD.

Positional Asphyxia

Positional asphyxia is a poorly elucidated respiratory complication often attributed to the use of restraints that results in asphyxia and eventually death. The specifics of respiratory embarrassment

secondary to physical restraint are vague and unproven and have not been reproduced in volunteers, who do not experience severe pulmonary compromise from restraint. Thus, though often implicated, the exact contribution of restraint to sudden death is unclear. Obesity, underlying cardiac and pulmonary disease, prone positioning, and concurrent stimulant use are thought to be contributing factors.^{26,28,30–33} The hog-tied position (see Fig. 69.7), in which a patient's hands and feet are bound behind the back, places a patient at theoretical risk for positional asphyxia and should therefore not be used in the ED.^{26–28,33–36} Placing restrained patients in the supine position and frequently reevaluating them will help prevent positional asphyxia. Continuous monitoring of respiratory status, including oxygenation, ventilation, and tidal volume, is indicated in all physically restrained and chemically sedated patients, especially those with obesity, COPD, or intoxication from stimulant drugs.

Cocaine-Associated Agitated Delirium

Cocaine-associated agitated delirium is a syndrome consisting of hyperthermia with delirium and severe agitation that can progress to multisystem failure, coagulopathy, respiratory arrest, and death.^{28,30,32,34,37} Much of the pathology may be due to cocaine alone, but restrained patients appear to be at particularly high risk for this syndrome. The syndrome was first described in 1985, but its incidence increased significantly in the 1990s because of the popularity of crack cocaine.^{34,35}

The pathophysiology of cocaine-associated agitated delirium is a complex process involving downregulation of dopamine receptors with subsequent dopamine excess during times of cocaine binges.^{34,38–40} When patients with cocaine-associated agitated delirium are restrained, especially in the prone position, interference with normal respiratory mechanics increases the likelihood of hypoventilation, hypercapnia, and hypoxemia and ultimately leads to asphyxia and death. It has also been suggested that the stress caused by the restraining process increases the risk for fatal cardiac arrhythmias secondary to catecholamine surge in an already cocaine-sensitized myocardium.³⁴ Chronic stimulant use leads to adrenergic-induced cardiomyopathy, which is often clinically silent until the individual is severely stressed. The potential for malignant arrhythmias is unknown, but they have been implicated in some cases of sudden death in restrained patients.

Metabolic Acidosis

In patients who have been restrained, continued agitation and struggling can lead to severe metabolic acidosis.³⁷ Their pH is often lower than 7.0. The etiology of this acidosis is unclear but probably involves the production of lactic acid from physical exertion compounded by sympathetic-induced vasoconstriction. Such vasoconstriction may result from agitation or cocaine (and other stimulant) use and is believed to enhance exercise-induced lactic acidosis by impeding clearance of lactate by the liver.^{41,42} In some patients the buildup of lactate is further increased by the presence of psychosis and delirium, which may alter pain sensation and allow exertion far beyond normal physiologic limits.³⁷ In addition, some restraint positions (e.g., prone, hog-tied) may not allow adequate respiratory compensation, thereby resulting in further enhancement of the acidosis. A common scenario is an out-of-hospital cardiac arrest in which a severely agitated individual suddenly stops struggling and experiences a bradycardic, asystolic death that is not immediately recognized. Such patients may have been subdued by force,

by TASER, by mace or by pepper spray, which has led to unproven speculation that these interventions may have caused the change in patient status.

Regardless of the etiology, profound metabolic acidosis has been associated with cardiovascular collapse and sudden and unexpected death in restrained patients.³⁷ Individuals suffer a bradycardic, pulseless electrical activity, asystolic cardiac arrest, and resuscitation is unlikely once cardiac arrest ensues. Patients who remain combative despite restraints, especially those who have used cocaine or other sympathomimetic agents, are at particularly high risk for death.³⁷ Clues to the presence of metabolic acidosis include severe agitation, abnormal vital signs (e.g., persistent tachycardia, tachypnea, and hyperpyrexia), and decreased or concentrated urine output despite adequate IV fluid administration. Laboratory testing, including arterial or venous blood gas analysis, serum electrolytes, and serum creatine phosphokinase, is recommended in patients with signs and symptoms suggestive of metabolic acidosis and in those with potentially lethal co-ingestion (e.g., salicylates and toxic alcohols).

Restrained patients with severe metabolic acidosis should receive aggressive saline hydration and sedation with benzodiazepines to counteract the sympathetic hyperactivity.³⁷ The utility of sodium bicarbonate is unknown and it is probably best reserved for patients with a pH below 7.0.

Chemical Restraint

Agitation leading to delirium and culminating in ExDS is a continuum with no rigidly defined parameters. This chapter discusses the treatment of mild agitation, as well as life-threatening ExDS, but it is important to realize that the recommendations are subject to alteration or modification depending on the degree of impairment and the necessity of the clinician to intervene differently in individuals with varying degrees of impairment. The exact role of chemical restraint will always be a clinical judgment call made at the bedside and based on the scenario at hand. It is, however, axiomatic that chemical restraint is mandated when physical restraint and other modalities have failed. Medically compromised patients who appear mentally incompetent, are unable to comprehend or participate in the evaluation or treatment of a serious medical condition, or are otherwise unable to cooperate with required diagnostic or therapeutic medical interventions should be chemically restrained.

Chemical restraint, more aptly termed chemical sedation, describes the act of quelling an agitated patient by the administration of approved sedative-hypnotic, antipsychotic, or dissociative medications. Early, liberal use of appropriate anxiolytic and sedating medications permits thorough evaluation of a patient's medical condition. In some cases, administration of anxiolytic drugs (e.g., benzodiazepines) may be the optimal treatment of a person with an undifferentiated delirious state such as delirium tremens.⁴³ This is supported by Khan and associates, who identified an association between the use of physical restraint and death in patients with delirium tremens.⁴⁴ Although a clear causal relationship between restraint and death is lacking, early use of chemical sedation may be safer than physical restraint for treatment of an undifferentiated delirium.

The CMS states that chemical restraint is “a medication used to control behavior or to restrict the patient's freedom of movement and is not a standard treatment for the patient's

medical or psychiatric condition.”⁸ Curiously, TJC defines chemical restraint as “the inappropriate use of a sedating psychotropic drug to manage or control behavior.”¹⁵ These definitions lack perspective on the use of chemical sedation in the ED, where these medications are typically used after all other measures fail and the health and safety of the patient or staff are threatened. Such statements do not reflect standard care in the ED and should not be interpreted as prohibition of the appropriate short-term use of chemical sedation.

The pathogenesis of agitation is poorly understood; however, the advent of anxiolytic and antipsychotic medications has revolutionized the treatment of acute agitation. Not only has sedation become safer, but many of these new agents also have the added benefit of treating underlying psychotic states.⁴ Benzodiazepines, with rare exception, have replaced barbiturates for the treatment of acute agitation. Recently, intramuscular (IM) preparations of “atypical antipsychotic” medications such as olanzapine, ziprasidone, and aripiprazole have provided additional treatment options for rapid control of acute psychosis.^{45,46}

Oral administration is a reasonable first-line option in the cooperative patient and is the preferred route as consent is implied when he or she willingly ingests it.^{47,48} Previous reports have shown that patients prefer oral formulations during the treatment of psychotic episodes because they are participating in their own care plan.^{49,50} Oral lorazepam and oral risperidone have demonstrated increased efficacy when compared with the IM administration of haloperidol.⁵¹ However, in the uncooperative agitated patient, where rapid tranquilization is usually the goal, medications are typically administered IV or IM. Obtaining early IV access allows titration of rapidly acting medications but may not be possible in some patients. When IV access is not possible, IM administration is recommended and, in some cases, has been shown to be as efficacious and safe as IV administration.⁵² Other routes (oral, transmucosal) may be used when parenteral administration is not practical or feasible.

An ideal drug for chemical sedation in the ED should have multiple routes of administration (e.g., IV, IM, transmucosal), a rapid onset of action, negligible hemodynamic effects, and a good safety record with minimal adverse effects. Although no medication fits this profile perfectly, with proper patient assessment and careful drug selection, most ED patients can be rapidly and safely sedated. The remainder of this chapter discusses the safety, efficacy, side effect profile, and recommended dosages of the medications most commonly used for chemical sedation. Recommendations for drug selection are also discussed (Table 69.1).

Other Methods of Drug Delivery

Under most circumstances, sedative medications are best administered IV. A peripheral vein is adequate but may be difficult to access or maintain in a struggling patient. Although an indwelling catheter is preferable, to titrate escalating doses, the first dose may be directly administered into a peripheral vein via a syringe/needle, so-called “mainlining” (Fig. 69.10). A large extremity vein in the arm or leg is usually available if the extremity can be adequately immobilized. The external jugular vein presents another route. The head can often be more easily stabilized than a muscular extremity, and the external jugular vein is usually quite prominent in a struggling patient. Note that some antipsychotics, such as olanzapine and ziprasidone, have indications only for use IM. Haloperidol is universally administered IV, although it has no formal indication

Figure 69.10 When intravenous (IV) access is problematic in a patient in urgent need of IV sedation, an alternative is to mainline medication into a large vein directly from a syringe. **A**, The external jugular vein is usually prominent in a struggling patient, and the head and upper part of the torso are easier to control than an extremity. A finger occluding the distal end of the vein (arrow) allows better access. **B**, Other options include the antecubital fossa and **C**, the greater saphenous ankle vein, if the respective extremity can be temporarily immobilized. Use a 23- to 25-gauge needle. When blood is aspirated, push the medication. Ketamine is effective within 1 to 2 minutes by the intramuscular route (anterior thigh or deltoid area) and is an option to IV benzodiazepines and antipsychotic medications.

for this route. Intranasal midazolam is another alternative route of administration that may have prehospital utility.

Indications

Chemical sedation is used to prevent patients from injuring themselves or others, attenuate psychosis, decrease the time

TABLE 69.1 Drugs Used for Chemical Restraint in the ED

AGENT	DOSAGE	ONSET/DURATION OF ACTION	INDICATIONS	CONTRAINDICATIONS	ADVERSE EVENTS	COMMENTS*
Haloperidol	Adults: 0.5–10 mg IM/IV/ PO q 1–4 hr Children/Adolescents: 0.05–0.15 mg/kg IM/IV q 1 hr (max 5 mg)	Onset: IM/IV: 30–45 min Duration: IM/IV: 4–24 hr	All forms of agitation	Patients with a history of QT prolongation, thyrotoxicosis, Parkinson's disease, and severe hepatic disease	EPSs, QTc prolongation, NMS, hypotension, cholinergic blockade	Can be given alone or in combination with a benzodiazepine; may lower the seizure threshold
Droperidol	Adults: 5 mg IM/IV	Onset: IM/IV: 3–10 min Duration: IM/IV: 2–12 hr	All forms of agitation	Patients with a history of QT prolongation, thyrotoxicosis, Parkinson's disease, severe hepatic disease, and intoxication with LSD	EPSs, QTc prolongation, NMS, hypotension, cholinergic blockade	Black box warning regarding QT prolongation and serious arrhythmias; rapid-onset IM; use with caution in children
Lorazepam	Adults: 1–3 mg IM/IV/PO q 30–60 min Children: 0.05–0.1 mg/kg (max 4 mg/dose) Geriatric: < 2 mg/dose	Onset: IM: 15–20 min IV: 2–3 min Duration: IM/IV: 8–10 hr	All forms of agitation	Patients with respiratory depression and pregnant women	Respiratory depression, ataxia, hypotension	First-line therapy for children; use with caution in patients with alcohol intoxication because of the risk for respiratory depression
Diazepam	Adults: 2–10 mg IV/IM/PO Children: 0.04–0.3 mg/kg per dose IM/IV (max 0.6 mg/kg in 8 hr) Geriatric 2 mg PO	Onset: IV: 1–5 min IM: unknown Duration: IM/IV 15–60 min	All forms of agitation	Patients with respiratory depression and pregnant women	Respiratory depression, ataxia, hypotension	Use with caution in patients with alcohol intoxication because of the risk for respiratory depression
Midazolam	Adults: 1–5 mg IM/IV Children: 0.1–0.2 mg/kg IV/IM (max 0.5 mg/kg or 10 mg) Geriatric: 1–3 mg IM/IV	Onset: IV: 3 min IM: 5 min Duration: IM/IV: 30–120 min	All forms of agitation	Patients with respiratory depression and pregnant women	Respiratory depression, ataxia, hypotension	First-line therapy for children; rapid onset IM; use with caution in patients with alcohol intoxication because of the risk for respiratory depression

Ziprasidone	Adults: 10 mg IM q 2 hr, 20 mg IM q 4 hr (max 40 mg/day) Children: not indicated	Onset: 15–30 min Duration: 4 hr	Psychoses, intoxications	Patients with dementia	QT prolongation, somnolence, EPSs	Lower incidence of EPS than with haloperidol and droperidol; black box warning regarding use in elderly patients with dementia
Olanzapine	Adults: 5–10 mg IM Children: not indicated Geriatric: 2.5–10 mg IM	Onset: 15–30 min Duration: 2–24 hr	Psychiatric illness	Patients with dementia	Somnolence, EPSs	Lower incidence of EPS than with haloperidol and droperidol; black box warning regarding use in elderly patients with dementia
Aripiprazole	Adults: 5.25–9.75 mg IM (maximum, 30 mg/day) Children: not indicated Geriatric: 2.5–10 mg IM (max 15 mg/day)	Onset: 15–30 min Duration: unknown	Psychiatric illness	Patients with dementia, leukopenia, or neutropenia	NMS, EPSs	Black box warning to avoid use for dementia-related psychosis; may cause or increase suicidal ideation
Ketamine	Adults/children: 1–2 mg/kg IV, 4–5 mg/kg IM	Onset: IV: < 1 min IM: 3–5 min Duration IV: 15 min (recovery 1–2 hr) IM: 30 min (recovery 3–4 hr)	Acute agitation	Acute upper respiratory infection, children < 3 mo of age	Emergence phenomenon, potential increased intracranial and intraocular pressure, hypertension, tachycardia, salivation, vomiting, laryngospasm	Doses provided are for achieving a dissociative state; use ketamine when rapid sedation is required for lifesaving interventions

*Many of the caveats concerning the safety and efficacy of long-term use cannot be equated to short-term ED use. These medications are currently often used in doses far exceeding those recommended by the manufacturer or under other clinical circumstances; safety and efficacy for short-term sedation have been demonstrated in clinical ED practice.

ED, Emergency department; EPS, extrapyramidal symptoms; IM, intramuscularly; IV, intravenously; LSD, lysergic acid diethylamide; NMS, neuroleptic malignant syndrome; PO, per os (oral).

spent in physical restraint, and calm patients enough to permit a medical history, physical examination, diagnostic testing, and procedures.

Contraindications and Adverse Effects

Absolute and relative contraindications, as well as adverse effects, vary by medication and are discussed separately for each drug.

Neuroleptic Agents

Neuroleptic medications or “typical antipsychotics” have been used safely and effectively for years to manage patients with undifferentiated agitated delirium in the ED. The antipsychotic effects of neuroleptic agents do not usually take place for 7 to 10 days, but the onset of sedation is rapid, thus making them useful to calm an acutely agitated patient. Potent neuroleptic agents such as haloperidol and droperidol are preferred because they lack tolerance after repeated uses, have a low addiction potential, and possess a high therapeutic index. Low-potency neuroleptics such as chlorpromazine are less desirable because of a higher incidence of hypotension, seizures, and anticholinergic effects.⁵³

Contraindications

Haloperidol and droperidol are contraindicated in patients with thyrotoxicosis (neurotoxicity may develop), Parkinson’s disease, or severe hepatic disease. These drugs can lower the seizure threshold, so they should be used with caution or be avoided altogether in patients with a history of seizures or those who may be at known risk for the development of seizures (i.e., meningitis, sympathomimetic intoxication). Nevertheless, droperidol has been used safely to manage patients with known seizure disorders.⁵⁴ In addition, like all neuroleptic agents, haloperidol and droperidol can cause QT prolongation. It is not standard, however, to obtain an electrocardiogram prior to their use. However, they should be used with caution in patients at risk for QT prolongation and torsades de pointes (Box 69.4). Droperidol has also been associated with serotonin syndrome in patients taking lysergic acid diethylamide (LSD) and should be avoided in these patients.^{53,55}

Adverse Effects

Adverse effects common to all neuroleptic agents include extrapyramidal symptoms (EPSs), QTc prolongation, neuroleptic malignant syndrome (NMS), hypotension, and cholinergic receptor antagonism.

EPSs include akathisia (restlessness), dystonia (muscular spasms of the neck, eyes [oculogyric crisis], tongue, or jaw), drug-induced parkinsonism (muscle stiffness, shuffling gait, drooling, tremor), and tardive dyskinesia. These effects are due to the drugs’ antidopaminergic action and, though distressing to the patient, are seldom if ever life-threatening. Anticholinergic agents such as diphenhydramine (25 to 50 mg orally [PO], IM, or IV) and benztropine (1 to 2 mg PO, IM, or IV) are very effective in preventing or minimizing EPSs.

A potentially deadly, but exceedingly rare effect of neuroleptic drug use is prolongation of the QTc interval, which can lead to torsades de pointes, a polymorphic ventricular arrhythmia that can progress to ventricular fibrillation and sudden death.⁴ Droperidol has been the most publicized agent associated with QTc prolongation. It is currently the only neuroleptic agent that has received a “black box warning” for its propensity to cause QTc prolongation and sudden death.⁵⁶ In addition, a

BOX 69.4 Risk Factors for QTc Prolongation and Torsades de Pointes

NONPHARMACOLOGIC

- Congenital long QT syndromes
- Cardiac disorders (ventricular hypertrophy, heart failure, bradycardia)
- Electrolyte imbalance (especially hypokalemia)
- Overdose of an antipsychotic drug
- Female sex
- Use of restraints and psychological stress
- Substance abuse
- Miscellaneous factors (obesity, hypothyroidism)
- Elderly patients
- Renal and hepatic impairment

PHARMACOLOGIC

Pharmacokinetic Factors

- Inhibition of specific cytochrome P-450 enzymes
- Competition for specific cytochrome P-450 enzymes

Pharmacodynamic Factors

- Independent QTc prolongation

number of case reports and small case series have documented QTc prolongation and torsades de pointes after the administration of haloperidol.⁵⁷ Risk factors for QTc prolongation and torsades de pointes are listed in Box 69.4.

Patients in whom symptoms of NMS develop exhibit autonomic instability, including rigidity of the extremities, hyperthermia, and delirium. Treatment includes cooling measures, sedation with benzodiazepines, and in severe cases, bromocriptine, dantrolene, neuromuscular paralysis, and endotracheal intubation.⁵³

Hypotension is usually orthostatic in nature and tends to be more pronounced when the drugs are administered IV. In general, haloperidol and droperidol have a lower incidence of hypotension than do lower-potency neuroleptic agents. Likewise, the anticholinergic effects (e.g., confusion, dry mouth, blurred vision, urinary retention) of haloperidol and droperidol are much less severe than those of the lower-potency agents.

Haloperidol

Haloperidol is a very commonly used neuroleptic and a butyrophenone. It is categorized as a high-potency neuroleptic because of its strong antidopaminergic activity. The antidopaminergic activity is responsible for both its intended effects against delusions, hallucinations, and psychomotor agitation and its unintended parkinsonian symptoms. Administration of haloperidol both alone and in combination with benzodiazepines has been evaluated in a large number of clinical trials.^{58–63} These studies have demonstrated the use of haloperidol IM to be both safe and effective for the management of acute agitation from virtually any cause.

Dosage and Administration. Haloperidol can be administered PO, IV, and IM and has a low incidence of oversedation regardless of which route is chosen.⁴ Despite a lack of US Food and Drug Administration (FDA) approval for use IV, haloperidol is typically administered IV. The recommended

starting dosage to achieve sedation is 5 mg IM or IV, titrated to effect. There is no absolute maximum dose, and in cases of severe ExDS, doses of 10 to 30 mg are common. Occasionally, extrapyramidal reactions occur but are easily treated. The dose should be halved when administered to elderly patients. In children 6 to 12 years of age, the dosage is 1 to 3 mg IM every 4 to 8 hours with a maximum of 0.15 mg/kg per day. Children older than 12 years can receive the adult dosage. Haloperidol administered IM has a peak clinical effect within 30 to 45 minutes and may last up to 24 hours when given for acute agitation. Haloperidol is metabolized by the liver and excreted by the kidneys.⁶⁴

Droperidol

Droperidol, an analogue of haloperidol, is a high-potency butyrophenone with rapid sedating effects. It also possesses significant antidopaminergic activity. Droperidol acquired FDA approval in 1970 first as an antiemetic and antipsychotic agent. Soon thereafter, psychiatric EDs found it useful for chemical sedation.⁶⁵ Many physicians prefer droperidol to haloperidol because of its more rapid onset and shorter duration of action.

Use of droperidol as a chemical sedative continued until 2001, at which time the FDA issued a black box warning regarding the potential for fatal dysrhythmias.⁶⁶ Many hospitals and pharmacies subsequently sought to restrict or prohibit its use. However, two large retrospective studies encompassing more than 15,000 patients failed to demonstrate increased morbidity or mortality associated with the use of droperidol for the management of acute agitation.^{54,65} This controversy prompted an independent review of the data submitted to the FDA that led to the black box warning. The authors of this review found a number of anomalies and duplicate reports. They concluded that droperidol is a safe drug when used at the recommended dosage (i.e., 5 to 10 mg).⁶⁷ Despite an apparent lack of evidence behind the black box warning, use of droperidol has declined dramatically.⁶⁸

Studies comparing a variety of agents for rapid sedation have found that droperidol provides more rapid and effective control than do lorazepam,⁶⁹ haloperidol,⁵⁸ midazolam,^{70,71} and ziprasidone.⁷⁰ In addition, droperidol has been proved to be safe in patients with head injuries, alcohol and cocaine intoxication, and seizure disorders.⁵⁴

Dosage and Administration. The initial dosage used for sedation is 5 mg IV or IM. Its onset of action is 3 to 10 minutes with a peak clinical effect achieved in 30 minutes. The elimination half-life is 2 to 4 hours, but the sedative effects of droperidol may last up to 12 hours.⁷²

Benzodiazepines

All benzodiazepines enhance the neurotransmission of γ -aminobutyric acid and thereby result in anxiolysis, sedation, hypnosis, and muscle relaxation. This combination makes them an excellent choice for tranquilization of agitated patients. Because of a desirable safety profile, benzodiazepines are an excellent choice for sedating medically undifferentiated patients. The differences in clinical effects (e.g., onset, duration, adverse effects) are primarily related to dosage, route of administration, and pharmacokinetics. Benzodiazepines can be used as single agents or in combination with an antipsychotic drug. Lorazepam and midazolam are the benzodiazepines most commonly used for chemical sedation. This is probably due to their rapid and predictable absorption when given IV or IM, as well as a long

history of safety and efficacy. Unlike neuroleptics, benzodiazepines do not treat underlying psychiatric disorders. Some clinicians prefer to administer diazepam IV for the treatment of delirium related to sedative-hypnotic withdrawal.⁴³

Contraindications

There are few contraindications to the use of benzodiazepines as a chemical sedating agent. Because of the possibility of respiratory depression, use benzodiazepines with caution in patients in respiratory distress or identified pulmonary pathology like obstructive sleep apnea.

Adverse Effects

As discussed previously, benzodiazepines may cause respiratory depression. Additionally, hypotension, deep sedation, and paradoxical agitation have been reported. However, when administered in the doses recommended for agitation, adverse events are rare, thus making benzodiazepines the drugs of choice in most circumstances.

Respiratory compromise is dose dependent and typically occurs only in the presence of other respiratory depressants.^{73,74} Because of an increased risk for respiratory depression, administer benzodiazepines cautiously to elderly patients and those with underlying pulmonary diseases such as apnea and COPD. In healthy patients, particularly those suffering from agitated delirium, respiratory depression is very unlikely to occur, even when large doses of benzodiazepines are used. If available, end-tidal carbon dioxide monitoring (e.g., capnography) may assist the practitioner in detecting the onset of respiratory depression before it becomes clinically significant.^{75,76}

The most appropriate benzodiazepine is the one that the clinician is most comfortable administering and that has a duration of action most appropriate for the clinical situation. Titrate all benzodiazepines administered IV until the desired level of sedation is reached. In the setting of severe delirium, there is no maximum dose described for any benzodiazepine, and doses well in excess of the manufacturer's recommendation, and even those considered toxic under other circumstances, are commonly used. One difference that does bear mentioning is the use of propylene glycol, a solvent needed to keep non-water-soluble benzodiazepines (e.g., lorazepam, diazepam) in solution. In large doses, propylene glycol can cause an increased osmolar gap and metabolic acidosis and may precipitate or contribute to hypotension in some patients.

Lorazepam

Lorazepam is the benzodiazepine most frequently studied for the management of acute agitation. It enjoys popularity as part of the well-known "five and two" treatment regimen, which consists of haloperidol, 5 mg IM, and lorazepam, 2 mg IM.⁷⁷ In a number of clinical trials, lorazepam was shown to be an effective drug for rapid chemical sedation.^{59,62,63,69} In these studies, lorazepam had no extrapyramidal effects and was better tolerated than the neuroleptics. However, when compared with haloperidol, droperidol, midazolam, and a combination of haloperidol and lorazepam, the onset of sedation after administering lorazepam IM was more delayed.^{59,62,69}

Dosage and Administration. When used alone, lorazepam is usually given in 2- to 4-mg doses and can be administered PO, sublingually, IM, IV, or rectally. No maximum dose has been established. Following an injection of lorazepam IM, adequate sedation is usually achieved in 30 to 45 minutes.⁶⁹

When given IV, sedation occurs in 15 to 20 minutes.⁶² The elimination half-life is 12 to 15 hours, which produces a duration of effect of 8 to 10 hours. This makes lorazepam a better choice when long-term sedation is the goal. Lorazepam is rapidly conjugated to an inactive glucuronide. This does not require involvement of the cytochrome P-450 system, so lorazepam has few drug-drug interactions. Preparations of lorazepam intended for use IV or IM must be refrigerated, thus potentially limiting its use in underdeveloped countries and in the prehospital setting.⁴

Midazolam

Midazolam has been shown to be effective for rapid sedation.^{61,62,70,71} It has a more rapid onset and shorter duration of action than other benzodiazepines do, which makes it a good choice when rapid short-term sedation is desired. Midazolam also compares favorably with haloperidol, droperidol, and ziprasidone for the treatment of acute agitation in the ED.^{61,62,71} With the exception of droperidol, which has a similar time until onset (5 to 10 minutes), midazolam has a more rapid onset of sedation than the other drugs in these studies. The studies also noted that midazolam, as expected, has a shorter duration of sedation.

Dosage and Administration. The initial dosage of midazolam for an agitated adult is 5 mg IV or IM, and it may be repeated at 5- to 10-minute intervals. No maximum dose has been established. Nasal administration is also an option. The onset of sedation occurs approximately 3 minutes after IV administration, 5 minutes after an IM injection, and 15 minutes after nasal administration. Midazolam is hydroxylated by the cytochrome P-450 system to its primary metabolite, α -hydroxymidazolam, which undergoes glucuronide conjugation before being excreted in urine. Its duration of action is between 30 and 120 minutes and does not vary significantly by route of administration.^{62,78}

Diazepam

Diazepam has a long history of safe use in the management of agitated delirium, especially delirium tremens and alcohol withdrawal.^{43,79} For patients experiencing delirium tremens the usual dose is 5 to 10 mg IV every 5 to 10 minutes until the desired level of sedation is achieved (lower doses are appropriate for less severe agitation or agitation from other causes). No maximum dose has been established, and doses of up to 2000 mg have been used safely over a 24-hour period in patients experiencing delirium tremens.^{43,80} Because of erratic absorption, IM administration of diazepam is not recommended. Following the administration of diazepam, peak sedation is reached in approximately 5 to 6 minutes, which allows additional titrated doses if the desired clinical effect is not achieved initially.

Atypical Antipsychotic Agents

Atypical antipsychotic agents have high affinity for 5-HT (serotonin) receptors and less affinity for D₁ and D₂ receptors. As a result, they have a lower incidence of EPSs than haloperidol and droperidol.⁶⁴ In the past, medications in this class were available only in an oral formulation, thus limiting their use in the management of acute agitation. Recently, formulations of ziprasidone, olanzapine, and aripiprazole have been developed and are intended for IM administration. When administered IM, all three drugs are effective for the treatment of acute agitation.⁸¹ However, the delay in onset from IM medications

may be a disadvantage of these medications in circumstances that require rapid sedation. Often sedation is markedly prolonged from the relatively high doses required. However, the combination of IM administration and the low incidence of EPSs makes these newer agents an attractive option for rapid sedation of ED patients with undifferentiated agitation. This is particularly true for patients with a history of mental illness, for whom this class of medications is now considered appropriate first-line management.⁸²

Contraindications

In 2005, a meta-analysis of placebo-controlled trials demonstrated an increased risk for death associated with the atypical antipsychotic agents used to treat elderly patients with dementia-related psychosis.⁸³ This report led the FDA to issue a black box warning regarding the use of atypical antipsychotics for “behavioral disorders” in elderly patients with dementia. Such warnings have not resulted in the prohibition of such agents for short-term use in the ED. The FDA has also advised caution with ziprasidone because of its tendency to prolong the QTc interval, especially when used in patients taking other drugs or with medical conditions that increase the risk for prolongation of the QTc interval (see [Box 69.4](#)).⁸³ Ziprasidone prolongs the QTc interval more frequently than haloperidol, droperidol, and olanzapine do,⁴ but the degree of prolongation is considered minor and is rarely greater than 500 msec.⁸⁴ To date, there have been no clinical reports of adverse events as a result of QTc prolongation with the short-term ED use of atypical antipsychotic agents. Experience with these agents in undifferentiated acutely agitated patients in the ED is limited, but their use is increasing, and although initial reports are supportive, they are not yet definitive.

Adverse Effects

Atypical antipsychotic agents may cause somnolence, EPSs (though less often than with haloperidol and droperidol), QTc prolongation, and rarely, anticholinergic symptoms and NMS.

Ziprasidone

Ziprasidone is a benzyloisothiazolylpiperazine antipsychotic agent whose effects are the result of dopamine and serotonin 5-HT_{2A} receptor antagonism.^{4,81,85} This was the first atypical antipsychotic agent available in a fast-acting preparation administered IM. In a double-blind, randomized study, Martel and associates noted that ziprasidone was as effective as midazolam and droperidol in controlling acute agitation. Patients receiving ziprasidone and droperidol took longer to be sedated (30 minutes as compared with 15 minutes for midazolam) but were more deeply sedated at 60 and 120 minutes.⁷⁰ In a prospective, open-label study, ED patients receiving ziprasidone exhibited progressive improvement in anxiety, hostility, and cooperativeness starting at 15 minutes and continuing through the 90-minute study period.⁴⁶ In an observational study of agitated psychiatric ED patients with nonspecific psychosis, alcohol intoxication, or substance-induced psychosis, ziprasidone, 20 mg IM, was effective in sedating patients as quickly as 15 minutes.⁸⁶ Ziprasidone has not been approved by the FDA for the treatment of dementia-related psychosis.⁸⁵

Dosage and Administration. The recommended dosage of ziprasidone is 10 mg IM, which can be repeated at 2 hours, or 20 mg IM, which may be repeated at 4 hours. The drug

reaches peak plasma concentrations in 30 to 45 minutes and has an elimination half-life of 2 to 4 hours. Following an IM injection, sedation usually begins within 15 to 30 minutes and peaks at approximately 2 hours. The clinical effects usually last at least 4 hours.⁸⁷

Olanzapine

Olanzapine is a second-generation thienobenzodiazepine antipsychotic agent that is thought to exert its effects through antagonism of both dopamine and serotonin type 2 receptors. Olanzapine in an IM formulation has been approved by the FDA for the treatment of agitation in acutely psychotic patients. IM olanzapine is comparable to haloperidol or lorazepam monotherapy for acute agitation associated with schizophrenia and dementia^{60,88,89} and superior to lorazepam monotherapy in the management of agitation associated with bipolar disorder.⁹⁰ To date, there have been no clinical trials using IM olanzapine for undifferentiated agitation in the ED, but its use is increasing.

Dosage and Administration. The recommended dosage is 5 to 10 mg IM. Additional doses may be considered 2 to 4 hours after the preceding dose with a maximum recommended dose of 30 mg/day IM. Olanzapine reaches peak plasma concentrations in 15 to 45 minutes and has an elimination half-life of 21 to 54 hours. The onset of sedation usually begins 15 to 30 minutes after IM administration and typically lasts at least 2 hours. In some patients, the clinical effects have lasted as long as 24 hours. The drug is metabolized via direct glucuronidation and cytochrome P-450–mediated oxidation.⁹¹

Aripiprazole

Aripiprazole is an atypical antipsychotic that acts at both serotonin and dopamine receptors. Rates of EPSs are lower than with other antipsychotics, which may be a result of the drug's partial agonistic activity at dopamine receptors. IM administration has been approved for acute agitation related to schizophrenia and bipolar mania. To date, there have been no clinical trials using aripiprazole IM for undifferentiated agitation in the ED.

Dosage and Administration. The recommended dosage is 5.25 to 9.75 mg IM. Additional doses may be considered 2 to 4 hours after the preceding dose with a maximum recommended dose of 30 mg/day IM. Peak serum levels occur within 1 to 3 hours, with an elimination half-life of approximately 75 hours.

Dissociative Agents

Ketamine

Ketamine is a dissociative agent that has been used safely throughout the world for major surgery and with minimal monitoring.⁹² Many clinicians are familiar with ketamine as a safe and rapidly effective dissociative agent for tracheal intubation and for both adults and children undergoing painful procedures in the ED. When given IM or slow IV (e.g., greater than 60 seconds), ketamine has no significant adverse effects on respiration. It inhibits the reuptake of catecholamines promoting bronchodilation and increases in both heart rate and blood pressure. Commonly raised as a caution, there is no proven issue with ketamine causing harmful increased intracranial pressure.^{93,94} Possible side effects of ketamine include salivation, vomiting, laryngospasm, and emergence phenomena consisting of nightmares, short-lived bizarre thoughts, and

hallucinations. Fortunately, serious emergence phenomena have not been described as significant issues following ED use.

Literature supporting ketamine for the control of agitated and delirious patients has grown over the past decade. The drug's pharmacologic profile lends itself for use in acute, potentially violent situations. For example, ketamine has been used successfully in aeromedical transport as a sedative agent for patients with agitation.⁹⁵ It has also been effective in the prehospital management and transport of patients with ExDS and in combative trauma patients (including those with head injury),^{96,97} acutely agitated cocaine-intoxicated patients,⁹⁸ and agitated suicidal patients.⁹⁹

Dosage and Administration. The dose of ketamine to produce profound dissociation is 1.5 to 2.0 mg/kg IV or 4 to 5 mg/kg IM. IM administration is ideal in the ED when access for IV administration is not readily available. The anterior aspect of the thigh is a preferred site of injection for rapid tranquilization. Time of onset may vary slightly, but both routes have a rapid onset of action (30 seconds IV, 3 to 5 minutes IM). At the current time, ketamine is undergoing resurgence in popularity among emergency physicians, and the role of ketamine for the chemical control of acutely agitated and delirious patients in the ED is evolving.

Choosing the Best Agent

Undifferentiated Agitation

The safest agent for undifferentiated agitation in the ED has traditionally been a benzodiazepine administered IV, often combined with judicious doses of haloperidol. Chan and associates demonstrated the combination of an antipsychotic and midazolam had a shorter time to sedation than midazolam alone.¹⁰⁰ Ketamine and newer atypical antipsychotics are gaining favor, but their track record is short. Administering escalating doses of benzodiazepines is a prudent choice in such circumstances when the clinician is comfortable prescribing a drug from this class. There is little concern for respiratory or cardiovascular depression with the prudent use of carefully titrated IV benzodiazepines in the monitored setting. Fig. 69.1 suggests a possible management approach to an acutely agitated patient in the emergency setting. It must be emphasized that benzodiazepine doses considered exceeding high or even toxic by other standards are routinely and safely administered in the ED when aggressive sedation and chemical control are mandated as clinical priorities. In severe cases, benzodiazepines alone may not be totally effective.

Agitation Caused by Alcohol and Drugs of Abuse

For patients who are suspected of intoxication from alcohol or other sedative agents, haloperidol, droperidol, or ziprasidone will provide rapid, safe, and effective tranquilization.^{54,65,71} Benzodiazepines should be administered with caution to alcohol-intoxicated patients and those taking sedative agents because of the possibility of respiratory depression.^{73,74} In contrast, benzodiazepines are the drugs of choice in patients who are agitated as a result of alcohol or benzodiazepine withdrawal. Large doses may be required, and the safety profile is wide. Patients who are agitated because of sympathomimetic agents such as cocaine, methamphetamines or hallucinogens, such as PCP or LSD, may be treated safely with large doses of benzodiazepines, butyrophenones, or a combination of the two.^{54,59,69} Droperidol has been associated with serotonin syndrome in patients taking LSD and should be avoided in these patients.^{53,55}

Agitation Caused by Medical Illness

In patients whose agitation is due to medical illness, treatment should be aimed at correcting the underlying pathology. If rapid sedation is required, typical antipsychotics or benzodiazepines should be used as first-line therapy. If the patient is frail or elderly or is known to have renal impairment, consider using smaller doses of a single agent.

Agitation Caused by an Underlying Psychiatric Disorder

Patients with an established psychiatric history and agitation attributed to schizophrenia, schizoaffective disorder, or the manic phase of bipolar disorder may be treated with typical antipsychotic agents, atypical antipsychotic agents, or benzodiazepines. However, a growing body of evidence seems to support the use of atypical antipsychotic agents in this circumstance.^{46,60,70,86,88,89,98,101,102}

Agitation in Children

Because of years of experience and a proven safety record, benzodiazepines are considered first-line therapy for the management of agitation in children. The IM dose of lorazepam is 0.05 to 0.1 mg/kg and the IM dose of midazolam is 0.1 to 0.2 mg/kg. Neuroleptic agents have also been used to manage agitation in children. The IM dose of haloperidol is 0.025 to 0.075 mg/kg, with a maximum dose of 2.5 mg. Children older than 12 years can receive the adult dose, usually 2.5 to 5.0 mg IM (see [Table 69.1](#)). Although droperidol is a highly effective drug for rapid sedation of adults, there is a paucity of literature supporting its use in children. The pediatric dose of droperidol is 0.03 to 0.07 mg/kg with a maximum initial dose of 2.5 mg.⁵³ Combination therapy is not generally recommended for children.⁷⁷ Recently, ketamine has been described as an effective agent for sedation in pediatric cases refractory to benzodiazepines.¹⁰³

Agitation in Pregnancy

Psychotropic and anxiolytic medications should be used during pregnancy only when the potential risk to the fetus from exposure is outweighed by the risk of not treating the disorder in the mother.¹⁰⁴ Based on years of accumulated clinical experience but very little scientific data, conventional antipsychotic agents such as haloperidol and droperidol (pregnancy class C) are recommended to control agitation in pregnant women.¹⁰⁵ In pregnancy, benzodiazepines (pregnancy class D) may be associated with teratogenicity (especially craniofacial abnormalities) when used for an extended period.¹⁰⁶ Although clear causation has not been proved, benzodiazepines are generally avoided during the first trimester to minimize the risk for fetal malformation.¹⁰⁷ Judicious benzodiazepine administration should be considered a viable option in the acute ED setting in the second and early third trimesters.

