If an unexpected or atypical organism is found in an abscess culture, the clinician should consider an underlying process that is not readily apparent from the history or physical examination. For example, tuberculosis or fungal isolates are sometimes found in immunocompromised patients (e.g., those with diabetes or acquired immunodeficiency syndrome). Finding *Escherichia coli* suggests an enteric fistula or even self-inoculation of feces in some patients with a psychiatric illness such as Munchausen’s syndrome. Recurrent abscesses without an obvious underlying cause could indicate clandestine drug use. What appears to be a typical recurrent abscess may be a manifestation of an underlying septic joint, osteomyelitis, or rarely, metastatic or primary cancer (see Fig. 37.2).

Special Considerations

Parenteral drug users, insulin-dependent diabetics, hemodialysis patients, cancer patients, transplant recipients, and individuals with acute leukemia have an increased frequency of abscess formation when compared with the general population. At initial evaluation, the patient may emphasize an exacerbation of the underlying disease process or an unexplained fever, with symptoms of an abscess being a secondary complaint. In these situations, abscesses tend to have exotic or uncommon bacteriologic or fungal causes and typically respond poorly to therapy.^{16–18} Patients with diabetes-induced ketoacidosis (DKA) should be evaluated extensively for an infectious process; a rectal examination should be included with the physical examination to rule out a perirectal abscess as the infectious trigger of DKA. This is also true for patients who are immunocompromised. There are several reasons why patients with diabetes and parenteral drug users are at increased risk for abscess formation: intrinsic immune deficiency, an increased incidence of staphylococcal carriage, potentially compromised tissue perfusion, and frequent needle punctures, which allow a mode of entry for pathogenic bacteria.¹⁹

Patients who use IV drugs frequently use veins in the neck and in the femoral areas, which can produce abscesses and other infectious complications at these sites.²⁰ Any abscess near a vein of the antecubital fossa or dorsum of the hand should alert the clinician to possible IV drug use; however, substance users may also inject directly into the skin (“skin popping”), which can cause cutaneous abscesses distant from veins (Fig. 37.3).

A foreign body may serve as a nidus for abscess formation. Patients with a history of IVDU frequently break needles in skin that has been toughened by multiple injections, so the clinician should maintain a high index of suspicion for retained needle fragments. If an abscess is recurrent or if the patient is a known or suspected IV drug user, consider radiographs or other

Figure 37.2 An abscess that appears in an atypical place or recurs after successful initial treatment should raise the possibility of rare or underlying conditions. **A**, This patient had a large “abscess” on the lateral chest wall that initially drained unusual gelatinous material, not frank pus. **B**, At follow-up 3 days later, the abscess was much improved. The contents of the abscess had been sent for pathologic analysis because it had an unusual consistency, and a highly undifferentiated soft tissue malignancy was demonstrated. The fluid was sterile. Normally, analyzing or culturing the contents of an abscess will not yield helpful information, but in this case the unusual consistency of the collection prompted further analysis. **C**, This intravenous drug user had an “abscess” of the chest wall drained in various emergency departments several times over a 2-month period, and it seemed to initially respond to drainage and antibiotics. He still had an area of cellulitis, minor fluctuance, and continued drainage near the center of the chest. This is an atypical place for a simple cutaneous abscess. Magnetic resonance imaging demonstrated osteomyelitis and an abscess of the sternoclavicular joint that was draining to the skin and simulating a recurrent cutaneous abscess. He required extensive surgical débridement and prolonged antibiotics. The etiologic organism was never ascertained, but *Pseudomonas* is often present. **D**, This patient underwent a sternotomy for bypass surgery a few months previously. She had been treated sporadically for a minor wound infection, but then a draining fluctuant mass developed at the inferior border of the sternum. This is the external manifestation of extensive sternal osteomyelitis.

techniques to search for foreign bodies, an underlying septic joint, or osteomyelitis.²¹ Ultrasound is also a useful adjunct to evaluate for foreign bodies that are not radiopaque.