Agitation in Older Patients

Patients 65 years or older are particularly susceptible to adverse drug reactions because of coexisting medical illness, use of multiple prescription medications (which increase the risk for drug-drug interactions), and age-associated changes in pharmacokinetics and pharmacodynamics. Research suggests that conventional antipsychotic medications such as haloperidol and droperidol are safe and effective for both psychotic symptoms and nonpsychotic agitated behavior.¹⁰⁸ Low doses (e.g., half the usual dose) of benzodiazepines can also be used

but require close observation for respiratory depression. Continued use (> 8 to 10 weeks) of atypical antipsychotic agents has been associated with increased rates of death in cases of dementia-related psychosis.⁸³

Conducted Electrical Weapons (CEWs)

CEWs, including TASERs (TASER International, Inc., Scottsdale, AZ) and stun guns, are used by law enforcement agencies throughout the world. These nonlethal weapons use a temporary high-voltage low-current electrical discharge to overcome a body's voluntary muscle-triggering mechanisms, which results in widespread involuntary muscle contractions that incapacitate the victim. The current is delivered by direct contact with a handheld device (i.e., electric shock prods) or via a small dart-like electrode fired from a gun using small gas charges (e.g., TASER) similar to some air rifle propellants. There are also electrical weapons that cause intense pain without incapacitating the target, so-called drive stun devices. Law enforcement and correctional personnel typically use drive stun devices as a pain compliance technique. A TASER may deliver approximately 1200 V with direct skin contact.¹⁰⁹

The exact street scenario of ExDS, physical restraint, and a TASER-linked death will probably never be studied with unchallenged scientific accuracy, and hence one is left with animal and human volunteer data to intuit the cause and effect of untoward events. Despite claims of lethality in the press, emotional testimony and unscientific reports from human rights organizations, and poorly documented claims in case reports, there have been no documented deaths directly and indisputably attributable to a TASER discharge in humans.¹¹⁰ Volunteer studies and animal models failed to provoke cardiac arrest, significant cardiopulmonary, or metabolic derangements after standard electrical discharges, even when animal models included stimulant toxicity and human volunteers were exercised to exhaustion.¹⁰⁹ Nevertheless, CEWs have been temporally linked to a number of fatalities.¹⁰⁹⁻¹¹¹ The majority of these cases involved sympathomimetic drug intoxication (e.g., cocaine, methamphetamines), prolonged physical exertion, or both.¹¹¹ The role of severely altered metabolic and autonomic parameters, drug intoxication, or underlying comorbid conditions, including cardiomyopathy, obscures the exact contribution of CEW use in unexpected deaths. A complete discussion of this topic is beyond the scope of this chapter, but it has been well reviewed elsewhere.^{112,113} Darts from a CEW often penetrate the skin and must be removed, so the remainder of this section focuses on the procedure for removing embedded TASER electrodes.

Electronic Control Devices

TASER is an acronym for "Thomas A. Swift's Electric Rifle" and has been in existence since the early 1990s ([Fig. 69.11](#)). More than 11,000 law enforcement, correctional, and military agencies in 44 countries deploy TASER devices, and many municipalities in the United States allow civilians to purchase and carry these weapons for personal protection.¹¹⁴ A TASER uses compressed nitrogen to propel two electrode-tipped barbs at 180 ft/sec at the target. The electrode-tipped barbs are attached to the electric device via two thin 21-foot wires and are similar in size to a No. 8 fishhook measuring 4 mm in length ([Fig. 69.12](#)). The barbs may attach to clothing and fail to penetrate the skin, or they may become embedded in skin and must be removed.

Figure 69.11 TASER electrical control device (TASER International, Inc., Scottsdale, AZ).

Figure 69.12 TASER dart/electrode-tipped barb. *Note:* The groove in the shaft (*arrow*) lines up with the barb tip to aid in removal.

Figure 69.13 Removal of an electrode-tipped barb. Barbs embedded in soft tissue can easily be removed with direct pressure. Place one hand on the skin surrounding the barb to hold the skin taut and use the other hand to apply direct pressure to the barb.

Removal Techniques

Barbs embedded in soft tissue can easily be removed with direct pressure. Place one hand on the skin surrounding the barb to hold the skin taut and use the other hand to apply direct pressure to the barb^{108,109} (Fig. 69.13). If the patient cannot tolerate the procedure, inject a small amount of local anesthetic near the barb and use a No. 11 scalpel blade to cut down through the soft tissue to the tip of the barb.¹¹⁴ Because of the small size and linear shape of the barb, there is no need to advance the barb through the skin to remove the tip as is commonly performed during the removal of fishhooks.¹¹⁵ After removal, clean and dress the wound (see Chapter 34), but do not suture it. Analgesics (e.g., nonsteroidal antiinflammatory drugs, acetaminophen) may be administered.

After removing the barb, provide standard wound care. Advise the patient to watch for signs of infection; a 48-hour wound check may be prudent with contaminated wounds, when

the barb was difficult to remove, or if there is concern for a retained foreign body. Tetanus status should be reviewed and updated if necessary. Significant infection after barb removal is rare, and prophylactic antibiotics are unnecessary. Following removal of a TASER dart, the disposition of the patient is based on the individual social scenario, and long-term ED observation is not required.

Complications

The risk for penetrating injury to the heart, lungs, or bowel from a TASER device is minimal, because of the small size of the barb. There are, however, increasing case reports of scrotal trauma, frontal sinus penetration, intraocular, and intracranial injuries resulting from TASER barbs.^{116–123} Management will depend on the specific structure affected and can carry significant morbidity if not recognized. A barb embedded in a vascular structure can probably be removed with manual traction followed by direct pressure on the wound because the size of the barb is similar to the size of devices used to obtain central venous access.¹¹⁵ Consultation with an appropriate consultant can help manage these rare but potentially serious penetrating injuries.

Severe involuntary muscle contractions from the electrical discharge has been implicated as a cause of acute thoracic compression fractures.^{124,125} Based on a literature review in 2011 by Vilke and colleagues, there is currently no indication for routine diagnostic or laboratory testing in asymptomatic patients following short-duration exposure (< 15 seconds) to a CEW.¹²⁶

TASER Use in the ED

Although data are difficult to confirm, it has been estimated that approximately 150 hospitals allow hospital security guards to carry TASERS. Those equipped with TASERS should have specific training, and policies on the use of the TASER in the hospital setting should be in place and training periodically updated. CMS regulations do not disallow TASERS in the hospital, but CMS and most states do not sanction the use of such devices to restrain a patient or to make them comply with medical treatment. Whenever possible, the least restrictive methods should be used to de-escalate aggressive behavior, or to calm agitated or disruptive individuals, such as a quiet and low-stimulation environment, reasonable bargaining, redirection of the patient, involvement of family, reality orientation, talk down, or a show of force. It is a gray area, indeed, as to when, or to what extent, any intervention is considered necessary to restrain a patient, or to protect a patient or medical personnel from harm. Every situation is somewhat unique so dogmatic approaches cannot be used. When a mentally incompetent or potentially suicidal patient wants to leave the ED against medical advice, and does not have insight into the adverse effects of such an egress, involuntary commitment is initiated. Effective measures are usually initiated by the emergency physician because psychiatric evaluation on such short notice is impractical or unavailable and important decisions must be made immediately with limited data. Such patients may assault those attempting to keep them from leaving the ED in their incompetent mental state, when medical consequences, suicide, or harm to others could be the ultimate outcome.

Per CMS guidelines, the use of weapons by security staff is considered a law enforcement action, not a health care intervention. CMS does not support the use of weapons by any hospital staff as a means of subduing a patient to place

that patient in restraint or seclusion. CMS interpretive guidelines to section 482.13(e) of the State Operations Manual say: *“If a weapon is used by security or law enforcement personnel on a person in a hospital (patient, staff, or visitor) to protect people or hospital property from harm, we would expect the situation to be handled as a criminal activity and the perpetrator placed in the custody of local law enforcement.”*

In one small nonvalidated study, Ho and colleagues¹²⁷ concluded that the introduction of the TASER into the health care setting (a large urban tertiary care teaching hospital) demonstrated the ability to avert and control situations that could result in injury to medical personnel and patients, by simple TASER presentation or rarely actual use. In that study there was a reduction in personnel injury rates and the contention that one suicide was averted. Further study is required

before definitive statements can be made. In summary, the use of the TASER in the ED has not yet been clarified, and there are advocates as well as critics. Any weapon, including the TASER, should not be used to force a patient to comply or to induce restraint in the absence of reasonable suspicion of impending harm or actual assault of medical personnel.

ACKNOWLEDGMENT

We would like to thank the previous author, Adam K. Rowden, for his work on earlier editions of this chapter.

Noncardiac Implantable Devices

Paul Jhun and Christopher R. Peabody

In addition to cardiac pacemakers and defibrillators, a number of noncardiac devices have been developed for electronic neuromodulation and drug delivery.^{1,2} Although these devices are placed by a variety of subspecialists for the treatment of chronic illnesses, if the devices malfunction, patients may arrive at the emergency department in an acute state, thereby necessitating intervention by the emergency provider.

INSULIN INFUSION DEVICES

Background

External insulin infusion devices have become increasingly popular since their introduction in 1974. By 2007, there were more than 375,000 external insulin infusion pumps in use in the United States.³

Anatomy

An external insulin infusion pump device consists of a portable, programmable infusion pump connected to a subcutaneously implanted catheter that is maintained in place with adhesive tape (Fig. 70.1). The implanted catheter site varies, but it is commonly placed in the subcutaneous tissue of the abdomen in adults and the buttocks in young children. The thighs, hips, and upper part of the arms are other sites. It is recommended that the implanted catheter be replaced every 2 to 3 days.⁴

Device Complications

In 2010, the Food and Drug Administration (FDA) published a panel report that highlighted problems associated with insulin infusion devices.³ From the top five device manufacturers, the FDA noted 16,640 adverse events, including 310 deaths, 12,093 injuries, and 4294 malfunctions. Box 70.1 lists the most frequently reported problems with devices in descending frequency. Box 70.2 lists the most frequently reported patient-oriented adverse reactions, which include hyperglycemia and hospitalization. Similar findings were reported in a 2014 prospective study, in which the most clinically significant adverse events related to insulin infusion devices were hyperglycemia and ketosis.⁵

Of the 310 deaths reportedly related to insulin infusion pumps in the FDA report, the vast majority of problems with the device were not known to the patient or providers at the time, and the root cause of failure of the device was not identified by the manufacturer. In 29 deaths, problems with the device that were identified included overinfusion, bent cannulas, disconnection, pump alarming, failure to deliver, suspected electromagnetic interference, and display failure.

Procedure

If the device appears to be functioning normally, the American Association of Clinic Endocrinologists recommends that, should the patient be unable to manage his/ her own pump while in the emergency department (ED), “the specialist(s) responsible for the patient’s ambulatory pump management should be contacted promptly to make decisions about infusion adjustments.”⁴ Moreover, device malfunction should be considered in patients with insulin infusion devices who present to the ED with symptoms that may be related to blood glucose. In addition to medical management, troubleshoot the device and remove it in cases of uncertainty or emergency.

To remove the catheter, simply peel off the adhesive and embedded catheter together to discontinue the flow of injected medication into the patient. There are a variety of proprietary pump manufacturers, each with their own device programming. Call the appropriate manufacturer to troubleshoot the device, visit the manufacturer’s website for an online troubleshooting manual, or simply instruct the patient to discontinue use of the device and return to a standard calculated insulin schedule by manual injection until the device-related complication is investigated and resolved.

INTRATHECAL DRUG DELIVERY SYSTEMS

Background

Intrathecal (spinal canal/subarachnoid space) drug delivery systems (IDDSs) have been in clinical use since the 1980s. The FDA approved the use of intrathecal baclofen in 1992 for severe spasticity secondary to spinal cord injury, multiple sclerosis, cerebral palsy, or stroke. Subsequently, the FDA approved the use of intrathecal morphine in 1995 and intrathecal ziconotide in 2004 for chronic pain refractory to traditional medical therapies. Ziconotide is a non-opioid calcium channel blocker, but its use may be complicated by confusion, somnolence, and other neurologic side effects. Although limited data demonstrate efficacy of intrathecal morphine and ziconotide in relieving refractory pain⁶⁻⁹ and efficacy of intrathecal baclofen in reducing spinal cord injury-induced spasticity,¹⁰ more quality clinical evidence is needed.¹¹ IDDS devices are also used for the delivery of chemotherapeutic medications for specific oncologic conditions. Moreover, there are several off-label uses of various intrathecal medications.¹¹ Pumps are often used to deliver analgesics to patients with intolerable side effects from oral or parenteral analgesics, such as nausea, pruritis, and cognitive dysfunction. Other medications used include bupivacaine, hydromorphone, fentanyl, sufentanil, clonidine, midazolam, and meperidine. Some patients will receive a combination of medications. There is minimal data comparing various medications and current regimens have been empirically derived.

The advantage of IDDSs for chronic pain is the ability to get medication directly to receptors in the spinal cord by placing the medication into the subarachnoid space. For intrathecal morphine infusions, approximately 1% of the total daily morphine dose is a standard starting point. Such small intrathecal doses reduce systemic concentrations and minimize side effects. Patients in chronic pain may also use oral analgesics on a rescue basis.

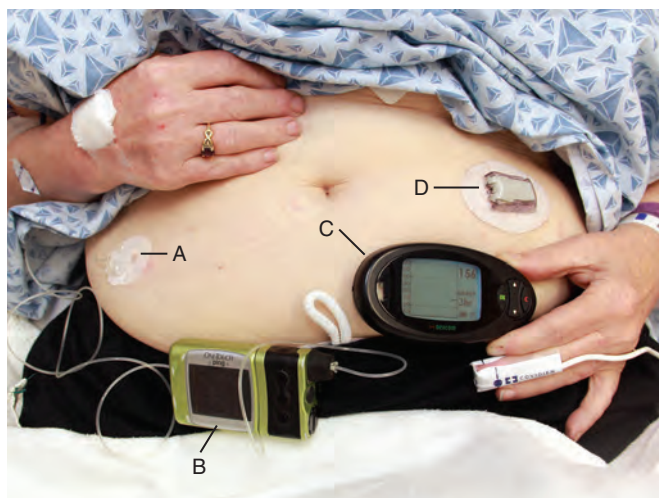

Figure 70.1 External insulin infusion pump. Components include a subcutaneously implanted catheter (A) and a programmable infusion pump (B) (OneTouch Ping, Animas Corporation, West Chester, PA). To discontinue the flow of insulin into the patient, simply peel off the adhesive and embedded catheter together. Also shown is a wireless continuous glucose monitoring receiver (C), along with its sensor and transmitter (D) (exCom SEVEN PLUS, DexCom, Inc., San Diego, CA).

BOX 70.1 Most Frequently Reported Problems With Insulin Infusion Pump Devices

1. Unknown (19.7%)
2. Replace (9%)
3. Audible alarm (6%)
4. Use-of-device issue (5%)
5. Device displays error message (4.8%)
6. Not applicable (4%)
7. Failure to deliver (3%)
8. No information (3%)
9. Repair (3%)
10. Self-activation or keying (1.8%)

BOX 70.2 Most Frequently Reported Patient Problems With Insulin Infusion Pump Devices

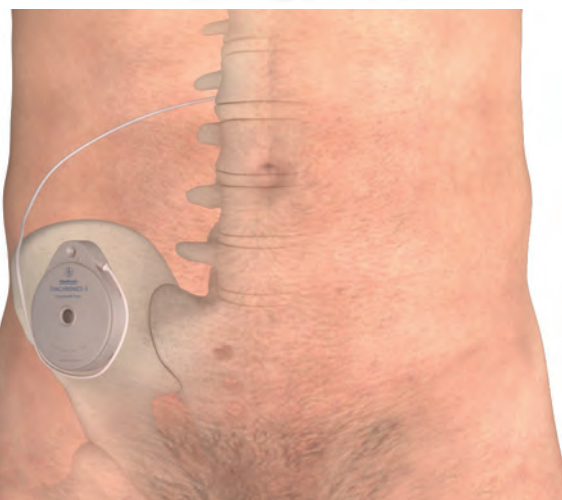

1. Hyperglycemia (24.6%)
2. Hospitalization (21%)
3. Diabetic ketoacidosis (8%)
4. Treatment with medication (6%)
5. Blood glucose low (4.7%)
6. Therapy, nonsurgical management (4%)
7. No consequences to the patient (4%)
8. Unknown (3%)

Anatomy

There are two types of IDDS: continuous infusion devices and programmable devices. In the United States, the Codman 3000 (Codman & Shurtleff, Inc., Raynham, MA) is an FDA-

A

B

Figure 70.2 A, The Medtronic (Minneapolis, MN) SynchroMed II Programmable Infusion Pump is used primarily for intrathecal (cerebrospinal fluid) administration of opioids, baclofen, calcium channel blockers, or other medications used alone or in combinations. B, The pump is usually implanted in a subcutaneous pocket in a lower abdominal quadrant, with the catheter tunneled subcutaneously to an appropriate lumbar interspace. Severe and difficult to treat withdrawal may occur if opioids or baclofen infusions are interrupted by a drained drug reservoir or pump malfunction.

approved continuous infusion device, whereas the Medtronic (Minneapolis, MN) SynchroMed II and the Flowonix (Mount Olive, NJ) Prometra are FDA-approved programmable devices. IDDS devices consist of an infusion pump connected to an intrathecal catheter (Fig. 70.2A). Codman's infusion pump is available with a refillable reservoir of either 15, 30, or 50 mL.¹² Medtronic's refillable reservoir is available in either 20 or 40 mL,¹³ whereas Flowonix's refillable reservoir has a 20-mL capacity.¹⁴ The Codman 3000 does not utilize a battery and does not need to be replaced. SynchroMed II's battery life ranges between 4 to 7 years, whereas Flowonix's battery life is reportedly more than 10 years. Normal refill intervals vary based on usage, typically on the order of every few months.

To place an intrathecal catheter, a small incision is made in the back and the catheter tip is placed into the cerebrospinal fluid. The catheter is advanced to the desired level of medication

delivery, based on symptoms. The catheter is then tunneled around the abdomen, placed in the lower abdominal wall, and attached to the subcutaneous pump. The pump has a port in the center that can be accessed by a needle placed through the skin. Medications are placed into the pump and refilled as needed (see Fig. 70.2B).

Continuous infusion devices, such as those made by Codman, are regularly refilled via manual bolus injections. Programmable devices are interrogated and programmed via an external manufacturer-specific device.

Device Complications

IDDS device complications requiring surgical intervention were found to occur with a frequency of 10.5% per year, with 35% pump related and 65% catheter related.^{15,16}

The most frequent and serious adverse events related to the device and implant procedures are catheter dislodgement from the intrathecal space, catheter fracture, implant site infection, and meningitis. Internal device programming errors that cause underdosing or overdosing are less common. If the drug supply is depleted, systemic symptoms related to acute drug withdrawal will occur. This is characteristic for the specific drug being delivered and should be anticipated.

A unique complication related to IDDSs that is the subject of a warning by the FDA is the formation of a granuloma at the tip of the intrathecal catheter. This can obstruct infusion of the medication and lead to withdrawal symptoms.^{17,18} Interestingly, catheter-tip granuloma formation appears to be primarily associated with intrathecal opioids, and most granulomas regress spontaneously when the offending agent is discontinued.^{9,11}

Common adverse effects related to intrathecal opioids include centrally mediated respiratory depression, nausea, vomiting, sedation, pruritis, constipation, urinary retention, cognitive impairment, and headache.^{19–21} One study using Medtronic's device registration system found a mortality rate of 3.9% at 1 year in IDDS patients being treated with intrathecal opioid. The deaths were associated with respiratory arrest, although not causally proven.²²

Intrathecal ziconotide may result in dizziness, nausea, vomiting, urinary retention, gait imbalance, nystagmus, and confusion. Although respiratory depression is uncommon, ziconotide may be associated with rare cases of rhabdomyolysis and psychosis.^{8,9,19}

Common adverse effects related to intrathecal baclofen include hypotonia, somnolence, headache, dizziness, urinary retention, nausea, and paresthesias. It is more common to have an underdose of medication due to pump malfunction or a break or dislodgement of the catheter than to have an overdose. In the ED, it is usually impossible to accurately determine the exact cause of reduced medication delivery. In such cases, withdrawal syndromes will occur. In patients experiencing opioid, baclofen, or other medication withdrawal, treatment may be quite difficult because large doses of systemic medications are required to equal the effects of intrathecal medications. Hospital admission and careful monitoring is often the most prudent tactic. Acute intrathecal baclofen withdrawal, which may resemble alcohol or benzodiazepine withdrawal can be serious and difficult to manage.^{13,19}

Baclofen withdrawal can lead to hemodynamic instability or seizures. As withdrawal is due to loss of medication at the spinal level, it may not be possible to safely deliver enough

BOX 70.3 Drainage of the Infusion Pump Reservoir

EQUIPMENT

Antiseptic agent
22-gauge non-coring needle
20-mL Luer-Lok syringe or syringes

PROCEDURE

1. Palpate and locate the pump on the patient (typically in the lower abdominal subcutaneous layer). The reservoir fill port is located in the center of the pump.
2. Cleanse the injection site with the antiseptic agent.
3. Attach the 20-mL syringe to the 22-gauge needle and insert the needle through the skin into the center of the reservoir fill port until the needle touches the metal needle stop (see Fig. 70.3).
4. Use negative pressure to withdraw fluid from the reservoir. Empty the reservoir until backflow has stopped. Depending on pump volume, more than one syringe may be needed. Intrathecal drug delivery systems vary in their reservoir capacity from 15 to 50 mL.^{12–14}
5. Remove the needle from the reservoir fill port.
6. Record the amount of medication fluid removed from the reservoir.

medication systemically to quell baclofen withdrawal symptoms. A propofol infusion has been suggested to treat baclofen withdrawal, but the patient may need to be intubated to facilitate a sufficient amount of propofol. Specialty consultation is required to address most complications of intrathecal pumps.

Procedure for Treating Medication Overdose

When there is concern for medication overdose secondary to the rare malfunction of the device, in addition to emergency medical management, the emergency physician can empty the pump reservoir by using the steps outlined in Box 70.3.

One may also access the manufacturer-specific online manuals to review the steps necessary to remove the contents of the pump reservoir and thus prevent further infusion of intrathecal medication (Fig. 70.3).¹³ Published guidelines suggest, in the absence of contraindications, withdrawal of an additional 30 to 40 mL of cerebrospinal fluid (CSF) by lumbar puncture to reduce the drug's concentration in CSF.²³

VAGAL NERVE STIMULATORS

Background

Since the 1930s, several studies have shown the effects of vagal nerve stimulation on cerebral activity. In 1985, Zabara demonstrated the anticonvulsant effect of vagal nerve stimulation through animal studies.²⁴ In 1997 the FDA approved use of the vagal nerve stimulator (VNS) as an adjunctive treatment of medically refractory partial-onset epilepsy.²⁵ Subsequently, in 2005 the FDA approved use of the VNS as an adjunctive therapy for treatment-resistant depression.^{26,27}

Figure 7.0.3 The contents of the intrathecal pump reservoir can be removed with a syringe and 22-gauge needle (see Box 70.3). Cerebrospinal fluid may be withdrawn directly from a side port on the pump if a lumbar puncture is required.

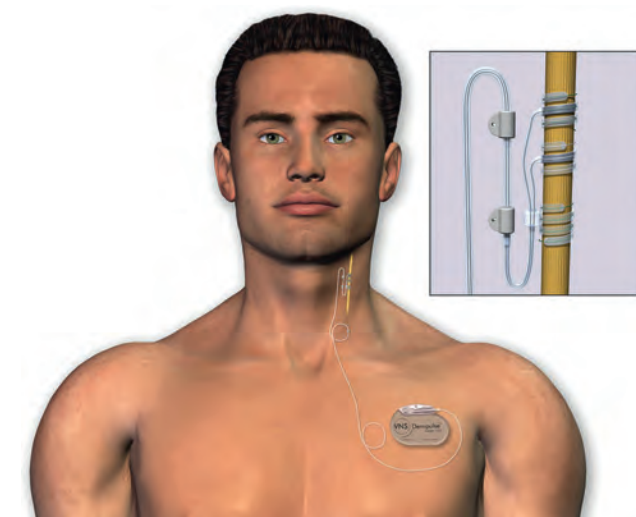

Figure 7.0.4 Vagal nerve stimulator (Aspire HC, Cyberonics, Inc., Houston, TX).

Anatomy

Currently, only one company in the United States, Cyberonics (Houston TX), manufactures the VNS under the brand name VNS Therapy System.

The device is composed of a generator attached to a bipolar VNS lead. Fig. 7.0.4 shows how the generator is implanted into subcutaneous tissue in the left upper part of the chest, with the electrode lead being attached to the left cervical vagus nerve trunk. Interrogation and programming of the device are conducted with an external programming wand connected to a handheld computer. The variable settings that can be adjusted include current output, signal frequency, pulse width, and on/off stimulation times.²⁸

Assuming normal parameters and output, the VNS generator has a projected battery life of approximately 10 years. Of note, VNS devices are implanted only on the left vagus nerve because

BOX 70.4 Vagal Nerve Magnet Applications

TO DELIVER ON-DEMAND STIMULATION

Place the magnet over the generator for at least 1 second and then quickly remove it. The generator turns off and then immediately on again, thereby delivering a burst of vagal nerve stimulation based on the preprogrammed settings.

This maneuver can be repeated as needed.

TO TURN OFF THE STIMULATION

Hold and maintain the magnet over the pulse generator. If the device is properly turned off, the patient should notice loss of episodic adverse effects, such as stimulation-induced voice alteration or pain.^{28,32}

the right vagus nerve directly innervates cardiac tissue and may have undesired cardiac effects if stimulated.

Device Complications

The device is typically turned on 10 to 14 days after implantation to allow adequate wound healing. Be aware that patients seen postoperatively during the first 2 weeks after implantation may not have had their device activated yet.

In addition to surgery-related risks and complications, if the patient complains of severe neck pain, worsening hoarseness, choking, or difficulty breathing, consider device-specific complications. Voice alteration or hoarseness is the most common device-specific adverse effect, with more than 50% of patients being affected.²⁹⁻³¹ Other common side effects include increased coughing, shortness of breath, and pharyngitis. Less common device-specific adverse effects reported during clinical studies include ataxia, dyspepsia, dysphagia, hypoesthesia, infection, insomnia, laryngismus, nausea, pain, paresthesia, and vomiting.²⁸

Procedure

In cases of emergency, diagnostic uncertainty, or significant adverse effects, turn off the pulse generator temporarily by holding a magnet over the generator (Box 70.4). Holding a magnet over the pulse generator for at least 65 seconds (5 seconds in the Model 106) will turn *off* any ongoing stimulation while the magnet is held in place. Once the magnet is removed, the normal operation will resume. Alternatively, manual on-demand stimulation may be triggered by passing the external VNS magnet over the generator for at least 1 second and then immediately removing it. This on-demand stimulation, if initiated at the onset of an aura or seizure, may abort the attack or, if initiated during a seizure, may halt its progression.²⁸

Unlike the typical donut-shaped magnet of a cardiac pacemaker, the VNS magnet is bar shaped, as shown in Fig. 70.5. Be aware that patients with VNSs are typically provided with two magnets: one fitted with a wristband and the other fitted with a belt clip.

OTHER IMPLANTABLE DEVICES

There are several additional noncardiac implantable devices that the emergency provider may encounter, which are outlined

TABLE 70.1 Additional Noncardiac Implantable Devices

DEVICE	DESCRIPTION	MALFUNCTION
Bladder stimulator or sacral nerve stimulator	Stimulator wire is inserted into the S3 sacral foramen adjacent to the sacral nerve for the treatment of urinary incontinence in the setting of severe neurologic disease ³³	Hardware complications include infection, skin irritation, and wire migration ³³
Deep brain stimulator	Stimulator implanted into the thalamus for treatment of Parkinson's disease, tremor, and dystonia ¹	Hardware complications include infection and lead migration ³⁴
Gastric pacemaker	Neurostimulator with implanted leads into the gastric musculature to improve gastroparesis ³⁵	Gastric wall perforation, infection, and lead migration ³⁵
Peritoneovenous (Denver) shunt	A shunt that drains peritoneal fluids directly into the venous system to treat refractory ascities ³⁶	Shunt occlusion, pulmonary edema, pulmonary embolism, disseminated intravascular coagulopathy, superior vena cava thrombosis, infection, tumor emboli ^{37,38}
Phrenic nerve stimulator or diaphragmatic pacemaker	Electrodes implanted into each phrenic nerve with a receiver implanted into subcutaneous tissue. An external transmitter controls the receiver. Used to treat respiratory insufficiency secondary to upper motor neuron paralysis or respiratory drive dysfunction. ^{39,40}	Pneumothoraces have been described immediately after implantation. Infection and wire migration have been described. ^{39,40} Failure of the pacemaker is treated by ventilatory support.

**Figure 70.5** Vagal nerve stimulator magnet.

in Table 70.1. However, should these devices malfunction, there may not be specific procedures to be aware of in the emergency setting beyond supportive treatment.

MRI AND IMPLANTABLE DEVICES

For patients with electrically, magnetically, or mechanically activated implants, the FDA requires labeling stating that

magnetic resonance imaging (MRI) is contraindicated,⁴¹ and indeed, manufacturers of gastric, urinary, diaphragmatic, and spinal cord stimulators list these devices as absolute contraindications to MRI.³⁴ However, there are a number of clinical series and case reports indicating the compatibility of certain devices with MRI. For VNSs, the manufacturer recommends avoiding the use of any transmit coil for 3T or 1.5T imaging,^{28,34} as it may cause heat injury and damage the device. For deep brain stimulation, some studies have suggested that MRI is safe in certain circumstances,⁴² but reports of patient injury can be found in the literature.⁴³ For IDDS devices, pumps have been shown to stop operating while in the magnetic field but resume functioning once removed.⁴¹ Both SynchroMed II and Prometra pumps are MRI compatible. However, the Prometra device is only MRI compatible after complete removal of medication from the reservoir, whereas there is no need to remove medication from the SynchroMed II device.^{9,13,14} Insulin pumps may easily be removed in the event that MRI is required.

In summary, the issue of MRI compatibility with implantable devices is very complex. In the event that MRI appears to be necessary, a case-by-case risk-benefit analysis involving the relevant subspecialist and radiologist is recommended.

Radiation in Pregnancy and Clinical Issues of Radiocontrast Agents

Phillip R. Peterson

The annual, population-wide exposure to ionizing radiation from medical sources increased a staggering 750% from 1980 to 2009, and medical imaging now comprises nearly one-half of Americans' radiation exposure.¹ The World Health Organization classifies x-rays officially as carcinogens,² and indeed a report by the National Academy of Science indicates that a 100 mGy dose is associated with a lifetime attributable risk for development of a solid cancer or leukemia of 0.1%.^{3,4} Efforts were undertaken to reduce unnecessary exposure, and in 2011 the Joint Commission on Accreditation of Healthcare Organizations published a report² that suggests risks can be reduced by the following: (1) raising awareness among staff and patients of the increased risk associated with cumulative doses; (2) providing the right test and the right dose (as low as reasonably achievable [ALARA]) through efficient processes and safe technology; and (3) promoting a culture of safety to make sure that doses are as low as possible while achieving the purpose of the study.

Such risks associated with exposure to ionizing radiation during medical care are sources of anxiety and concern in the pregnant patient, based on questions submitted to Health Physics Society's "Ask the Expert" website.⁵ Furthermore, clinicians add a great deal of confusion and fear by providing exposed women with potential erroneous or inadequate information. Clinicians, nurses, and even radiologists may be ignorant of the effects of ionizing and nonionizing radiation.⁶ This misinformation contributes not only to undue and unnecessary anxiety and confusion but may lead to inappropriate abortions and litigation. For example, 23% of pregnancies in Greece were terminated after the Chernobyl incident because of unsubstantiated fears.⁷ A better understanding of the risks and effects enables providers to make informed decisions and counsel patients that appropriate radiology examinations provide more benefit than harm.

According to the American College of Obstetricians and Gynecologists, "With few exceptions, radiation exposure through radiography, computed tomography scan, or nuclear medicine imaging techniques is at a dose much lower than the exposure associated with fetal harm. If these techniques are necessary in addition to ultrasonography or magnetic resonance imaging or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient."⁸ The risks of medically-indicated diagnostic studies generally outweigh the future risks of irradiation,⁵ and nowhere is this more evident than in the emergency setting, where the risk of not obtaining an indicated study can be high.

When evaluating the pregnant patient who has been or may be exposed to ionizing radiation and attempting to estimate risk, consideration must be given to a number of factors. These include not only factors related to gestational age, dose and type of radiation, and the studies performed or to be performed, but also to the mother herself, as studies raise concern about exposure of maternal breast tissue to ionizing radiation and the future risk of breast cancer.^{9,10} This chapter provides a review of ionizing and nonionizing radiation, its uses in diagnostic radiological examinations, the risks of its use, and strategies for minimizing risk to assist the clinician in counseling the patient to arrive at the most appropriate shared decision.

TYPES OF RADIATION

Simply stated, radiation is the emission or transmission of energy, which can take the form of electromagnetic radiation, such as visible light and x- and gamma-rays (the difference lying in the origin of the photon: electron orbital and nucleus, respectively); particle radiation, such as alpha particles (helium nuclei), beta particles (electrons, positrons), and neutrons; and acoustic radiation. As radiation propagates through space, it can impart or give-up some or all of its energy to surrounding material or tissues, and detection of this energy or its absence forms the basis of diagnostic medical imaging. Radiation is further classified by its effects on the absorbing material. Non-ionizing radiation lacks sufficient energy to liberate electrons, and its deposited energy subsequently manifests as heat, whereas ionizing radiation is of sufficient energy to liberate electrons, thereby breaking chemical bonds, forming highly reactive free radicals, and damaging DNA and cellular machinery.

RADIOBIOLOGY AND RADIOPHYSICS

The detrimental effects of radiation on health are grouped broadly into tissue reactions (also called deterministic effects, nonstochastic effects) and stochastic effects (Table 71.1). Tissue reactions are the result of cell killing and manifest as lethality, central nervous system (CNS) abnormalities, cataracts, growth retardation, malformations, and behavioral disorders.⁶ Tissue effects are dependent on the energy imparted to the tissue and demonstrate a threshold below which they are not observed but above which they are reliably observed, with their severity rising with dose. Stochastic effects include cancer and potential hereditary effects. Unlike tissue reactions, they have no identifiable threshold. Their probability of occurrence rises with dose, and their severity is independent of the dose.

The quantity of energy that is imparted by radiation to the material or tissue is a physical quantity, can objectively be measured, and is called the *absorbed dose* (D). It is defined as the mean energy imparted to matter per unit mass, and the *mean absorbed dose* (D_T) in an organ or tissue is the average absorbed dose over that organ or tissue. The Systeme International (SI) unit for both absorbed dose and mean absorbed dose is the joule per kilogram (J/kg) with the special name *grey* (Gy). In the centimeter-gram-second (CGS) variant of the metric system, the unit is given the special name *rad*: 1 rad = 100 erg/g = 0.01 J/kg = 0.01 Gy = 10 mGy. This unit is deprecated but remains in use in some countries (notably the United States).

TABLE 71.1 Stochastic and Tissue Reaction (Threshold) Comparison

PHENOMENON	PATHOLOGY	DISEASES	RISK	DEFINITION
Stochastic	Damage to a single cell may result in disease	Cancer, germ cell mutation	Some risk exists at all dosages; at low doses the risk may be less than the spontaneous risk	The incidence of the disease increases with dose, but the severity and nature of the disease remain the same
Tissue Reactions	Multicellular injury	Intrauterine death, organ malformations, mental impairment, growth retardation	No increased risk below the threshold dose	Both the severity and the incidence of the disease increase with the dose

Modified from Brent RL: Utilization of developmental basic science principles: the evaluation of reproductive risks from pre- and postconception environmental radiation exposures, *Teratology* 54:182, 1999.

The many forms of radiation differ in their abilities to impart energy to the absorbing material and cause ionizing events. Neutrons, alpha particles, and other heavy charged particles (e.g., carbon ions) impart their energy more readily, thereby producing more densely spaced ionizing events, whereas the converse is true for electromagnetic radiation and light charged particles (e.g., beta particles). Another quantity, the *equivalent dose* (H_T), is therefore necessary and derived from the mean absorbed dose by scaling with a *radiation weighting factor* (w_R), $H_T = w_R D_T$, and the *effective dose* for an organism is the tissue-weighted sum of the equivalent doses for all tissues, radiation sources, and energies. The radiation weighting factor, previously called the quality factor, is dependent only on the type of radiation (and for neutrons, its energy) and is dimensionless. Per the International Committee on Radiological Protection, $w_R = 1$ for all photons and electrons; $w_R = 2$ for protons and charged pions; $w_R = 20$ for alpha particles, heavy ions, and fission fragments; and w_R is a continuous function of energy for neutrons. Equivalent dose and effect dose therefore have SI units of joule per kilogram (J/kg) with the special name *sievert* (Sv). In CGS, they have units of *roentgen equivalent in man* (rem), and 1 rem = 100 erg/g = 0.01 J/kg = 0.01 Sv = 10 mSv. As diagnostic radiology examinations involve essentially only photons, the equivalent and effective doses have essentially the same magnitude as the absorbed dose. As an example, a mean absorbed dose of 100 mGy results in an effective dose of 100 mSv if the source is electromagnetic radiation or 2 Sv if the source is alpha radiation.

Radioactive decay or radioactivity is the process by which the nucleus of an unstable atom emits energy in the form of radiation. At the quantum level, the process is stochastic, but at the macroscopic level, the decay of a sufficiently large collection of unstable atoms can be calculated and is represented by the half-life, or the time it takes for the collection of unstable atoms to reduce by half. The SI unit of radioactivity is the becquerel (Bq) and is defined as one nuclear decay event per second. Its units are therefore inverse seconds (1 Bq = 1 s⁻¹), as a nuclear decay event is dimensionless. A frequently encountered, non-SI unit of radioactivity is the curie (Ci). Its definition is based on the amount of radioactivity in one gram of radium and also has units of events per second; 1 Ci = 3.7 × 10¹⁰ Bq = 37 GBq. Doses of radioactive substances used in medicine are typically on the MBq and mCi scale (e.g., 1 mCi = 37 MBq). These units encode neither the type nor energy of the radiation emitted by the nuclear decay process.

EFFECTS OF RADIATION

Exposure to radiation is among many recognized agents and environmental exposures which can produce deleterious effects, resulting in mental retardation, neurobehavioral effects, convulsive disorders, congenital malformations, fetal growth retardation, embryonic death, and cancer.^{5,6} The significant background prevalences of these events are 0.5% to 1% for mental retardation, 3% for major congenital malformation,^{5,11} 3% for growth retardation,^{5,11} 15% for miscarriage⁵ (with a reported variation as wide as 30% to 50%),⁶ 11% for genetic disease,⁵ and 7% for prematurity,⁵ and in the United States there is a 21% background lifetime risk of fatal cancer in the offspring.⁵

As previously discussed, the effects of radiation are broadly divided into two categories (see Table 71.1): stochastic effects (which include cancer and hereditary disease) have no dose threshold, and the frequencies of which rise with increasing dose; and tissue reactions (which include the remaining effects) have identifiable thresholds above which they are reliably observed, the severities of which do not depend on dose, and whose manifestations depend on the stage of fetal development in which the exposure occurs.^{6,11} Dependence on the duration of time over which the exposure occurs is also noted,⁵ as a protracted exposure is less likely to produce an effect than a single exposure of high intensity (e.g., the dose from continuous exposure during flight).^{5,12} Fractionation of the dose (e.g., multiple radiographs over a period of hours or days), like protraction, also decreases the severity of and increases the threshold for tissue reactions.⁵ The dependence of the effects of radiation on the stage of development is demonstrated in Fig. 71.1.¹¹

Stages of Fetal Development

Development of the fetus is expressed as postconception age and divided into three major stages: (1) the preimplantation and implantation phase (conception to implantation), (2) organogenesis (3RD to 8th week), and (3) fetal development (9th week until birth), which includes the majority of CNS development (8th to 25th week). The risks of radiation are most significant during organogenesis and the early fetal period, somewhat less in the second trimester, and least in the third trimester.¹² This relationship is demonstrated in Fig. 71.1, and the main effects and their thresholds are summarized in Table 71.2.

Preimplantation and Implantation Phase

The preimplantation and implantation phase has been designated an “all or none” period, as embryonic cells are few in number and totipotent, and can replace damaged neighboring cells. It is in this stage of development that the embryo is least likely to be malformed,⁵ and the predominant effect of radiation exposure is failure to implant,¹² resulting in abortion.¹³ The threshold for mortality in this stage of development is quite high, estimated at 100 to 200 mGy^{5,12,13} and rises with fetal age such that at term the threshold for mortality is 1 Gy¹³ to 1.5 Gy⁵ (see Table 71.2). Embryos that survive exposure in this period of development demonstrate no increased risk for malformations or growth retardation.⁵

Figure 71.1 Schematic presentation of the various adverse effects associated with high-dose radiation and their relative incidence at different stages of gestation. (Adapted from Mettler FA Jr, Upton A, editors: *Medical effects of ionizing radiation*, ed 2, Philadelphia, 1995, Saunders.)

Organogenesis

Exposure to high doses of radiation during the period of organogenesis is likely to affect the organ system or systems under development at the time of the exposure and results from reduced ability to replace those cells damaged or killed by the exposure. Although any organ system can be affected, the predominantly observed effects are microcephaly and growth retardation,^{5,12-14} and have a dose threshold of 50 to 200 mGy,^{12,13} which is significantly higher than doses obtained from diagnostic radiology examinations. Temporary growth retardation can be observed with doses of 100 to 250 mGy,¹⁴ but these infants recover fully and attain normal adult stature and weight. The dose threshold for permanent growth retardation depends on postconception age and is 200 to 500 mGy in the 3rd to 5th weeks, 250 to 500 mGy in the 6th to 13th weeks, and greater than 500 mGy from the 14th week onward⁵ (see Table 71.2). Exposure to less than 50 mGy during the period of organogenesis results in no change in the risk for organ malformations or growth retardation.¹⁴

Fetal Period

At the end of the period of organogenesis, the fetus has diminished vulnerability to multiple organ system teratogenesis,⁵ but beginning in the 8th week and continuing through the 25th week is development of the CNS, during which it can be seriously affected by high doses of ionizing radiation, resulting in mental impairment, mental retardation, neurobehavioral effects, and convulsive disorder. CNS sensitivity to ionizing radiation is not uniform throughout its development, with highest sensitivity from the 8th through 15th weeks,^{12,14} during which there is a rapid increase in the number of neurons that migrate and differentiate, losing their ability to divide. This process is largely concluded by the 15th week, at which point and lasting until the 25th week, further differentiation

TABLE 71.2 Risks and Threshold Doses of the Main Effects of Prenatal Irradiation

HUMAN GESTATIONAL AGE (WEEKS) [POSTCONCEPTION AGE]	MINIMUM LETHAL DOSE TO EMBRYO OR FETUS (Gy)	APPROXIMATE LD50	MINIMUM DOSE FOR PERMANENT GROWTH RETARDATION IN THE ADULT (Gy)	MINIMUM DOSE FOR GROSS ANATOMIC MALFORMATIONS (Gy)	INCREASED INCIDENCE OF MENTAL RETARDATION (Gy)
3rd to 4th [1st to 2nd pc]	0.15 to 0.2	< 1	No increased incidence of GR in survivors	No increased incidence of congenital malformation in survivors	
5th to 7th [3rd to 5th pc]	0.25 to 0.5	1.4–2	0.2–0.5	> 0.2 but most malformations require > 0.5	
8th to 15th [6th to 13th pc]	> 1	> 2	0.25–0.5		
16th to term [14th pc to term]	> 1.5	Same as for the mother	> 0.5		
10th to 27th [8th to 25th pc]					SMR at doses > 0.5; (lower 95% CI value of ~ 0.3)

CI, Confidence interval; GR, growth retardation; pc, postconception; SMR, severe mental retardation.

and architectural definition occur,¹¹ and the CNS becomes slightly less susceptible to damage.

Mental Impairment and Retardation

It is important to note that all clinical observations of significant IQ reduction and severe mental retardation (SMR) are associated with high doses of radiation in excess of 500 mGy,^{12,14} a level not easily approached with diagnostic radiology examinations. The highest risk for SMR exists in the 8th through 15th weeks and with a high dose threshold of 1 Gy,¹² and the severity of the retardation does appear to have some dependence on the dose. For survivors of the atomic bombings of Japan who were between 8 and 15 weeks after conception at the time of their exposure, a drop of 0.3 IQ points per 10 mGy of exposure, with a threshold of 500 mGy, was observed.¹⁴ There is no documented risk for mental retardation in humans at gestational ages less than 8 weeks or greater than 25 weeks with exposure less than 500 mGy.¹⁵ Furthermore, the risk of exposure to 100 mGy or less is far smaller than the 3% background risk of a child being born with an IQ less than 70, and exposure to less than 100 mGy cannot be clinically identified with reduction in IQ.¹²

Convulsive Disorders

Convulsive disorders are a broad category encompassing various diagnoses, etiologies, and manifestations. The risk for convulsive disorder following in utero radiation exposure was evaluated in several studies on Japanese survivors of the atomic bombing.^{16–18} Among these survivors, no convulsive disorders were identified in those receiving a dose less than 100 mGy. Those at highest risk for seizure disorder were those exposed in the 8th through 15th weeks postconception and who were also mentally retarded. The association of convulsive disorders with radiation exposure between the 8th and 15th weeks postconception without mental retardation was borderline significant. There is no increase in convulsive disorders from exposure before the 8th week or after the 25th week.⁵

Growth Retardation

Growth retardation can occur with exposure to ionizing radiation in the fetal period, though exposure is more likely to result in microcephaly.¹⁴ Studies on the atomic bombing survivors who were exposed in utero show divergent thresholds for microcephaly. For survivors of Nagasaki, the threshold is estimated at 1.5 Gy, whereas for the survivors of Hiroshima, a threshold of 100 to 190 mGy is reported.¹⁵ This latter finding is consistent with a threshold of 100 to 200 mGy for microcephaly that was observed in mammalian animal models.¹⁹ Irradiation of the human fetus at doses less than 100 mGy has not been observed to cause congenital malformations or growth retardation (see Table 71.2).^{6,8,11}

Stochastic Risks

The remaining effects (cancer and hereditary effects) are stochastic, notably in that risk exists at all levels of exposure (see Table 71.1). Childhood malignancies account for less than 1% of total cancer diagnoses in the United States, and the cumulative risk to 15 years of age is 1 to 2.5 per 1000 in most western countries.⁵ Additionally, lymphoma, leukemia, and brain tumors account for 70% of childhood cancers, which stands in contrast with adult malignancies, the majority of which are epithelial in origin.

Cancer

The Oxford Survey was published 60 years ago and reported a twofold increase in risk in total childhood cancer mortality in the offspring of mothers undergoing abdominal diagnostic radiographs.²⁰ These results were met initially with skepticism and criticized on the basis of recall bias, but the effect persisted in later studies in which a 1.3- to 1.5-fold risk was reported.^{5,21,22} Aside from the Oxford Survey, which reported a relative risk of 1.5 for all solid tumors and 1.4 for CNS tumors, all other studies on CNS tumors did not find a statistically significant increase.⁵ These findings are consistent with an analysis of later epidemiologic studies that found a relative risk of 1.4 for childhood cancer after exposure to 10 mGy.¹² Efforts were undertaken to estimate the risk per gray from exposure and to determine the excess absolute risk coefficient of ~6% per Gy (2.5% per Gy for leukemia).^{12,13,23} These results must be interpreted in the context of the background incidence; for a fetus exposed to 1 mGy, the risk for carcinogenesis is 0.006%, or 3 additional diagnoses for every 50,000 exposures, as compared with the background incidence of 0.2% to 0.3%, or 100 to 150 per 50,000. Exposure to 50 mGy, the generally accepted upper limit for exposure in utero, may double the risk for childhood malignancy in the offspring, but this absolute risk remains low (0.5% to 0.6%).

Hereditary Effects

Early research with flies and animals demonstrated ionizing radiation can induce germ-cell mutations, but these findings have failed to be demonstrated in humans^{5,12} and were so small in the irradiated Japanese survivors as to be statistically insignificant.²⁴ Others report an excess absolute risk for hereditary disease of 1% per Gy.^{14,19} In the context of a background incidence of 3%, an exposure of 50 mGy might then be expected to raise this risk to 3.05%.²⁵

Radiography and Computed Tomography

Table 71.3 lists the absorbed dose of the fetus or embryo and the gonads from ionizing radiation of various studies. The vast majority of diagnostic imaging studies do not result in significant fetal exposure. Computed tomography studies (CT scans) of the maternal abdomen and pelvis in which the fetus or embryo lies directly in the field of study can deliver doses approaching the safe threshold of 50 mGy, and CT of the pelvis may have the potential to exceed this threshold.¹² Alternative diagnostic imaging algorithms have therefore been developed to assess the pregnant patient in clinical scenarios where CT might otherwise have been indicated.

Whereas fetal position in relationship to the field of study is a major factor determining fetal exposure from CT scans, variables such as slice thickness, number of cuts, and helical movement pattern (i.e., spiral CT) also affect the amount of ionizing radiation used. In helical or spiral CTs, the study is completed in less time,²⁶ resulting in less radiation exposure, and the use of 16-slice over 4-slice equipment can also lead to a reduction in the dose by 20% to 30%.²⁷

The principal concern in obtaining a CT scan in the pregnant patient is exposing the fetus or embryo to ionizing radiation. Situations may also arise in which it is necessary to use iodinated contrast material in the study, and the potential harmful effects of the contrast must also be considered. The most important potential effect of iodinated contrast material is depression of fetal thyroid function. By 12 weeks, the fetus is producing

thyroxine under the influence of thyroid-stimulating hormone, and the fetal pituitary-thyroid axis is considered independent of the mother.²⁸ Intravenous iodinated contrast can cross the placenta where it depresses fetal thyroid function.^{9,28} This transport may be bidirectional, and depressed maternal renal function may prolong fetal exposure to the contrast. This effect appears limited to ionic contrast agents, as depressed fetal

thyroid function has not been observed with high doses of nonionic contrast.^{28,29} However, neonates are routinely screened for hypothyroidism in the United States. Lactating and nursing mothers may also inquire about interrupting nursing after receiving intravenous (IV) contrast. Very little of the contrast reaches the milk, and only a tiny fraction of that is absorbed in the gut. Interruption of nursing is therefore unnecessary.²⁸

NUCLEAR MEDICINE STUDIES

Unlike radiographs and CT, which rely on an external source of radiation that is passed through the body before detection, nuclear medicine detects radiation from unstable isotopes that are introduced into the body within which they emit their radiation. Furthermore, whereas the other ionizing modalities are primarily concerned with imaging specific anatomy, nuclear medicine studies are concerned with the assessment of the physiologic (or pathophysiologic) function of a tissue or organ system. Like studies involving external sources of ionizing radiation, nuclear medicine studies can extract information in two dimensions, such as in scintigraphy, or in three dimensions, such as single photon emission CT (SPECT) and positron emission tomography (PET).

The radioactive isotopes are bound to substrates or tracers that are processed differently in pathologic states. The detection of the altered distribution in time and space of radiation from these radiotagged substrates (radiopharmaceuticals) forms the basis for the nuclear medicine examination. The metastable nuclear isomer of technetium-99 (^{99m}Tc) is frequently encountered in diagnostic nuclear medicine studies and emits radiation in the form of gamma-rays.³⁰ Many different isotopes, however, are employed in nuclear medicine studies (see Table 71.3) and the absorbed dose to the fetus or embryo is dependent on the activity and amount of the isotope and the specific metabolism of the substrate to which it is bound.

Some radiopharmaceuticals, such as ^{131}I and ^{32}P , cross the placenta and are generally not used in pregnant patients.¹² For the remainder, the dose to the fetus is derived from the activity in maternal tissues, the proximity of these tissues to the fetus, and the excretion of the radiopharmaceutical. For example, the ventilation portion of a ventilation-perfusion (\dot{V}/\dot{Q}) study for pulmonary embolism (PE) can be done with either ^{133}Xe or ^{99m}Tc -DTPA. Use of ^{133}Xe results in little fetal exposure, as its activity is confined to the maternal lungs, remote from the fetus or embryo, but ^{99m}Tc -DTPA is excreted by the kidneys and can collect in the urinary bladder, where it and other renally excreted radiopharmaceuticals can expose the fetus or embryo.¹² Strategies for reducing fetal exposure therefore include maternal hydration and frequent voiding, considering the use of smaller administered doses and longer imaging times, selecting alternative radiopharmaceuticals (e.g., ^{133}Xe vs. ^{99m}Tc -DTPA), and adjusting the examination protocol (e.g., obtaining the perfusion portion of a \dot{V}/\dot{Q} study first which, if normal, precludes obtaining the ventilation portion).

Nonpregnant women may inquire about delaying pregnancy after undergoing a nuclear medicine examination. It is advised that pregnancy be delayed until the dose from the remaining radiopharmaceutical is less than 1 mGy, which is generally not a consideration except for ^{59}Fe (metabolism studies) and ^{75}Se (adrenal studies), for which delays of 6 and 12 months, respectively, are advised.¹² Lactating women must also be counseled to cease breastfeeding¹² for at least 12 hours for ^{99m}Tc , except for labeled red blood cells, phosphates, and DTPA, for which a period of at least 4 hours is advised. For other less frequently encountered isotopes in the emergency department, it is advised that breastfeeding be ceased for a period of 3 weeks for most ^{131}I and ^{125}I compounds, except hippurate (12 hours) and for ^{22}Na , ^{67}Ga , and ^{201}Tl .

The clinician may also encounter a patient undergoing a nuclear medicine examination who is also the household contact of a pregnant woman. These individuals pose no risk to the

pregnant woman, the fetus, or any other household contact, as the total decay dose measure at 0.5 m and 1 m is 0.02 to 0.25 mGy and 0.05 to 0.1 mGy, respectively.¹²

DIAGNOSIS OF PE

In the developed world, PE is the leading cause of maternal death, accounting for some 20% of maternal deaths in the United States,³¹ and for every 2000 pregnancies there is one PE.⁹ Mortality for untreated, acute PE is 30% compared with 2% to 10% in those diagnosed and treated in a timely fashion.^{32,33}

Both CT of the pulmonary arteries (CTPA) and \dot{V}/\dot{Q} nuclear medicine studies can be used to assess for PE but employ ionizing radiation in different manners, leading to different risks and benefits, though exposure to the fetus in both studies is minimal.²⁶ Fetal or embryological exposure from a CT chest scan varies with gestational age and is 0.013 to 0.026 mGy in early pregnancy, rising to 0.01 to 0.1 mGy in late pregnancy.³⁴ Fetal exposure is also dependent on the equipment and is less for multidetectors than for single detectors.^{9,12} A combined 185 MBq ^{99m}Tc perfusion and 370 MBq ^{133}Xe ventilation study equates to 2.25 mGy fetal exposure,³⁵ which is greater than that for a CTPA³⁶ but remains a small exposure. The dose in a \dot{V}/\dot{Q} study can be lowered, resulting in a suitable study, but one in which the fetal exposure from the ^{99m}Tc perfusion portion is 0.1 to 0.6 mGy in early pregnancy and 0.6 to 0.8 mGy in later pregnancy and from the ^{99m}Tc ventilation portion is 0.1 to 0.3 mGy for a total exposure less than 1.1 mGy³⁴ (Box 71.1). And whereas pulmonary angiography was long considered the gold standard in the diagnosis of PE, it is now thought to be no more accurate than CTPA⁹ and results in no less fetal exposure: 2.2 to 3.7 mGy when done via the femoral route or 0.5 mGy when performed by the brachial route.²⁶

The two modalities also differ, not only in the radiation exposure to the fetus or embryo, but also in the exposure to the mother, in that CTPA exposes a woman's breasts to a higher level of radiation and elevates her risk for cancer.^{9,10} It is estimated that every 10 mGy of exposure to the breasts of a woman aged 35 years or more increases her risk by 14% over the background.^{9,37} By this exposure and risk to the mother alone, some authors justify the use of \dot{V}/\dot{Q} studies over CTPA as the primary examination in a pregnant patient.³⁸

The American Thoracic Society therefore recommends, and the American College of Obstetricians and Gynecologists has endorsed, an algorithm in which pregnant women suspected of PE are assessed first for clinical evidence of deep venous thrombosis (DVT). If DVT is suspected, an ultrasound (US) of the bilateral lower extremities is obtained, followed by treatment if positive. If the US is negative, or the patient has no evidence of DVT, a chest x-ray (CXR) is performed. Patients with normal CXRs undergo \dot{V}/\dot{Q} studies in which the dose is reduced and the perfusion portion is performed first, followed by the ventilation portion if necessary. Patients with nondiagnostic \dot{V}/\dot{Q} studies or abnormal CXRs undergo CTPA. This algorithm is depicted in Fig. 71.2. The clinician may also consider obtaining a bedside echocardiogram initially in the unstable or critically ill patient,⁹ and it is worthwhile to note that strategies exist to reduce the exposure from CTPA⁹ (Box 71.2).

The utility of a D-dimer level in excluding PE in pregnant patients remains under investigation.^{39,40} D-dimer levels are

BOX 71.1 The Technique of V/Q Scanning

This test uses both intravenous (perfusion) and aerosolized (ventilation) agents.

PERFUSION

1. Before injection, prepare the intravenous technetium. Mix sodium pertechnetate ^{99m}Tc with macroaggregated human albumin (MAA) to form ^{99m}Tc -MAA, the substance that is injected intravenously to investigate blood flow in the lungs. If the preparation is not used within 8 hours, discard it.
2. The usual dose is 37–111 MBq (1–3 mCi). Doses as low as 37 MBq are used in pregnancy.
3. Within 5 minutes of injection, more than 90% of the ^{99m}Tc -albumin aggregate is trapped in the arterioles and capillaries of the lung. The particle size determines where the ^{99m}Tc will be localized in the body.
4. Accumulation in the lung is temporary, and the fragile albumin aggregate quickly breaks down, thereby allowing ^{99m}Tc to enter the general circulation.
5. Once in the body, the half-life of ^{99m}Tc is 6 hours.
6. The majority of ^{99m}Tc is excreted in urine. If it remains in the urinary bladder, it is in close proximity to the fetus.
7. Technetium in the bladder exposes the fetus to small amounts of radiation.

8. Frequent voiding or bladder catheterization after the study will lessen exposure of the fetus to radiation.
9. Technetium is relatively contraindicated in patients with severe pulmonary hypertension (because ^{99m}Tc -MAA temporarily blocks blood flow in the lungs).
10. Allergic reactions to technetium and human serum albumin are extremely rare.
11. The radiation exposure to the total body from 92.5 MBq (2.5 mCi) is extremely low: less than 1 mGy.

VENTILATION

1. Some radiologists forgo the ventilation portion of the \dot{V}/\dot{Q} scan in pregnancy to limit the total radiation exposure.
2. Most hospitals use ^{133}Xe for the ventilation portion of the \dot{V}/\dot{Q} scan.
3. Fetal radiation exposure from xenon is extremely low, and the 50 mGy threshold is not reached until more than 125 scans have been performed.
4. The estimated dose to the fetus of the standard 370 MBq (10 mCi) of xenon used in a \dot{V}/\dot{Q} scan is 0.4 mGy.
5. If ^{99m}Tc -based aerosol is the marker used for the ventilation portion, fetal exposure is higher than with xenon aerosol.

\dot{V}/\dot{Q} , Ventilation-perfusion.

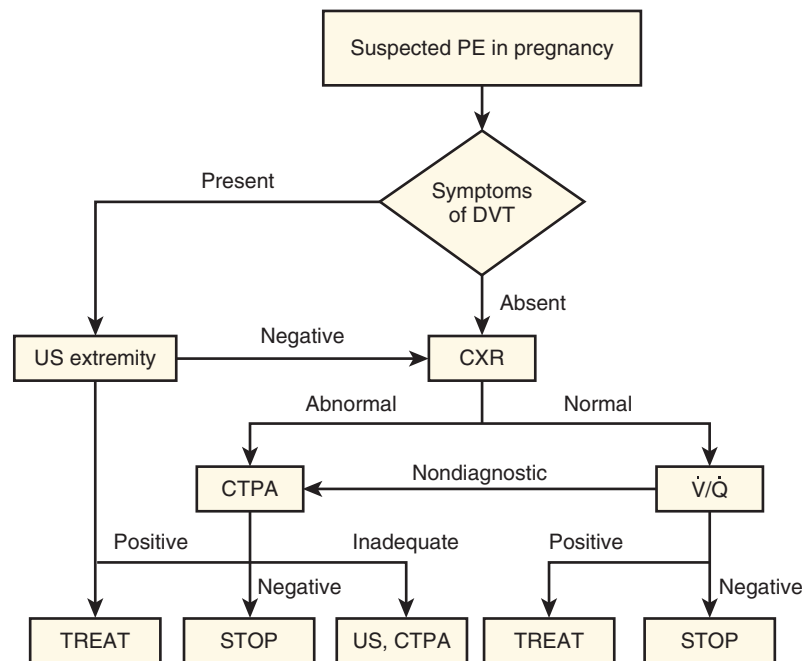

Figure 71.2 Suggested imaging algorithm for investigation of suspected pulmonary embolism in pregnancy. *CTPA*, Computed tomography of the pulmonary arteries; *CXR*, chest x-ray; *DVT*, deep venous thrombosis; *PE*, pulmonary embolism; *US*, ultrasound; *V/Q scan*, ventilation-perfusion scan. (Modified from Leung AN, Bull TM, Jaeschke R, et al: An official American Thoracic Society/Society of Thoracic Radiology clinical practice guideline: evaluation of suspected pulmonary embolism in pregnancy, *Am J Respir Crit Care Med* 184(10):1200–1208, 2011.)

known to rise throughout pregnancy such that 79% of non-pregnant women attempting to conceive have a level lower than 0.5 mg/L, and 50% of women in the first trimester, 22% in the second trimester, and 0% in the third trimester have a level lower than 0.5 mg/L.⁴¹ Use of the D-dimer in excluding

PE may be useful in low- and intermediate-risk individuals in the first trimester and becomes useful again 4 weeks after delivery,³² but further investigation is necessary to establish appropriate thresholds in the three trimesters and test them in the clinical setting.⁹

BOX 71.2 Dose Reduction Methods When Using CT Pulmonary Angiography to Image Suspected Pulmonary Embolic Disease in Pregnancy

Reduce milliamper-second (mAs) settings.
 Reduce kilovoltage (kVp).
 Increase pitch.
 Increase detector and beam collimation.
 Reduce the field of view.
 Reduce z-axis scan volume (caudal extent limited to the top of the diaphragm).

Eliminate frontal and lateral scout views.
 Use circumferential shielding of the abdomen and pelvis.

CT, *Computed tomography.*

From Scarsbrook AF, Evans AL, Owen AR, et al: Diagnosis of suspected venous thromboembolic disease in pregnancy, Clin Radiol 61:1, 2006.

Figure 71.3 Magnetic resonance imaging (MRI) for appendicitis in pregnancy. Right lower quadrant pain presents a diagnostic dilemma in pregnant patients, and abdominal computed tomography is generally eschewed in favor of modalities that do not use ionizing radiation. Ultrasound may be utilized but the appendix is often difficult to visualize, especially in the third trimester. **A**, MRI (fast spin echo, fat saturated) of a patient who is 33 weeks pregnant. A dilated appendix (12 mm) and periappendiceal edema are noted adjacent to the right psoas muscle (*arrow*), indicative of acute appendicitis. **B**, A coronal section from the same study reveals the fetus in a frank breech presentation. MRI is thought to present no risk to the fetus at any stage of pregnancy.

DIAGNOSIS OF APPENDICITIS

Acute appendicitis is the most common nonobstetric emergency requiring surgery during pregnancy. Appendicitis is associated with premature labor, fetal morbidity and mortality, and an increased rate of perforation. Concern for appendicitis in a pregnant patient warrants early surgical consultation and discussion of the need and type of imaging. Patel and coauthors³⁶ published an algorithm that uses US and magnetic resonance imaging (MRI) techniques before exposing patients to ionizing radiation. They recommended the use of graded-compression US followed by abdominal/pelvic US to search for other pathology if needed. If the US studies are negative, the authors recommend MRI of the abdomen and pelvis (Fig. 71.3). Notably, some authors have found that using a nonionic oral contrast agent (a mixture of ferumoxsil [category B] and barium sulfate) improved sensitivity and specificity in detecting appendicitis in pregnancy.⁴² The authors noted that US imaging of the appendix was more easily done during the first and early second trimester and that the left lateral decubitus position assisted

in visualization of the appendix in third-trimester patients. Finally, if US and MRI are still inconclusive, CT of the abdomen and pelvis may be considered. Definitive surgical exploration should be discussed with a general surgeon before proceeding to ionizing radiation. If CT is required, the authors reported an estimate of approximately 1 cancer per 500 fetuses exposed to 30 mGy. These guidelines are consistent with the American College of Radiology's appropriateness criteria that suggest US should be performed first, followed by MRI if inconclusive, and reserves CT as a last resort.

DIAGNOSIS OF PREGNANCY AND CONSENT

If exposure to less than 50 mGy does not measurably affect the exposed embryo, why should the clinician determine the pregnancy status of the patient? Brent⁶ reported sound reasoning for diagnosing pregnancy before a radiographic study. The principle of informed consent must remain paramount. It is beneficial and more sound ethically to have the patient informed

of her pregnancy status before imaging. An informative discussion about the risk-benefit aspects of the test before the study conveys concern for the patient and fetus. Discussing the risk-benefit aspects of imaging after the study may be misconstrued as “backpedaling” and has the potential to upset the patient. Many lawsuits are stimulated by the factor of surprise. Frank discussion before imaging may prevent misguided litigation. More importantly, having patients both understand the problem (imaging in pregnancy) and take part in the management discussion can help them become more empowered and potentially reduce the anxiety associated with their condition and with their pregnancy.

Determination of pregnancy by the history and physical examination alone can be problematic. The menstrual history by itself may not be totally reliable in determining pregnancy. Amenorrhea and physical changes in the size and shape of the uterus may be consistent with pregnancy. A history of recent menstruation, use of an intrauterine device, tubal ligation, absence of coitus, or proper use of birth control pills can result in a suggestion of nonpregnant status more than 90% of the time, but these parameters are not 100% accurate. If the diagnosis of pregnancy is in the differential or imaging is ordered, or both, definitive determination of the patient’s pregnancy status should be strongly considered if the clinical scenario is reasonable. A menstrual history and other information should be obtained whenever possible, and a confirmatory urine pregnancy test should be considered. Urine pregnancy tests to detect early pregnancy are quite sensitive and reliable, and it is not necessary to routinely order a quantitative serum test. Theoretically, there will be a few days’ window between fertilization and implantation, a period when no method will confirm the presence or absence of early pregnancy.

A pregnant patient has the right to know the magnitude and type of risks that might result from in utero exposure to radiation. The Annals of the International Commission on Radiological Protection Publication 84¹² summarized the need for informed consent as follows:

The need and degree of disclosure is usually measured by what a reasonable person believes is material to the mother’s decision to be exposed to radiation. The level and degree of disclosure should be related to the level of risk. For low-dose procedures, such as chest x-rays, <100 mrad, the only information that may be needed is a verbal assurance that the risk is judged to be extremely low. When fetal doses are >100 mrad, usually a more detailed explanation is given. The information should include potential radiation risks and potential alternative modalities as well as the risk of harm from not having the medical procedure. The degree of documentation of such explanations and consent is variable but many clinicians will include a note of any such counseling or consent in the record of the patient.

PATIENT COUNSELING

When a pregnant patient requires an imaging study, be prepared to discuss the risk associated with the test. Counseling can be done after attempting to estimate the dose received by the conceptus from the procedure and comparing the radiation risk with other risks of pregnancy. It is important to use terminology that is easily understood by the patient. Fig. 71.4 depicts three different strategies to inform the patient about the level of exposure from her study and established limits.

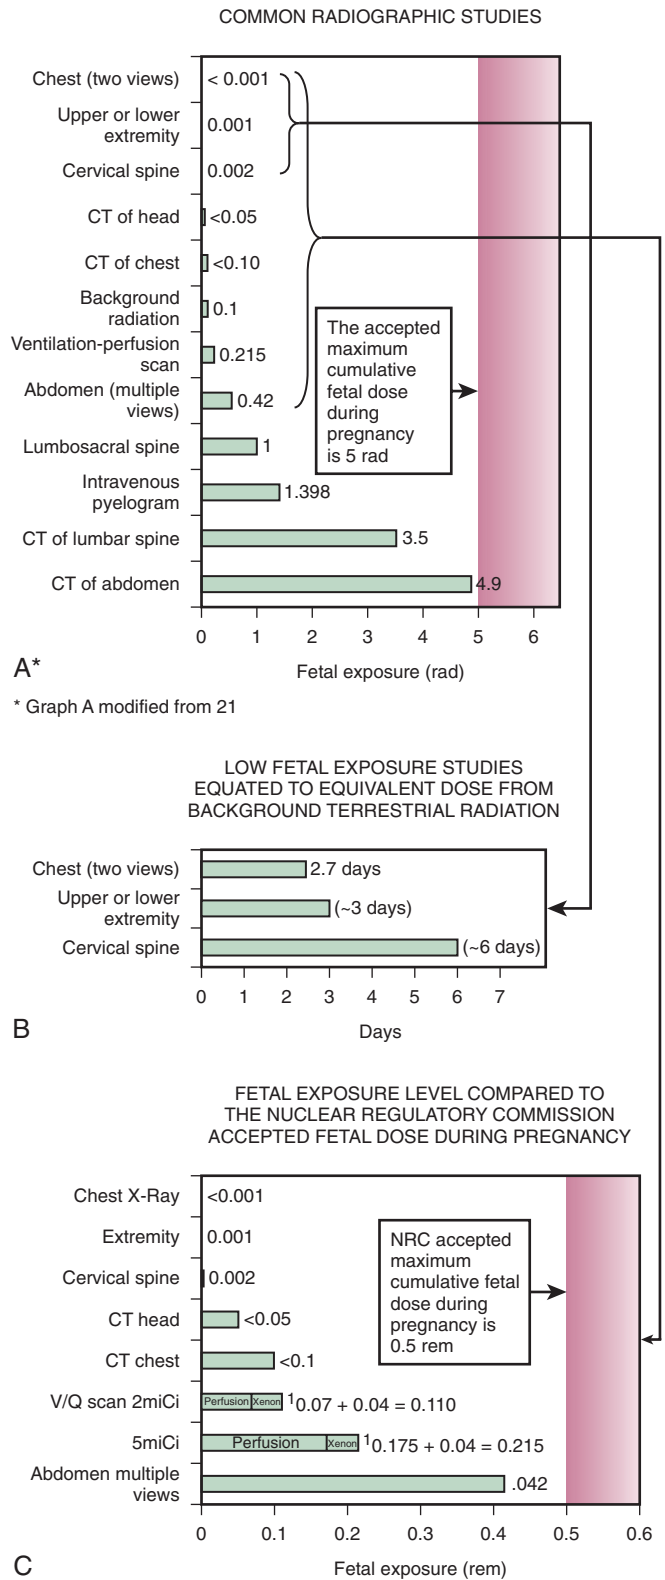

Figure 71.4 A, Comparison of common radiographic studies with the accepted 50 mGy (5 rad) cumulative fetal exposure limit. B, Low-fetal exposure studies equated to the equivalent dose from background terrestrial radiation. C, Fetal exposure level compared with the fetal dose during pregnancy accepted by the Nuclear Regulatory Commission. ^aRounded values. The radiation risk for genetic mutation is assumed to be 0.01%/rad fetal dose with a linear dose-response relationship. The background rate for genetic mutation is estimated to be 3%. From Osie IK: Fetal doses from radiological examinations, *Br J Radiol* 72:773, 1999.

^bRounded values. The radiation risk for fatal cancer is assumed to be 0.06%/rad fetal dose with a linear dose-response relationship. Many epidemiologic studies suggest that the risk may be lower than that assumed here. The background risk for childhood cancer is calculated from NCI-SEER: *Surveillance, epidemiology and end results cancer statistics review 1973-1991: tables and graphs*, Bethesda, MD, 1994, National Cancer Institute.

CT, Computed tomography; V/Q, ventilation-perfusion.

Modified from International Commission on Radiological Protection. Publication 84: Pregnancy and medical radiation, *Ann ICRP* 30:iii,1-43, 2000.

Table 71.4 compares the level of exposure with established background risks.

The main bar graph (A) in Fig. 71.4 compares the fetal exposure level for various radiographic studies with the maximum accepted fetal dose during pregnancy (50 mGy). A patient's particular study may be plotted on this graph to show the clear margin of safety that exists for all single diagnostic tests.

The middle graph (B) equates the exposure from low-level diagnostic studies to the number of hours needed to accumulate a similar exposure dose from background terrestrial radiation. One of the most commonly ordered studies in pregnancy is a chest radiograph. The potential risk to the fetus can be put into perspective for the patient by comparing the absorbed dose for the chest radiograph with the natural background radiation exposure. The environmental background radiation over a 9-month period results in a cumulative dose of 1 mGy.⁴³ The fetal dose exposure for a chest radiograph (two views) is estimated to be less than 0.1 mGy. Therefore the exposure dose to the fetus from a chest radiograph is equivalent to the same amount of naturally occurring background radiation to which the patient was exposed in the previous 2.7 days.

The lower graph (C) depicts the upper limit of the Nuclear Regulatory Commission (NRC) for cumulative gestational dose versus various diagnostic studies. The NRC has established occupational radiation dose limits for pregnancy. Its recommendation is that the dose to the fetus not be allowed to exceed 5 mSv during gestation. Brent⁶ noted that this factor-of-10 lowering of the widely accepted threshold is "extremely conservative." One can explain to the patient that the level of

exposure from her radiograph is below the conservative cumulative acceptable dose for a pregnant employee at a nuclear facility in the United States.

Another useful approach is to indicate to the patient the probability of not having a child with either a malformation or cancer and how that probability is affected by radiation. Table 71.4 depicts the probability of bearing healthy children as a function of radiation dose. This discussion should be coupled with the fact that a nonexposed fetus has a baseline incidence of spontaneous abortion, multiple developmental abnormalities, and subsequent childhood cancer.

Numerous organizations have declared fetal exposure to less than 50 mGy as being safe. Box 71.3 presents various conclusions from key organizations on the use of radiation and pregnancy. The International Commission on Radiological Protection concluded that fetal doses below 100 mGy should not be considered a reason for terminating a pregnancy.¹² If a patient still has considerable concern or has possibly received greater than 50 mGy, referral to a radiation physicist or genetic specialist for further counseling is reasonable.

NONIONIZING RADIATION

Despite the United States Food and Drug Administration's (FDA) caution that "the safety of magnetic resonance examinations has not been completely established for embryos and fetuses,"⁴⁴ MRI and US are often the preferred imaging modalities in the pregnant patient, provided the diagnostic information can be obtained satisfactorily, as they do not involve the use of ionizing radiation.⁵

BOX 71.3 Key Statements on Diagnostic Imaging Modalities During Pregnancy**RADIOGRAPHS AND COMPUTED TOMOGRAPHY**

“No single diagnostic procedure results in a radiation dose that threatens the well-being of the developing embryo and fetus.” (American College of Radiology; from Hall EJ: Scientific view of low-level radiation risks, *Radiographics* 11:509, 1991.)

“[Fetal] risk is considered to be negligible at 5 rad or less when compared to the other risks of pregnancy, and the risk of malformations is significantly increased above control levels only at doses above 15 rad.” (National Council on Radiation Protection and Measurements; from NCRPM: *Medical radiation exposure of pregnant and potentially pregnant women*, NCRPM Report No. 54, Bethesda, MD, 1977, NCRPM.)

“Prenatal doses from most properly done diagnostic procedures present no measureable increased risk of prenatal death, malformation, or impairment of mental development over the background incidence of these entities.” (From International Commission on Radiological Protection: Pregnancy and medical radiation, *Ann ICRP* 30(iii):1, 2000.)

“With few exceptions, radiation exposure through radiography, computed tomography (CT) scan, or nuclear medicine imaging techniques is at a dose much lower than the exposure associated with fetal harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient.” (American College of Obstetricians and Gynecologists [ACOG]. Committee on Obstetric Practice: *Guidelines for diagnostic imaging during pregnancy* [ACOG Committee Opinion No. 656], Washington, DC, 2016, ACOG.)

MAGNETIC RESONANCE IMAGING

“Ultrasonography and magnetic resonance imaging (MRI) are not associated with risk and are the imaging techniques of choice for the pregnant patient, but they should be used prudently and only when use is expected to answer a relevant clinical question or otherwise provide medical benefit to the patient.” (American College of Obstetricians and Gynecologists [ACOG]. Committee on Obstetric Practice: *Guidelines for diagnostic imaging during pregnancy* [ACOG Committee Opinion No. 656], Washington, DC, 2016, ACOG.)

ULTRASONOGRAPHY

“There have been no reports of documented adverse fetal effects for diagnostic ultrasonography procedures, including duplex Doppler imaging.” (American College of Obstetricians and Gynecologists [ACOG]. Committee on Obstetric Practice: *Guidelines for diagnostic imaging during pregnancy* [ACOG Committee Opinion No. 656], Washington, DC, 2016, ACOG.)

Magnetic Resonance Imaging

MRI functions by using a strong magnetic field to align the spins of the proton in a hydrogen atom. A nonionizing radio-frequency (RF) field then excites some of these protons to a higher energy level by realigning their spins. Several gradient magnets are then employed to alter the local magnetic field at the anatomic location of interest as the RF field is turned off, thereby allowing the excited protons to relax to their base

spin-orientation state, releasing the energy absorbed from the, again, nonionizing RF pulse. This energy is subsequently detected and transformed by a computer into anatomic images. The fetus is therefore exposed to both magnetic and electromagnetic fields from three sources: (1) the RF field with frequencies in the 10s to 100s of MHz, (2) time-dependent magnetic field gradients with changes on the order of 10 T/s, and (3) the static magnetic field (i.e., “field strength”) on the order of 1.5 to 3 T.

As MRI employs the use of a nonionizing RF field, the primary concern for effects of the RF field arises from tissue heating, as the dissipated energy manifests as heat. As with any thermal injury, the greater the amount of energy dissipated as heat over the shorter interval of time, the greater the rise in temperature and the greater the potential for injury. The amount of energy deposited by the RF field is called the average specific absorption rate (SAR), which depends on the specifics of the MRI protocol in use and is measured in energy per unit time (i.e., power) per unit mass, J/s/kg per kg = W/kg. SAR is calculated using the patient’s entire mass rather than that of a specific tissue. The FDA limits SAR to no more than 4 W/kg for the whole body averaged over 15 or more minutes and 3.2 W/kg for the head averaged over 10 or more minutes.⁴⁵ These limits are the same for fetuses or embryos and for mothers. The International Electrotechnical Commission (IEC) has established three levels of operation which are programmed into the MRI: (1) normal, which permits whole-body SARs up to 2 W/kg, (2) first-level controlled, which permits whole-body SARs up to 4 W/kg and requires approval of the radiologist, and (3) second-level controlled in which whole-body SARs can exceed 4 W/kg but which requires signed patient consent and can be used only under an institutional review board–approved protocol. Whole-body SARs of 2 W/kg and 4 W/kg are not expected to raise core body temperature by more than 0.5°C and 1°C, respectively.

Implied in these estimates are the assumptions of an ideal study environment for the dissipation of heat and normal thermoregulatory mechanisms in the patient. The embryo or fetus, however, exists in a well-insulated environment with more limited heat-removal systems and maintains a temperature of approximately 0.5°C to 1°C above the maternal temperature.⁴⁶ Furthermore, the amount of energy deposited by the RF field is heterogeneous, leading to local SARs that differ from the whole-body SAR. The FDA therefore limits local SAR to 8 W/kg for any 5-minute period in 1 g of tissue, and the IEC limits local SAR to 10 W/kg for any contiguous 10 g of tissue. A 2006 analysis⁴⁷ concludes that fetal SAR rises through pregnancy, peaking in the 5th month, and operation in normal mode does not violate the IEC local SAR limits, but it finds that operation in first-level controlled may exceed the IEC limit on local SAR beginning in the 3rd month. It is therefore recommended that scans above normal mode are avoided, the maternal abdomen is kept out of the RF field when possible, care is exercised to identify fetuses with poor placental function (i.e., growth retardation), and to avoid scanning pregnant women with impaired thermoregulatory function (e.g., febrile pregnant women).⁴⁸

The remaining two sources of exposure in MRI include the time-dependent magnetic fields and the static magnetic field. The time-dependent magnetic field produces an electric field that can cause painful stimulation of nerves and muscles. The FDA imposes a limit for the rate of change on these time-dependent magnetic fields at a threshold “sufficient to produce severe discomfort or painful nerve stimulation.” The IEC has

imposed more technical limitations, and the FDA limits for the fetus are the same as for the mother. Finally, at high-static magnetic field strengths, various nonharmful side effects (e.g., vertigo) and the induction of electric currents have been observed. The FDA therefore limits the field strength of the static magnetic field to 4 T for neonates and infants aged 1 month or less, and to 8 T for patients aged more than 1 month.⁴⁵

Gadolinium-based contrast agents are sometimes used intravenously during MRI studies. The FDA gives these contrast agents a pregnancy risk factor classification of C (i.e., “risk cannot be ruled out”), but a review by the European Society of Urogenital Radiology concludes gadolinium-based agents are likely safe for pregnant and lactating women.²⁸

ULTRASONOGRAPHY

Ultrasonography continues to be the screening modality of choice for evaluation of the maternal pelvis and the fetus because of its safety profile, relatively low cost, and real-time capability. Obstetric and gynecologic US accounts for more than half of the US imaging volume in the United States.⁴⁹ In the 40 years since its introduction into clinical practice, US has not been shown to convey any significant health risk to the fetus or mother,⁵⁰ although most safety data were collected before 1992, when the permissible power output of scanners for fetal use was increased⁵¹ from 94 mW/cm² to 720 mW/cm². Generally, the increasing power output raises concern for thermal and mechanical effects on developing tissue. A large fraction of US energy is absorbed as it passes through tissue, approximately 20% for each centimeter traveled. Damage can occur if the amount of deposited energy exceeds the tissues' ability to dissipate the heat, but significant temperature increases⁵ are not seen until ultrasonic intensities exceed 10 W/cm². These issues are small with standard B-mode imaging, which operates with power less than 50 mW/cm², and more concerning with the use of higher-power Doppler devices, which have the capacity to raise temperatures by several degrees and use powers approaching the established limit.⁵ US societies have developed unitless output display standards, namely, a thermal index and mechanical index, to allow the operator to determine whether the study exceeds a generally accepted safe range.⁵² The radiologic principle known as ALARA is generally supported and promotes a balance between obtaining the necessary medical information while using minimal settings and examination time. Human data accumulated over a 25-year period have revealed no consistent adverse effects from prenatal diagnostic US examination.^{53,54} US in pregnancy is considered a safe procedure.