MRSA

First acknowledged in the 1960s as a cause of infection in patients in health care settings, MRSA has now become the most common identifiable cause of community-acquired skin and soft tissue infections in many metropolitan areas in the United States. The spread of this organism is considered an epidemic and it is very virulent and aggressive.^{22,23} One study found an MRSA prevalence as high as 75% to 80% in some parts of the country.²⁴

Virulent community-acquired MRSA (CA-MRSA) causes rapid and destructive soft tissue infection because of the presence of two bacterial toxins elaborated by the omnipresent USA-300 and USA-400 strains. Panton-Valentine leukocidin enhances tissue necrosis, and phenol-soluble modulins are toxic to neutrophils. Methicillin resistance is mediated by PBP-2a, a penicillin-binding protein encoded by the *mecA* gene, which permits the organism to grow and divide in the presence of methicillin and other β -lactam antibiotics. *S. aureus* acquires methicillin resistance through a mobile staphylococcal cassette chromosome (SCC) that contains the *mecA* gene complex (SCC*mec*). MRSA probably arose as a result of antibiotic selective pressure.^{25,26}

A single clone probably accounted for most MRSA isolates discovered during the 1960s; by 2004, six major MRSA clones

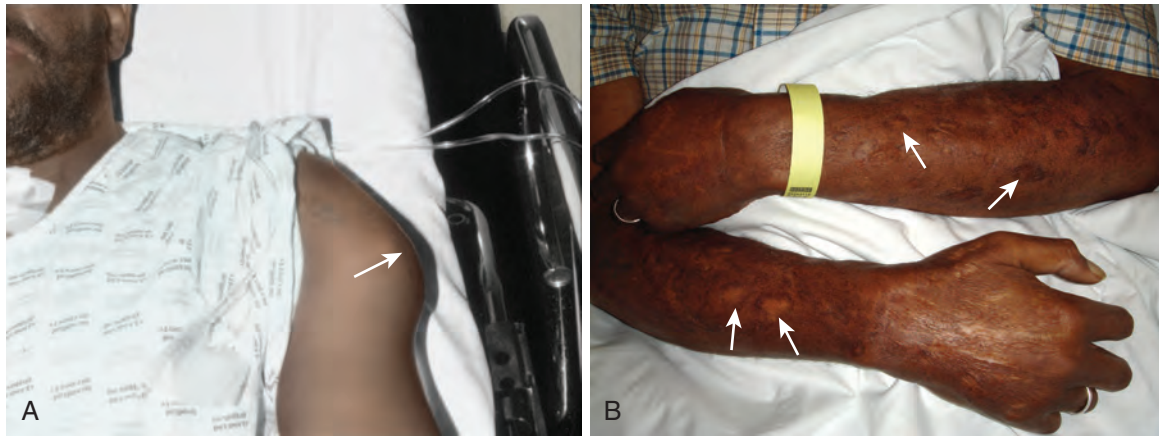

Figure 37.3 This patient had a large abscess in the deltoid area (*arrow*) and could offer no explanation for it. This is a typical scenario for a drug user who injects directly into the skin. **B**, The characteristic circular skin lesion from “skin popping” found on the arms (*arrows*) confirmed the clinical suspicion. Even though a drug screen was positive for opioids, the patient denied drug use and attributed the leg lesions to frequent trauma on the job. Drug users with abscesses are at risk for numerous infections, including brain abscess, endocarditis, and occult osteomyelitis.

Figure 37.4 A–C, Examples of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) infections. These aggressive infections can spread rapidly. The patient frequently describes a small pustule that becomes an abscess in 24 to 48 hours. Patients often believe that it is a spider bite because of its rapid onset in an otherwise healthy person with no other reason for the lesion. A CA-MRSA abscess, though clinically aggressive, is usually treated like any other cutaneous abscess.

had emerged.²⁷ The spread of resistance is thought to be mediated by horizontal transfer of the *mecA* gene and related regulatory sequences thereon.²⁸

In 1980, the spread of MRSA from hospitals into communities became evident. More recently, community-acquired infections have occurred more frequently, even in people without

known risk factors. A small pustule can become a large abscess in 24 to 48 hours (Fig. 37.4). Such lesions are often mistaken for a spider bite or drug use because of their rapid progression and seemingly spontaneous onset in an otherwise healthy person. These observations have led to the identification of some risk factors for CA-MRSA, including skin trauma (e.g., lacerations,

tattoos, IV and intradermal drug use, shaving), incarceration, shared razors or towels, and close contact with others colonized or infected with MRSA.²⁹⁻³⁷ Animals can also carry MRSA and can function as a source of transmission.³⁸ Importantly, many patients with CA-MRSA have no identifiable risk factors for acquisition of the disease.³⁹ CA-MRSA tends to be more virulent than health care-associated MRSA (HA-MRSA) and is associated with more frequent serious complications such as osteomyelitis, joint infections, sepsis, and death. However, these organisms fortunately tend to be susceptible to a broader array of antibiotics.⁴⁰

The prevalence of MRSA has increased in both health care and community settings. For example, the prevalence of methicillin resistance among *S. aureus* isolates in intensive care units in the United States has been reported at 60%,²² and more than 90,000 invasive infections by MRSA occurred in the United States in 2005.⁴¹

HA-MRSA and CA-MRSA differ with respect to their clinical epidemiology and molecular structures. HA-MRSA is defined as MRSA infection that occurs following hospitalization (hospital onset, formerly “nosocomial”) or MRSA infection that occurs outside the hospital within 12 months of exposure to a health care setting (e.g., history of surgery, hospitalization, dialysis, or residence in a long-term care facility—community onset instead of community acquired).²²

HA-MRSA is usually associated with severe, invasive disease, including skin and soft tissue infection, bloodstream infection, and pneumonia.^{7,42} In fact, *S. aureus* continues to be a significant cause of surgical site infections.⁴¹ HA-MRSA strains tend to be resistant to multiple drugs. MRSA is one of the few pathogens routinely implicated in nearly every type of hospital-acquired infection. This is probably related in part to the organism’s capacity for biofilm formation on indwelling lines and tubes in hospital settings.²⁶ Biofilm facilitates survival and multiplication of MRSA on these surfaces, thereby prolonging the duration of exposure of the organism to antibiotics, as well as promoting the potential for the development of genetic resistance.²⁹

CA-MRSA is defined as MRSA infection that occurs in the absence of health care exposure. It is often associated with skin and soft tissue infections in young, otherwise healthy individuals.²⁹ Most CA-MRSA strains are sensitive to non- β -lactam antibiotics, although a multidrug-resistant isolate has been described in men who have sex with men.^{43,44} This strain contains the pUSA03 plasmid and carries resistance genes for β -lactams, fluoroquinolones, tetracycline, macrolides, clindamycin, and mupirocin.

The CA-MRSA and HA-MRSA classifications are no longer distinct as MRSA colonization can develop in one realm and manifestations of infection in another. In the mid-2000s in San Francisco, the annual incidence of CA-MRSA surpassed that of HA-MRSA.⁴⁵

Furthermore, community-onset HA-MRSA infections have been observed with increasing frequency. This was illustrated in a study of 209 patients discharged from hospitalized care; within 18 months following hospital discharge, 49% of new MRSA infections began outside the hospital.⁴⁶ In another series of 102 patients with CA-MRSA infections, 29% had molecular typing consistent with HA-MRSA.⁴⁷

CA-MRSA was initially reported in injecting drug users in the early 1980s and has since become the most frequent cause of skin and soft tissue infections seen in US EDs and ambulatory clinics. In an assessment of the prevalence of MRSA across the United States, Moran and colleagues⁴⁸ compiled data from

adults who sought treatment of acute skin and soft tissue infections in EDs in 11 American cities in August 2004. *S. aureus* was isolated from three fourths of the 422 patients who met the study criteria. Seventy-eight percent of the *S. aureus* isolates were resistant to methicillin. MRSA was isolated from 59% of patients in the study. The prevalence of MRSA ranged from 15% to 74% in the participating EDs. MRSA was the most common identifiable cause of skin and soft tissue infections in all but one of the EDs.