The American College of Obstetricians and Gynecologists has reviewed the effects of radiography, US, and MRI during pregnancy and suggested guidelines for radiographic examination during pregnancy (Box 71.4).⁸

SUMMARY

In summary, the threshold dose for the nonstochastic effects of radiation throughout the gestational period is greater than 50 mGy. Prenatal doses of less than 50 mGy present no measurable increased risk for prenatal death, malformation, growth retardation, or impairment of mental development over the background incidence of these entities. The risk for

BOX 71.4 Guidelines for ED Diagnostic Imaging during Pregnancy

1. Fetal risk of anomalies, growth restriction, or abortion have not been reported with radiation exposure of less than 50 mGy, a level above the range of exposure for diagnostic procedures.
2. If these techniques (radiographs, CT, NM) are necessary in addition to ultrasonography or magnetic resonance imaging or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient.
3. US and MRI are not associated with risk and are the imaging techniques of choice for the pregnant patient, but they should be used prudently and only when use is expected to answer a relevant clinical question or otherwise provide medical benefit to the patient.
4. Consultation with an expert in dosimetry calculations may be helpful in calculating the estimated fetal dose when multiple diagnostic radiographs are performed on a pregnant patient.
5. Radioactive isotopes of iodine are contraindicated for therapeutic use during pregnancy. Technetium-99m is the isotope of choice.
6. Radiopaque and paramagnetic contrast agents are unlikely to cause harm and may be of diagnostic benefit, but these agents should be used during pregnancy only if the benefit justifies the potential risk to the fetus.

CT, *Computed tomography*; ED, *emergency department*; MRI, *magnetic resonance imaging*; NM, *nuclear medicine*; US, *ultrasonography*.

stochastic effects, carcinogenesis, or mutagenesis, is related to the fetal absorbed dose and is very low in comparison to the natural background incidence of childhood cancer and genetic disease for most diagnostic procedures.

The vast majority of radiographic imaging obtained in the emergency department exposes the fetus to 100 times less than the threshold for adverse effects. The 50 mGy threshold for onset of concern for adverse fetal effects is quite conservative, and any statistically significant change in fetal outcome probably requires at least several times this dose. One of the methods put forth in this chapter can be used to counsel pregnant patients in need of diagnostic imaging. For women inadvertently exposed to radiation before pregnancy is recognized, open and frank discussion can help educate patients and alleviate their fear.

CLINICAL USE OF RADIOCONTRAST MATERIAL

Emergency clinicians must frequently initiate studies with the use of radiocontrast material. A full discussion of these procedures is not within the scope of this chapter, but basic issues of contrast material-induced nephropathy, the possible prevention thereof, and recent concern over the use of gadolinium for MRI studies have been included for completeness and ready reference (Table 71.5 and Box 71.5).

TABLE 71.5 Prevention of Contrast-Induced Nephropathy**Renal Failure: Radiocontrast Agents**

Radiocontrast-induced acute renal failure is more likely to occur in the presence of advanced age, renal insufficiency, diabetes mellitus, severe congestive heart failure, multiple myeloma, volume depletion, low-cardiac output states, and high-dose contrast-enhanced studies (> 125 mL). The incidence of nephrotoxicity depends on the underlying risk factors and the sensitivity of the measure used to determine nephrotoxicity. When a rather sensitive index of renal dysfunction (an increase in the level of serum creatinine to > 0.3 mg/dL and > 20% on day 1, 2, or 3 and day 5, 6, or 7) is used, the incidence of nephrotoxicity is approximately 2% in nondiabetic, nonazotemic patients and 16% in diabetic, nonazotemic patients. Diabetic patients with azotemia had approximately a 38% incidence of nephrotoxicity. In a study of 59 diabetic patients with advanced azotemia (mean serum creatinine level, 5.9 mg/dL) undergoing coronary angiography, contrast-related nephrotoxicity developed in 30 (51%), as defined by a serum creatinine level that was 25% above baseline 48 hr after angiography. Nine patients (15%) required hemodialysis.

Risk Factors for Radiocontrast Nephrotoxicity

Advanced age

Renal insufficiency

Decreased absolute and effective circulatory volume

Diabetes mellitus

Multiple myeloma

Coadministration of other nephrotoxic agents

(From Brenner BM, editor: *Brenner and Rector's the kidneys*, ed 7, Philadelphia, 2004, Saunders, Table 34.3; from MD Consult.)

Note: Renal failure may be oliguric or nonoliguric, with nonoliguric renal failure being more common in patients with previously nearly normal renal function.

Most episodes of contrast-induced nephrotoxicity are mild and characterized by a reversible 1- to 3-mg/dL rise in serum creatinine; dialysis therapy is rarely needed and usually only in patients whose baseline serum creatinine level is high, for example, > 3 mg/dL.

Prevention of Radiocontrast Nephropathy

The development of acute renal failure significantly complicates the use of intravascular contrast medium (CM) and is linked with high morbidity and mortality. The increasing use of CM, an aging population, and an increase in chronic kidney disease (CKD) will result in an increased incidence of contrast-induced nephropathy (CIN), unless preventive measures are used. At the current time there is no universally accepted, agreed, or proven intervention to totally prevent CIN. However, the Canadian Association of Radiologists has developed guidelines as a practical approach to risk stratification and potential prevention of CIN. The major risk factor predicting CIN is preexisting CKD, which can be predicted from the glomerular filtration rate (GFR). In terms of being an absolute measure, serum creatinine is an unreliable measure of renal function. Patients with a GFR > 60 mL/min have a very low risk for CIN, and preventive measures are generally unnecessary. With a GFR < 60 mL/min, preventive measures should be instituted. The risk for CIN is greatest in patients with a GFR < 30 mL/min. As preventive measures, alternative imaging that does not require CM should be considered. Fluid volume loading is the single most important protective measure. Nephrotoxic medications should be discontinued 48 hr before the study. CM volume and the frequency of administration should be minimized, but satisfactory image quality should still be maintained. High-osmolar CM should be avoided in patients with renal impairment. There is some evidence to suggest that isosmolar CM reduces the risk for CIN in patients with renal impairment, but further study is necessary to determine whether isosmolar CM is superior to low-osmolar CM. *N*-acetylcysteine (NAC) has been advocated to reduce the incidence of CIN; however, not all studies have shown a benefit, and it is difficult to formulate evidence-based recommendations at this time. Use of NAC may be considered in high-risk patients but is not thought to be mandatory.

Additional Caveats

1. Metformin use is not a contraindication to the use of CM, but metformin should be withheld for 48 hr after CM and after evaluation of renal function.
2. Although the GFR is the best way to predict renal dysfunction after CM, patients with normal creatinine are at minimal risk.

(From Benko A: Canadian Association of radiologists: consensus guidelines for the prevention of contrast-induced nephropathy, *Can Assoc Radiol J* 58:79, 2007.)**Potential Prevention of Contrast-Induced Nephropathy^a****NAC**

Suggested regimen for oral NAC: 600 mg (3 mL of a 20% solution in liquid) twice a day for 24 hr before and 24 hr after procedure.

Suggested IV (intravenous) NAC: 150-mg/kg IV bolus over 30 min, followed by a 50-mg/kg infusion over 4 hr.^b

Example in a 80-kg patient: 12,000 mg NAC in 500 mL normal saline over 30 min, followed by 4000 mg NAC in 500 mL normal saline over 4 hr.

TABLE 71.5 Prevention of Contrast-Induced Nephropathy—cont'd**Hydration**

Suggested regimen for fluid therapy in elective cases: normal saline, at least 1 mL/kg per hr 12 hr before and 12 hr after the procedure.

Alternative if an emergency procedure is required: 5-mL/kg bolus of normal saline 1 hr before and 1 mL/kg per hr for 12 hr after the procedure.

Alternative fluid regimen with bicarbonate: add 154 mL of 1000 mEq/L sodium bicarbonate to 850 mL of 5% dextrose in water (D₅W) (or add 3 ampules of standard bicarbonate to 1 L D₅W). Initial bolus of 3 mL/kg for 1 hr before injection of contrast material, followed by 1 mL/kg per hr for 6 hr after the procedure.

^aSuggested but unproven, minimal downside.

BOX 71.5 MRI Contrast Agent Concerns and Contraindications**INFORMATION FOR HEALTH CARE PROFESSIONALS:
GADOLINIUM-BASED CONTRAST AGENTS FOR MRI
(MARKETED AS MAGNEVIST, MULTIHANCE, OMNISCAN,
OPTIMARK, PROHANCE)**

FDA ALERT (6/2006, updated 12/2006 and 5/23/2007): This updated alert highlights the FDA's request for the addition of a boxed warning and new warnings about the risk for nephrogenic systemic fibrosis (NSF) and full prescribing information for all gadolinium-based contrast agents (GBCAs) (Magnevist, MultiHance, Omniscan, OptiMARK, ProHance). This new labeling highlights and describes the risk for NSF following exposure to a GBCA in patients with acute or chronic severe renal insufficiency (glomerular filtration rate < 30 mL/min per 1.73 m²) and patients with acute renal insufficiency of any severity as a result of hepatorenal syndrome or in the perioperative liver transplantation period. In these patients, avoid the use of a GBCA unless the diagnostic information is essential and not available with non-contrast-enhanced MRI. NSF may result in fatal or debilitating systemic fibrosis. The requested changes in GBCA product labeling are summarized below.

- Evaluate renal function in all patients before administering a GBCA.
- Whenever possible, avoid GBCAs for MRI and MRA in patients with moderate to end-stage renal failure. Contrast agents that contain gadolinium include Magnevist, MultiHance, Omniscan, OptiMARK, and ProHance.
- If GBCAs must be used, consider prompt dialysis after the procedure to eliminate circulating gadolinium. However, it is unknown whether dialysis can prevent or treat NSF/NFD.
- Encourage patients to contact their health care provider if they have signs of NSF/NFD.
- Report cases of NSF/NFD to the FDA's MedWatch program at www.fda.gov/medwatch/index.html or by calling 1-800-332-1088 (1-800-FDA-1088).

CONTRAINDICATIONS TO MRI

(Because this is an area of continuing change and there are rapid advancements in the technology to produce MRI-safe materials, consultation with the radiology department is suggested if any questions arise concerning the safety of MRI.)

Overview

There are few contraindications to MRI. Overall, no biologic adverse effects are associated with conventional MRI. Most contraindications to MRI are relative and essentially precautions related to the effect of MRI on devices and material within the body that may be affected by the magnetic field of MRI.

Implanted Devices and Foreign Bodies

Electronic devices and magnetizable material represent potential hazards to the patient. Titanium objects are safe for MRI.

- **Intracoronary stents:** It is considered safe to perform MRI at any time after placement of coronary artery stents of any type.
- **Sternal wires after sternotomy:** Sternal wire sutures are considered safe for MRI.
- **Mechanical cardiac valves:** It is safe to scan most prosthetic cardiac valves because at most, they experience only a mild torque. An exception involves the pre-6000 series Starr-Edwards caged ball valves; devices rarely used now.
- **Pacemakers, implantable defibrillators, and implanted electronic devices:** The risks of scanning patients with cardiac pacemakers are related to possible movement of the device, magnetically induced changes in programming, electromagnetic interference, and induced currents in lead wires leading to heating and/or cardiac stimulation. It is currently considered inadvisable for patients with pacemakers or other intracardiac wires to undergo MRI. Nerve stimulators, insulin pumps, cochlear implants, and other implanted electronic devices may also be affected by MRI and are considered unsafe.
- **Implanted vagal nerve stimulator:** Brain MRI performed at less than 2 T, with a send and receive head coil and the stimulator turned off, appears to be safe under guidelines published by the manufacturer. Other MRI studies are not known to be safe.
- **Aneurysm clips and magnetizable material:** Any ferromagnetic object within the body represents a potential hazard when exposed to the large magnetic field of an MRI system. The hazard primarily reflects the possibility of deflecting the foreign body sufficiently to injure vital structures. For example, certain older-model vascular clips

BOX 71.5 MRI Contrast Agent Concerns and Contraindications—cont'd

used for cerebral aneurysms are ferromagnetic and could be moved by the magnetic field, with obviously dire consequences.

- **Intraorbital or intraocular metallic fragments**, such as might be acquired from machining, are a potential risk and generally a contraindication to MRI.
- **Cutaneous metal objects**: Although most metallic biomaterial is now nonferrous and nonmagnetizable, any metallic device within or connected to the patient needs to be evaluated for safety. Dental alloys, wires, splints, dental braces, and prostheses do not appear to pose a risk to the patient, although such material may result in artifactual changes. Cutaneous burns can result from contact of the skin with metal objects, including neurosurgical halo pins, pulse oximetry probes, and drug-eluting medical patches that contain metal foil (e.g., nicotine patch), although the mechanism of this injury is unclear.
- **Orthopedic/neurosurgical hardware**: It is safe to perform MRI in patients with titanium implants, screws, rods, and artificial joints.
- **Bullets/shrapnel**: These foreign objects within the body are relative contraindications to MRI. Many bullets are safe, but those with metal (specialized bullets, such as metal jackets) may pose a risk.
- **Tattoos**: The majority of professionally obtained tattoos are safe for MRI; however, tattoos containing lead, such as those obtained in prison, can burn the skin if exposed to MRI.
- **Oxygen cylinders**: Standard metal oxygen cylinders should not be used in the MRI suite. Safe oxygen cylinders are available.
- **Credit cards**: Credit card and other information-containing strips may be destroyed in the MRI scanner.

Procedures in the Setting of Anticoagulation

Joseph D'Orazio

INTRODUCTION

Performing an invasive procedure on an anticoagulated emergency department (ED) patient can be challenging for the emergency provider (EP). Regardless of the procedure, some anticoagulated patients are at potential significant risk of hemorrhage from the procedure. However, emergency reversal of anticoagulation in order to perform the procedure may also place the patient at risk for serious thrombotic complications. When deciding to perform a procedure on an anticoagulated ED patient, the EP must weigh the risks of bleeding with the risk of disrupting anticoagulation, emergency reversal of anticoagulation, and delaying a potentially critical intervention. If the procedure is not needed for life-saving therapy, postponing the procedure or providing empiric treatment may be a reasonable choice. In contrast, emergency procedures to reverse an imminent life-threatening condition should never be withheld and emergency reversal of anticoagulation may be required. This chapter reviews current literature and recommendations for select ED procedures such as lumbar puncture, central venous catheterization, arthrocentesis, paracentesis, thoracentesis, and tube thoracostomy in the anticoagulated patient.

ASSESSING RISK OF BLEEDING AND THROMBOSIS

All anticoagulants inhibit stable clot formation and increase the risk of bleeding. Routine coagulation testing, that is prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), and platelet count, in anticoagulated patients, is recommended prior to performing an invasive procedure. Although laboratory tests to determine drug presence, drug concentration, and level of anticoagulant effect can be useful in the assessment of bleeding risk, standard coagulation assays accurately monitor the degree of anticoagulation for only a few agents. PT and INR conveniently assay the extrinsic pathway to monitor the quantitative effect of warfarin therapy. PTT or activated partial thromboplastin time (aPTT) accurately monitors the anticoagulant effect of heparin. Newer nonvitamin K antagonist oral anticoagulants (NOACs) were developed to have predictable pharmacokinetics with minimal interactions to avoid the need for routine laboratory testing. Coagulation assays to quantify the effect or presence of a NOAC would be useful in many clinical circumstances such as in active bleeding, suspected overdose, and the perioperative period, but do not exist for many. The direct measurement of drug concentration is not suitable in clinical practice because of the time required to perform the laboratory analysis. Standard coagulation assays can be useful in extreme scenarios,

but are generally insufficient in determining drug concentration or degree of anticoagulant effect of NOACs (Table 72.1).

Normal thrombin time is suitable for excluding significant dabigatran levels but too sensitive for determining the degree of anticoagulant effect.^{1,2} Dilute thrombin time, ecarin chromogenic assay, and ecarin clotting time may be useful to determine the degree of anticoagulant effect, but is not standardized across laboratories. Although using standard coagulation assays to quantify dabigatran effect is not recommended, an elevated PT/INR suggests a suprathreshold dabigatran effect, and a normal PTT excludes it.² Unfortunately, none of these tests are accurate predictors of bleeding risk with dabigatran and patients may have bleeding when these tests are within the normal range.³

Anti-factor Xa activity is valuable to determine the effect of factor Xa inhibitors such as rivaroxaban and apixaban, but this test is not widely available. Although it is not recommended to use standard coagulation assays to quantify drug effect, a normal PT and INR level virtually excludes suprathreshold rivaroxaban effect.²

For patients on warfarin, understanding how INR correlates to the risk of bleeding is important. Spontaneous bleeding events are uncommon when the INR is normal or within a therapeutic range (i.e., 2 to 3).⁴ The relative risk for bleeding with an INR between 3 and 5 is 2.7 (95% confidence interval [CI] 1.8–3.9). However, when the INR is above 5, the relative risk of a spontaneous hemorrhagic event increases dramatically to 21.8 (95% CI 12.1–39.4). These findings are similar to a previous retrospective review in 1995 that also showed adverse events occurred in 75 per 100 patient-years for an INR greater than or equal to 6.5.⁵ Patients with severe coagulopathy (INR greater than 9) have a poor prognosis, with 67% experiencing spontaneous hemorrhagic events and a 74% mortality rate.⁶

Patients without a history of bleeding or anticoagulant use do not require routine coagulation studies prior to performing a procedure unless history or physical examination suggest a bleeding disorder or use of anticoagulation.⁷ A 2005 systematic review failed to demonstrate the utility of routine coagulation studies on nonanticoagulated patients prior to the performance of a procedure.⁸ Abnormal laboratory findings such as thrombocytopenia, an elevated INR, or other coagulation abnormalities are not necessarily absolute contraindications to performing an invasive procedure. Numerous studies have demonstrated that select procedures can safely be performed even in the setting of anticoagulation with a vitamin K antagonist (VKA).^{9–12} Determining a patient's risk for bleeding requires examination of both the procedure to be performed, the anticoagulant medication, and the level of anticoagulation. Unfortunately, there are no validated systems available to quantify risk of bleeding.

The risk of thrombosis after anticoagulant reversal is significant for a subset of ED patients. These patients include those with a recent diagnosis of pulmonary embolism, significant clot burden, or those with mechanical hardware such as a prosthetic cardiac valve. When clinically feasible, it is best to allow the anticoagulant effect of a medication to wane rather than emergently reversing the medication in these patients. This approach is rarely possible in the ED, so timing of the procedure should be coordinated with the inpatient provider if the patient requires admission.

Many procedures report contraindications with severe coagulopathy (INR greater than 9) and disseminated intravascular coagulation (DIC). Proper coagulation is significantly

TABLE 72.1 Summary of Anticoagulant Testing and Management

ANTICOAGULANT	LABORATORY TESTING TO CONSIDER	PHARMACOLOGY	AGENTS TO REVERSAL OF REMOVAL
Vitamin K Antagonists			
Low-molecular-weight heparin (LMWH)	Anti-Factor Xa	3–6 hours	Consider protamine sulfate or rVIIa in life-threatening bleeding
Unfractionated heparin	PTT, aPTT	60–90 minutes	Protamine sulfate
Warfarin	PT/INR	20–60 hours (duration of action 2–5 days)	Vitamin K, fresh frozen plasma (FFP), prothrombin complex concentrate (PCC), recombinant Factor VIIa
Direct Thrombin Inhibitors			
Argatroban	Activated clotting time (ACT), aPTT	39–51 minutes	Consider hemodialysis, rVIIa or FFP but generally not indicated due to short half-life
Dabigatran	Thrombin time (TT), dilute TT, ecarin chromogenic assay (ECA), and ecarin clotting time (ECT), PT/INR, PTT	12–17 hours	Idarucizimab, PCC, hemodialysis
Factor Xa Inhibitors			
Apixaban Rivaroxaban	Anti-Factor Xa, PT/INR	12 hours 5–9 hours	PCC
Anti-Platelet Agents			
Aspirin Clopidogrel Prasugrel Ticagrelor	Platelet function testing	Duration of action 7–10 days, irreversibly inhibits platelet 7–10 hours	Platelet transfusion

aPTT, Activated partial thromboplastin time; INR, international normalized ratio; PT, prothrombin time; PTT, partial thromboplastin time.

disrupted in these clinical settings and invasive procedures may lead to severe bleeding. However, life-saving measures such as thoracostomy, central venous catheterization, and endotracheal intubation are sometimes required even in these severe settings. Additional life-saving procedures that may carry a high risk of bleeding in the setting of anticoagulation, but should not be withheld, include defibrillation and pericardiocentesis. The gravity of the clinical scenario is important to keep in mind when weighing the risk of performing a procedure in the setting of anticoagulation.

Limited data are available on the safety of performing procedures on patients taking newer NOACs. These NOACs may confer the same, less, or increased risk of bleeding as traditional VKA agents. The lack of an effective reversal agent for many of the NOACs is another factor that complicates the decision to perform a procedure in the setting of anticoagulation. Fortunately, many of the NOACs have a duration of action that is less than the traditional VKAs.

MANAGEMENT OF ANTICOAGULANT ASSOCIATED BLEEDING

Although periprocedural bleeding is typically not life threatening and can often be controlled with direct pressure, predicting

which anticoagulated patients will bleed from a procedure is difficult. Furthermore, the simple act of controlling periprocedural bleeding may not entirely end the risk of serious harm. For instance, periprocedural bleeding with percutaneous coronary intervention is associated with an increased short- and long-term morbidity and mortality, including major adverse cardiovascular events and readmission rates well after the bleeding is controlled.^{13,14}

When managing spontaneous, periprocedural, or postprocedural bleeding associated with anticoagulation, there are a few principles to consider. Most importantly, never withhold emergency life-saving procedures such as endotracheal intubation, tube thoracostomy, cardiac defibrillation, pericardiocentesis, or vascular access when necessary.

Stabilization with supportive treatments such as oxygenation, intravascular volume resuscitation, and repletion of blood products via transfusion are the initial steps of assessment and management of bleeding in the anticoagulated patient. Patients with prolonged or severe bleeding may have presenting symptoms in various stages of circulatory shock. Poor blood supply and intravascular volume leads to poor tissue perfusion. Cellular hypoxia, damage, and resulting inflammatory response from hypoperfusion can exacerbate the patient's clinical status. Adequate resuscitation and stabilization is key to the initial phase of management.

Hemostatic measures such as direct compression of a bleeding or oozing vessel, wound, or region should be performed concurrently with stabilization to prevent further blood loss. Additional measures may be needed to control bleeding when compression fails or when the bleeding originates from a noncompressible site. These measures include the use of topical hemostatic agents, systemic hemostatic agents (i.e., tranexamic acid), procedural intervention, operative management, or intraarterial embolization.

The clinician can assess the severity of coagulopathy with laboratory analysis. Patients may experience bleeding at subtherapeutic, therapeutic, or supratherapeutic levels of anticoagulation. Determining qualitative level of anticoagulation may help guide therapy. However, many anticoagulants do not have an associated diagnostic test that is accurate, timely, and clinically relevant to determine severity of coagulopathy like warfarin or heparin. Obtain routine coagulation assays (i.e., PT, PTT, and INR) when no relevant study exists. Routine coagulation assays may sometimes be helpful in determining the lack of a supratherapeutic anticoagulant effect but are often difficult to interpret.

When bleeding is severe, life-threatening, refractory to hemostatic efforts, or the coagulopathy is determined to be severe, restoring the ability to generate an effective clot by administration of an antidote, coagulation factor, blood product, or removal of the offending anticoagulant (i.e., hemodialysis) may be necessary. Consideration for the anticoagulant's duration of action is also important when deciding whether to reverse anticoagulation.

Withholding further doses of anticoagulation may be necessary after stabilization and disposition. When the clinical decision to withhold anticoagulant is not clear, consultation with the prescribing physician (e.g., cardiologist prescribing aspirin and clopidogrel for cardiac stent) or hematologist may be warranted.

Reversal of Anticoagulation

The decision to discontinue or reverse anticoagulation prior to a procedure is difficult. Although there are no validated data that can accurately stratify risk for peri- or postoperative thromboembolism, the American College of Chest Physicians (ACCP) has published guidelines that stratify patients into low-, moderate-, and high-risk groups.¹⁵ These guidelines are listed in Table 72.2.

Risk factors that increase the likelihood of a thromboembolic event with anticoagulant disruption include a prosthetic heart valve, atrial fibrillation, recent cerebrovascular accident (CVA) or transient ischemic attack, recent venous thromboembolism (VTE), the presence of a VTE risk factor (i.e., protein C/S deficiency, antiphospholipid antibody), and a high CHAD₂ score (congestive heart failure, hypertension, age, diabetes mellitus, CVA).^{15,16} Patients with mechanical valves are at higher risk for thromboembolic events when anticoagulation is disrupted than patients with bioprosthetic valves. Mitral valves present a higher risk of thromboembolic events than aortic prosthetic valves. The postoperative period just after (less than 3 months) mechanical valve placement is also a high-risk time for thromboembolic events.¹⁶

Procedures on patients with prosthetic valves typically require a delayed approach to operative management, except when there is an emergency. In general, discontinuing anticoagulation in a patient with a prosthetic valve is safer than reversal of anticoagulation to perform a procedure. Reversal of anticoagulation puts patients at higher risk for thromboembolic events than does simply discontinuing the anticoagulant. When possible, discontinue anticoagulation and delay invasive procedures on patients with prosthetic valves until coagulation status returns to near normal. For patients with low risk bioprosthetic valves that require discontinuation of anticoagulation, warfarin should be discontinued 48 to 72 hours prior to the procedure or until the

TABLE 72.2 Suggested Patient Risk Stratification for Perioperative Arterial or Venous Thromboembolism

Indication for VKA Therapy			
RISK STRATUM	MECHANICAL HEART VALVE	ATRIAL FIBRILLATION	VTE
High	Any mitral valve prosthesis Older (caged-ball or tilting disc) aortic valve prosthesis Recent (within 6 mo) stroke or transient ischemic attack	CHADS ₂ score of 5 or 6 Recent (within 3 mo) stroke or transient ischemic attack, Rheumatic valvular heart disease	Recent (within 3 mo) VTE Severe thrombophilia (e.g., deficiency of protein C, protein S or antithrombin, antiphospholipid antibodies, or multiple abnormalities)
Moderate	Bileaflet aortic valve prosthesis and one of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age > 75 yr	CHADS ₂ score of 3 or 4	VTE within the past 3 to 12 mo; Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation); Recurrent VTE; Active cancer (treated within 6 mo or palliative)
Low	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	CHADS ₂ score of 0 to 2 (and no prior stroke or transient ischemic attack)	Single VTE occurred 12 mo ago and no other risk factors

CHADS₂, Congestive heart failure-hypertension-age-diabetes-stroke; VTE, venous thromboembolism.

From Douketis JD, Berger PB, Dunn AS, et al: The perioperative management of antithrombotic therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition), *Chest* 133:299S, 2008.

INR drops below 1.5.¹⁶ Anticoagulation may then be restarted 24 hours following the procedure. High-risk patients with prosthetic valves (e.g., mitral valve) require bridging therapy to reduce the time off anticoagulation.¹⁶

For patients taking VKAs that require reversal of anticoagulation for an urgent procedure, administration of oral vitamin

K is recommended.¹⁵ If more immediate reversal is required for a procedure, administration of fresh-frozen plasma or prothrombin complex concentrate in addition to oral vitamin K is recommended.¹⁵ For patients taking antiplatelet agents such as aspirin or clopidogrel, platelet transfusion is recommended for reversal of the effect (Fig. 72.1).¹⁵

Figure 72.1 Anticoagulant and coagulopathy reversal agents. **A**, Oral vitamin K reverses the effect of vitamin K antagonists, such as warfarin. Onset of action ranges from hours to days. **B**, Intravenous vitamin K can be used in patients who require emergency procedures; however, onset of action is measured in hours, as the liver must regenerate coagulation factors. There is a risk of anaphylaxis with intravenous vitamin K, and it should be administered via slow infusion (over 20 to 60 minutes.) **C**, Fresh frozen plasma (FFP) can be used to reverse the effect of vitamin K antagonists in emergency situations. **D**, Prothrombin complex concentrates (such as the four factor PCC Kcentra [CSL Behring LLC., Kankakee, IL], pictured) provides rapid international normalized ratio correction and may be safer than FFP. PCCs can also be used to reverse the effects of direct thrombin inhibitors (e.g., dabigatran) and factor Xa inhibitors (e.g., apixaban). **E**, Platelet transfusions can be used to reverse the effects of antiplatelet medications such as aspirin or clopidogrel, and also to correct thrombocytopenias.

Procedures

Lumbar Puncture

The decision to perform a lumbar puncture (LP) should be individualized and based on an assessment of the risks and benefits of the procedure. When the risks of an LP are high, empiric antibiotic therapy may be appropriate for conditions such as meningitis. When the condition is difficult to diagnose or treat, LP may be necessary. In these cases, consultation with interventional radiology or anesthesiology may be warranted to reduce the risk of hemorrhage.

When an LP is performed in an anticoagulated ED patient, it is critical to monitor for complications. The most important complication associated with LP in the setting of anticoagulation is a spinal epidural hematoma (SEH). This rare, but catastrophic, complication is more likely to occur with a difficult or traumatic LP in anticoagulated patients or those with a platelet disorder.¹⁷ An emergency magnetic resonance image should be performed if there is suspicion for an SEH. If an SEH is diagnosed, immediate decompression with a laminectomy should be performed to avoid irreversible spinal cord ischemia.¹⁸

Many clinicians feel that spinal procedures such as an LP may be safely performed on patients taking aspirin or a nonsteroidal antiinflammatory drug (NSAID) without discontinuing the medication or transfusing platelets.¹⁹⁻²⁴ It is important to consider the specific medication. Aspirin irreversibly inactivates cyclooxygenase-1 (COX-1) and blocks thromboxane production for the life of a platelet (7–10 days) within an hour of ingestion. Therefore platelet function does not return to normal until the permanently inhibited platelets are replaced by enough newly synthesized active platelets. The ability for platelets to aggregate can be seen after 4 days following aspirin cessation, as it requires only a few uninhibited platelets (newly synthesized or transfused) to recruit aspirin treated platelets to action.^{25,26} Horlocker and colleagues studied 391 patients undergoing spinal anesthesia and also on antiplatelet therapy including aspirin, naproxen, piroxicam, ibuprofen, indomethacin, dipyridamole, and sulindac.²¹ One hundred and thirteen patients were on multiple antiplatelet agents preoperatively. No SEHs were reported in this study. The authors concluded that preoperative antiplatelet medication was not a contraindication to spinal anesthesia. Importantly, it is not recommended to perform an LP on patients who are using aspirin or an NSAID concurrently with another anticoagulant such as heparin, low-molecular-weight heparin (LMWH), or other antiplatelet agents.²⁴

The safety of performing an LP in patients receiving newer antiplatelet agents, including clopidogrel, ticlopidine, abciximab, eptifibatide, or tirofiban is not well studied. The American Society of Regional Anesthesia and Pain Medicine (ASRA) recommends discontinuation of these medications prior to LP.²⁴ Reversing the effect of these medications and the period of discontinuation prior to the performance of the procedure depends on the medication. Pharmacologically, normal platelet activity is expected 8 hours after discontinuing tirofiban and eptifibatide, 24 to 48 hours after discontinuing abciximab, and 1 to 2 weeks after discontinuing clopidogrel and ticlopidine.²⁴ The ASRA, ACCP, and the American Heart Association (AHA) recommend discontinuing clopidogrel 7 to 10 days prior to neuraxial anesthesia or surgery. Other organizations recommend a 5-day washout period prior to giving spinal injections in patients receiving these medications.^{15,19,24,27}

Heparin increases the risk of SEH. In a study from 1981, 2% (7 of 342) of patients receiving heparin for anticoagulation developed SEH after LP. Risk for SEH increased with a traumatic procedure, starting anticoagulation within an hour of the LP, and concomitant aspirin therapy.²⁸ Patients with preexisting coagulopathy were excluded from this study. This study suggests that the risk of SEH in patients on heparin prior to the LP is at least 2%. In a study by Tryba and colleagues, the risk of SEH increased tenfold in patients receiving heparin or aspirin who experienced a traumatic LP.²⁹ As intravenous (IV) heparin has a short duration of action, it should be discontinued for at least 4 hours prior to the LP and the aPTT has normalized.¹⁹ Heparin infusion should not be resumed for at least an hour after an LP is performed.²⁸ The risk for SEH from LP in patients on twice daily subcutaneous heparin for the prophylaxis of deep venous thrombosis is low.³⁰ Nonetheless, it is recommended to discontinue for at least 8 hours prior to neuraxial procedures.¹⁹

LMWH has a half-life that can range between 2 and 6 hours depending on the dose, route of administration, and renal function. The ASRA guidelines recommend discontinuing LMWH 12 hours prior to neuraxial procedures when used at doses intended for deep vein thrombosis prophylaxis and 24 hours when used at doses intended for anticoagulation.¹⁹ Anticoagulation with LMWH should be withheld for 18 to 24 hours after the LP to prevent SEH.²³

Warfarin is associated with a high risk of SEH following an LP. Warfarin should be stopped for 5 days and the INR normalized prior to performing an LP.¹⁹ The administration of vitamin K with fresh frozen plasma (FFP), or the administration of prothrombin complex concentrates (PCCs) is recommended for complete warfarin reversal.

There is currently no study that has evaluated the safety of LP in the setting of anticoagulation with the new direct thrombin inhibitors or factor Xa inhibitors. Little is known about procedural safety when anticoagulated with these medications, although many clinicians assume that the risk of bleeding is increased similarly to warfarin.^{19,20} Duration of action, reversal strategies, and diagnostic testing are complicated and medication specific.

Performance of an LP in patients with hemophilia is safe following 100% factor replacement. In a study by Silverman and colleagues, 30 of 33 patients (91%) with severe factor deficiency had no serious complications with LP after adequate factor replacement.¹⁷ In a review of six articles that evaluated neuraxial procedures in patients with hemophilia, there were no SEHs in 107 procedures on 85 patients, of which 53 of the procedures were diagnostic LPs in the ED. In 105 of the 107 procedures (98%), factor levels were replaced to normal. One case of an SEH with neurologic impairment occurred in a patient with undiagnosed hemophilia.³¹

There is scant literature on the performance of an LP in patients with select platelet disorders, including von Willebrand disease (vWD) and idiopathic thrombocytopenic purpura (ITP). Choi and colleagues evaluated 74 neuraxial procedures (all for obstetrical anesthesia) performed in 72 patients with vWD.³¹ Sixty-four patients (86%) required no treatment secondary to normal vWD indices, whereas 10 patients required treatment with desmopressin (DDAVP), vWF/factor VIII concentrate, or factor VIII alone. No complications were noted. In the same study, there were no complications reported in 326 neuraxial procedures in patients with ITP. Pretreatment with corticosteroids, IV immune globulin, or platelet transfusion

was variable among the reports. No pretreatment was provided in 103 procedures that included a patient with a platelet count of $2 \times 10^9/L$. Based on the results of their study, the authors concluded that it is safe to perform a lumbar puncture without providing platelet transfusion when the platelet count is greater than $50 \times 10^9/L$.

Performing an LP in the setting of thrombocytopenia has been well studied in the pediatric oncology population. In 2000, Howard and colleagues reported on the safety of performing LPs in children with platelet counts greater than $10 \times 10^9/L$ without transfusing platelets. Nine hundred forty-one procedures were performed on patients with platelet counts below $50 \times 10^9/L$ without the development of an SEH. Twenty-nine procedures were performed on patients with platelet counts less than or equal to $10 \times 10^9/L$. No complications were reported, although the study was not powered to determine patient safety. Nonetheless, the authors recommended platelet transfusion for an LP when the platelet count is less than or equal to $10 \times 10^9/L$.³²

A 2010 systematic review by van Veen states that a platelet count greater than or equal to $40 \times 10^9/L$ is safe to perform an LP provided that the platelet count is stable, the patient does not have an acquired or congenital coagulopathy, the platelet function is normal, and the patient is not receiving an antiplatelet or anticoagulant medication. The authors also stated that it may be safe to perform an LP at platelet counts 20 to $40 \times 10^9/L$, however there were insufficient data to recommend safety at this platelet level without transfusion.^{32a} The American Association of Blood Banks recommends prophylactic platelet transfusion for patients having an elective diagnostic LP for a platelet count less than $50 \times 10^9/L$.³³ However, this is a weak recommendation based on very low-quality evidence.

Vascular Access

Patients frequently require central venous access for resuscitation, medication administration, or hemodynamic monitoring. Critically ill patients are sometimes anticoagulated or develop a coagulopathy secondary to their illness. Providers are oftentimes hesitant to perform central venous cannulation in anticoagulated patients or those with a coagulopathy because of the risk of bleeding.

Bleeding complications during central venous catheterization in patients with abnormal hemostasis is relatively low.^{34,35} Arterial puncture is the most common complication associated with central venous catheter insertion, and occurs in 3% of catheters placed in the internal jugular vein and 0.5% of catheters placed in the subclavian vein.³⁶ Numerous studies have demonstrated that central venous cannulation is safe in patients with a coagulopathy or disorder of hemostasis.^{8,33,34,36-38} Emergency reversal of anticoagulation prior to the insertion of a central venous catheter is common practice but does not appear to be evidence-based.^{8,34,35,40} In one study, 76 consecutive patients with various disorders of hemostasis (thrombocytopenia, anticoagulation with heparin, anticoagulation with warfarin, and abnormalities in coagulation assays) received central venous access procedures. Of the 104 procedures, only one patient required an intervention beyond 20 minutes of site compression to control bleeding.³⁴ The authors noted that bleeding problems are uncommon and serious bleeding is rare. Providers should make a case-based clinical decision weighing the risk of hemorrhage versus the risk of thrombosis and fluid overload associated with reversal.

In a 2000 study evaluating the complications of central venous catheter placement in patients with various hemostasis disorders, thrombocytopenia (platelet count less than $50 \times 10^9/L$) was the only significant predictor for bleeding complications.³⁵ However, the authors call into question the utility of platelet transfusion because the complications were easily addressed with compression and suturing. Other studies have also found that a platelet count less than $50 \times 10^9/L$ is an independent risk factor for bleeding.^{34,35,41} Further studies are required to assess the benefit of preprocedural platelet transfusion for central venous catheter insertion.⁴² Platelet transfusion to maintain counts greater than $50 \times 10^9/L$ is recommended in patients with evidence of postprocedural bleeding at catheter insertion site until hemostasis is achieved.⁴³

In 1999, Fisher and colleagues demonstrated a low incidence of major vascular complications in patients with cirrhosis and an elevated INR. Of 658 cannulations, there was one major event (hemothorax) caused by accidental subclavian artery puncture. The mean INR was 2.4 (range 1 to 16) and no attempt was made to reverse coagulopathy prior to the procedure.⁴¹ Similar results were found in two additional studies on coagulopathic patients including patients with liver disease receiving central venous access.^{34,39}

Patients with DIC should have vigorous correction of coagulation abnormalities in conjunction with hematology consultation prior to central venous catheterization when patient stability allows for it.⁴³ Targets for correction include PT less than 1.5 times normal and fibrinogen greater than 1.0 g/L.

Factor replacement is recommended for patients with hemophilia prior to central venous cannulation.^{44,45} The goal of management is to achieve a circulating factor level of 100% prior to the procedure followed by a continuous factor infusion for 2 to 3 days afterwards to prevent serious bleeding complications.

In nonurgent situations IV heparin infusion should be discontinued for 3 hours prior to central venous cannulation.⁴³ In patients receiving therapeutic anticoagulation with subcutaneous LMWH, the recommendation is to wait 18 hours after the last injection before performing nonurgent central venous cannulations.⁴³ Similarly, nonurgent central venous cannulation in patients on warfarin should be withheld until the INR is less than 1.5.⁴³

The use of ultrasound for the placement of central venous catheters is well established and has been shown to increase success rates and decrease complication rates.⁴⁶⁻⁵⁰ The use of ultrasound in patients with disorders of hemostasis is safe and preferred when available.^{46,50} There are no data comparing ultrasound-guided versus traditional approach in the setting of anticoagulation.⁴⁹

In emergency situations site selection for central venous cannulation may improve outcomes. The safest technique in an anticoagulated patient appears to be an ultrasound-guided internal jugular approach. The lower risk of malposition, ease of ultrasound-guided technique, and the ability to manually compress a bleeding vessel in the event of a bleeding complication, makes the internal jugular access approach favored over the subclavian approach.³⁶ Though the subclavian approach is associated with fewer arterial punctures, the provider is unable to manually compress bleeding vessels effectively. The femoral approach is also suitable for emergency central venous access because it is amenable to ultrasound-guided technique, and the provider is able to manually compress a bleeding vessel.