Frazer and associates,⁴⁰ reporting from an ED in northern California, found that half of the 137 patients in their study were either infected with or colonized by MRSA. Three fourths of all *S. aureus* isolates were MRSA. In addition, 76% of cases met a strict clinical definition of CA-MRSA. The incidence of CA-MRSA, genetically unrelated to nosocomial isolates, increased steadily from 1990 to 2001 and then dramatically in 2002 and each year thereafter.^{49,50}

MRSA has also emerged as a potential sexually transmitted disease. Roberts and colleagues described their treatment of two patients who came to their urban ED with abscesses, probably transmitted by heterosexual oral-genital contact. Both tested positive for MRSA.²³ A 2010 case report drew a similar conclusion. It reported orogenital transmission of MRSA to an immunocompetent 22-year-old man who tested orally positive for MRSA and group B (genital) *Streptococcus* after oral contact with a female partner in whom MRSA-positive gluteal lesions had previously been diagnosed.⁵⁰ MRSA abscesses have been described following skin-to-skin contact during a lap dance.

In a retrospective chart review, Roberts and colleagues found that 18% of the 524 subcutaneous abscesses treated in their urban ED in 2006 were confined to the genital area. Almost three fourths of the 272 outpatient wound cultures performed on that year’s patient population were positive for MRSA.²³

MANIFESTATIONS OF CUTANEOUS ABSCESES

The diagnosis of cutaneous abscess formation is usually straightforward. The presence of a fluctuant mass in an area of induration, erythema, and tenderness is clinical evidence that an abscess exists (see Fig. 37.1). An abscess may appear initially as a definite, tender, soft tissue mass, but in some cases a distinct abscess may not be readily evident. If the abscess is deep, as is true of many perirectal, pilonidal, and breast abscesses, the clinician may be misled by the presence of a firm, tender, indurated area without a definite mass. If the findings on physical examination are equivocal, needle aspiration or ultrasound examination may be performed to assist in the diagnosis.⁵¹ This approach may also identify a mycotic aneurysm or an inflamed lymph node simulating an abscess. A specific entity commonly mistaken for a discrete abscess is the sublingual cellulitis of Ludwig’s angina (see Chapter 65).

Parenteral injection of illicit drugs can produce simple cutaneous abscesses that unpredictably advance to extensive necrotizing soft tissue infections. The emergency clinician must maintain a high index of suspicion to avoid missing this potentially life-threatening condition.⁹ Cellulitis and abscess formation can lead to bacteremia and sepsis, especially in immunocompromised patients.

The pain of an abscess often brings the patient to the hospital before it spontaneously ruptures, or the patient can have a draining abscess that appears to have undergone spontaneous

rupture and is self-resolving. The patient may have even punctured the abscess in an attempt to drain it. In most cases, a formal I&D procedure will be necessary to effectively manage the condition, even though copious drainage may not be encountered. Although no formal drainage may be required after the spontaneous rupture of a simple cutaneous abscess, conditions such as a perirectal abscess, Bartholin gland abscess, and breast abscess are usually best managed with further appropriate drainage and packing.

IMAGING

Ultrasound-Guided Needle Aspiration

Radiologists have been performing ultrasound-guided needle aspiration of abscesses for some time, and emergency clinicians are now becoming more comfortable with the procedure. High-resolution ultrasound technology is being used to obviate “blind” procedures done in the ED (e.g., joint aspiration and central line placement).