Importantly, femoral venous catheters are less favorable long-term because of an increased risk of infection.

The use of intraosseous access is not contraindicated in anticoagulated patients. The manufacturer of the EZ-IO (Vida-Care, San Antonio, TX) device notes that applying pressure to the site for 1 to 2 minutes controls bleeding after needle removal, but more time may be required for patients on anticoagulant therapy.⁵¹

Patients requiring temporary placement of a hemodialysis catheter for emergency hemodialysis may have an increased risk of complications with central venous access as a result of comorbid conditions leading to anticoagulation or impaired hemostasis, particularly uremia-induced platelet dysfunction. If a patient requires emergency access for hemodialysis, the preferred approach site is the femoral vein because of the lower complication rate. Whereas complication rates are similar to typical central venous catheter placement, inadvertent dilation of the artery or unrecognized arterial puncture with a hemodialysis catheter can lead to massive bleeding. Although there are no data or guideline specifically targeted for the placement of hemodialysis catheters in the setting of anticoagulation, mechanical errors may be complicated by anticoagulation.

Arthrocentesis

Though numerous providers recommend reversing anticoagulation in patients receiving warfarin who require an arthrocentesis, there are little data to support this practice.^{52,53} In the largest study to date, Ahmed and Gertner evaluated the safety of arthrocentesis in patients receiving a VKA medication.¹¹ Among the 456 procedures performed, there were no statistical differences in overall bleeding complications between patients with an INR greater than 2 and those with an INR less than 2. The authors concluded that arthrocentesis can be performed on patients who are anticoagulated without the need for reversal or discontinuation of anticoagulation prior to the procedure. Of note, 103 of the procedures were on patients with an INR greater than 3 and the highest INR was 7.8. In the latest study by Bashir and colleagues, 2084 knee and shoulder joint injections were performed on patients taking warfarin.¹² The mean INR was 2.77 (range 1.7 to 5.5). Eighty-seven percent of the patients had an INR greater than or equal to 2. Nineteen- or 21-gauge needles were used for the arthrocentesis. There were no procedural complications noted in this study, leading the authors to conclude that joint injections are safe in the setting of therapeutic anticoagulation with warfarin. Additional studies have failed to demonstrate a higher risk of bleeding with arthrocentesis in the setting of anticoagulation.⁹⁻¹² There appears to be no difference between the types of joint requiring arthrocentesis. Most studies have included both shoulder and knee joint aspiration.

There is no available literature evaluating the safety of arthrocentesis in patients receiving an antiplatelet agent or a nonvitamin K anticoagulant.

Hemarthrosis is a common presentation for patients with bleeding disorders such as hemophilia. It is typically recommended that patients or parents replace factors to achieve circulating factor activity of 40% to 50% at the first sign of acute bleeding episodes. Arthrocentesis is not always required to make the diagnosis of hemarthrosis in this clinical setting. However, if performing an arthrocentesis in the setting of hemophilia is required, the recommendation is to perform the procedure after appropriate factor replacement.

Spontaneous nontraumatic hemarthrosis is an infrequent complication with supratherapeutic anticoagulation and may even occur within the target therapeutic range.⁵⁴ Routine coagulation studies are recommended if hemarthrosis is suspected in an anticoagulated patient. Temporary discontinuation of anticoagulants is typically recommended as part of treatment of hemarthrosis. If arthrocentesis is required, reversal of anticoagulation is not recommended if the INR is less than 4.5.⁹ Although arthrocentesis can safely be performed in the setting of supratherapeutic anticoagulation as previously mentioned, there are no safety data for the setting of hemarthrosis.¹¹ Clinical judgement should be used to determine the necessity of this procedure.

Paracentesis

Paracentesis is a relatively safe procedure. The frequency of complications such as minor bleeding, or major complications such as abdominal hematoma that require a transfusion is low.⁵⁵ In one report, abdominal hematomas occurred in only 1% of patients despite cirrhosis being a common comorbidity.⁵⁶ There are currently no data to support the routine administration of FFP or platelets prior to paracentesis in patients with mild to moderate coagulopathy (PT or PTT up to twice normal) or thrombocytopenia (platelet count 50 to $99 \times 10^9/L$).^{55,57,58} However, caution should be exercised in patients with severe coagulopathy or DIC.⁵⁵

In a 2009 prospective study evaluating the complication rate of paracentesis in cirrhotic patients, local bleeding occurred in 2.3% of cases and major bleeding requiring a medical or surgical intervention occurred in 1% of cases. Two of the five patients with major bleeding included a major hematoma, whereas three cases involved bleeding into the peritoneal cavity. A nonsignificant trend towards increased risk of complications was seen in patients with a platelet count less than $50 \times 10^9/L$. Therefore, the authors advised caution when performing paracentesis on patients with a platelet count greater than $50 \times 10^9/L$.⁵⁹

In a 2011 retrospective study evaluating the safety of paracentesis in patients with cirrhosis, the authors concluded that the procedure was safe.⁶⁰ Of 209 paracenteses reviewed for the study, 19% were performed on patients with a coagulopathy. The most common complication was local bleeding (3%). One patient experienced an abdominal hematoma, but no further data were given about this patient. The authors concluded that performing a paracentesis in the setting of coagulopathy is safe and the only absolute contraindications are DIC and fibrinolysis.

Although ultrasound-guidance technique has been shown to decrease the risk of bleeding with paracentesis in typical conditions, there are no data demonstrating this benefit in anticoagulated patients.⁶¹

Thoracentesis and Tube Thoracostomy

The major procedural complication associated with thoracentesis is pneumothorax, not bleeding.⁶² Numerous studies have failed to demonstrate an increased risk of bleeding with thoracentesis in the setting of anticoagulation.^{57,63,64}

Additionally, the correction of abnormal coagulation laboratory values prior to the procedure is unlikely to have benefit. In a 2013 retrospective study of 1009 ultrasound-guided thoracenteses, Hibbert and colleagues evaluated patients treated with and without preprocedural transfusion of FFP or platelets for abnormal coagulation profiles.⁶⁴ The authors

found no statistical difference in the bleeding complication rate (overall 0.4%) between those treated with transfusion prior to the procedure and patients not treated with blood products. In this study, the patients who did not receive FFP or platelet transfusions had a mean INR of 1.9 prior to the procedure. Seventy-four patients (14%) who were not treated with a transfusion had a platelet level of less than $50 \times 10^9/L$. There were no bleeding complications seen in the group that did not receive FFP or platelets compared with four bleeding complications that occurred in the group that received transfusions.

When performed under ultrasound guidance, the risk of bleeding is low even when coagulation studies or the platelet count are abnormal.^{61,63–65} However, there are no data available to demonstrate a lower bleeding complication rate of ultrasound-guided technique compared to the traditional approach in anticoagulated patients.

Recent studies have raised concerns about the risk of bleeding when thoracentesis is performed on patients taking clopidogrel. One prospective study of 25 consecutive patients noted a low rate of clinically significant hemorrhage in patients receiving thoracentesis while on clopidogrel, but further studies are required to determine safety. In that study, one patient developed a significant hemothorax requiring blood transfusion and tube thoracostomy.⁶⁶ A 2013 case report also raised similar concerns as a patient on clopidogrel and aspirin developed a hemothorax after chest tube insertion.⁶⁷ However, there are no data to support this recommendation. In fact, two studies failed to demonstrate a high risk for bleeding in patients taking clopidogrel especially when using small bore chest tubes.^{68,69}

In patients with a tension pneumothorax there are no absolute contraindications to tube thoracostomy. In stable patients undergoing chest tube placement, the need for anticoagulation reversal should be considered. Several clinicians have recommended that coagulopathies and platelet defects be corrected prior to tube thoracostomy.^{70,71}

Dental Procedures

Managing postoperative bleeding after a dental procedure can be a challenging task for EPs especially in the setting of anticoagulation. Dental procedures such as extractions are commonly performed without the cessation of anticoagulants. Multiple studies and authors have concluded that the risk of cessation of anticoagulation including antiplatelet therapy is much greater than the risk of significant bleeding with continued anticoagulation for dental procedures.^{72–78} Multiple organizations including the AHA, ACCP, American College of Surgeons, American Dental Association, and The American College of Cardiology all agree that single or dual antiplatelet therapy should not be interrupted for dental procedures. To date there are no clinical trials demonstrating the safety of dental procedures in patients taking NOAC medications. Some have concluded that it appears safe to continue NOAC medications such as dabigatran or rivaroxaban for dental procedures based on management recommendations for warfarin and LMWH.⁷⁹

Bleeding and oozing from a dental procedural site is common after extractions such as wisdom tooth extractions even in the setting of normal coagulation. Patients commonly come to the ED after futile attempts to control the bleeding at home. Simple local therapy such as compression, packing, and vasoconstrictor infiltration is typically sufficient to control bleeding, even in the anticoagulated patient (see Chapter 72). Although none are specific for anticoagulated patients, there

are multiple commercially available products that can be utilized to achieve hemostasis. Thrombin soaked gelatin sponges, oxidized cellulose material, chitosan coated gauze dressing, and topical tranexamic acid have all been described for this purpose.

Patients with hemophilia and vWD have an increased risk of bleeding during and after dental procedures. In addition to utilizing standard therapies, IV or local tranexamic acid and epsilon-aminocaproic acid in patients with hemophilia may also aid in achieving hemostasis, as has been described in a limited number of trials.^{80–82} However, a 2015 Cochrane review was unable to definitively conclude its efficacy.⁸³

Although no studies exist looking specifically at the safety of performing simple oral and dental procedures in the ED such as incision and drainage of a dental abscess, they are likely benign, considering the safety data for more invasive dental procedures such as extraction.

Epistaxis

Epistaxis is a common presenting symptom in the ED and may be complicated by anticoagulant use. Whether the bleeding is the result of excessive anticoagulation, achieving hemostasis may be more difficult than normal clinical scenarios. Evaluation of coagulation parameters (PT, INR, PTT, platelet count, or other anticoagulant-specific laboratory assays) should be routinely ordered for anticoagulated patients presenting with epistaxis. A complete blood count is also suggested for patients with prolonged or severe bleeding with epistaxis.

Anticoagulant reversal is rarely necessary unless laboratory findings reveal a markedly abnormal degree of anticoagulation or the patient has severe, symptomatic, or life-threatening bleeding. Specific factor replacement is necessary for patients with hemophilia and severe bleeding.

A variety of topical hemostatic agents are available and can be applied to the nasal cavity for the management of epistaxis in the anticoagulated patient when standard therapy is not adequate. Cellulose, gelatin, and thrombin compounds can be placed directly on the bleeding site to promote clot formation even in fully anticoagulated patients. Both topical and IV use of tranexamic acid has also been described in the management of epistaxis, but there is a lack of evidence-based data supporting its efficacy.^{84–86} Recently a case report described the successful use of topical tranexamic acid in the management of rivaroxaban associated epistaxis after failure with a thrombin-soaked inflated nasal tampon.⁸⁷

Nasogastric Tube Insertion

There is a lack of information available about the safety of placing a nasogastric tube (NGT) in the setting of anticoagulation. Severe coagulopathy is a commonly stated relative contraindication of NGT passage for risk of epistaxis without reference to evidence-based data.

Similarly, the often stated NGT placement contraindication of esophageal varices is unproven. Although mechanical or chemical irritation is thought to cause esophageal varices rupture and bleeding, there are no evidence-based data that stratifies the risk of NGT placement in this clinical setting. In an anesthesia study of patients undergoing hepatic transplantation with esophageal varices, 0 of 75 patients developed bleeding after NGT placement.⁸⁸ This further calls into question the link between NGT placement and causation of bleeding esophageal varices. Additional research is required to prove or disprove this link.

Thrombocytopenia is a common finding in cirrhosis and is a poor indicator for risk of future gastrointestinal hemorrhage.⁸⁹ Furthermore, routine coagulation assays are not reliable indicators of coagulation status in patients with cirrhosis.⁸⁹ Whereas platelet transfusion is commonly recommended prior to endoscopy for a platelet count of less than $30 \times 10^9/L$, there is no analogous recommendation for NGT insertion.⁹⁰

Labor and Delivery

Delivery of a newborn in the ED is a relatively rare event. Postpartum bleeding and hemorrhage is a complication exacerbated by maternal factors such as anticoagulation and bleeding disorders.

Pregnant patients diagnosed with venous thromboembolism are typically treated with LMWH. In the final weeks of pregnancy obstetricians occasionally switch patients to unfractionated heparin to reduce time to normalization of coagulation studies when labor begins. However, fully anticoagulated patients may present with precipitous labor and develop postpartum hemorrhage. Reversal of anticoagulation may be necessary in the event of refractory bleeding. There is no recommendation for prophylactic reversal of anticoagulation for delivery.⁹¹

Patients with vWD are at increased risk for postpartum hemorrhage. These patients have a higher risk of delayed postpartum hemorrhage reported up to 2 to 3 weeks after delivery. According to case reports, postpartum hemorrhage may still occur despite prophylaxis with factor VIII, cryoprecipitate, FFP, and DDAVP. Expert opinion recommends that a von Willebrand factor activity of greater than or equal to 50 IU/dL should be achieved before delivery and maintained for at least 3 to 5 days afterward. Prophylaxis with DDAVP or von Willebrand factor concentrate should be given prior to childbirth if time permits.⁹² However, there are no randomized trials that have studied DDAVP's efficacy to prevent or treat postpartum hemorrhage.⁹³

Although a rare occurrence because of its X-linked nature, replacement of factors is recommended for pregnant women with severe hemophilia A or B in labor. Risk for bleeding begins when levels are below 30% of normal. Risk increases with severity of disease especially those with less than 1% normal factor activity.⁹⁴

Wound Management

Control of Hemorrhage

Hemostasis is an essential step in wound management. Inadequate hemostasis can lead to the formation of a hematoma within a closed wound, which may cause dehiscence of wound edges, impaired healing, and increased risk for wound infection. Anticoagulated patients may come to the ED for prolonged or severe episodes of bleeding from an acute traumatic wound. Most bleeding wounds are effectively managed with routine application of direct pressure and elevation. However, anticoagulants may impair the integral mechanisms of hemostasis and prevent adequate spontaneous hemostasis.

There are multiple techniques that can be utilized to control a bleeding wound including compression, vessel crushing,

ligation, electrocautery, or application of a vasoconstrictor or hemostatic agent. These traditional techniques are not specific to anticoagulated patients, but they may be useful in achieving hemostasis. There are a few topical hemostatic agents that have been shown effective in the setting of anticoagulation.

Chitosan is a complex carbohydrate derived from chitin that interacts with platelets and red blood cells to form a gel-like clot independent from coagulation factors. In a heparinized swine model, Millner showed chitosan granules (Omni-Stat, Medtrade Products Ltd., Crewe, United Kingdom) and dressings (Celox Gauze, Medtrade) were both efficacious in providing hemostasis over plain gauze compression.⁹⁵ The long-term stability of the clot is not well-established and therefore these products are used as temporary management if definitive therapy such as surgical intervention is required. Chitosan-based dressings (Hemcon, Tricol Biomedical, Portland, OR) have also been used externally for hemostasis in pediatric patients with bleeding tendencies from congenital or acquired bleeding disorders.⁹⁶

Topical thrombin has also shown efficacy as a topical hemostatic agent in anticoagulated patients, in particular heparin and clopidogrel therapy.^{97,98} These commercially available topical thrombin products aid in the production of fibrin in one of the final steps of the coagulation pathway to create a stable clot.

IV tranexamic acid has been shown to be efficacious in trauma patients especially when given early after injury.^{99,100} However, anticoagulated patients were not included in the study. The use of topical tranexamic acid for the control of bleeding has been promising in many clinical scenarios but remains unproven especially in the setting of anticoagulation.

Incision and Drainage

There is no literature reporting complications in anticoagulated patients who undergo incision and drainage. Although bleeding is a risk with incision and drainage, local therapy alone is typically sufficient to provide hemostasis. EPs should make a case-based clinical decision weighing the risk of hemorrhage for patients requiring incision and drainage.

SUMMARY

Procedures in the setting of anticoagulation present a unique complexity in the ED. The EP should be mindful of potential bleeding complications and should be prepared to identify and treat these events. Reversal of anticoagulation is not always necessary prior to performing a procedure and the EP should be attentive to the risk of thrombosis. In some instances, the risk-benefit ratio may favor delaying a procedure until the patient's coagulation status returns to normal range with time, or the use of medications or blood products. Lastly, emergency procedures to correct an imminent life-threatening life-saving condition should never be withheld in the setting of anticoagulation.

Commonly Used Formulas and Calculations

Matthew Veltkamp, Eric D. Katz, and Brent E. Ruoff

INTRODUCTION

This appendix presents a list of calculations commonly used by emergency physicians. It is not all-inclusive and purposely does not include decision tools or scales that do not require algebraic calculations. Many of these equations can be found in online calculators on websites such as <https://www.mdcalc.com> or <http://reference.medscape.com/guide/medical-calculators>.

ENGLISH-TO-METRIC CONVERSIONS

Patients frequently express common figures such as weight, temperature, and volume in standard measurements. Please see [Table A.1](#) for conversion factors and simple examples.

MEAN ARTERIAL PRESSURE

Calculation of mean arterial pressure (MAP) provides a weighted average of systolic blood pressure (SBP) and diastolic blood pressure (DBP). It is a determination of tissue perfusion pressure and is normally 70 to 100 mm Hg in adults. To determine MAP:

$$\text{MAP} = [\text{SBP} + (2 \times \text{DBP})] / 3$$

Example: A hypertensive emergency is diagnosed in an elderly, hypertensive patient. Current recommendations are to reduce MAP by 10% to 20% in the first hour. His blood pressure is 240/120. To calculate the current MAP,

$$\text{MAP} = [240 + (2 \times 120)] / 3 = 160 \text{ mm Hg}$$

QT AND QTc INTERVALS

The QT interval on the electrocardiogram (ECG) represents the period of ventricular electrical activity from activation to repolarization. The most important determinant of the QT interval is the heart rate. As the heart rate increases, the QT interval shortens. Many ECG machines calculate this; however, the presence of U waves or other ECG abnormalities can result in inappropriate readings. To calculate the rate-corrected QT interval (QTc) using Bazett's formula, divide the QT interval by the square root of the R-R interval (the interval between the R wave on two consecutive QRS complexes). The R-R interval may be measured from the ECG or calculated as 60 divided by the heart rate (in beats/min). The interval is represented in seconds or milliseconds:

$$\text{QTc} = \text{QT} / \sqrt{(\text{R-R})}$$

The QTc is normally less than 0.46 second in men and 0.44 second in women. This may be calculated online at: <http://www.medical-calculator.nl/calculator/QTc/>.

The list of drugs that can cause QTc prolongation is quite lengthy. The clinical significance of QTc prolongation is often unclear. The following Internet websites offer up-to-date information on this ever-changing topic:

<https://crediblemeds.org/>
<http://www.ncbi.nlm.nih.gov/pmc/articles/PMC1767957/>.

[Table A.2](#) shows the normal range of the QT interval in adults.

Example: A 21-year-old man ingested a large quantity of amitriptyline (tricyclic antidepressant) tablets. His ECG revealed a QT interval of 0.37 second and a heart rate of 120 beats/min. The QTc is calculated as:

$$\text{R-R interval} = 60 / 120 = 0.50$$

$$\text{QTc} = 0.37 / \sqrt{0.5} = 0.523 = 523 \text{ msec}$$

The patient's QTc is significantly prolonged for his heart rate and indicates significant cardiac effects from overdose of a tricyclic antidepressant.

PREDICTED PEAK EXPIRATORY FLOW RATE

The peak expiratory flow rate (PEFR), measured in liters per minute, is a useful means of assessing airway obstruction. It is measured by having a patient exhale maximally through a peak-flow meter. Normal values range from 350 to 600 L/min. Comparison between the initial and posttreatment PEFR in patients with exacerbations of asthma helps determine the degree of severity. Patients with an initial PEFR of less than 20% of predicted or with a subsequent value of less than 60% of predicted after initial therapy may require further evaluation, treatment, or both. Many patients monitor PEFR on themselves and are able to state a personal best, which is the preferred standard for that individual. Other patients may be monitored with an estimated PEFR. Estimations are based primarily on a patient's gender, age, and height. Although graphs and tables are available to provide values across a range of ages and heights, the PEFR can also be approximated by using the following formulas:

$$\text{Adults: PEFR} = 13 \times (\text{Height (in)} - 40) + 110$$

Female children/adolescents:

$$\text{PEFR} = \text{Height (m)} \times 5.5 - \text{Age} \times 0.03 - 1.11$$

Male children/adolescents:

$$\text{PEFR} = \text{Height (m)} \times 6.14 - \text{Age} \times 10.043 + 0.15$$

These may also be found online in many places including: <http://www.mdcalc.com/estimatedexpected-peak-expiratory-flow-peak-flow/>.

ENDOTRACHEAL TUBE SIZE

Adults

Select the largest-diameter endotracheal tube (ETT) that can be tolerated for adults. A 7.5-mm cuffed ETT is well tolerated

TABLE A.1 Standard-to-Metric Calculations

Fahrenheit to Celsius $^{\circ}\text{C} = (^{\circ}\text{F} - 32)/1.8$	A patient's temperature is 100.4°F $(100.4^{\circ}\text{F} - 32)/1.8 = 38^{\circ}\text{C}$
Pounds to kilograms $\text{kg} = \text{lbs}/2.2$	A patient reports his weight to be 154 lb $154 \text{ lb}/2.2 = 70 \text{ kg}$
Inches to centimeters $\text{cm} = \text{inches} \times 2.54$	The patient's height is 72 inches $72 \text{ inches} \times 2.54 = 182.9 \text{ cm}$
Fluid ounces to milliliters $\text{mL} = \text{oz} \times 30$	The child drinks 4 oz of formula at a sitting $4 \text{ oz} \times 30 = 120 \text{ mL}$

TABLE A.2 Normal Range of the QT Interval in Adults

HEART RATE (beats/min)	NORMAL QT RANGE (sec)
40	0.42–0.53
50	0.37–0.48
60	0.34–0.44
70	0.31–0.41
80	0.29–0.38
90	0.28–0.36
100	0.27–0.34
110	0.25–0.32
120	0.24–0.31
130	0.23–0.30
140	0.22–0.29
150	0.21–0.28

by most adult female patients. An 8.0-mm cuffed ETT is well tolerated by most adult male patients.

Pediatrics

An uncuffed ETT should be used for children younger than 8 years. A number of techniques are available for estimating the appropriate size of ETT in children. Commonly used formulas for estimating tube size and depth of insertion use age in years and are as follows:

$$\text{ETT size} = (\text{Age} + 16)/4 \text{ or } (\text{Age}/4) + 4$$

To estimate depth of insertion for a child older than 2 years:

$$\text{Depth of insertion} = 3 \times \text{Internal diameter of the ETT}$$

VENTILATOR SETTINGS

The recommended initial ventilator settings follow. Adjustments in these ventilator settings may be made according to the patient's clinical situation:

$$\text{Tidal volume (V}_T) = 6 - 12 \text{ mL/kg}$$

V_T is often based on ideal body weight, and there is greater recognition that a lower V_T may be beneficial, such as 5 to 10 mL/kg. (Adjust V_T to limit inflation or plateau pressures to 30 cm H_2O or lower. Lower tidal volumes are recommended to limit ventilator-induced lung injury.)

Rate = 10 to 12 breaths/min for adults, 16 to 20 breaths/min for children, and 20 to 30 breaths/min for infants.

FiO_2 (fraction of inspired oxygen) = 50% to 100% initially; reduce FiO_2 as quickly as possible to avoid oxygen toxicity.

Inspiratory-to-expiratory (I/E) ratio = 1 : 2. To allow complete exhalation, the I/E ratio should be at least 1 : 2.

$$\text{Minute ventilation (}\dot{V}_E) = \text{Rate} \times V_T$$

\dot{V}_E will vary with the patient's mass and disease process; the normal adult range is approximately 7 to 10 L/min.

Example: A 6-year-old girl with asthma has respiratory distress and altered mental status and requires endotracheal intubation. Her weight is 20 kg. To prepare for intubation and mechanical ventilation, use the following equipment and settings:

$$\text{ETT size (mm): } (6 + 16)/4 = 5.5\text{-mm ETT (uncuffed).}$$

$$\text{Depth of insertion: } 3 \times 5.5 = 16.5 \text{ cm.}$$

$$V_T = 12 \text{ mL/kg} \times 20 \text{ kg} = 240 \text{ mL.}$$

$$\text{Respiratory rate} = 16 \text{ breaths/min.}$$

$$\text{FiO}_2 = 100\%.$$

$$\text{I/E ratio} = 1 : 2.$$

IDEAL BODY WEIGHT

Ideal body weight (IBW) is used in many applications including mechanical ventilator settings, drug dosing, and renal function measurement. Many equations have been described but the Devine formula is the most widely used. This formula, however, cannot be used for patients less than 5 feet (60 in) tall.

$$\text{IBW (male)} = 50 \text{ kg} + [2.3 \times (\text{height (in)} - 60)]$$

$$\text{IBW (female)} = 45.5 \text{ kg} + [2.3 \times (\text{height (in)} - 60)]$$

Calculate online at: <http://www.mdcalc.com/ideal-body-weight/>.

Example: A 55-year-old female presents with an asthma exacerbation and is intubated. She has a weight of 112 kg and body mass index of 40 and so IBW is used in calculating tidal volume. Her height is 66 inches.

$$\text{IBW} = 45.5 \text{ kg} + [2.3 \times (66 \text{ in} - 60)] = 59.3 \text{ kg}$$

ABSOLUTE NEUTROPHIL COUNT

The absolute neutrophil count (ANC) is the total number of neutrophils in the blood, both mature and immature. The value represents the actual number of neutrophils as compared to a percentage of white blood cells (WBCs). It can be an important measure in an immunocompromised patient as it can help to assess a patient's risk for developing opportunistic infections and guide treatment. Immunocompromised patients who are neutropenic and present with fever are at high risk of developing sepsis. It is calculated as:

$$\text{ANC} = [(\% \text{ neutrophils} + \% \text{ bands})/100] \times \text{WBC count}$$

Normal: > 1500 cells/ μL .

Mild neutropenia: 1000 to 1500 cells/ μL .

Moderate neutropenia: 500 to 1000 cells/ μL .

Severe neutropenia: < 500 cells/ μL .

WHITE BLOOD CELL CORRECTION IN CEREBROSPINAL FLUID

When performing a lumbar puncture on a patient to evaluate for meningitis, the number of WBCs in the cerebrospinal fluid (CSF) is an important value for diagnosis. However, a traumatic lumbar puncture can falsely elevate this value. A formula using the WBCs and red blood cells (RBCs) in CSF and in blood can correct the WBCs in CSF. The normal value for WBCs and RBCs in CSF is < 5 cells/ μL . All values are in cells/ μL except RBCs in blood, which is cells $\times 10^6/\mu\text{L}$.

$$\begin{aligned} \text{Adjusted WBC}_{\text{CSF}} \\ = \text{WBC}_{\text{CSF}} - [(\text{WBC}_{\text{blood}} \times \text{RBC}_{\text{CSF}}) / (\text{RBC}_{\text{blood}} \times 10^6)] \end{aligned}$$

Example: A 25-year-old male presents with fever, sore throat, and headache. Meningitis is suspected. His blood shows elevated WBC at 15,000 cells/ μL . A lumbar puncture (LP) is completed and results show elevated WBCs of 25 cells/ μL . The rest of his CSF values are unremarkable. His RBC in blood is $5 \times 10^6/\mu\text{L}$.

$$\text{Adjusted WBC in CSF} = 25 - [(15,000 \times 7000) / (5 \times 10^6)]$$

$$\text{Adjusted WBC in CSF} = 4 \text{ cells}/\mu\text{L}$$

His WBCs in CSF are actually within normal range and the elevation is likely due to a traumatic LP.

RENAL FUNCTION

Creatinine clearance (Cr_{Cl}) occasionally needs to be calculated by emergency physicians to risk-stratify patients undergoing imaging studies requiring intravenous (IV) contrast material, as well as to determine the severity of renal failure in patients without a known baseline. Cr_{Cl} is best calculated from a collection of urine over a 24-hour period. However, if the patient's Cr_{Cl} is in steady state (i.e., without recent change), it is possible to estimate Cr_{Cl} by using a formula that incorporates serum creatinine (S_{Cr}) in mg/dL, lean body weight (LBW) in kg, age in years, and gender:

$$\text{Cr}_{\text{Cl}} (\text{men}) = [(140 - \text{Age}) \times (\text{LBW})] / [72 \times S_{\text{Cr}}]$$

$$\text{Cr}_{\text{Cl}} (\text{women}) = 0.85 \times [(140 - \text{Age}) \times \text{LBW}] / [72 \times S_{\text{Cr}}]$$

Normal values: 74 to 160 mL/min.

Mild renal impairment: 40 to 60 mL/min.

Moderate renal impairment: 15 to 40 mL/min.

Severe renal impairment: < 15 mL/min (indication for renal dialysis).

The following examples illustrate the importance of calculating Cr_{Cl} :

Example 1: A 71-year-old woman has upper abdominal tenderness. A computed tomography (CT) scan is planned, but the clinician is concerned about the risk for contrast-induced nephropathy. The patient's S_{Cr} is 1.4 mg/dL and she weighs 55 kg. To calculate her Cr_{Cl} :

$$\begin{aligned} \text{Cr}_{\text{Cl}} (\text{women}) &= 0.85 \times [(140 - 71) \times (55 \text{ kg})] / (72 \times 1.4) \\ &= 32.0 \text{ mL}/\text{min} \end{aligned}$$

The patient has moderate renal impairment.

Example 2: A 21-year-old man has right lower quadrant tenderness. A CT scan is planned, but the radiologist is concerned about the risk for contrast-induced nephropathy. The patient's S_{Cr} is 1.4 mg/dL, and he has an LBW of 100 kg. To calculate his Cr_{Cl} :

$$\text{Cr}_{\text{Cl}} (\text{men}) = (140 - 21) \times (100 \text{ kg}) / (72 \times 1.4) = 118 \text{ mL}/\text{min}$$

The patient has adequate Cr_{Cl} . Note that despite an identical serum creatinine level, the second patient has normal renal function, whereas the first has renal insufficiency.

FRACTIONAL EXCRETION OF SODIUM

Acute kidney injury (AKI) can have many etiologies. Calculating the fractional excretion of sodium (FE_{Na}) can help to differentiate prerenal disease, intrinsic renal disease, and postrenal disease. The calculation measures the percent of filtered sodium that is excreted in the urine. Low values of FE_{Na} , less than 1%, in the setting of AKI suggests a prerenal etiology as the kidneys are appropriately retaining sodium in response to decreased perfusion. Higher values of FE_{Na} , greater than 2%, suggests an intrinsic etiology of AKI. The higher values can be caused by either salt wasting by damaged nephrons or an appropriate response by remaining nephrons to volume expansion. FE_{Na} greater than 4% can be suggestive of a postrenal cause of AKI. To calculate FE_{Na} a serum creatinine (S_{Cr}), serum sodium (S_{Na}), urine creatinine (U_{Cr}), and urine sodium (U_{Na}) need to be measured.

$$\text{FE}_{\text{Na}} = (S_{\text{Cr}} \times U_{\text{Na}}) / (S_{\text{Na}} \times U_{\text{Cr}}) \times 100$$

Example: A 65-year-old previously healthy male had a syncopal episode while working outside on a hot day. He was found to have AKI with an S_{Cr} of 2.0 mg/dL. His S_{Na} is 150 mEq/L, U_{Na} is 18 mEq/L, and U_{Cr} is 30 mg/dL.

$$\text{FE}_{\text{Na}} = (2.0 \times 18) / (150 \times 30) \times 100$$

$$\text{FE}_{\text{Na}} = 0.8\%$$

The patient's FE_{Na} is less than 1% which suggests a prerenal cause, likely hypovolemia.

SODIUM DEFICIT

The following formula may be used to calculate the Na⁺ deficit in hyponatremia:

$$\text{Na}^+ \text{ deficit (men)} = 60\% \times \text{Weight (kg)} \\ \times (\text{Desired Na}^+ - \text{Measured Na}^+)$$

$$\text{Na}^+ \text{ deficit (women)} = 50\% \times \text{Weight (kg)} \\ \times (\text{Desired Na}^+ - \text{Measured Na}^+)$$

Symptoms related to hyponatremia are variable, and the severity of symptoms should guide therapy. Sodium replacement is most commonly given as isotonic saline, which contains 154 mmol of Na⁺/L. Patients who are severely symptomatic may require 3% saline solution, which contains 513 mmol of Na⁺/L. The volume of solution needed to replace the Na⁺ deficit (in mmol) can be calculated by using the concentrations in the saline solutions listed earlier.

Example: A young man is seizing on arrival at the emergency department (ED). He is known to have schizophrenia and compulsive water drinking. His Na⁺ is 116 mmol/L. He weighs 65 kg. To determine his sodium deficit:

$$\text{Na}^+ \text{ deficit} = 0.6 \times 65 \text{ kg} \times (140 - 116) = 936 \text{ mmol of Na}^+$$

This amount of Na⁺ deficit can be corrected by administering approximately 6 L of isotonic saline or 1.8 L of hypertonic saline. Na⁺ should be replaced very slowly to avoid the possibility of inducing central pontine myelinolysis, which results from overaggressive correction of sodium. Most recommendations state a rise in serum sodium of 4 to 6 mmol/L in a 24-hour period is ideal.

Calculate sodium deficit and replacement rate online: <http://www.mdcalc.com/sodium-correction-rate-in-hyponatremia/>.

SODIUM CORRECTION

Factitious hyponatremia may be due to hyperglycemia. In this hyperosmolar state, glucose tends to stay in extracellular fluid and draws water out of cells into extracellular fluid. Serum sodium is decreased by approximately 1.6 mmol/L for each 100 mg/dL of excess glucose. To calculate the corrected sodium:

$$\text{Corrected Na}^+ \text{ (mmol/L)} = \text{Measured Na}^+ \text{ (mmol/L)} \\ + [0.016 \times (\text{Glucose (mg/dL)} - 100)]$$

Many laboratories automatically make this adjustment, so it is important to check with your laboratory to determine the necessity for this correction.

Example: An obtunded elderly man appears dehydrated. His sodium level is 126 mmol/L and his glucose is 1000 mg/dL.

$$\text{Corrected Na}^+ = 126 \text{ mmol/L} [0.016 \times (1000 - 100)] \\ = 126 + 14.4 = 140.4 \text{ mmol/L}$$

His corrected Na⁺ suggests that he has factitious hyponatremia because of hyperglycemia.

HYPERNATREMIA

Elevation of the serum sodium concentration is proportionate to the free water deficit when volume is depleted. Because

60% of the adult body is water, the total-body free water deficit is calculated by using measured Na⁺, desired Na⁺, and body weight in kilograms. To calculate the free water deficit:

$$\text{Ideal total body water (TBW)} = 60\% \times \text{weight (kg)}$$

$$\text{TBW deficit} \\ = [(\text{Measured Na}^+ - \text{Normal Na}^+) / \text{Normal Na}^+] \times \text{TBW}$$

(Assume normal Na⁺ to be 140 mmol/L.)

Example: An elderly man is brought to the ED in a coma. He has severe dehydration, his IBW is 70 kg, and his serum Na⁺ level is 165 mmol/L. To determine his free water deficit:

$$\text{Ideal TBW} = 0.6 \times 70 \text{ kg} = 42 \text{ L}$$

$$\text{Free water deficit} = [(165 - 140) / 140] \times 42 = 7.5 \text{ L}$$

Fluid correction for hypernatremia should take place over a 48- to 72-hour period to avoid the potential for cerebral edema.

Calculate free water deficit and fluid rate online: <http://www.mdcalc.com/sodium.html>.

POTASSIUM

Serum potassium (K⁺) levels change with acid-base status. In acidotic states, K⁺ moves out of cells as H⁺ moves in, thus raising serum K⁺ levels. In alkalotic states, K⁺ moves into cells as H⁺ moves out, thus lowering serum K⁺ levels. The change in K⁺ varies inversely with pH at the following rates:

The serum K⁺ concentration increases 0.6 mmol/L for each 0.1-unit decrease in pH.

The serum K⁺ concentration decreases 0.6 mmol/L for each 0.1-unit increase in pH.

CALCIUM

Approximately 50% of serum calcium is bound to serum proteins (primarily albumin), 40% is in the free ionized state (the physiologically active form), and 10% is mixed with serum anions (phosphate, bicarbonate, citrate, and lactate). For this reason, serum calcium is lowered approximately 0.8 mg/dL for every decrease in albumin of 1 g/dL. To correct for decreased albumin (at levels < 4 g/dL), the following formula can be used:

$$\text{Corrected Ca}^{2+} \text{ (mg/dL)} = \text{Serum Ca}^{2+} \text{ (mg/dL)} \\ + (0.8 \times [4.0 - \text{serum albumin \{g/dL\}}])$$

Example: A malnourished man has a serum calcium level of 7.5 mg/dL and a serum albumin level of 2 g/dL. To calculate his corrected calcium level:

$$\text{Corrected Ca}^{2+} \text{ (mg/dL)} = 7.5 \text{ mg/dL} \\ + [0.8 \times (4.0 - 2.0 \text{ g/dL})] = 9.1$$

MAINTENANCE IV FLUID RATE

To calculate maintenance IV fluids for a pediatric patient, use the following formula:

4 mL/kg per hr for the first 10 kg, plus
2 mL/kg per hr for the second 10 kg, plus
1 mL/kg per hr for each further kg.

Example: A 5-year-old boy weighs 19 kg and requires maintenance IV fluids. To calculate his IV fluid rate:

4 mL/kg per hr for the first 10 kg: $4 \times 10 \text{ kg} = 40 \text{ mL/hr}$, plus
 2 mL/kg per hr for the second 10 kg: $2 \times 9 \text{ kg} = 18 \text{ mL/hr}$
 $40 \text{ mL/hr} + 18 \text{ mL/hr} = 58 \text{ mL/hr}$.

FLUID RESUSCITATION OF BURNED PATIENTS

Various formulas for IV fluid resuscitation in patients with burns have been recommended. The Parkland formula is commonly used and is calculated as follows:

$$\text{Replacement fluid} = 4 \text{ mL} \times (\text{Weight [kg]}) \times (\% \text{ Body surface area [BSA] burned}).$$

Count only second- and third-degree burns in calculating BSA.

The total volume should be administered in the first 24 hours with half the fluid given in the first 8 hours and the remaining half in the next 16 hours. Clinical parameters, including urine output, vital signs, and central venous pressure or pulmonary capillary wedge pressure, should be monitored carefully to assess the adequacy of resuscitation.

Example: A 65-kg woman has second- and third-degree burns covering 35% of her BSA. To determine her anticipated 24-hour fluid resuscitation needs:

$$\text{Replacement fluid} = 4 \text{ mL} \times 65 \times 0.35 = 9100 \text{ mL}$$

$$\text{Half is given in the first 8 hours: } 9100/2 = 4550 \text{ mL}$$

$$4550 \text{ mL}/8 \text{ hr} = 569 \text{ mL/hr for the first 8 hours}$$

$$\text{Half is given in the second 16 hours: } 284 \text{ mL/hr}$$

Do not forget to add maintenance fluid rates to the results of the Parkland formula. Most online calculators do not include this!

ANION GAP

The anion gap (AG) is an estimate of the amount of unmeasured negatively charged ions in serum that are not bicarbonate (HCO_3^-) and chloride (Cl^-). The AG is calculated by subtracting the sum of HCO_3^- and Cl^- values from sodium (Na^+), which

is the major positive charge in serum. An elevated AG usually means that there is some unmeasured anion, toxin, or organic acid in the blood. **Box A.1** lists many substances that can cause an AG acidosis. The AG is normally 8 to 12 mmol/L:

$$\text{AG} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = 8 - 12 \text{ mmol/L}$$

Example: A suicidal young male drank an unknown amount of antifreeze. His electrolyte levels are Na^+ , 144; K^+ , 3.1; Cl^- , 108; and HCO_3^- , 14. The AG is calculated as follows:

$\text{AG} = [144 - (108 + 14)] = 22 \text{ mmol/L}$. His AG is abnormally elevated, presumably because of ingestion of ethylene glycol.

OSMOLAL GAP

Serum osmolality can be measured in the laboratory by freezing point depression. The measured serum osmolality is usually higher than the calculated osmolality, and the difference is termed the *osmolal gap* (OG). The OG is normally 5 to 10 mOsm/kg. If there is a higher gap, the osmols unaccounted for may represent methanol, ethylene glycol, isopropyl alcohol, or other solutes (**Table A.3**). Large doses of medications such as lorazepam contain propylene glycol diluent that can raise the OG. To calculate serum osmolality (Osm_{calc}) and the OG:

$$\text{Osm}_{\text{calc}} = 2 \times \text{Na}^+ + [\text{BUN (mg/dL)}/2.8] + [\text{Glucose (mg/dL)}/18]$$

$$\text{OG} = \text{Osm}_{\text{meas}} - \text{Osm}_{\text{calc}}$$

where BUN is the blood urea nitrogen.

BOX A.1 Substances Associated with a High Anion Gap

Aspirin	Lactate (multiple causes)
Methanol, metformin	Ethylene glycol/propylene glycol (diluent)
Uremia	Carbon monoxide, cyanide
Diabetic ketoacidosis	Alcoholic ketoacidosis
Paraldehyde, phenformin	Toluene
Isoniazid, iron	

*Follows the mnemonic A MUDPILE CAT.

TABLE A.3 Effect of Some Solutes on Serum Osmolality

EACH mg/dL OF	INCREASES SERUM mOsm/kg BY	FOR EACH SERUM mOsm/kg INCREASE DUE TO	THE CORRESPONDING mg/dL CHANGE IS (= Mol Wt/10)
Methanol	0.31	Methanol	3.2
Ethanol	0.22	Ethanol	4.6
Acetone	0.17	Acetone	5.8
Isopropyl alcohol	0.17	Isopropyl alcohol	6.0
Ethylene glycol	0.16	Ethylene glycol	6.2
Glycerol	0.11	Glycerol	9.2
Mannitol	0.05	Mannitol	18.2

Modified from Kullig K, Duffy JP, Linden CH, et al: Toxic effects of methanol, ethylene glycol and isopropyl alcohol, *Top Emerg Med* 6(2):16, 1984.

Calculate online: https://www.healthcare.uiowa.edu/path_handbook/Appendix/Calculators/OsmoGap.html.

Table A.3 shows the effect of some solutes on serum osmolality. The increase in osmolality caused by a solute can be calculated by dividing its serum concentration by the tabulated value.

Example: An intoxicated patient has serum chemistry results as follows: Na⁺, 142; K⁺, 4.5; Cl⁻, 100; HCO₃⁻, 22; glucose, 90; BUN, 14. His ethanol level is 240 mg/dL and his measured serum osmolality is 354. You want to know whether he has ingested other osmotically active substances. His calculated serum osmolality is:

$$\text{Osm}_{\text{calc}} = 2 \times 142 + (14/2.8) + (90/18) = 294$$

To evaluate for the effect of ethanol on osmolality, refer to Table A.3 and add the alcohol level divided by 4.6:

$$240/4.6 = 52$$

$$\text{Osm}_{\text{calc}} = 294 + 52 = 346$$

Finally, calculate the OG:

$$\text{OG} = \text{Osm}_{\text{meas}} - \text{Osm}_{\text{calc}} = 354 - 346 = 8$$

His elevated osmolality is explained by the ethanol.

ACID-BASE BALANCE

A thorough understanding of blood gas interpretations is crucial for critically ill patients but is beyond the reach of this section. Unfortunately, most online calculators either struggle with mixed acid-base disorders, or cannot handle different units (kPa vs. mm Hg).

By using the combination of an arterial blood gas (ABG) sample and serum electrolyte levels, a patient's acid-base status can be evaluated. A single acid-base disorder may be present as a primary disorder (respiratory acidosis, respiratory alkalosis, metabolic acidosis, or metabolic alkalosis), or several disorders may be present at the same time. When an acid-base disorder is present, the body will try to compensate to preserve the pH as close to normal as possible. The compensatory responses in relation to the primary disorder are as follows:

Primary Disorder	Compensatory Response
Metabolic acidosis	Increased ventilation
Metabolic alkalosis	Decreased ventilation
Respiratory acidosis	Increased renal reabsorption of HCO ₃ ⁻ in the proximal tubule Increased renal excretion of H ⁺ in the distal tubule
Respiratory alkalosis	Decreased renal reabsorption of HCO ₃ ⁻ in the proximal tubule Decreased renal excretion of H ⁺ in the distal tubule

When interpreting acid-base disorders, the following basic steps are suggested:

Knowledge of normal values:

Normal serum pH = 7.40

Normal partial pressure of carbon dioxide (Pco₂) = 40 mm Hg

First, determine the patient's pH status. Acid-base changes are either metabolic or respiratory. Simple disturbances are

TABLE A.4 Acidosis and Compensatory Response

PRIMARY DISTURBANCE	PREDICTED COMPENSATORY RESPONSE
Metabolic acidosis	↓ in Pco ₂ = 1.3 × ↓ in HCO ₃ ⁻
Metabolic alkalosis	↑ in Pco ₂ = 0.6 × ↑ in HCO ₃ ⁻
Respiratory acidosis	<i>Acute:</i> For every Pco ₂ ↑ of 10 mm Hg, ↑ by 1 mmol/L <i>Chronic:</i> For every Pco ₂ ↑ of 10 mm Hg, HCO ₃ ⁻ ↑ by 4 mmol/L <i>Acute:</i> For every Pco ₂ ↓ of 10 mm Hg, HCO ₃ ⁻ ↓ by 2 mmol/L <i>Chronic:</i> For every Pco ₂ ↓ of 10 mm Hg, HCO ₃ ⁻ ↓ by 5 mmol/L

Modified from Rutecki GW, Whittier FC: Acid-base interpretation, *Consultant* 31:44-59, 1991.

categorized by examining pH, Pco₂, and HCO₃⁻ (Table A.4). If pH is less than normal (< 7.35), the patient is acidemic. If pH is above normal (> 7.45), the patient is alkalemic. If the patient is acidemic and Pco₂ is elevated (> 45 mm Hg) as a primary disorder, respiratory acidosis is present. If the patient is alkalemic and Pco₂ is decreased (< 35 mm Hg) as a primary disorder, respiratory alkalosis is present. If the patient is acidemic and the arterial HCO₃⁻ level is less than normal (< 22 mEq/L) as a primary disorder, metabolic acidosis is present. If the patient is alkalemic and the HCO₃⁻ level is greater than normal (> 26 mEq/L) as a primary disorder, metabolic alkalosis is present.

Acid-base homeostasis is normally maintained because a change in pH will usually trigger a compensatory change to minimize the change in pH, although the compensation is never complete. The degree and timing of compensation are determined by the primary disturbance itself and by individual physiology. Respiratory compensation for metabolic disorders is more rapid and occurs through a change in the respiratory rate, which in turn adjusts the Pco₂. Metabolic compensation for a respiratory disturbance requires renal adjustment of HCO₃⁻ and can take 3 to 5 days. The predicted compensatory responses for the primary disturbances are shown in Table A.4. It is important to remember that physiologic compensatory mechanisms may themselves be compromised or overwhelmed by the acid-base disorder (Fig. A.1).

Example 1: A 58-year-old woman has had profuse diarrhea for 1 week. Initial laboratory data include the following: Na⁺, 133; K⁺, 2.8; pH 7.26; Cl⁻, 118; Pco₂, 13; HCO₃⁻, 5.

1. Acidosis is present (pH < 7.40).
2. The primary process is metabolic (HCO₃⁻ < 22 mmol/L, and Pco₂ is not increased).
3. Compensation. In primary metabolic acidosis, the formula that checks for compensation is:

$$\Delta \text{Pco}_2 = 1.3 \times \Delta \text{HCO}_3^-$$

(where ΔHCO₃⁻ is normal – current values)

$$\Delta \text{Pco}_2 = 1.3 \times (25 - 5) = 26 \text{ mm Hg}$$

$$\begin{aligned} \text{The predicted Pco}_2 &= \text{the normal Pco}_2 - \Delta \text{Pco}_2 \\ &= 40 - 26 = 14 \end{aligned}$$

The actual Pco₂ is 13 mm Hg.

Figure A.1 Acid-base map.

The respiratory compensation is predicted by the equation and suggests that no other acid-base disorder is present.

Example 2: A 74-year-old nursing home resident is admitted to the hospital with hypotension (96/70) and fever (39°C). He has had a positive urine culture for *Escherichia coli* and two positive blood cultures with the same organism. His laboratory values are as follows:

Sodium, 138 mmol/L.
Potassium, 3.2 mmol/L.

Chloride, 105 mmol/L.

pH, 7.49.

Pco₂, 25 mm Hg.

HCO₃⁻, 22 mmol/L.

1. Alkalosis is present (pH > 7.44).
2. The primary process is respiratory (Pco₂ < 40 mm Hg and HCO₃⁻ was not increased).
3. Compensation. The decrease in Pco₂ is 40 – 25, or 15 mm Hg. The formula for an expected decrease in HCO₃⁻

is 2 mmol for every 10-mm Hg decrease in P_{CO_2} . In this instance the expected decrease in HCO_3^- for the 15-mm Hg decrease in P_{CO_2} is 3 mmol/L, which is nearly identical to the actual decrease (i.e., 25 – 22). Therefore only acute respiratory alkalosis is present with normal compensation.

WINTER'S FORMULA

In a pure primary metabolic acidosis, the body's normal response is a change (decrease) in PCO_2 . The expected compensation can be predicted by Winter's formula:

$$\text{Expected } PCO_2 = 1.5 \times HCO_3^- + 8 + 2$$

Example: HCO_3^- calculated from ABG analysis is 10 mEq/L. With pure metabolic acidosis the expected PCO_2 is:

$$\text{Expected } PCO_2 = 1.5 \times 10 + 8$$

$$\text{Expected } PCO_2 = 23 \text{ mm Hg (range, 21–25 mm Hg)}$$

If the measured PCO_2 is higher than the expected PCO_2 , a concomitant respiratory acidosis is also present. Normocapnia or hypercapnia in the presence of severe metabolic acidosis may be a harbinger of impending respiratory failure and suggests the possible need for mechanical ventilation.

A lower PCO_2 would suggest a concomitant respiratory alkalosis, such as seen with salicylate poisoning.

Another useful tool in estimating PCO_2 in metabolic acidosis is the recognition that PCO_2 is approximately equal to the last two digits of the pH. In the previous example, the expected pH should be 7.23.

GLASGOW COMA SCALE

For head-injured patients, the Glasgow Coma Scale (GCS) is a frequently referenced assessment of neurologic function. It is calculated by using the best result of neurologic testing of eye opening, motor function, and verbal function. Each of the three subscores is determined by using verbal and painful stimuli. Point assessments are listed in Table A.5, with adjustments noted for pediatric patients. Points are given for the best response observed for each category. For example, a person

with right-sided motor deficits but otherwise normal function would have a normal GCS score because left-sided function is normal. Scores of 13 to 15 correlate with mild brain injury, 9 to 12 with moderate brain injury, and 3 to 8 with severe brain injury.

Example: An intoxicated male is involved in a motor vehicle crash and is brought to your ED. He opens his eyes only to painful stimuli, is muttering incomprehensibly, and localizes pain on the left and withdraws from pain on the right. What is his GCS score, and what severity of injury does this score represent?

$$\text{GCS} = \text{Eye opening} + \text{Verbal response} + \text{Motor response}$$

$$\text{Eye opening to pain} = 2 \text{ points}$$

$$\text{Incomprehensible sounds} = 2 \text{ points}$$

Localizing pain is 5 points and withdrawal from pain is 4 points. The better score is used.

$$2 + 2 + 5 = 9 \text{ points}$$

NATIONAL INSTITUTES OF HEALTH STROKE SCORE

The full National Institutes of Health (NIH) stroke scale is shown in Table A.6. The scale includes directions for patient assessment, as well as recommended adjustments for special situations that might impair the ability of the patient to respond to the assessor. Training scenarios and the NIH stroke scale can be found at <http://www.nihstrokescale.org/>.

The scale itself, in unedited format, is presented in Table A.6. Scores range from 0 (normal neurologic function) to 34 (maximal injury). Use of thrombolytics has been suggested for patients with scores between 8 and 26 who have no contraindications and can receive the intervention within a specified time of onset; for many sites the time of onset should be within 3 hours.

Example: A 74-year-old, left-handed woman arrives at the ED 90 minutes after the onset of left-sided arm and leg weakness. She has no headache. By 2 hours from symptom onset, she has confirmed normal findings on head CT and does not have contraindications to thrombolytics. Her symptoms have

TABLE A.5 Glasgow Coma Scale Score (Adults/Children < 5 yr When Different)

POINTS	BEST EYE RESPONSE	BEST VERBAL RESPONSE	BEST MOTOR RESPONSE
1	No eye opening	No verbal response	No motor response
2	Opens eyes to pain	Incomprehensible/moans to pain	Extension to pain
3	Opens eyes to command/opens eyes to verbal cues	Inappropriate words/cries to pain	Flexion to pain
4	Spontaneous eye opening	Confused/decreased verbal ability, irritable crying	Withdrawal from pain
5	—	Orientated/age-appropriate speech or cooing	Localizes pain/localizes pain or withdraws from touch
6	—	—	Obeys commands/normal spontaneous movements

TABLE A.6 National Institutes of Health Stroke Scale

Administer stroke scale items in the order listed. Record performance in each category after each subscale examination. Do not go back and change scores. Follow the directions provided for each examination technique. Scores should reflect what the patient does, not what the clinician thinks that the patient can do. The clinician should record answers while administering the examination and work quickly. Except when indicated, the patient should not be coached (i.e., repeated requests to patient to make a special effort).

If any item is left untested, a detailed explanation must be clearly written on the form. All untested items will be reviewed by the medical monitor and discussed with the examiner by telephone.

Instructions	Scale Definition	Score
<p>1a. Level of Consciousness (LOC): The investigator must choose a response, even if a full evaluation is prevented by obstacles such as an endotracheal tube, language barrier, or orotracheal trauma or bandages. A 3 is scored only if the patient makes no movement (other than reflexive posturing) in response to noxious stimulation.</p>	<p>0 = Alert; keenly responsive 1 = Not alert but arousable by minor stimulation to obey, answer, or respond 2 = Not alert, requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements (not stereotyped) 3 = Responds only with reflex motor or autonomic effects or is totally unresponsive, flaccid, areflexic</p>	<p>_____</p>
<p>1b. LOC Questions: The patient is asked the month and his or her age. The answer must be correct—there is no partial credit for being close. Aphasic and stuporous patients who do not comprehend the questions will score 2. Patients unable to speak because of endotracheal intubation, orotracheal trauma, severe dysarthria from any cause, language barrier, or any other problem not secondary to aphasia are given a 1. It is important that only the initial answer be graded and that the examiner not “help” the patient with verbal or nonverbal cues.</p>	<p>0 = Answers both questions correctly 1 = Answers one question correctly 2 = Answers neither question correctly</p>	<p>_____</p>
<p>1c. LOC Commands: The patient is asked to open and close the eyes and then to grip and release the nonparetic hand. Substitute another one-step command if the hands cannot be used. Credit is given if an unequivocal attempt is made but not completed because of weakness. If the patient does not respond to command, the task should be demonstrated (pantomime) and the result scored (i.e., follows none, one, or two commands). Patients with trauma, amputation, or other physical impediments should be given suitable one-step commands. Only the first attempt is scored.</p>	<p>0 = Performs both tasks correctly 1 = Performs one task correctly 2 = Performs neither task correctly</p>	<p>_____</p>
<p>2. Best Gaze: Only horizontal eye movements will be tested. Voluntary or reflexive (oculocephalic) eye movements will be scored, but caloric testing is not done. If the patient has a conjugate deviation of the eyes that can be overcome by voluntary or reflexive activity, the score will be 1. If a patient has an isolated peripheral nerve paresis (cranial nerve III, IV, or VI), score a 1. Gaze is testable in all aphasic patients. Patients with ocular trauma, bandages, preexisting blindness, or other disorders of visual acuity or fields should be tested with reflexive movements and a choice made by the investigator. Establishing eye contact and then moving about the patient from side to side will occasionally clarify the presence of a partial gaze palsy.</p>	<p>0 = Normal 1 = Partial gaze palsy. This score is given when gaze is abnormal in one or both eyes but forced deviation or total gaze paresis is not present 2 = Forced deviation or total gaze paresis not overcome by the oculocephalic maneuver</p>	<p>_____</p>

Continued

TABLE A.6 National Institutes of Health Stroke Scale—cont'd

<i>Instructions</i>	<i>Scale Definition</i>	<i>Score</i>
<p>3. Visual: Visual fields (upper and lower quadrants) are tested by confrontation, with finger counting or by visual threat used as appropriate. Patient must be encouraged, but if they look at the side of the moving fingers appropriately, this can be scored as normal. If there is unilateral blindness or enucleation, visual fields in the remaining eye are scored. Score 1 only if a clear-cut asymmetry, including quadrantanopia, is found. If the patient is blind from any cause, score 3. Double simultaneous stimulation is performed at this point. If there is extinction present, the patient receives a 1 and the results are used to answer question 11.</p>	<p>0 = No visual loss 1 = Partial hemianopia 2 = Complete hemianopia 3 = Bilateral hemianopia (blind, including cortical blindness)</p>	<p>_____</p>
<p>4. Facial Palsy: Ask or use pantomime to encourage the patient to show his or her teeth or raise the eyebrows and close the eyes. Score the symmetry of grimace in response to noxious stimuli in a poorly responsive or noncomprehending patient. If facial trauma, bandages, an orotracheal tube, tape, or other physical barrier obscures the face, these impediments should be removed to the extent possible.</p>	<p>0 = Normal symmetric movement 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling) 2 = Partial paralysis (total or nearly total paralysis of the lower part of the face) 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower parts of the face)</p>	<p>_____</p>
<p>5 and 6. Motor Arm and Leg: The limb is placed in the appropriate position: extend the arms (palms down) 90 degrees (if sitting) or 45 degrees (if supine) and the leg 30 degrees (always tested supine). Drift is scored if the arm falls before 10 seconds or the leg before 5 seconds. An aphasic patient is encouraged by using urgency in the voice and pantomime, but not noxious stimulation. Each limb is tested in turn, beginning with the nonparetic arm. Only in the case of amputation or joint fusion at the shoulder or hip may the score be “9,” and the examiner must clearly write the explanation for scoring as a “9.”</p>	<p>0 = No drift; the limb holds 90 (or 45) degrees for a full 10 seconds 1 = Drift; the limb holds 90 (or 45) degrees but drifts down before a full 10 seconds; does not hit the bed or other support 2 = Some effort against gravity; the limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to the bed, but has some effort against gravity 3 = No effort against gravity; the limb falls 4 = No movement 9 = Amputation, joint fusion; explain 5a. Left Arm 5b. Right Arm 0 = No drift; the leg holds a 30-degree position for a full 5 seconds 1 = Drift; the leg falls by the end of the 5-second period but does not hit the bed 2 = Some effort against gravity; the leg falls to the bed by 5 seconds but has some effort against gravity 3 = No effort against gravity; the leg falls to the bed immediately 4 = No movement 9 = Amputation, joint fusion; explain 6a. Left Leg 6b. Right Leg</p>	<p>_____</p>

TABLE A.6 National Institutes of Health Stroke Scale—cont'd

Instructions	Scale Definition	Score
<p>7. Limb Ataxia: This item is aimed at finding evidence of a unilateral cerebellar lesion. Test with the eyes open. In case of a visual defect, ensure that testing is done in the intact visual field. The finger-nose-finger and heel-shin tests are performed on both sides, and ataxia is scored only if present out of proportion to weakness. Ataxia is absent in a patient who cannot understand or is paralyzed. Only in the case of amputation or joint fusion may the item be scored "9," and the examiner must clearly write the explanation for not scoring. In the case of blindness, test by touching the nose from an extended arm position.</p>	<p>0 = Absent 1 = Present in one limb 2 = Present in two limbs. If present, is ataxia in the Right arm: 1 = Yes, 2 = No 9 = Amputation or joint fusion; explain Left arm: 1 = Yes, 2 = No 9 = Amputation or joint fusion; explain Right leg: 1 = Yes, 2 = No 9 = Amputation or joint fusion; explain Left leg: 1 = Yes, 2 = No 9 = Amputation or joint fusion; explain</p>	<p>_____</p> <p>_____</p> <p>_____</p> <p>_____</p>
<p>8. Sensory: Sensation or grimace in response to a pinprick when tested or withdrawal from a noxious stimulus in an obtunded or aphasic patient. Only sensory loss attributed to stroke is scored as abnormal, and the examiner should test as many body areas (arms [not hands], legs, trunk, face) as needed to accurately check for hemisensory loss. A score of 2, "severe or total," should be given only when severe or total loss of sensation can be clearly demonstrated. Stuporous and aphasic patients will therefore probably score 1 or 0. A patient with a brain stem stroke who has bilateral loss of sensation is scored 2. If the patient does not respond and is quadriplegic, score 2. Patients in coma (item 1a = 3) are arbitrarily given a 2 on this item.</p>	<p>0 = Normal; no sensory loss 1 = Mild to moderate sensory loss; the patient feels that a pinprick is less sharp or dull on the affected side or there is a loss of superficial pain with pinprick but the patient is aware of being touched 2 = Severe to total sensory loss; the patient is not aware of being touched on the face, arm, and leg</p>	<p>_____</p>
<p>9. Best Language: A great deal of information about comprehension will be obtained during the preceding sections of the examination. The patient is asked to describe what is happening in the attached picture, to name the items on the attached naming sheet, and to read from the attached list of sentences. Comprehension is judged from responses here, as well as to all the commands in the preceding general neurologic examination. If visual loss interferes with the tests, ask the patient to identify objects placed in the hand, repeat, and produce speech. An intubated patient should be asked to write. A patient in coma (question 1a = 3) will arbitrarily score 3 on this item. The examiner must choose a score in a patient with stupor or limited cooperation, but a score of 3 should be used only if the patient is mute and follows no one-step commands.</p>	<p>0 = No aphasia; normal 1 = Mild to moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation in ideas expressed or form of expression. Reduction in speech and/or comprehension, however, makes conversation about the material provided difficult or impossible. For example, in conversation about the materials provided, the examiner can identify a picture or naming card from the patient's response. 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by the listener. The range of information that can be exchanged is limited; the listener carries the burden of communication. The examiner cannot identify materials provided from the patient's response. 3 = Mute, global aphasia; no usable speech or auditory comprehension</p>	<p>_____</p>
<p>10. Dysarthria: If the patient is thought to be normal, an adequate sample of speech must be obtained by asking the patient to read or repeat words from the attached list. If the patient has severe aphasia, the clarity of articulation of spontaneous speech can be rated. Only if the patient is intubated or has another physical barrier to producing speech may the item be scored "9," and the examiner must clearly write an explanation for not scoring. Do not tell the patient why he or she is being tested.</p>	<p>0 = Normal 1 = Mild to moderate; the patient slurs at least some words and, at worst, can be understood with some difficulty 2 = Severe; the patient's speech is so slurred that it is unintelligible in the absence of or out of proportion to any dysphasia or is mute or anarthric 9 = Intubated or other physical barrier; explain</p>	<p>_____</p>

Continued

TABLE A.6 National Institutes of Health Stroke Scale—cont'd

Instructions	Scale Definition	Score
<p>11. Extinction and Inattention (Formerly Neglect): Sufficient information to identify neglect may be obtained during the prior testing. If the patient has a severe visual loss preventing visual double simultaneous stimulation and the cutaneous stimuli are normal, the score is normal. If the patient has aphasia but does appear to attend to both sides, the score is normal. The presence of visual spatial neglect or anosognosia may also be taken as evidence of abnormality. As the abnormality is scored only if present, the item is never untestable. This is an additional item, not a part of the NIH Stroke Scale score.</p>	<p>0 = No abnormality 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities 2 = Profound hemi-inattention or hemi-inattention to more than one modality. Does not recognize own hand or orients to only one side of space</p>	_____
<p>A. Distal Motor Function: The patient's hand is held up at the forearm by the examiner and the patient is asked to extend the fingers as much as possible. If the patient cannot or does not extend the fingers, the examiner places the fingers in full extension and observes for any flexion movement for 5 seconds. The patient's first attempts only are graded. Repetition of the instructions or of the testing is prohibited.</p>	<p>0 = Normal (no flexion after 5 seconds) 1 = At least some extension after 5 seconds, but not fully extended. Any movement of the fingers that is not command is not scored 2 = No voluntary extension after 5 seconds. Movements of the fingers at another time are not scored a. Left Arm b. Right Arm</p>	_____

NIH, National Institutes of Health.

TABLE A.7 Definitions of Commonly Used Epidemiologic Terms

Prevalence	$= (a + c)/(a + b + c + d)$	= Incidence of disease in the population tested	
Sensitivity	$= a/(a + c)$	= Probability of a positive test result, disease present	
Specificity	$= d/(b + d)$	= Probability of a negative test result, disease absent	
False-negative rate	$= c/(a + c)$	= Probability of a negative test result, disease present	
False-positive rate	$= b/(b + d)$	= Probability of a positive test result, disease absent	
Positive predictive value	$= a/(a + b)$	= Probability of a disease present, test positive	
Negative predictive value	$= d/(c + d)$	= Probability of a disease absent, test negative	
Overall accuracy	$= (a + d)/(a + b + c + d)$	= Probability of a "true" test result	
Disease State			
Test Result	Present	Absent	
Positive	a (True positive)	b (False positive)	a + b = All positive tests
Negative	c (False negative)	d (True negative)	c + d = All negative tests
	a + c = All patients with disease	b + d = All patients without disease	a + b + c + d = All patients tested

Modified from Goldman L: Quantitative aspects of clinical reasoning. In Isselbacher KJ, Braunwald E, Wilson JD, editors: *Harrison's principles of internal medicine*, ed 13, New York, 1994, McGraw-Hill, p 44.

not changed in any way since onset. Using the NIH stroke scale, she is determined to have the following findings. On cognitive testing she is keenly responsive (0 points), knows her age and the current month (0 points), and can follow two-step commands with the unaffected side (0 points). She has a partial gaze palsy without forced deviation (1 point);

partial hemianopia (1 point); unilateral, complete paralysis of her face (3 points); no drift on her right arm (0 points); no movement of her left arm (4 points); no drift on her right leg (0 points); and some effort of her left leg against gravity, although it falls to the bed within 2 seconds of elevation (2 points). She has no ataxia (0 points). Her sensation to pinprick

is decreased, although she is aware of the testing (1 point). She has a mild expressive aphasia but is easily comprehensible (1 point), has some slurring of words but is still comprehensible (1 point), and exhibits no evidence of neglect (0 points). Her total NIH score is 14, and as a result she may be a candidate for thrombolytic therapy.

DIAGNOSTIC PROBABILITY

The probability of obtaining a certain test result in the presence or absence of a particular disease entity for a given population with a given disease prevalence is presented in [Table A.7](#).

No medical test is totally accurate. The parameters listed in [Table A.7](#), when available, can help guide a clinician's test

selection. When this information is not available, it may be difficult to identify random laboratory errors or detect failures. Knowledge of disease prevalence, combined with the sensitivity and specificity of the test, yields the positive (or negative) predictive value of that test. For a given sensitivity and specificity, predictive value is directly proportional to prevalence. Hence, even a test with high sensitivity and specificity may not detect a rare disease. This underscores the importance of pretest clinical evaluation.

ACKNOWLEDGMENT

The editors and authors wish to acknowledge the contributions of M. John Mendelsohn to this Appendix in previous editions.

 slit lamp examination of, 1328–1331
- Anterior chamber angle, 1299, 1300f
- Anterior tibialis muscle syndrome, 1073t, 1102f, 1103–1104
- Antibiotic prophylaxis, for infection, in IVADs, 455
- Antibiotics
 for CSF, 1278
 for dental trauma, 1392–1393
 for epistaxis management, 1372
 for foreign body removal, 734–735
 for frostbite, 1419
 for head and neck infections, 1401–1403
 for hypothermia, 1411
 for marine foreign body, 726
 following nasal packing, 1372
 ointment, 643
 for burns, 787
 for otitis externa, 1355, 1356f
 for peritonsillar abscess drainage, 1348
 prophylactic
 for animal bites, 649–650
 for bacteremia, 747
 for endocarditis, 746–747, 747b
 for extensor tendon injury, 962
 for human bites, 651–653
 after sexual assault, 1235–1236
 tube thoracostomy with, 214–216
 for septic bursitis, 1089
 for soft tissue abscess, 745–747, 747b
 solutions, for wound care, 628, 643
- Antibodies, red blood cell, 500, 501f
- Anticoagulation
 assessing risk of bleeding and thrombosis in, 1520–1521
 procedures in setting of, 1520–1528
 arthrocentesis in, 1526
 dental procedures in, 1527
 epistaxis and, 1527
 labor and delivery and, 1528
 lumbar puncture in, 1524–1525
 nasogastric tube insertion in, 1527–1528
 paracentesis and, 1526
 thoracentesis and tube thoracostomy and, 1526–1527
 vascular access in, 1525–1526
 reversal of, 1522–1523, 1522t
 testing and management, 1521t
 wound management and, 1528
 control of hemorrhage in, 1528
 incision and drainage in, 1528
- Anticonvulsants
 in increased intracranial pressure, 1247–1248
 rectal administration of, 486–488, 487t
- Antidepressants, serotonin syndrome with, 1425
- Antiemetics, rectal administration of, 487t, 488
- Anti-factor Xa activity, anticoagulation and, 1520
- Antifreeze poisoning, 1462
- Antigen test, for CSF, 1276
- Antigens, red blood cell, 500, 501f
- Antihemophilic factor
 human, 513
 recombinant, 513
- Antimicrobials
 in IVADs, 455
 topical, for burn injury, 786
- Antiplatelet agents, lumbar puncture and, 1524
- Antiretroviral agents, 1478–1479
- Antiseptics, for wound care, 627–628, 627t
- Anus
 anatomy of, 904
 examination of, 905f
 in sexual assault evaluation, 1232–1234, 1234f
- Anxiety, local anesthesia and, 543
- Aorta
 cross-clamping of, 349–351, 349f
 identification of, difficult, 350, 350f
 occlusion of, Conn compressor for, 350–351, 350f
- Aortic crossover, esophageal foreign bodies in, 809f

 - femoral vein for, 407, 408f, 409t, 410, 420, 424–425, 425f
 - guidewire for, 411–412, 412f
 - placement of, 413–417, 415f–416f, 418f
 - for high-flow fluid bolus, 408
 - historical perspective on, 405
 - for hyperalimentation, 409
 - for inability to achieve peripheral access, 408
 - indications for, 406f, 407–409
 - internal jugular vein, 405–407, 407f, 409t, 410, 415f–416f, 420, 422–424, 423f
 - needle for, 411, 411f, 411t, 414–417, 417f
 - over-the-needle technique for, 419
 - pediatric, 364–367, 364t
 - complications of, 367
 - equipment and setup for, 364
 - femoral, 365–366, 365f
 - indications and contraindications in, 364
 - internal jugular vein, 366, 367f
 - subclavian, 366–367
 - umbilical, 367–369, 368f–369f
 - preparation for, 413
 - problems related to, 301
 - radiographs for, 429, 429f
 - Seldinger (guidewire) technique for, 410, 413–417
 - for serial blood drawing, 408
 - sheath introducer in, 417–418, 419f
 - subclavian vein for, 405, 407f, 409t, 410, 420
 - infraclavicular, 420–421, 421f
 - supraclavicular, 421–422, 422f
 - technique for, 413–419, 415f–416f, 419f
 - training for, 438
 - ultrasound for, 411, 413, 414f, 426b–428b, 426f–427f, 1525
 - survey, 414f
- Central venous pressure
 - measurement of, 430
 - complications of, 431f
 - contraindications to, 430, 431f
 - errors in, 433–434, 434b
 - indications for, 430, 431f
 - interpretation of, 434
 - manometry for, 432–433, 432f
 - transducer for, 432–433, 433f
 - monitoring of, 407–408, 430–435
 - in cardiac tamponade, 434–435
 - in fluid challenge, 434
 - physiology of, 431
- Cephalic vein
 - catheterization of, 430
 - venous cutdown of, 441–442, 441f
- Cerebral blood flow (CBF), 1245
- Cerebral infarction, carotid sinus massage and, 228
- Cerebral perfusion pressure (CPP), 1245, 1246f
- Cerebrospinal fluid (CSF), 1244–1245, 1245f, 1263f
 - anatomy of, 1258–1259
 - examination of, 1258–1280
 - analysis with infections, 1275–1279
 - appearance in, 1272–1273
 - in bacterial infections, 1275, 1275t
 - cells in, 1273
 - in cryptococcal meningitis, 1279
 - culture in, 1276
 - in cytomegalovirus infection, 1280
- Cerebrospinal fluid (CSF) (*Continued*)
 - glucose in, 1273–1274, 1273b
 - in immunocompromised patients, 1279–1280
 - in mycobacterial tuberculosis, 1280
 - in neurosyphilis, 1278
 - pressure in, 1269
 - in primary CNS lymphoma, 1280
 - in progressive multifocal leukoencephalopathy, 1280
 - protein in, 1274
 - red blood cells in, 1272
 - in toxoplasmosis, 1279–1280
 - in intracranial shunt
 - assessment of, 1256–1257, 1257f
 - excessive drainage of, 1253
 - physiology of, 1258–1259
- Cerumen impaction removal, 1351–1355, 1352f, 1354f
 - ceruminolytics in, 1353, 1354f
 - complications of, 1353–1355
 - contraindications to, 1352, 1352f
 - indications for, 1352
 - irrigation in, 1353, 1354f
 - manual instrumentation in, 1353, 1354f
 - procedure for, 1352–1353
- Ceruminolytics, 1353, 1354f
- Cervical collars, 921, 921f
 - application of, 925f
- Cervical esophagostomy, 840
- Cervical extrication splints, 921–922, 921f
- Cervical myofascial pain syndrome, 1103
- Cervical pharyngostomy, 840
- Cervical spine
 - immobilization of
 - C-collars for, 921, 921f
 - complications of, 930
 - extrication splints for, 921–922, 921f
 - helmet removal and, 942
 - indications for, 919
 - in pediatric patients, 929–930
 - procedure for, 924–929, 925f
 - injury to, 918–919
- Cervicitis, vaginal discharge in, 1217
- Cervix
 - dilation of, 1190
 - effacement of, 1190, 1190f
- Cesarean section, perimortem, 1207, 1208f
- Chair technique
 - in elbow dislocation, 1001, 1001f
 - in shoulder dislocation, 993
- Chandy maneuver, 55–57
- Chelation therapy, for chromic acid injury, 800
- Chemical burns, 780, 780f, 795–800, 795b, 801t
- Chemical cautery, for hemorrhage, in IVADs, 458–459
- Chemical neuritis, 562
- Chemical terrorism, assessment and triage of victims of, capnography and, 33, 33.e1t
- Chemotherapeutic agents, extravasated, antidotes for, 402t
- Cherry-red spot, 1331, 1333f
- Chest compression
 - in CPR, 333
 - for foreign body airway obstruction, 41
 - hemopericardium with, 312
- Chest escharotomy, 805
- Chest radiography
 - for empyema, 200f
 - pacemaker and, 260f–261f, 265
 - for pericardial effusion or tamponade, 317
 - in pleural effusion, 183–184, 183f–186f
 - for pneumothorax, 197f, 201–202, 201f–202f

- Chest radiography (*Continued*)
 after thoracentesis, 191, 193f
 in transvenous cardiac pacing, 299
 after tube thoracostomy, 210–212, 214f
- Chest thrusts, 41–42
- Chest trauma, 342–343, 343f
- Chest tube, intrapleural anesthesia in, 537
- Chest wall disease, evaluation of, spirometry for, 23
- Chest wall rigidity, fentanyl and, 615
- Chicken bones, in throat, 821–822, 824f
- Child abuse, burns and, 792–794, 793f
- Childhood coin ingestion, 820–821, 821f–823f
- Children
 agitation in, 1496
 airway in adults *vs.*, 76t
 arterial blood sampling in, 356–359, 358f–359f
 automated external defibrillators in, 253

 mucosal application of, 527b, 528
 TAC and, 532
- Emollients, for burns, 788
- Empyemas, 199–200, 200f
 in stable patients, 201
 tube thoracostomy for, 206–207
- Encephalopathy syndrome, 1426
- Endless loop syndrome, 269
- Endocarditis, prophylactic antibiotics in, 746–747
- Endoscopic intubation, flexible, through intubating laryngeal mask airway, 93–95
- Endoscopic third ventriculostomy (EVT), 1257
- Endoscopy, for esophageal foreign bodies, 813
- Endotracheal administration, of medication, 476–481, 476f
- Endotracheal intubation, preoxygenation prior to, 48
- Endotracheal tube, 81f
 monitoring position of, during transport, 32
 pediatric, 70f
 placement, verification of, capnography and, 31–32
 replacing, 108f
 size, 1529–1530
 standard, using, 93
- End-tidal CO₂ pressure (PETCO₂), 29–30, 30f
 accuracy of, ET tube placement and, 31–32
 in acute respiratory distress, 33, 33f
 colorimetric detector for, 30
 CPR effectiveness and, 32
 detection, 83–84
 serum bicarbonate and, 34–37, 37f
- English nail anvil, 1067f, 1068–1069
- English-to-metric conversions, 1529, 1530t
- Entrapment, of esophageal foreign bodies, 808t
- Envenomation
 coelenterates, 724
 stingray, 726
- Enzyme-linked immunosorbent assay, in meningitis, 1276
- Enzymes, in diagnostic peritoneal lavage, 884
- Eosinophils, CSF, 1273
- Epicondylitis, 1078t
 lateral, 1085–1086, 1085f–1086f
 medial, 1085–1086, 1085f, 1087f
- Epidermoid tumor, 1271
- Epididymitis, acute, 1142
- Epidural blood patch, 1270
- Epidural hematoma, 1248, 1248f–1249f
 spinal, 1260–1261
- Epiglottitis, in esophageal foreign bodies, 808
- Epiglottoscopy, 72
- Epinephrine
 anxiety and, 543
 in auricular field blocks, 1351
 in CPR, 249
 depot effect of, 477
 endotracheal drug administration of, 477t
 local anesthesia and, 526, 533–534, 535b, 538, 540t
 for priapism, 1148, 1148t
 push-dose, how to make, 114b, 115f
 regional anesthesia and, 561
 for wound, 632
- Epinephrine-cocaine, 532–533
- EpiPen accident, 653–654, 653f–654f
- Epiphysis, intraosseous infusion-related injury to, 475
- Episiotomy, 1203–1205, 1204f
- Epistaxis
 anatomy of, 1361, 1361f
 anticoagulation and, 1527
 patients with, 1363
 management of, 1363–1373, 1363f–1365f
 anterior nasal packing for, 1366–1368, 1367f
 antibiotics for, 1372
 cautery for, 1365–1366, 1366f
 complications of, 1368, 1369f, 1372
 contraindications to, 1364
 equipment for, 1364, 1364f
 indications for, 1364
 inflatable balloon packs for, 1369, 1371f
 patient disposition in, 1372
 posterior gauze pack for, 1368–1369, 1369f–1370f
 posterior nasal packing for, 1368–1372, 1370f
 testing for, 1363–1364
- Epley maneuver procedure, 1287, 1287f
- Epstein-Barr virus (EBV), transfusion transmission of, 503
- Epulis gravidarum, 733–734
- Equipment failure, of tracheostomy, 153
- Equivalent dose (H_T), 1505
- Ergonovine maleate, for postpartum hemorrhage, 1205t
- Erythromycin, for antibiotic-resistant *N. gonorrhoeae*, 1235–1236
- Escharotomy
 complications of, 805
 emergency, 803–805
 indications for, 804
 technique of, 804–805
 for chest, 805
 for limbs, 804–805, 804f
 for neck, 805
 for penis, 805
- Eskimo technique, in shoulder dislocations, 991f–992f, 993
- Esmolol, in supraventricular tachycardia, 234
- Esophageal bougienage, for removal, of esophageal foreign bodies, 819–820, 820f, 820t
- Esophageal detector device, of tracheal tube, 81–83