For ultrasound-guided drainage of a cutaneous abscess, use a high-resolution probe (7.5–10 MHz) and maintain sterility throughout the procedure. Place the sterile transducer over the main body of the abscess and insert the needle through the skin adjacent to the transducer. Adjust their relative relationships in keeping with the depth and location of the abscess cavity. Guide the needle, seen as a bright artifact, directly into the abscess. Watch the abscess cavity collapse as pus drains out. Scan the entire area of the suspected abscess and beyond to capture unexpected extensions of the abscess. Be sure to drain all pockets.

LABORATORY FINDINGS

A complete blood count (CBC), blood cultures, and Gram stain are not standard or required for the treatment of straightforward cutaneous abscesses in the ED. Recommendations for culturing abscesses encountered in the ED are confusing and clinical practice varies. Firm recommendations for the emergency clinician are difficult to standardize, partly because of insufficient data but also because the recommendations promulgated are not confined to ED abscess treatment. In addition, “complicated” and “uncomplicated” criteria are somewhat arbitrary. Traditionally, culturing the contents of a readily drainable cutaneous abscess was not indicated, nor standard. It simply provided no additional useful information to the clinician under most circumstances. Many clinicians still forgo routine culturing, even in the CA-MRSA milieu. Currently, there is no agreement concerning routine culturing, and reasonable arguments can be made for a culture or no-culture approach to most abscesses treated in the ED. The authors support selective, not routine culturing but acknowledge that some now consider cultures to be indicated for all abscesses drained in the ED. A culture will potentially identify an unusual or resistant organism, especially if I&D is not curative. Culture will also permit identification of antibiotic susceptibility and assist in customization of antibiotic therapy. Cohort results also provide a framework for local epidemiology and resistance patterns. Culturing the abscess contents will distinguish between MRSA and nonresistant abscesses and will provide useful sensitivity information when managing complicated cases.

Culturing should be performed for recurrent, unusual, or atypical abscesses. This information could be useful if the patient responds poorly to initial surgical drainage, if secondary spread of the infection occurs, or if bacteremia develops.^{52,53} It also appears prudent to obtain cultures from abscesses and other purulent skin and soft tissue infections in patients already taking antibiotics, in immunosuppressed patients, in those with signs of systemic illness, in patients who have not responded adequately to initial treatment, if there is concern for a cluster or outbreak of infection, or in patients with severe local infection.⁵³ Severe local infection can be defined as an abscess larger than 5 cm in diameter, multiple lesions, or extensive surrounding cellulitis. However, the degree of surrounding cellulitis qualifying as “extensive” is ill defined.

When obtaining a specimen for culture, the most accurate and complete culture results will be obtained if one aspirates pus with a needle and syringe before I&D. The material should be cultured for aerobic and anaerobic bacteria. Most clinicians, however, still culture free-flowing purulent material obtained with a cotton swab during I&D. For uncomplicated ED abscesses, this culture technique is standard and adequate to isolate aerobic organisms, including MRSA. A “sterile” culture from a specimen collected with a standard cotton swab after incision is frequently the result of improper anaerobic culture technique. In selected patients, such as immunocompromised hosts or IV drug users, isolation of possible anaerobic organisms by needle aspiration with a syringe through appropriately cleaned (e.g., with chlorhexidine) skin before I&D will enhance the results of culture and can add information that may be clinically relevant to subsequent therapy. There is a general misconception that foul-smelling pus is a result of *E. coli*. This foul odor is actually caused by the presence of anaerobes; the pus associated with *E. coli* is odorless.

The discovery of solid or suspicious material in an abscess should prompt histologic evaluation because a malignancy may mimic cutaneous abscesses (see [Fig. 37.2A and B](#)).

The majority of patients with an uncomplicated cutaneous abscess will have a normal CBC and will not experience fever, chills, or malaise. Therefore, in the absence of extenuating circumstances, it is not standard to analyze blood from patients with typical cutaneous abscesses because laboratory test results do not lead to a specific therapeutic path. An abscess may produce leukocytosis, depending on the severity and duration of the purulent process; however, the presence or absence of leukocytosis has virtually no diagnostic or therapeutic implications. Bacteremia may occasionally be manifested as a peripheral abscess resulting from septic emboli, and it usually produces clinical characteristics dissimilar to those associated with simple cutaneous abscesses. A cutaneous abscess itself rarely produces bacteremia.