- Esophageal foreign bodies, 807–827
 anatomy and, 807–808, 808f
 clinical findings of, 808, 808t
 complications of, 807–808, 808b
 epidemiology of, 807
 esophageal pharmacologic maneuvers, 813–816, 814t
 gas-forming agents, 815–816
 glucagon, 814–815, 815f
 indications and contraindications to, 813
 nitroglycerin and nifedipine, 815
 papain, 816
 esophagoscopy for, 813
 evaluation of, 808
 radiology of, 809–813
 computed tomography (CT) in, 810, 811f
 contrast-enhanced esophagograms, 810–812, 812f
 follow-up, 812, 812t
 indications for, 809
 plain radiographs in, 809–810, 809f–811f
 removal of, 816–820
 esophageal bougienage for, 819–820, 820f, 820t
 Foley catheter, 817–819, 818f
 Magill forceps, 816–817, 816f–817f
 special situations in, 820–827
 button battery ingestion, 824–825, 826f
 childhood coin ingestion, 820–821, 821f–823f
 fish or chicken bones, in throat, 821–822, 824f
 impacted food bolus, 811f, 823–824
 magnets, 825–826, 826f
 nonradiopaque objects, in esophagus, 823
 patient in distress, 826
 sensation, in throat, 826–827
 sharp objects, in esophagus, 823, 825f
 visualization of, 813, 813f
- Esophageal leads, for electrocardiography, 284
- Esophageal pharmacologic maneuvers, 813–816, 814t
 gas-forming agents, 815–816
 glucagon, 814–815, 815f
 indications and contraindications to, 813
 nitroglycerin and nifedipine, 815
 papain, 816
- Esophageal sphincter
 lower, in esophageal foreign bodies, 807, 810f
 upper, in esophageal foreign bodies, 807
- Esophagoscopy, for esophageal foreign bodies, 813
- Esophagostomy, feeding tube, 840, 841f
- Esophagus
 anatomy of, 807
 tracheal tube in, 95
- Ethanol infusion, 1467t–1468t, 1468–1469
- Ethyl alcohol
 for skin disinfection, 1453
 toxicologic tests on oral secretions using, 1463–1464
- Ethyl chloride spray, 530
- Ethylene glycol poisoning, 1462, 1462f, 1467t–1468t
- Etidocaine, 525t–526t
- Etomidate
 in cardioversion, 255–256, 256t
 in increased intracranial pressure, 1246
 ketamine vs., 117
 in procedural sedation and analgesia, 611t–612t, 614
 for rapid-sequence intubation, 116–117, 117t
- Evaporation, heat loss with, 1407
- Evaporative cooling, 1427–1428, 1427t
- Excited delirium syndrome (EXDS), 1481–1483
- Explosion, defibrillation and, 243
- Exsanguination, for intravenous regional anesthesia, 593
- Extensor carpi radialis brevis, 956, 957f–958f
- Extensor carpi radialis longus, 956, 957f–958f
- Extensor carpi ulnaris, 956–958, 957f–958f
- Extensor digiti minimi, 956, 957f–958f
- Extensor digitorum communis, 956, 958f, 961f, 968f
- Extensor digitorum longus, 972, 972f
- Extensor hallucis longus, 972, 972f
- Extensor indicis proprius, 956, 958f
- Extensor pollicis brevis, 956, 957f–958f
- Extensor pollicis longus, 956, 957f–958f
- Extensor tendon injury
 foot, 972–973, 972f
 in hand and wrist, 956–972, 957f
 antibiotics in, 962
 functional anatomy of, 956–958, 957f–958f, 960f
 general approach of, 958–962, 961f
 repair of
 aluminum foam splint in, 963f, 970f
 care after, 971
 complications of, 970–971
 preparation for, 961f, 962
 zones 1 and 2, 968–970, 969f
 zone 3, 967–968, 967f
 zone 4, 965f, 966–967
 zone 5, 965–966, 965f
 zone 6, 963–965, 964f
 zone 7 and 8, 963
 knee, 978–979, 979f
 patterns and management of, 962–970
 postrepair care and rehabilitation of, 971–972
- External auditory canal, 1348–1349
 anesthesia of, 1350f, 1351
 examination of, 1351, 1351f
 foreign body removal in, 1355–1358, 1358f
 complications of, 1357–1358
 contraindications to, 1356
 cyanoacrylate for, 1357, 1358f
 Fogarty catheters for, 1357, 1358f
 indications for, 1356
 insects in, 1357, 1358f
 manual instrumentation for, 1357, 1358f
 suction-tipped catheters for, 1356–1357, 1357f
- External cardiac defibrillation, in patients with implantable pacemakers, 265–268
- External hemorrhoids, 907f, 908
 surgical excision of, 908–910, 910f
- External jugular vein
 anatomy of, 396, 396f
 cannulation of, 399, 399f
- External laryngeal manipulation (ELM), 72, 75–77, 77f
- External rotation method, in shoulder dislocations, 990, 991f–992f
- Extracorporeal cardiopulmonary resuscitation (E-CPR), 335–336, 336f
- Extraglottic airway devices, 39, 52–61
- Extrapyramidal symptoms (EPSs), 1492
- Extravasated chemotherapeutic agents, antidotes for, 402t
- Extravasation
 in intravenous regional anesthesia, 593
 retrograde cystogram with, 1181
 retrograde urethrogram with, 1179, 1180f
- Extraction splints, cervical, 921–922, 921f
- Exudates, 181, 182b
 culture in, 194t, 195
 cytology in, 194t, 195
 differential cell count in, 194, 194t
 glucose in, 194, 194t
 pleural fluid hematocrit in, 194t, 195
 transudates vs., 193, 193b–194b
- Eye drops, 1302, 1302f
- Eyebrow lacerations, 689
- Eyelids
 laceration, 689, 690f
 retractors for, 1305, 1307f
 sty of, 1336, 1337f
- Eyes
 black, with lacerations, of forehead, 687–689, 688f
 contact lens procedures, 1317–1319
 dilating, 1298–1302
 agents for, 1299–1301, 1299t, 1301f
 complications of, 1301–1302, 1302b, 1302f
 contraindications to, 1299, 1300f
 indications for, 1299, 1300f
 procedure for, 1301
 direct pressure on, 231
 fluorescein examination of, 1302–1305
 contraindications to, 1303
 indications for, 1303
 interpretation of, 1303–1304, 1304f–1305f
 procedure for, 1303, 1304f
 foreign body, removal of, 1312–1316
 irrigation of, 1305–1308
 complications of, 1308
 contraindications to, 1305
 duration of, 1306–1307
 equipment for, 1305
 indications for, 1305
 Morgan lens, 1307, 1308f
 procedure for, 1305–1307, 1306f–1307f
 prolonged, 1307
 normal, 1300f
 optokinetic nystagmus testing of, 1296, 1298f
 patching of, 1316
 penlight examination of, 1300f
Pseudomonas infection of, 1318
 slit lamp examination of, 1328–1331
 sty of, 1336, 1337f
 tonometry of, 1322–1328
 transillumination of, 1299, 1300f
 visual acuity, assessment of, 1295–1296
- EZ-IO Device, 465–466, 466f
- ## F
- Face
 abscess in, 1399–1400
 laceration of, 685–686, 685f–687f
 epithelial stitch in, 685, 687f
 natural skin lines and, 685, 685f
 stellate, 683–685, 684f
 tape closure in, 685–686, 687f
 natural wrinkles of, 685, 685f
 topical wound anesthesia for, 532
- Facial burns, 791–792, 792f
- Factor II, direct inhibitors, 516–517, 517t
- Factor VII, 511–513
 for hemophilia, 512
 for intracranial hemorrhage, 512–513
 for trauma, 513
 warfarin reversal in, 515–516, 516t
- Factor VIII
 concentrates, 513
 in cryoprecipitate, 511

- Factor VIII (*Continued*)
 inhibitor-bypassing activity, 513–514
 for anti-factor Xa anticoagulants, 518t
 for warfarin reversal, 515t–516t
 long-acting, 513
- Factor IX concentrate, 514
- Factor Xa, direct inhibitors of, 517
- Fahrenheit, metric conversions of, 1530t
- Failed airways, 68
- False passage, of tracheostomy, 153
- Fascia iliaca block, 577, 577f
- Fasciculations, succinylcholine-related, 121
- E-FAST exam, 1439
- FAST (Focused Assessment with Sonography for Trauma) exam, 1439
- FAST-1 Intraosseous Infusion System, 465, 465f, 468, 470f
- Fasting, in procedural sedation and analgesia, 596, 597f
- Fat embolism
 with autotransfusion, 498
 with intraosseous infusion, 475
- Fatty tissue, foreign bodies in, 717f, 719–720
- FB. *see* Foreign body
- Feeding tubes
 clogged, 850–851
 esophagostomy, 840
 gastroenterostomy, 840–850
 jejunostomy, 840–850
 nasogastric, 828–836
 nasogastric, 828–836
 pharyngostomy, 840
- Felon, 765t, 767–770, 768f
 drainage of, 768, 769f
- Femoral artery, for arterial cannulation, 389–390, 390f
- Femoral head, avascular necrosis of, 1013
- Femoral nerve block, 562t, 575–577, 576f
- Femoral vein
 catheterization of, 365–366, 365f, 409t, 420, 424–425, 425f, 435b
 anatomy of, 407, 408f
 complications of, 438, 438f
 contraindications to, 410
 ultrasound for, 426b–428b, 426f
 internal, for transvenous cardiac pacing, 294t
 for transvenous cardiac pacing, 295
 for venipuncture, 354–356, 358f
- Femur
 distal, for intraosseous infusion, 467
 fracture of, 934–935, 935f
- Fentanyl
 for burn injury, 784
 in cardioversion, 255–256, 256t
 for increased intracranial pressure, 1246
 for pain management, 483
 in procedural sedation and analgesia, 606b, 611t–612t, 614–615
 for rapid-sequence intubation, 117t, 120
- Ferno-Trac Traction Splint, 936, 936f–937f
- Ferric chloride test, 1462–1463, 1465f
- Fetal development, radiation effects on stages of, 1505–1507, 1506f, 1506t
 cancer in, 1507
 computed tomography and, 1507–1508, 1508t
 convulsive disorders in, 1507
 fetal period and, 1506–1507
 growth retardation in, 1506t, 1507
 hereditary effects of, 1507
 implantation phase of, 1506, 1506t
 mental impairment in, 1507
 organogenesis in, 1506, 1506t
 preimplantation phase of, 1506, 1506t
 retardation in, 1507
 stochastic risks of, 1505t, 1507
- Fetal fibronectin (fFN), 1187
- Fetal heart tones, 12
- Fetal hemoglobin, pulse oximetry and, 28
- Fetal period, 1506–1507
- Fetus
 auscultation of, 1191, 1192f
 breech presentation of, 1188–1190, 1188f, 1200–1203, 1202f
 distress in, 1191–1193
 heart rate of, 1187, 1187f, 1191, 1192f
 lie of, 1187, 1188f
 position of, 1188
 shoulder dystocia in, 1200, 1200f–1201f
 station of, 1191, 1191f
 vertex presentation of, 1188–1189, 1189f, 1198f
- FEV₁/FVC ratio, 24

 Stack, 1042
 ulnar gutter, 1041, 1043f
 subungual hematoma of, 697, 698f–699f
 trephination of, 697, 698f
 swan neck deformity of, 970, 971f
 tourniquet, 634, 636f
 trephination of, 770–771, 771f
 trigger, 1094–1095, 1095f
 tube gauze dressing for, 640f
- Finger(s) (*Continued*)
 tuft fracture of, 702
 wound tape on, 656f, 657
- Fingertip
 amputations of, 702–706, 705f, 953f
 classification of, 953, 953f
 subungual hematoma of, 770–773, 770f
- Finkelstein test, 1091, 1092f
- Fire coral stings, 724, 725f
- Firearm injuries, emergency department thoracotomy for, 339
- Fish bones, in throat, 821–822, 824f
- Fishhook removal, 720–721, 720f–721f
- Fissure, anal, 915–916, 915f
- Fistulas
 arterial venous, 451–452, 451f–452f
 gastrocolic, gastroenterostomy feeding tube and, 850
 tracheoesophageal, 154
- Flap laceration, 706–707, 706f–707f
- Flash burns, 791, 792f
- Flexible endoscopic intubation, through intubating laryngeal mask airway, 93–95
- Flexible endoscopy, 68
- Flexible laryngoscopy, 1338–1339, 1341f
- Flexor tendon injuries, 973–975, 974f–977f
- Flow spirometers, 23
- Flowmeter, standard, for oxygen therapy, 47, 47f
- Fluid management, in increased intracranial pressure, 1247
- Fluid ounces, metric conversions of, 1530t
- Fluid resuscitation
 in burns, 781, 1533
 in hypothermia, 1409–1410
- Fluid-pressurized systems, for arterial cannulation, 387
- Flumazenil
 for drug overdose, 1466
 endotracheal drug administration of, 478
 in procedural sedation and analgesia, 611t–612t, 619
- Flunitrazepam, as date-rape drug, 1240
- Fluorescein
 examination, 1302–1305
 contraindications to, 1303
 indications for, 1303
 interpretation of, 1303–1304, 1304f–1305f
 procedure for, 1303, 1304f
 pulse oximetry and, 28
 urinary, 1462
- Fluorescent treponemal antibody absorption (FTA-Abs) test, 1278
- Fluoroquinolones, tendinopathy with, 1071
- Fluoroscopy
 feeding tube and, 840–841, 842f
 in foreign body removal, 714–715
- Flushing, corticosteroid injection and, 1076
- Foam padding, for immobilization, 924, 924f
- Foams, 641
- Focused Assessment with Sonography for Trauma (FAST) exam, 340–341
- Fogarty catheters
 arterial embolectomy, for feeding tube declogging, 850–851
 for ear canal foreign body removal, 1357
 for nasal foreign body removal, 1377–1378, 1377f
- Foley catheters
 as feeding tube, 841, 845f, 850
 for posterior nasal packing, 1369, 1371f
 for rectal foreign body removal, 911f, 912
 for removal, of esophageal foreign bodies, 817–819, 818f

- Foley catheters (*Continued*)
 for retrograde urethrography, 1179, 1180f-1181f
 for urethral catheterization, 1164, 1164f
- Folliculitis, 754-756, 756f
- Fomepizole, for ethylene glycol poisoning, 1468
- Food bolus
 Heimlich maneuver for, 41
 impacted, 811f, 823-824
- Foot
 basketball, 1023
 bunion of, 1057
 burns, 790, 790f
 compartment syndrome of
 central (calcaneal) compartment and, 1138-1139
 medial compartment and, 1138
 needle placement techniques for, 1138-1139
 dislocations of, 1023-1026
 forefoot, 1024
 hindfoot, 1023
 interphalangeal, 1025-1026, 1025f
 metatarsophalangeal, 1024-1025, 1025f
 subtalar, 1023-1024, 1025f
 talus, 1024
 evaluation of, 1063
 extensor tendon injury of, 972-973, 972f
 foreign body in
 infection with, 1065, 1065f
 removal of, 1064f
 coring technique for, 1063-1064, 1065f
 ganglion cyst of, 1060, 1060f
 hard shoe as, 1052, 1052f
 nerve blocks at, 562t
 neuroma of, 1058-1060, 1059f
 nontraumatic conditions of, 1057-1060
 pads for, 1057, 1058f
 plantar fasciitis, 1058, 1059f
 puncture wounds of, 639f, 1062-1063
 infection with, 1065, 1065f
 sole of, puncture wounds in, 717-718, 718f
- Football helmet removal, 943, 944f
- Footpad, 1057, 1058f
- Forced expiratory volume in 1 second (FEV₁), 23, 24f
- Forced vital capacity (FVC), 23
 spinal immobilization effect on, 930
- Forearm
 nerve block, 582b-587b, 585f-586f
 splints for, 1039-1042
- Forefoot
 dislocations of, 1024
 neuroma of, 1058-1060, 1059f
- Forehead, lacerations of, 686-689, 687f-688f
 black eyes with, 687-689, 688f
 U-shaped, 686-687, 688f
 windshield, 688f, 689
- Foreign body
 abscess and, 739-740
 airway obstruction of, 41-42
 esophageal, 807-827
 anatomy of, 807-808, 808f
 clinical findings of, 808, 808t
 complications of, 807-808, 808b
 epidemiology of, 807
 esophagoscopy for, 813
 evaluation of, 808
 pharmacologic maneuvers, 813-816, 814t
 gas-forming agents, 815-816
 glucagon, 814-815, 815f
 indications and contraindications to, 813
 nitroglycerin and nifedipine, 815
 papain, 816
- Foreign body (*Continued*)
 radiology of, 809-813
 computed tomography (CT) in, 810, 811f
 contrast-enhanced esophagograms, 810-812, 812f
 follow-up, 812, 812t
 indications for, 809
 plain radiographs in, 809-810, 809f-811f
 removal of, 816-820
 bougienage for, 819-820, 820f, 820t
 Foley catheter, 817-819, 818f
 Magill forceps, 816-817, 816f-817f
 special situations in, 820-827
 button battery ingestion, 824-825, 826f
 childhood coin ingestion, 820-821, 821f-823f
 fish or chicken bones, in throat, 821-822, 824f
 impacted food bolus, 811f, 823-824
 magnets, 825-826, 826f
 nonradiopaque objects, in esophagus, 823
 patient in distress, 826
 sensation, in throat, 826-827
 sharp objects, in esophagus, 823, 825f
 visualization of, 813, 813f
- foot, removal of, 1064f
 coring technique for, 1063-1064, 1065f
- ocular
 location of, 1313, 1314f
 multiple, 1316
 removal of, 1312-1316
 aftercare, 1316
 complications of, 1316
 contraindications to, 1312
 equipment for, 1312
 indications for, 1312
 intraocular, consideration of, 1312-1313, 1312f-1313f
 procedure for, 1313-1316, 1315f
 rust rings with, 1316
- rectal, 911f, 913f
 management of, 910-912
 complications of, 912
 contraindications to, 910
 equipment of, 912, 912f
 indications for, 910
 procedure for, 912
 removal of, 911f, 913f
- removal of, 708-737
 decision, 715-716
 discharge instructions for, 737
 disposition management of, 734-737
 antibiotics for, 734-735
 tetanus for, 734
 equipment and preparation for, 716, 716f
 evaluation and diagnosis of, 708-715, 709f-711f
 external auditory canal, 1355-1358, 1358f
 complications of, 1357-1358
 contraindications to, 1356
 cyanoacrylate for, 1357, 1358f
 Fogarty catheters for, 1357, 1358f
 indications for, 1356
 insects in, 1357, 1358f
 manual instrumentation for, 1357, 1358f
 suction-tipped catheters for, 1356-1357, 1357f
- nasal, 1376-1379
 balloon catheter for, 1377-1378, 1377f
 complications of, 1379
- Foreign body (*Continued*)
 contraindications to, 1376
 equipment for, 1376-1377
 indications for, 1376
 manual instrumentation for, 1377, 1377f
 positive pressure for, 1377f-1378f, 1378-1379
 operative technique of, 716-717, 717f
 physical examination, imaging
 techniques for, 708-715, 712t
 computed tomography, 711-712
 fluoroscopy, 714-715
 magnetic resonance imaging, 712-714
 plain radiography, 708-709, 711f, 713f-714f
 ultrasound, 709-711, 714b-715b, 714f-715f
- reactions to, 735-737, 736f
- special scenarios and techniques in, 717-734
 body-piercing, 728-730, 729f-730f
 cactus spine, 726-727, 727f
 in fatty tissue, 717f, 719-720
 fishhooks, 720-721, 720f-721f
 foot, sole of, puncture wounds in, 717-718, 718f
 hair-thread tourniquet, 734, 735f
 marine, 723-726
 metallic fragments and bullets, 719, 719f
 pencil lead/graphite, 717f, 720
 postoperative suture, 730
 ring, 727, 728f
 subungual, 718-719, 719f
 TASER darts, 732, 733f
 tick, 730-731, 731f
 traumatic tattooing, 722-723, 723f
 wooden splinters, 721-722, 722f-723f
 zipper, 731-732, 731f-732f
 superficial, 708
 retained, 646, 646f
 scalp, 646f
 TASER dart, 1497, 1497f
 vaginal, removal of, 1217
- Formulas, 1529-1541
- Four-letter pacemaker code, 289t
- Fractional excretion of sodium, 1531
- Fractional saturation, 25
- Fractures
 of alveolar bone, 1394, 1394f
 of catheter, in IVADs, 459-460
 compartment syndrome and, 1129
 dental, 1387-1390
 of femur, 934-935, 935f
 hematoma block for, 536-537, 536f
 hip dislocations with, 1012-1013
 of humeral neck, 985
 Lisfranc, 1023, 1025f
 mallet, 970f
 of metatarsal, 1061-1062, 1062f
 odontoid, 918-919, 919f

- Gag reflex method, for mandible dislocation reduction, 1381
Gamekeeper's thumb, 1007–1008, 1008f
splint for, 1040–1041, 1042f
Ganglion cysts
foot, 1060, 1060f, 1090f
wrist, 1089–1090, 1090f
Gas-forming agents, for esophageal foreign bodies, 815–816
Gastric decontamination, in poisoned patient, 859–871
activated charcoal in, 864–868, 865f
complications of, 867–868
contraindications to, 866
indications for, 865–866, 866f
multiple doses of, 868–869, 868f
technique for, 865f, 866–867, 867f
cathartics in, 869
complications of, 869
contraindications to, 869
indications for, 869
technique for, 869
gastric lavage in, 859–864, 860f
complications of, 864
contraindications to, 860–861
equipment and preparation of, 861, 862f–864f
indications for, 860, 860f
technique for, 861–864, 862f
use of endoscopy for, 864
whole bowel irrigation in, 869–871
complications of, 871
contraindications to, 870–871
indications for, 870, 870f
technique for, 871, 871f
Gastric lavage, 859–864, 860f
complications of, 864
contraindications to, 860–861
equipment and preparation of, 861, 862f–864f
in hyperthermia, 1427t, 1431
in hypothermia, 1414–1415
indications for, 860, 860f
technique for, 861–864, 862f
use of endoscopy for, 864
Gastric pacemaker, 1503t
Gastrocull card, 1460
Gastrocnemius muscle syndrome, 1073t, 1102f, 1104
Gastroenterostomy feeding tube, 840–850, 842f–846f
clogged, 850–851
complications of, 846–850
equipment for replacing dislodged, 842–843, 847f
removal of, 843–846, 848f
securing, 846, 848f
verification of, 846, 849f
Gastroesophageal varices, balloon tamponade of, 852–858, 852f–853f
aftercare, 854–857
chest radiography for, 857f
complications of, 852f, 857–858
contraindications to, 852f, 853
endoscopic band ligation in, 853
historical perspective on, 852, 853f
indications for, 852f, 853
procedure for, 854, 855f–857f
sclerotherapy in, 853
vasoactive agents in, 853
Gastrografin, for contrast-enhanced esophagograms, 811–812
Gastrointestinal hemorrhage, bedside tests for, 1458–1460
Gastrointestinal tract
cold water lavage and, 830
evaluation of, in procedural sedation and analgesia, 596–598, 597f
nasogastric tube in, 829
terminal, anatomy of, 905f
Gastrothorax, tension, 836
Gel, rectal administration of, 486
Gelfoam, in oral hemorrhage, 1397, 1397f
Genital examination, in sexual assault evaluation, 1228, 1229f–1230f

- Hemorrhoids
 conservative treatment of, 908
 external, 907f, 908
 surgical excision of, 907f, 908–910, 909f–910f
 internal, 904, 907f
 management of, 907–910
- Hemostasis, wound management and, 1528
- Hemostatic agents, for hemorrhage
 control of, 632
 in IVADs, 458
- Hemothorax, 199
 autotransfusion with, 492, 492f
 with central venous catheterization, 436, 436f
 symptoms of, 200
 thoracentesis and, 195
 tube thoracostomy for, 205–206, 206b
 ultrasound in, 492, 492f
- Heparin
 central venous cannulation and, 1525
 low-molecular-weight, 1524
 spinal epidural hematoma and, 1524
- Heparin-associated coagulopathy, in IVADs, 459
- Hepatitis B
 occupational exposure to, 351–352, 1476
 prevention of, sexual assault and, 1236
- Hepatitis B immune globulin (HBIG), for hepatitis B, 1236
- Hepatitis C
 occupational exposure to, 351–352, 1477
 transfusion transmission of, 502–503
- Herniation
 after lumbar puncture, 1270–1271, 1271b
 of brain, 1243, 1244f, 1270
- Heroin, body packing of, 870, 870f
- Herpes zoster, dental pain and, 1387f
- Herpetic keratitis, 1303
- Herpetic whitlow, 765t, 767, 767f
- Hexachlorophene, 627, 627t
 for skin disinfection, 1453
- Hexylresorcinol, 797
- Hickman catheter, 447
- HI-D Big Stick, 42, 42f
- Hidradenitis suppurativa, 756–758, 757f
- High-flow nasal cannula oxygen (HFNC), 48
- High-flow priapism, 1146
- High-frequency ventilation, 166
- Hill-Sachs deformity, 984–985
- Hindfoot, dislocations of, 1023
- HINTS examination, for vertigo, 1288–1290, 1289f
 complications of, 1290
 contraindications to, 1288
 indications for, 1288
 interpretation of, 1289–1290
 procedure for, 1288–1289
- Hip
 arthrocentesis of, ultrasound in, 1110b–1114b, 1113f
 corticosteroid injection of, 1095–1097
 dislocation of, 1012–1016
 analgesia and anesthesia for, 1013–1014
 anterior, 1015–1016, 1016f
 reduction techniques for, 1016, 1017f
 fractures with, 1012–1013
 posterior, 1014, 1014f
 Allis technique for, 1014, 1015f
 Captain Morgan technique for, 1014, 1015f
 reduction techniques for, 1014
 Stimson technique for, 1014, 1015f
 Whistler technique for, 1014, 1015f
 radiographic examination of, 1013, 1013f
 nerve blocks at, 562t
 prostheses, dislocation of, 1014–1015, 1016f
- Hognose device, 1357, 1357f
- Homatropine, ocular, 1299–1301, 1299t
- Honey, for burns, 787
- Hordeolum, 1336, 1337f
- Horizontal head impulse test, for vertigo
 interpretation of, 1289
 procedure for, 1288–1289, 1289f
- Horizontal mattress stitch, 679–680, 682f
- Horse collar, 926f
- Hot tar burns, 794–795, 794f–795f
- Housemaid's knee, 1097
- Huber needle, 448, 449f, 453
- Human antihemophilic factor, 513
- Human bites, 650–653, 651f, 733, 733f
 tendon injury with, 965–966, 965f
- β-human chorionic gonadotropin (β-hCG)
 testing, in sexual assault evaluation, 1234
 in urine, 1450, 1451f, 1451t
- Human immunodeficiency virus (HIV)
 infection
 CSF analysis in, 1279
 cytomegalovirus infection and, 1280

- Human immunodeficiency virus (HIV)
infection (*Continued*)
neurosyphilis in patients infected with,
1278–1279
occupational exposure to, 1477–1479,
1478*t*, 1479*f*
pericardial effusion and, 313
prevention of, sexual assault and, 1236
progressive multifocal
leukoencephalopathy and, 1280
- Humeral neck, fractures of, 985
- Humerus, for intraosseous infusion, 467–468
- Hyaluronidase technique, 1154, 1154*b*
- Hydrocarbon burns, 797
- Hydrocele, 901, 901*f*
- Hydrocephalus
communicating, 1244–1245, 1245*f*
obstructive, 1244–1245
- Hydrocolloids, 641
- Hydrofluoric acid injury, 797–800, 798*f*–799*f*
- Hydrogels, 641
- Hydrogen peroxide
in cerumen impaction removal, 1353
in coral sting, 724
in wound care, 627, 627*t*
- Hydropneumothorax, 201–202, 201*f*
- γ-Hydroxybutyrate (GHB), as date-rape
drug, 1240
- Hygiene
hand, 1476
respiratory, 1470
- Hymen
injury to, 1228, 1230*f*
normal, 1228, 1229*f*
- Hyperalimantation, 409
- Hyperbaric oxygen therapy
for air embolism, 351
for frostbite, 1419
for Jehovah's Witnesses, 519
- Hypercapnia, permissive, 174
- Hyperemia, 754
- Hyperglycemia, hyponatremia in, 1532
- Hyperkalemia, succinylcholine-related,
121–122
- Hypernatremia, 1532
- Hyperosmolar therapy, in increased
intracranial pressure, 1247
- Hypertension, 9
malignant, 1424–1425, 1424*b*
- Hyperthermia
malignant, 122
procedures pertaining to, 1421–1433
psychostimulant overdose and, 1425–1426
types of, 1423
- Hyperventilation
capnogram for, 34
increased intracranial pressure and, 1247
- Hyphema, 1332*f*
- Hypofibrinogenemia, cryoprecipitate for, 511
- Hyponatremia, 1532
- Hypopneic hypoventilation, 34
- Hypotension
endotracheal drug administration of, 478
intubation-related, 114
local anesthesia and, 542
neuroleptic agents and, 1492
- Hypothermia
accidental, 1405
acid-base disturbances in, 1417
airway management in, 1417
alcohol consumption and, 1410–1411
with burns, 780–782
cardiac arrest and, 342, 1410, 1416–1417
coagulopathies in, 1417
core temperature measurement in,
1406–1407, 1406*f*
environmental, 1420
- Hypothermia (*Continued*)
in increased intracranial pressure, 1248
intubation and, 1410
management guidelines, 1411–1416
medications in, 1417–1418
mild, 1405
moderate, 1405
mortality of, 1405, 1420
pathophysiology of, 1407
physiologic response in, 1418
prehospital care for, 1409–1410
procedures pertaining to, 1405–1421
risk factors for, 1405
severe, 1405
signs and symptoms of, 1407, 1407*t*
transvenous cardiac pacing in, 288*f*
trauma and, 1417
- Hypothermic retrograde jugular vein flush,
1432
- Hypothyroidism, pericardial effusion in, 314
- Hypoventilation
capnogram for, 34
types of, 34
- Hypovolemia, physiologic response to,
13–14, 14*b*
- Hypovolemic shock, in venous cutdown, 440
- Hypoxemia
arterial O₂ saturation (SaO₂) and, 26–27
respiratory distress without, 45
- Hypoxic respiratory failure, noninvasive
positive pressure ventilation in, 168
- Hypoxia
endotracheal drug administration and, 478
and suctioning, 43
tracheal suctioning and, 147
- I**
- Iatrogenic paraphimosis, 1151
- Ice packing
strategic, 1430–1431
whole body, 1427*t*, 1429–1430, 1430*f*
- Ice water immersion technique, 1428
- Iced-glove method, 1152–1154, 1154*f*
- Ice-pack test, for myasthenia gravis,
1292–1293, 1292*f*
- Idarucizumab, 517, 517*t*
- Ideal body weight, 1530
- Idiopathic intracranial hypertension (IIH),
1243, 1244*b*
- Idiopathic thrombocytopenic purpura (ITP),
lumbar puncture and, 1524–1525
- Ileus, postoperative, 829
- Illinois Sternal/Iliac Aspiration needle,
464–465, 464*f*
- Immersion therapy
in hyperthermia, 1427*t*, 1428–1429
in hypothermia, 1412, 1412*f*
- Immobilization, prehospital, 917–946
helmet, removal of, 940–946, 942*f*
lower extremity, 934–939, 935*t*
pelvic, 939–940, 939*f*–940*f*
spinal, 917–930, 918*b*
cervical. *see* Cervical spine,
immobilization of
thoracolumbar. *see* Thoracolumbar
spine, immobilization of
upper extremity, 930–934
- Immunization, tetanus, 726, 734
- Immunocompromised patients, CSF analysis
in, 1279–1280
- Immunoglobulin
CSE, 1278
hepatitis B, 1236, 1476
Rh₀(D) human, 507
- Immunoprophylaxis, tetanus, 644–645, 644*t*,
645*f*
- Immunosuppressed patients, noninvasive
positive pressure ventilation and, 168
- Impedance threshold device, in CPR, 334,
334*f*
- Implantable devices
ACLS interventions and, 265–268
acute myocardial infarction and, 269, 270*t*
assessment of, 258–274
automatic implantable cardioverter
defibrillators, 259–262
cardiopulmonary resuscitation and,
265–268
clinical evaluation of patients with,
264–268
complications and malfunction of, 268–269
electromagnetic interference and, 272,
273*b*
external cardiac defibrillation and, 265–268
indications for placement of, 262–263
left ventricular assist devices, 262
MRI and, 1503
pacemaker, characteristics of, 258–262
response to magnet placement, 263–264
- Impregnated catheters, for infection, in
IVADs, 455–456
- Impression technique, for tonometry,
1323–1328, 1324*f*, 1326*f*–1328*f*
- Inches, metric conversions of, 1530*t*
- Incision and drainage
abscess. *see* Abscess, soft tissue, incision
and drainage of
in breast abscess, 758, 758*f*
in felon, 767–770, 768*f*–769*f*
in paronychia, 763–767, 764*f*, 765*t*,
766*f*–767*f*
in perirectal abscess, 760–762, 761*f*
in pilonidal abscess, 758–760, 759*f*–760*f*
in sebaceous cysts, 762–763, 763*f*
wound management and, 1528
- Indermil, 657–659
- Indigo carmine, pulse oximetry and, 28
- Indirect laryngoscopy, for esophageal foreign
bodies, 813
- Indirect pathway, between vestibular and
oculomotor nuclei, 1281
- Indocyanine green, pulse oximetry and, 28
- Indomethacin, 1193, 1193*t*
rectal administration of, 487*t*
- Induction agents, for rapid-sequence
intubation, 116–120
- Indwelling vascular access devices (IVADs),
447–460
accessing, 452–453
aftercare instructions for, 460
arterial venous
accessing, 453, 454*f*
fistulas in, 451–452, 452*f*
grafts in, 452, 452*f*
catheter
displacement or malposition of, 459
fracture in, 459–460
occlusion in, 456
chronic HD vascular access in, 451, 451*f*
coagulopathy with, 459
heparin-associated, 459
uremic platelet dysfunction, 459
warfarin-associated, 459
complications of, 454–460, 454*b*
cuffed, tunneled right atrial catheters in,
447, 448*f*
embolization with, 456
Groshong catheter in, 448
hemodialysis, 450
accessing, 453
hemorrhage with, 456–459, 457*f*
approach to, 457–459, 457*f*–458*f*
chemical cautery for, 458–459

- Indwelling vascular access devices (IVADs)
(Continued)
 dialysis clamps for, 458, 458f
 direct pressure for, 457–458
 mechanical, 457
 suture for, 459, 459f
 thrombogenic and dermal adhesive agents for, 458
 vasoconstrictive agents for, 458
 historical perspective of, 447
 infection with, 454–456
 long-term venous access catheters in, accessing, 453
 midline peripheral catheters in, 449–450
 PICC in, 449, 449f–450f
 pinch-off syndrome in, 456
 steal syndrome with, 460
 temporary dialysis catheters in, 450–451, 450f–451f
 thrombus formation with, 456
 totally implantable, 448, 449f
 accessing, 453
- Infants
 arterial blood sampling in, 356–359, 358f–359f
 arterial catheterization in, percutaneous, 372–373
 back blows for, 41
 bag-mask ventilation for, 50
 capillary blood sampling in, 353–354, 355f
 central venous catheterization in, 364–367
 chest thrusts for, 41
 direct laryngoscopy for, 72–75, 75f
 heart rate in, 5
 heel stick in, 353, 1454
 hemorrhagic shock and encephalopathy syndrome in, 1426
 intraosseous infusion in, 463
 lumbar puncture in, 1266–1267
 with meningitis, 1259
 peripheral venous catheterization in
 “mini-cutdown”, 364f
 percutaneous, 359–361, 361f
 venous cutdown, 361–364, 363f
 rehydration techniques in, 373–376
 discharge after, 376
 laboratory tests and, 375
 nasogastric tube, 375
 nasogastric tube rehydration and, 375
 oral, 374–375, 374f
 parenteral, 375
 subcutaneous, 375–376, 376f, 376t
 umbilical artery catheterization in, 370–371, 370f–371f
 umbilical vein catheterization in, 367–369, 368f–369f
 urine collection in, 1442–1443
 venipuncture in, 354–356, 356f
- Infection
 in arterial cannulation, 391
 arthrocentesis and, 1115–1116
 autotransfusion and, 492
 central venous catheterization and, 435b, 437
 corticosteroid injection and, 1075
 CSF analysis with, 1275–1279
 dentoalveolar, 1398–1403
 foot puncture, 1065, 1065f
 of head and neck, 1400–1403, 1401f–1403f
 intracranial shunt, 1253
 in IVADs, 454–456, 454b
 joint, 1116
 in minor burns, 789–790
 nerve block and, 563
 sexual assault and, 1231–1232
 spinal puncture and, 1270
 from splinting, 1054
- Infection *(Continued)*
 tracheostomy and, 153
 in transfusion therapy, 502–503, 503t
 from urethral catheterization, 1168
 venous cutdown and, 445
 wound, 623, 637f, 653
- Infectious exposure management, 1470–1480
 Infectious keratitis, 1321–1322
 Infiltration anesthesia, 533–536, 533f
 agents for, 534, 534t
 buffering for, 535
 contraindications to, 533
 diphenhydramine and, 543
 epinephrine with, 534, 535b
 equipment for, 534–535
 field block anesthesia and, 533
 indications for, 533
 injection in, 535–536, 536f
 temperature manipulation in, 535
- Infraorbital nerve block, 551–552, 552f
 Infraspinatus muscle syndrome, 1073t, 1102f, 1103
- Infuse-A-Port, 448
 Inguinal hernia
 direct, 897, 898f
 indirect, 897, 898f
 pantaloon, 898
- Inhalation injury, 791, 792f
 Inhibitor-bypassing activity, factor VIII, 513–514
 for anti-factor Xa anticoagulants, 518t
 for direct factor II inhibitors, 516–517, 517t
 for warfarin reversal, 515t–516t
- Injury classification system, 963f
 In-line filtration, in autotransfusion, 493
 Innominate artery, tracheostomy-related bleeding from, 154–155, 155f
 Inspiratory-to-expiratory time ratio, 164, 164f
- Insulin infusion devices, 1499, 1500b, 1500f
 Insulin-dependent diabetics, abscess and, 739, 740f
- Intercostal muscle syndrome, 1073t, 1102f, 1103
- Intercostal nerve block, 562t, 563–566, 564f
 Intercostal space number, 278
 Internal hemorrhoids, 904, 907–908, 907f
- International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiopulmonary Care, 41
 International normalized ratio (INR)
 bleeding and, 1520
 elevated, management of, 512t
 in routine coagulation testing, 1520
 in warfarin reversal, 516t
- Interphalangeal joint
 arthrocentesis of, 1116–1117, 1117f, 1119, 1120f
 fingers, dislocation of
 distal, 1005f, 1010, 1011f
 proximal, 1009–1010, 1009f
 dorsal, 1005f, 1009–1010, 1009f
 lateral, 1010, 1010f
 volar, 1010
 foot, dislocation of, 1025–1026, 1025f
 thumb, dislocation of, 1006, 1006f
 toe, dislocation of, 1025–1026, 1025f
- Interscalene nerve block, 566, 582b–587b, 584f–585f
- Interscapular hypodermoclysis, 490f
 Intersection syndrome, 1090–1093, 1092f
 Intersphincteric abscess, 761, 761f
 Intervention, immediate, spirometry and, 23
- Intracranial hypertension
 idiopathic, 1259–1260
 rapid-sequence intubation and, 114–115
- Intracranial pressure (ICP)
 increased
 diuresis in, 1247
 fluid management, 1247
 glucose control in, 1248
 head position, 1247
 hyperosmolar therapy, 1247
 hyperventilation in, 1247
 hypothermia and, 1248
 management of, 1243–1257
 medical treatment of, 1246–1251
 operative management in, 1251
 oxygenation in, 1246
 paralytics in, 1246–1247
 pathophysiology of, 1243–1245, 1244b, 1244f
 sedation in, 1246–1247
 seizure prophylaxis in, 1247–1248
 signs and symptoms of, 1245–1246
 skull trephination and, 1248–1251, 1249f–1250f
 steroids in, 1248
 titration of ETCO₂ in, 32–33
 in intubation, 113
 in rapid-sequence intubation, 116b
 tracheal suctioning and, 145
- Intracranial shunts, 1251–1257
 assessment of, 1253–1255
 catheter for, 1251, 1251f
 clinical presentation of, 1253
 components of, 1252f
 failure of, 1253
 infection with, 1253
 management of, 1243–1257
 principle of, 1251
 tapping of, 1255–1257, 1257f
 valves for, 1251–1252, 1252f
- Intranasal administration, of medication, 481–485, 482f
- Intraoral laceration, 690–693, 693f
 Intraosseous infusion, 461–475
 anatomy for, 462–463, 462f
 blood transfusion through, 520
 Bone Injection Gun (BIG) for, 465, 465f, 468–470, 471f
 comparative trials between devices, 466
 compartment syndrome with, 475
 complications of, 462f, 471–475
 bony, 474–475
 soft tissue, 474–475
 technical difficulties, 471–474, 474f
 contraindications to, 462f, 464
 distal femur for, 467
 distal tibia for, 467, 467f
 duration of use for, 475
 epiphyseal injury with, 475
 equipment for, 462f, 464–467
 EZ-IO Device for, 465–466, 466f
 EZ-IO needle for, 470–471, 472f–473f
 FAST-1 Intraosseous Infusion System for, 465, 465f, 468
 fat embolism with, 475
 historical perspective on, 461–462
 humerus for, 467–468
 indications for, 462f, 463–464
 in infants, 463
 infection with, 474, 475f
 infusion rate in, 462
 manual needle insertion for, 468, 469f
 medications and fluids for, 463b
 needles for, 464–465, 464f
 NIO device for, 466, 466f, 471, 473f
 pain with, 475
 physiology of, 462–463
 proximal tibia for, 467, 467f
 setup for, 464–467

- Intraosseous infusion (*Continued*)
 simulation studies comparing devices, 466–467
 sites for, 467–468, 467f
 skin sloughing with, 474–475
 sternum for, 468
 training for, 475
 in US military, 463–464
- Intrathoracic pressure, increased, spirometry and, 23
- Intravaginal testicular torsion, 1142
- Intravascular hemolysis, 1447t
- Intravascular injection, of anesthetics, 563
- Intravenous access
 blood transfusion through, 519
 peripheral, 394–404, 394f, 398f, 402b–404b
 adjuncts for finding vein, 397
 anatomy of, 395–396, 396f
 anchoring device of, 399
 anesthesia of, 397
 appropriate site of, 397
 assembly, 397
 cannulation of, 399
 choosing catheter gauge, 397, 397f
 complications of, 394f, 400–401
 contraindications to, 394–395, 394f–395f
 dressing of, 399
 equipment of, 394f
 extravasation of medications and vasopressors, 401–404, 401b, 401f
 historical perspective of, 394
 indications for, 394–395, 394f–395f
 inspection of, 397–399
 maintaining patency of, 399
 percutaneous brachial vein cannulation, 399–400
 positioning of, 397–399
 preparation of, 396–400

 physical, 1484–1488
 belts/fifth-point, 1485, 1485f
 complications of, 1487–1488
 contraindications to, 1486
 hobble leg, 1485–1486, 1486f
 hog-tie, 1485–1486, 1486f
 increased agitation with, 1487
 indications for, 1486
 jackets and vests for, 1485, 1485f
 limb holders for, 1484–1485, 1485f
 local skin and, 1487
 metabolic acidosis with, 1488
 positional asphyxia with, 1487–1488
 procedure for, 1486–1487, 1486f–1487f
 respiratory compromise with, 1487
 vascular compromise with, 1487
 seclusion, 1484
- Resuscitation, principles of, 239
- Resuscitative thoracotomy, 338–352, 338f
 airway control in, 343
 anesthesia and amnesia and, 343
 anterolateral thoracotomy incision in, 343–345, 344f
 aortic cross-clamping in, 349–351, 349f
 blunt and penetrating abdominal injury and, 342
 and cardiopulmonary resuscitation, duration of, 340
 in children, 351
 complications of, 351–352, 352f
 Conn aortic compressor in, 350–351, 350f
 direct cardiac compressions in, 345–346, 345f
 equipment for, 342
 Foley catheter in, 347, 348f
 general technique for, 344f
 hemodynamic monitoring in, 351
 hemorrhagic cardiac wounds in, control of, 346–347, 346f–347f
 hemorrhagic great-vessel wounds in, control of, 349, 349f
 indications and contraindications to, 339–341, 339b
 air embolism as, 341–342
 blunt and penetrating abdominal injury as, 342
 blunt cardiac injuries as, 341
 nontraumatic arrest as, 342
- Resuscitative thoracotomy (*Continued*)
 nontraumatic hypothermic cardiac arrest as, 342
 penetrating cardiac injuries as, 340–341
 pulmonary injuries as, 341
 internal cardiac defibrillation and, 345
 neurologic outcomes and, 340
 partial-occlusion clamps in, 347, 349f
 pericardiomy and, 345
 procedure for, 342–351
 Sauerbruch maneuver in, 346–347, 347f
- Retardation, in fetal period, 1507
- Retrobulbar hemorrhage, 1333–1334, 1334f
- Retrocalcaneal bursitis, 1057–1058, 1101
- Retroglottic airway devices, 58–61, 59f
- Retrograde cystogram, 1178t, 1179–1181, 1182f–1183f
- Retrograde intubation, 106–109, 107f
 complications of, 106, 108
 contraindications to, 106
 equipment for, 106
 indications for, 106
 procedure for, 106–107
 technique of, 106–107
- Retrograde technique, for fishhook removal, 721, 721f
- Retrograde urethrogram
 aftercare for, 1181
 anatomy of, 1177
 complications of, 1181
 contraindications to, 1178
 indications for, 1177–1178
 key procedure sequence of, 1177
 pathophysiology of, 1177, 1178f–1179f
 procedure for, 1178–1179, 1178t, 1180f
- Return of spontaneous circulation (ROSC), capnography and, 32
- Reverse Bigelow technique, for anterior hip dislocation, 1016
- Reverse Wood's screw maneuver, 1200, 1201f
- Rewarming methods
 active core, 1413–1416, 1413f
 arteriovenous anastomoses, 1412
 bladder irrigation for, 1414
 cardiac bypass for, 1415–1416
 experimental, 1416
 external
 active, 1411–1413
 passive, 1411
 for frostbites, 1419
 gastric irrigation for, 1414
 heated humidified oxygen/air for, 1413–1414
 heated saline for, 1413, 1413f
 hemodialysis for, 1416
 peritoneal dialysis for, 1410t, 1414
 prehospital care, 1409, 1410t
 rate of, 1411, 1411t
 thoracic cavity lavage for, 1415
 warm hair inhalation for, 1411t
- Rh compatibility, 507
- Rh immune prophylaxis, 507
- Rh sensitization, 507
- Rhabdomyolysis, from drugs, 1125, 1126f
- RhoGAM, 507
- Rib fractures, intercostal nerve block for, 563, 564f
- Riddell Revolution football helmet, 945f
- Right bundle branch block (RBBB), transvenous cardiac pacing in, 290
- Right-sided heart catheterization, complications of, 301–303, 303f
- Rigid splints, 931, 932f, 933
- Ring block, 1156, 1158f
- Ring cutter, 727, 729f
- Ring removal, 727, 728f
- Ritgen maneuver, 1199f

Rivaroxaban, 517
 Rocuronium, for rapid-sequence intubation, 121*t*, 123
 Roentgen equivalent in man (rem), 1505
 Rotator cuff tear, 984
 Rubin maneuver, 1200, 1201*f*
 "Rule of nines", 777, 779*f*
 Runaway pacemaker syndrome, 269
 Running interlocking horizontal mattress suture (RIHM), 964*f*
 RUSH exam, 1440–1441, 1440*b*–1441*b*
 Rust ring, 1315*f*

S

Sacral nerve stimulator, 1503*t*
 Sacrum, injury to, 919
 Safe dose, maximum, of local anesthesia, 540, 540*t*
 Safe injection practices, 1470, 1471*f*–1472*f*
 Safety, in procedural sedation and analgesia, 594
 Sager Emergency Traction Splint, 936, 936*f*, 938*f*
 Salem sump tube, 828, 829*f*, 833
 Salicylate poisoning, 1462–1463, 1465*f*
 Saline
 hypertonic, in increased intracranial pressure, 1247
 warming of, 1413, 1413*f*, 1416
 Saline arthrography, 1124, 1124*f*
 SAM Sling, 939, 940*f*
 application of, 941*f*
 SAM splint, 931, 932*f*
 Saphenous nerve block, 562*t*, 579*f*–580*f*, 581
 Saphenous vein, cutdown of, pediatric, 361, 439
 Sauerbruch maneuver, 346–347, 347*f*
 Scalp
 anatomy of, 694, 694*f*
 anesthesia, 556–557, 556*f*
 foreign body in, 646*f*
 laceration, 632, 634*f*–635*f*, 694–697, 694*f*–697*f*
 bleeding with, 695, 695*f*
 closure of, 696, 696*f*
 fracture with, 695–696, 695*f*
 hair washing and, 696, 697*f*
 staples for, 663*f*
 subgaleal abscess with, 653, 653*f*
 tick removal from, 730–731, 731*f*
 vein, catheterization of, 360, 362*f*
 Scalpel, for splinting, 1030
 Scapholunate dissociation, 1011, 1011*f*
 Scapula
 dislocation of, 997
 muscles of, 1103
 Scapular manipulation technique, in shoulder dislocations, 989–990, 991*f*–992*f*
 Schiötz tonometry, 1323–1325, 1324*f*
 Schwann cell sheath, 524, 524*f*
 Sclera, hemorrhage of, 1337
 Scoop stretchers, 922–923, 923*f*
 Scopalamine, ocular, 1299*t*, 1301
 Scortten score, for toxic epidermal necrolysis (TEN), 802–803, 802*t*
 Scrotum, acute, 1142
 Sea urchin injury, 725, 725*f*
 Seashore sign, 177, 177*f*, 203*b*–204*b*, 203*f*
 Sebaceous cyst excision, 763*f*
 Seclusion, 1484
 "Sedated look," airway evaluation before RSI, 124
 Sedation, 594, 595*b*
 for awake intubation, 125
 capnography and, 33–34, 34*f*–36*f*, 35*t*–36*t*
 in cardioversion, 255–256, 256*t*

Sedation (*Continued*)
 deep, 595*b*
 dissociative, 595*b*
 intranasal administration, 483
 in mechanical ventilation, 171, 171*b*, 179
 minimal, 595*b*
 moderate, 594, 595*b*
 in rapid-sequence intubation, 116*b*
 Sedative-hypnotic agents, 606–614, 611*t*–612*t*
 Seidel test, 1303
 Seizures
 increased intracranial pressure and, 1247–1248
 intranasal midazolam for, 482–483
 in intravenous regional anesthesia, 593
 local anesthesia and, 541
 Seldinger technique
 for arterial cannulation, 385
 for pneumothorax aspiration, 217, 218*f*
 Selective serotonin reuptake inhibitors, 1425
 Self-inflicted injury, 793*f*
 Self-inflicted wounds, 707, 707*f*
 Sellick maneuver, 51–52, 75
 Semen, testing for, in sexual assault evaluation, 1234–1235
 Semirigid fiberoptic stylets, 101*f*
 Semirigid optical stylets, 101
 Semirigid orthosis, for ankles, 1051*f*, 1052
 Semispinalis capitis muscle syndrome, 1073*t*, 1101, 1102*f*
 Semont maneuver procedure, 1287–1288, 1288*f*
 Sengstaken–Blakemore tube (SB), 852, 853*f*, 854, 855*f*–857*f*. *see also* Gastroesophageal varices, balloon tamponade of
 Sepsis
 pulse amplitude and, 6
 transfusion therapy and, 502
 Septal hematomas, 1373–1374, 1373*f*
 Serotonin syndrome, 1425
 Serum bicarbonate, PETCO₂ and, 34–37, 37*f*
 Sesamoid bones, fracture of, 1060–1061, 1061*f*–1062*f*
 Sever's disease, 1057–1058
 Sexual assault
 child, examinations for, 1238–1239, 1238*f*, 1239*b*
 consent and, 1225
 definition of, 1225
 drug-facilitated, 1240–1241, 1240*b*
 evaluation and treatment of patients suffering from, 1225–1235
 anal, 1232–1234, 1234*f*
 chain of custody in, 1235
 collection of clothing in, 1227
 colposcopy in, 1230, 1231*f*
 consent in, 1225–1226
 general body examination in, 1227
 genital examination in, 1228, 1229*f*–1230*f*
 history in, 1226–1227
 imaging in, 1227
 oral, 1227–1228, 1228*f*
 perineal toluidine blue dye staining in, 1232, 1233*b*, 1233*f*
 physical examination in, 1227–1230
 preparation in, 1225, 1226*f*
 pubic hair samples in, 1228–1230
 reference samples in, 1234
 sperm recovery in, 1226, 1226*t*
 spermatozoa, semen, and DNA testing in, 1234–1235
 urine tests in, 1234
 vaginal washing in, 1230
 forensic evidence collection in, 1225, 1226*f*, 1230, 1230*b*, 1232*f*

Sexual assault (*Continued*)
 legal issues in, 1241
 male, evidentiary examinations for, 1238
 specific populations and, 1238–1241
 suspect examinations in, 1239–1240
 treatment for, 1235–1238
 hepatitis B prevention and, 1236
 HIV infection prevention and, 1236
 postexamination follow-up in, 1238
 pregnancy prophylaxis in, 1236–1237, 1237*t*
 psychological support in, 1237
 STD prophylaxis in, 1235–1236, 1235*b*–1236*b*, 1235*t*
 unconscious victim of, 1240–1241, 1240*b*
 use of force in, 1226
 victim of, examination of, 1225–1241
 Sexual assault crisis agency, 1237
 Sexual assault nurse examiners (SANEs), 1241
 Sexual assault response teams (SARTs), 1225, 1241
 Sexually transmitted disease (STD)
 MRSA as, 742
 prophylaxis for, 1235–1236, 1235*b*–1236*b*
 sexual assault evaluation of
 child and, 1239
 genital testing for, 1231–1232
 risk for, 1235*t*
 Sharp objects, in esophagus, 823, 825*f*
 Sheath introducer
 in central venous catheterization, 417–418, 419*f*
 in transvenous cardiac pacing, 296*f*–297*f*
 Shivering, 1407
 with cooling therapy, 1429
 Shock
 hemorrhagic, homeostatic mechanisms in, 14*b*
 hemorrhagic encephalopathy and, 1426
 hypovolemic, in venous cutdown, 440
 index, 11
 states, in oxygen therapy, 45
 Shoe, hard (cast, Reese), 1052, 1052*f*
 Shoe covers, 1470, 1471*f*
 Shoulder
 arthrocentesis of, 1118, 1119*f*
 ultrasound in, 1110*b*–1114*b*, 1111*f*–1112*f*
 calcareous tendinitis of, 1078*t*, 1081–1084, 1082*f*–1083*f*
 dislocations of, 983–997
 anterior, 983–994, 983*f*
 clinical assessment of, 983–984, 984*f*–985*f*, 984*t*
 post-reduction care for, 993–994, 993*f*
 post-reduction immobilization in, 994
 radiologic examination of, 984–986, 986*f*–988*f*
 reduction techniques for, 986–993, 989*f*
 best of both (BOB) technique, 990, 991*f*–992*f*
 Eskimo technique, 991*f*–992*f*, 993
 external rotation method, 990, 991*f*–992*f*
 Milch technique, 990, 991*f*–992*f*
 scapular manipulation technique, 989–990, 991*f*–992*f*
 Spaso technique, 991*f*–992*f*, 993
 Stimson maneuver, 988–989, 991*f*–992*f*
 traction-countertraction technique, 990–993, 991*f*–992*f*
 inferior (luxation erecta), 997, 997*f*
 reduction techniques for, 996*f*

- Shoulder (*Continued*)
- posterior, 994–997
 - clinical assessment of, 984*t*, 994, 994*f*
 - post-reduction care for, 997

 - stockinette for, 1029–1030, 1034
 - thickness and, 1035
 - toenail, 1070, 1070*f*
 - trauma scissors for, 1030
 - upper extremity, 930–931, 931*t*, 1036–1044
 - complications of, 934
 - contraindications to, 931
 - double sugar-tong splint as, 1038–1039, 1038*f*
 - equipment for, 931–933
 - figure-of-eight thumb splint as, 1042*f*
 - fingers and, 1042, 1045*f*
 - indications for, 931
 - long arm anterior splint as, 1037–1038
 - long arm posterior splint as, 1036–1037, 1037*f*
 - procedures for, 933–934
 - radial gutter splint as, 1041–1042, 1044*f*
 - sugar-tong splint as, 1039, 1040*f*
 - thumb spica splint as, 1040–1041, 1041*f*–1042*f*
 - ulnar gutter splint as, 1041, 1043*f*
 - volar splint as, 1039, 1039*f*
 - utility knife for, 1030
 - volar wrist splint and, 1031*f*
 - wood composite splinting material for, 1029, 1030*f*
- Sponge sting, 724–725
- Spontaneous bacterial peritonitis (SBP), 896
- Spontaneous breathing, mechanical ventilation and, 164–165
- Sport helmet removal, 943–946, 944*f*

- Sputum, transtracheal needle aspiration of, 153
- Square waveform, in mechanical ventilation, 164
- Stab wounds
cardiac, 311
diagnostic peritoneal lavage in, 876–877, 877f, 878t
heart, 340–341
thoracic, emergency department thoracotomy for, 339
- Standard flowmeter, for oxygen therapy, 47, 47f
- Standard Macintosh blades, video laryngoscopes with, 85–87, 86f
- Standard precautions, 1470–1480
barrier, 1470, 1471f
guidelines for, 1470–1476
injection practices, 1470, 1471f–1472f
respiratory, 1470–1473, 1472f, 1472t
- Standard-point Quincke cutting needle, for spinal puncture, 1261
- Staphylococcus aureus*, methicillin-resistant, 738, 740–742, 741f, 748b
- Staples
in cardiac hemorrhage, 346, 346f
for wound, 661–664, 661f
complications of, 663–664
equipment for, 661
indications and contraindications to, 661
procedure for, 661–663, 662f–663f
removal of, 663
- Starfish injury, 725
- Steal syndrome, in IVADs, 460
- Stellate laceration, 683–685, 684f
- Stenosis
subglottic, 135
tracheal, 153–154
- Stent, tracheal, 157
- Steri-Strips, 655, 656f
- Sternoclavicular joint, dislocation of, 999, 999f
- Sternocleidomastoid muscle syndromes, 1073t, 1101–1103, 1102f
- Sternum, for intraosseous infusion, 468
- Steroids
in increased intracranial pressure, 1248
in preterm labor, 1194
- Stevens-Johnson syndrome (SJS), 800–803, 801f
- Stiffneck collar, 921f
- Stimson maneuver
in anterior hip dislocation, 1016
in hip dislocation, 1014, 1015f
in shoulder dislocations, 988–989, 991f–992f
- Sting
catfish, 725–726, 726f
coelenterate, 724, 724f
coral, 724, 725f
- Stingrays, 726, 726f
envenomation of, 726, 726f
- Stirrup splint, 1050, 1051f
- Stitch abscess, 637–638
- Stockinette, for splinting, 1029–1030, 1034
- Stool, blood in, 1458–1460, 1459f
- Storz D-Blade, 87
- Straight-blade technique, 87
- Stress fractures, 1062b
metatarsal, 1061–1062, 1062f
- String sign, 1120, 1121f
- String-wrap ring removal, 727, 728f
- String-yank technique, for fishhook removal, 720, 721f
- Stroke, National Institutes of Health Stroke Score for, 1536–1541, 1537t–1540t
- Stryker intra-compartmental pressure measurement, for compartment syndrome evaluation, 1125f, 1127–1128, 1132–1134, 1133f
- Stump, 949–951, 951f
- Stun gun, 1496
- Stuttering priapism, 1147
- Stye, 1336, 1337f
- Subacromial bursitis, 1078t, 1080f, 1083f
- Subarachnoid hemorrhage, 1245f, 1259
- Subclavian artery, cross-clamping of, 349, 349f
- Subclavian vein
catheterization of, 409t, 420, 435b
anatomy of, 405, 407f
complications of, 437
contraindications to, 410
infraclavicular, 420–421, 421f
pediatric, 366–367
supraclavicular, 421–422, 422f
ultrasound for, 426b–428b, 427f
for transvenous cardiac pacing, 294, 294f, 294t
- Subconjunctival hemorrhage, 1337, 1337f
- Subcutaneous hydration (hypodermoclysis), 489b
- Subcutaneous rehydration, in infants and children, 375–376, 376f, 376t
- Subdiaphragmatic abdominal thrusts (Heimlich maneuver), 41, 42f
- Subdural hematoma, 1246, 1246f, 1248f–1249f
spinal, 1260–1261
- Subglottic stenosis, as complication, of cricothyrotomy, 135
- Subtalar joint, dislocations of, 1023–1024, 1025f
- Subungual foreign body, 718–719, 719f
- Subungual hematoma, 697, 698f–699f, 770–773, 770f, 772f
trephination for, 770–771, 771f
trephination of, 697, 698f
- Succinylcholine
hyperthermia with, 122
in increased intracranial pressure, 1246–1247
for rapid-sequence intubation, 121–122, 121t
- Suction systems, for tube thoracostomy, 213–214, 216f
- Suctioning, in basic airway management, 42–43, 42f
- Sufentanil, in procedural sedation and analgesia, 615
- Sugar technique, 1154, 1154b
- Sugar-tong splint, 1039, 1040f
double, 1038–1039, 1038f
- Sulfuric acid, burns from, 795
- Superficial peroneal nerve block, 562t, 579f–580f, 580
- Superficial trigger point, 1078t
- Superglue, in ear canal foreign body removal, 1357, 1358f
- Superior alveolar block
anterior middle, 551, 551f
anterior superior, 550–551, 550f
middle, 549–550, 550f
posterior, 546–549
- Supination method, in nursemaid's elbow reduction, 1004, 1004f
- Supine position, airway management in, 41
- Suppository, rectal, 486
- Suppurative thrombophlebitis, 400
- Suprapatellar bursitis, 1098
- Supraperiosteal nerve block, 546, 549f
- Suprapubic aspiration, 1170–1172, 1173f
- Supraspinatus tendinitis, 1081–1084, 1083f
- Supraventricular tachycardia, 221–237
with aberrancy, 225
accessory pathway in, 225
anatomy and physiology of, 221–237, 223f–224f
approaches to, 222b
cardioversion in, 235–239, 239f. *see also* Cardioversion
narrow-complex, 221
pharmacologic management of, 231–235, 231f, 232b
adenosine in, 232–233, 232f
β-adrenergic blockers in, 233–234
amiodarone in, 233
digoxin in, 225–226, 235
diltiazem in, 234–235
esmolol in, 234
procainamide in, 233
propranolol in, 234
sotalol in, 234
verapamil in, 235
reentry in, 222, 224f
vagal maneuvers for, 225b
apneic facial exposure to cold as, 231
carotid sinus massage as, 227–230, 229f
ECG changes with, 225, 225b
equipment and setup for, 226–227
indications for, 225–231
Valsalva maneuver as, 230–231
wide-complex, 221, 225
- Sural nerve block, 562t, 579f–580f, 580
- Surfactants, 627–628
- Sur-Fast Needle, 464f, 465
- Surgical airway, 68
- Sutlains ointment, 796
- Sutures, 664–706, 960f–961f, 965f
abscess with, 637–638, 756
absorbable, 664f, 665t, 666
complications of, 648
composition of, 664, 665t
continuous, 675–676, 677f–679f
dental, 1393f
for dog-ear correction, 683, 684f
drains in, 702
in ear lacerations, 689, 691f
eversion techniques for, 675, 675f–676f
in eyebrow lacerations, 689
in eyelid lacerations, 689, 690f
in facial wounds, 685–686, 685f–687f
figure-of-eight, 683, 683f
in forehead, 686–689, 687f–688f
handling and performance in, 664–666, 665t
for hemorrhage, in IVADs, 459, 459f
instruments for, 664, 664f
interrupted, 674f, 675
layered closure with, 670–671, 671f
in lip and intraoral lacerations, 690–693, 692f–693f
material of, 664–667, 664f, 665t
mattress, 679–681, 680f–682f
monofilament, 665t, 666
multifilament, 665t, 666
needles for, 667, 667f
nonabsorbable, 664f, 665t, 666
in nose lacerations, 689, 691f
principles of, 667–671, 670f
removal, 622, 646–647, 647f
for resuscitative thoracotomy, 346, 347f
in scalp laceration, 694–697, 694f–697f
size of, 666–667
skin preparation for, 667
in SQ layer, 671–672, 672f–673f
in stellate laceration, 683–685, 684f
strength of, 665t, 666–667
subcuticular, 676–679, 677f–680f
surface, 673, 674f–675f

- Sutures (*Continued*)
 techniques for, 667–685, 668f
 tension and, 670–671
 tie in, 669f
 in tongue lacerations, 693–694, 693f
 for tube thoracostomy, 212, 215f
 undermining and, 670, 670f
- Swathe and sling, 1043
- Sweat glands, abscess in, 756, 757f
- Swimmer's ear, 1355
- “Swirl” sign, 1246f
- Swiss roll technique, for paronychia, 765
- Synchronized intermittent mandatory ventilation, 165–166
- Syncope, in carotid sinus syndrome, 225–226
- Synovial fluid interpretation, 1120–1122
 cell count in, 1121
 fluid processing of, 1121
 glucose in, 1121
 mucin clot test of, 1120–1121
 polarizing microscope of, 1121–1122
 microscopic analysis of, 1122, 1122f–1123f, 1122t
 polarization physics of, 1121–1122
 protein in, 1121
 serology of, 1121
 string sign in, 1120, 1121f
- Synthetic dressings, 783–784
- Syphilis, transfusion transmission of, 502
- Syringe, for arterial puncture, 378–379, 378f
- Systemic inflammatory response syndrome, transfusion therapy and, 505–506
- Systemic toxicity, with local anesthetics, 563
- Systolic arterial blood pressure, 7–8
- T**
- Tachycardia
 pacemaker-mediated, 269
 transvenous cardiac pacing in, 291
- Talalgia, 1100–1101, 1100f
- Talus, dislocations of, 1024
- Tape, wound, 655–657, 656f, 658f–659f
- Tar burns, hot, 794–795, 794f–795f
- Targeted temperature management, for cardiac arrest, 1420–1421, 1422t
- TASER, 1496, 1497f
- darts, removal of, 732, 733f
- Tattooing, traumatic, 722–723, 723f
- Teeth, 1384, 1385f–1386f
 avulsion of, 1391–1393, 1393f
 deciduous, 1384, 1385f
 dry socket of, 1397–1398
 emergency materials for, 1403, 1403f
 extraction of, bleeding after, 1396
 fractures of, 1387–1390
 calcium hydroxide for, 1388, 1389f
 Ellis class I, 1387, 1388f
 Ellis class II, 1387–1389, 1388f
 Ellis class III, 1388f–1389f, 1389–1390
 soft tissue laceration with, 1387, 1387f
 intrusion of, 1391–1393, 1391f
 luxation of, 1390–1391, 1390f
 pain in, 1386
 permanent, 1385f
 reimplantation of, 1391–1392, 1393f
 subluxation of, 1390–1391
 supernumerary, 1384
- Tegaderm, 641
- Temperature, 17–21
 contraindications to, 18
 conversion scale for, 20f
 core
 afterdrop of, 1412
 measurement of, 1406–1407, 1406f
 ear, 20t
 indications for, 18
- Temperature (*Continued*)
 infiltration anesthesia and, 535
 interpretation of, 19–21
 measurement sites for, 18–19
 monitoring of, 20
 normal, 17–18, 20t
 oral, 18, 20t
 physiology of, 17–18
 pulse rate and, 5
 rectal, 18, 20t, 1406f, 1407
 respiratory rate and, 2–3
- Temporal arteries, for arterial cannulation, 390
- Temporary dialysis catheters, 450–451, 450f
- Temporomandibular joint (TMJ) dislocation, 1379, 1379f
- Tendinitis, 1071, 1072f
 ankle, 1098–1100
 bicipital, 1078t, 1080–1081, 1080f–1081f
 calcareous, 1078t, 1081–1084, 1082f–1083f
 supraspinatus, 1081–1084, 1083f
 treatment of, 1071–1104
- Tendon
 injection-related rupture of, 1076
 lacerations of, 625f
- Tendon sheaths, 1071
- Tennis elbow, 1085, 1085f
- Tenosynovitis, 1071, 1080–1081
 de Quervain's disease, 1078t, 1090–1093, 1091f–1092f
 digital flexor, 1094–1095, 1095f
 gonococemia causes, 1071
- Tension gastrothorax, 836

- Testicular torsion, 1141–1145
 anatomy of, 1142, 1143f
 intravaginal, 1142
 key procedure sequence of, 1141–1142
 manual detorsion in, 1143f, 1145
 aftercare for, 1145
 complications of, 1145
 contraindications to, 1144
 indications for, 1142–1144
 pathophysiology of, 1142
- Tetanus immunoprophylaxis, 644–645, 644t, 645f, 726, 734
- Tetracaine, 525t–526t
 base patch, 529–530
 mucosal application of, 527, 527t
 ocular, 1296, 1298t
- Tetracaine-adrenaline-cocaine (TAC), 531–532
 complications of, 533
- Tetracycline, for antibiotic-resistant *N. gonorrhoeae*, 1235–1236
- Thermoregulation, 1408f, 1422–1423
- Thimerosal, sensitivity reaction to, 1318
- Thiopental
 in cardioversion, 255–256, 256t
 in increased intracranial pressure, 1246
 in procedural sedation and analgesia, 611t–612t, 614
 in rapid-sequence intubation, 116b, 117t
 rectal administration of, 487t
- Thompson's test, 976–978, 978f
- Thoracentesis, 181–195
 anesthesia for, 188–190, 191f
 anticoagulation and, 1526–1527
 chest radiograph after, 191, 193f
- Thoracentesis (*Continued*)
 clopidogrel, risk of bleeding in patients taking, 1527
 complications of, 187f, 195
 contraindications to, 185–186, 187f
 equipment for, 186, 187f
 indications for, 185, 187f
 insertion site for, 187–188, 190f
 needle aspiration technique for, 190
 over-the-needle catheter insertion technique for, 191, 192f
 in parapneumonic effusion, 195, 195b
 patient position for, 187–188, 188f
 pediatric, 191
 technique for, 186–191
 ultrasound for, 187–188, 188f–190f, 189b–190b
- Thoracic cavity lavage, in hypothermia, 1415
- Thoracic duct laceration, catheter-related, 437
- Thoracic spine, injury to, 919
- Thoracolumbar spine, immobilization of
 complications of, 930
 full-body spine boards for, 922, 923f, 927–929
 full-body splints, 923–924, 923f
 procedure for, 926–929
 in recumbent position, 926–929
 scoop stretchers for, 922–923, 923f, 926–927
 in sitting position, 926
 in standing position, 929
- Thread tourniquet, hair, 734, 735f
- Three-bottle system, in autotransfusion, 494–495, 495f
- Three-in-one block. *see* Femoral nerve block

carotid sinus massage as, 227–230, 229f
ECG changes with, 225, 225b
equipment and setup for, 226–227
indications for, 225–231
Valsalva maneuver as, 230–231
- Vagal nerve stimulators, 1501–1502
anatomy for, 1502, 1502f
device complications of, 1502
procedure for, 1502, 1502b, 1503f
- Vagina, 1212f, 1217
blood supply of, 1218
examination of
in labor, 1190–1191, 1190f–1191f
in sexual assault, 1228, 1229f
fluid of, 1187
foreign body removal from, 1217
- Vaginal bleeding, during the third trimester, 1194–1197, 1195f–1196f
- Vaginal washing, in sexual assault evaluation, 1230
- Valsalva maneuver, 230–231
- Vascath catheter, 450–451
- Vascular steal syndrome, 460
- Vasoconstrictive agents, for hemorrhage, in IVADs, 458
- Vasopressin, 514
endotracheal drug administration of, 478
- Vasopressors, 401–404, 401b, 401f
- Vasospasm, in epinephrine, 563
- Vasovagal reactions, 543–544, 543f–544f
- Vecuronium
in mechanical ventilation, 170
for rapid-sequence intubation, 121t, 123
- Velpau bandage, 1043
- Venipuncture, pediatric, 354–356, 356f
antecubital fossa for, 354
external jugular vein for, 354–356, 357f
femoral vein for, 354–356, 358f
- Venous access, in transvenous cardiac pacing, 295
- Venous augmentation, 403f
- Venous cutdown, 439–446, 439f
anatomy for, 440–442
of basilic vein, 441, 441f
of cephalic vein, 441–442, 441f
in children, 439
contraindications to, 440
equipment for, 439f, 442
flow rates with, 442, 442.e1t–442.e2t
of great saphenous vein, 440–441, 440f–441f
in hypovolemic shock, 440
indications for, 439–440
pediatric, 361–364, 363f
selection of site for, 440–442
technique for, 442–445, 443f–444f
mini-cutdown as, 444–445, 445f
modified, 445
- “Venous occlusion” theory, of compartment syndrome, 1128
- Venous pulsations, pulse oximetry and, 29
- Ventilation
adequacy of, in patients with altered mental status, capnography and, 34
assessment of, device for, 23–37
jet, 127. *see also* Percutaneous translaryngeal ventilation (PTLV)
- Ventilation-perfusion (V/Q) scanning, fetal effects of, 1509, 1510b
- Ventilator settings, 1530
- Ventilator-associated pneumonia (VAP), tracheostomy and, 153
- Ventilator-associated tracheobronchitis (VAT), 153
- Ventilator-induced lung injury, 173
- Ventricular dysrhythmias, 239f
- Ventricular fibrillation (VF), 238, 239f
in children, 250
CPR in, 241–242
fine, 243–244
vs. pacing artifact, 305, 306f
- Ventricular free-wall rupture, 313
- Ventricular tachycardia, 223f
AICD-resistant, 266, 267f
carotid sinus massage in, 225, 226f–227f
overdrive pacing in, 307–308
pulseless, CPR in, 241–242
- Ventriculoperitoneal shunt, 1251, 1252f
- Venturi mask, 47–48, 47f
- Verapamil, in supraventricular tachycardia, 235
- Vertigo, neurologic tests and procedures for, 1285–1290
canalith-repositioning maneuvers, 1286–1288, 1287f–1288f
DIX-Hallpike test, 1285–1286, 1286f
HINTS examination, 1288–1290, 1289f
- Video intubating stylets, 101
- Video laryngoscopes, 85–95, 86f, 89f
with angulated blades, 87–90, 87f
with standard Macintosh blades, 85–87, 86f
with tube channel, 90–92, 90f
- Vinegar, in coelenterate sting, 724
- Violent behavior
de-escalation techniques for, 1484
restraint for. *see* Restraint
seclusion for, 1484
- Viral infection, meningial, 1275t
- Vision, unilateral loss of, 1331–1334
in central retinal artery occlusion, 1331–1333, 1333f
in orbital compartment syndrome, 1333–1334, 1334f

- Visual acuity, assessment of, 1295–1296
distant, 1295, 1297f–1298f
indications for, 1295, 1296f
near, 1295–1296, 1297f
optokinetic nystagmus in, 1296, 1298f
- Vital signs
abnormalities of, in pericardial tamponade, 315–316, 316t
in adults, 2
background of, 1b, 1.e1
for children, 1, 2t
determination of volume status, 12–13
measurement of, 1–22
normal values of, 1–2
orthostatic, 13–16
pain as, 21–22
during pregnancy, 2, 3t
in procedural sedation and analgesia, 600
- Vitamin K
epoxide reductase, 514
for warfarin reversal, 515t
- Vitamin K antagonists
arthrocentesis and, 1526
reversal of anticoagulation and, 1523, 1523f
- Vitamin K₁ (phytonadione), 514–515
- Voice restoration, transesophageal puncture for, 156
- Volar splint, 1039, 1039f
- Volume spirometers, 23
- Volume status, vital sign determination of, 12–13
- Volume-cycled ventilation, 165
- Volume-pressure relationship, in mechanical ventilation, 160
- Vomiting, in ketamine, 616
- von Willebrand disease (vWD)
dental procedures and, 1527
lumbar puncture and, 1524–1525
postpartum hemorrhage and, 1528
- von Willebrand factor (vWF), in cryoprecipitate, 511
- W**
- Walking boots, 1050–1052, 1051f
- Warfarin
coagulopathy from, 514–516
resistance, 515
reversal of, 511, 514–516, 515t
spinal epidural hematoma and, 1524
- Warfarin-associated coagulopathy, and IVADs, 459
- Warm hair inhalation, in hypothermia, 1411t
- Warts, plantar, 1057
- Washerwoman's sprain, 1090
- Water, total body, 1532
- Water-bottle heart, 317, 318f
- Weakness, neurologic tests and procedures for, 1290–1293, 1290f
edrophonium (Tensilon) test, 1291–1292, 1291f
ice-pack test, 1292–1293, 1292f
- Weaver's bottom, 1096
- Webril, for splinting, 1034
- West Nile virus (WNV), transfusion transmission of, 503
- Whistler technique, in hip dislocation, 1014, 1015f
- White blood cell (WBC)
correction, in cerebrospinal fluid, 1531
count, in diagnostic peritoneal lavage, 883–884
in pleural effusion, 194, 194t
urinary, 1449f
- White coat hypertension, 9
- Whitlow, herpetic, 765t, 767, 767f
- Whole bowel irrigation, 869–871
complications of, 871
contraindications to, 870–871
indications for, 870, 870f
technique for, 871, 871f
- Whole-body ice packing, 1427t, 1429–1430, 1430f
- Wick catheter, for compartment pressure measurement, 1127
- Windshield injury, 688f, 689
- Winter's formula, 1536
- Witzel tunnel, 837, 839f, 841
- Woodcast composite splinting material, 1029, 1029f–1030f
- Wooden splinters, removal of, 721–722, 722f–723f
- Wound care
animal bites, 648–650, 650f–651f, 652t
cleaning in, 625–634
antibiotic solutions for, 628
antiseptics for, 627–628, 627t
delay in, 623
irrigation for, 625, 628
mechanical scrubbing for, 625–627, 626f
patient preparation for, 625, 625f
recommendations for, 628
cosmesis in, 623
débridement in, 630–631, 631f
elevation in, 642–643, 643f
excision in, 630
gunshot wounds, 648, 650f
human bites, 650–653, 651f
ointments in, 643, 643f
patient instructions for, 645–646
puncture wounds, 648, 649f
reexamination in, 646, 646f
secondary, 646–647
splinting in, 642–643, 643f
systemic antibiotics in, 644
tetanus immunoprophylaxis in, 644–645, 644t, 645f
tourniquet in, 632–634
vessel ligation in, 632, 633f
- Wound closure, 634–637
débridement before, 628–629
delayed, 636–637, 638f
disinfection for, 629
drapes for, 629–630
dressings for, 637–642
absorbent layer of, 642
contact layer of, 639–642, 639b, 641t
functions of, 637–639
outer layer of, 642
excision before, 630
exploration for, 630
hemorrhage in, control of, 631–632
methods of, 655–707
flap lacerations, distally and proximally, 706–707, 707f
sutures for, 664–706. *see also* Sutures
tissue adhesive for, 657–661
wound staples for, 661–664, 661f–663f
wound tape for, 655–657, 656f, 658f–659f
- open wound management *vs.*, 634–636, 637f
preparation for, 628–634, 629f. *see also* Wound care
secondary, 636–637
selective débridement before, 630–631
sterile gloves for, 629–630
suture removal, 622
- Wound management
anticoagulation and, 1528
control of hemorrhage in, 1528
incision and drainage in, 1528
- Wound management (*Continued*)
hemostasis and, 1528
open, wound closure *vs.*, 634–636, 637f
- Wound staples, 661–664, 661f
complications of, 663–664
equipment for, 661
indications and contraindications to, 661
procedure for, 661–663, 662f–663f
- Wound tape, 655–657
background and tape comparisons, 655, 656f
complications of, 657
contraindications to, 655–656
equipment for, 656–657, 656f
indications for, 655, 656f
procedure for, 656f, 657, 658f–659f
- Wounds
abrasions, 624
avulsions, 624
classification of, 624
combination, 624
contaminants in, 624
crush, 624
cultures, 643–644
devitalized tissue in, 624–625, 630
evaluation of, 623–625
healing, 621–623, 622f
complications of, 648–654
corticosteroids on, 643
hemorrhage in, control of, 631–632, 633f
scalp, 632, 634f–635f
tourniquet in, 632–634, 636f
vessel ligation in, 632, 633f
history for, 623
infection of, 623
infiltration anesthesia for, 533
lacerations, 624
location of, 624
management, principles of, 621–654
open management of, 634–636, 637f
physical examination of, 623–624
puncture, 624
self-inflicted, 707, 707f
topical anesthesia for, 531–532, 531f
in underlying structure, 624–625, 625f
- Wrist
arthrocentesis of, 1117, 1117f
carpal tunnel syndrome of, 1078r, 1093–1094, 1093f
de Quervain's disease, 1078t, 1090–1093, 1091f–1092f
extensor tendons in, 972
ganglia, 1078t
ganglion cysts of, 1089–1090, 1090f
intersection syndrome, 1090–1093, 1092f
nerve blocks at, 562t, 567–569, 569f–570f
- Wrist pivot method, for mandible dislocation reduction, 1380f, 1381
- X**
- Xanthochromia, 1272, 1274–1275
- X-ray. *see* Chest radiography; Radiography
- Y**
- Yergason's test, 1080–1081, 1081f
- Yuzep method, 1236–1237
- Z**
- Zavanelli maneuver, 1200
- Zipper, penis entrapment by, 731–732, 731f–732f
- Ziprasidone, for restraint, 1490t, 1494–1495
- Zolpidem, as date-rape drug, 1240
- Z-tract technique, 1076

Fast answers and trusted evidence

Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

Fast

Anticipates your query, recognizing concepts and offering shortcuts

Complete

Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

Convenient

Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

Trusted

Content from Elsevier, the name healthcare professionals worldwide rely on