Gram stain is neither indicated nor standard in the care of uncomplicated simple abscesses. However, patients who appear “toxic” or immunocompromised and those who require prophylactic antibiotics (see the section on [Prophylactic Antibiotics](#) later in this chapter) may benefit from Gram stain in addition to cultures. Gram stain results have been shown to correlate well with subsequent culture results, so in compromised hosts the test can be used to direct the choice of antibiotic therapy. Anaerobic infections should be suspected when multiple organisms are noted on Gram stain, when a foul odor is associated with the purulence, when free air is noted on radiographs of the soft tissue, and when no growth is reported on cultures.¹⁴

ULTRASOUND BOX 37.1: Cellulitis and Abscesses

by Christine Butts, MD

Ultrasound offers a distinct advantage when evaluating a patient with suspected soft tissue infection and may change management. A recent study from *Academic Emergency Medicine* by Tayal and colleagues evaluated the effect of soft tissue ultrasound on the management of cellulitis in the emergency department.¹ The authors found that in patients with a low suspicion for abscess, ultrasound changed management in 56% of cases. Peritonsillar abscesses are difficult to diagnose from the physical examination alone, and some clinicians may feel hesitant to attempt blind drainage. Ultrasound of suspected peritonsillar abscesses has been found to be reliable in making the diagnosis. The overall size of the abscess, as well as its proximity to the carotid artery, can be evaluated with ultrasound, which will perhaps improve the confidence of the clinician in attempting drainage.^{2,3}

General Considerations

Typically, a high-frequency (7.5 to 10 MHz) transducer should be used to evaluate the superficial soft tissues. The higher frequency will allow the clinician sufficient resolution to identify changes consistent with soft tissue infection. The entire area should be scanned in detail, in multiple planes, to identify fluid pockets. Surrounding structures in the area should also be evaluated, especially when incision and drainage are planned. When evaluating the posterior pharynx for a potential peritonsillar abscess, an intracavitary transducer should be used.

Normal Soft Tissue

Normal soft tissue is characterized by well-defined layers, with clear demarcation between these layers (Fig. 37.US1). The top of the screen corresponds to the most superficial soft tissue, including the epidermis and dermis. It should appear hyperechoic (light gray to white), thin, and clearly separate from the underlying layers. Subcutaneous tissue is found beneath the dermis and is of varying thickness. However, as with the most superficial layers, this layer should appear thin and well demarcated from the surrounding layers. Underneath the subcutaneous tissue, muscle will typically be seen as layers of striated tissue separated by bright layers of fascia.

Figure 37.US1 Ultrasound image of normal soft tissue. In this image, the tissue planes are clearly defined, with well-demarcated boundaries between the layers. This clean, organized appearance is lost with soft tissue edema and cellulitis.

Cellulitis

Cellulitis is recognized on ultrasound by thickening of the skin and subcutaneous layers (Fig. 37.US2). The tissue may also appear more hyperechoic than normal soft tissue. When a significant amount of edema is present within the tissue, bands of hypoechoic (dark gray) or anechoic (black) fluid may be seen within the area of thickened tissue. This is known as “cobblestoning” (Fig. 37.US3). Cobblestoning appears as thin bands of fluid throughout the tissue and can be distinguished from an abscess by the lack of a discrete fluid collection.

Abscess

An abscess is seen as a focal, discrete fluid collection within an area of cellulitis (Fig. 37.US4). The presence of surrounding cellulitis is the key to distinguishing an abscess from other fluid collections such as cysts. The character of the fluid may be variable, depending on the

Figure 37.US2 Ultrasound image of cellulitis. Thickening of subcutaneous tissue can be seen with loss of organized tissue planes. A small artifact is seen at the center of the image.

Figure 37.US3 Ultrasound appearance of cobblestoning. Thickened subcutaneous tissue can be seen in this image with strands of hypoechoic (dark gray) fluid interwoven between the tissue (arrow). This interweaving gives the appearance of a “cobblestoned” street and is consistent with soft tissue edema.

ULTRASOUND BOX 37.1: Cellulitis and Abscesses—cont'd

Figure 37.US4 Ultrasound appearance of an abscess. A large, well-contained hypoechoic (*dark gray*) fluid collection (*arrow*) can be seen surrounded by thickened subcutaneous tissue.

content of the abscess. Collections that are completely fluid will appear as anechoic (black) areas, whereas areas with more solid components will appear to have “internal echoes” within the collections (Fig. 37.US5). Once a focal fluid collection has been located, it can be evaluated in detail to determine the overall size and depth from the surface. Peritonsillar abscesses appear as rounded hypoechoic (dark gray) to anechoic (black) collections of variable size. In addition to confirming the presence of an abscess, the location and depth of the carotid artery can also be judged before an attempt at aspiration.

Figure 37.US5 Ultrasound image of a peritonsillar abscess. A rounded area of mixed density (both anechoic and hypoechoic areas) is seen in the center of the image.

INDICATIONS FOR AND CONTRAINDICATIONS TO I&D

Surgical I&D is the definitive treatment of a soft tissue abscess⁵⁴; antibiotics alone are often inadequate. Drainage of a suppurative focus generally results in marked resolution of the symptoms in most uncomplicated cases. In the initial stages, only induration and inflammation may be found in an area destined to produce an abscess. Premature incision, before localization of pus, will not be curative and may theoretically be deleterious because extension of the infectious process and, rarely, bacteremia can result from manipulation. In some cases, the application of heat to an area of inflammation may ease the pain, speed resolution of the cellulitis, and facilitate the localization and accumulation of pus. Nonsurgical methods are not a substitute for surgical drainage and should not be continued for more than 24 to 36 hours before the patient is reevaluated.

PROPHYLACTIC AND THERAPEUTIC ANTIBIOTIC THERAPY

The utility of antibiotics remains unproven for prophylaxis against and for treatment of uncomplicated and adequately

drained cutaneous abscesses in immunocompetent hosts. For simple abscesses, I&D alone is likely to be quite adequate and curative, even if the causative organism is MRSA. Routine administration of antibiotics after I&D is not currently standard, although the topic is subject to ongoing investigations. Simply stated, drainage alone for uncomplicated abscesses is usually curative. Furthermore, the use of antibiotics may in fact be harmful. Antibiotic misuse has also been shown to complicate resistance patterns, both in general and in specific patients.

Even though no randomized controlled trial data definitively demonstrate the need for antibiotic therapy in conjunction with I&D of uncomplicated cutaneous abscesses in healthy, immunocompetent patients (without the specific types of valvular heart disease discussed later), there is strong consensus for antibiotic treatment of abscesses associated with the following conditions: severe or extensive disease (e.g., involving multiple sites of infection) or rapid progression in the presence of associated cellulitis, signs and symptoms of systemic illness, associated comorbid conditions, immunosuppression, extremes of age, abscess in an area difficult to drain (e.g., face, hand, and genitalia), associated septic phlebitis, and lesions that are unresponsive to I&D alone.⁵⁵

Antibiotic use is indicated for abscesses with associated severe cellulitis (this term is not well defined and generally is a clinical judgement) and those with *purulent cellulitis*. Purulent

cellulitis is defined as cellulitis associated with purulent drainage or exudate in the absence of a drainable abscess. Purulent cellulitis is usually caused by MRSA. Nonpurulent cellulitis, defined as cellulitis with no purulent drainage or exudate and no associated abscess, is usually due to β -hemolytic streptococci. Empirical therapy for MRSA, pending culture results, is recommended for patients who have failed non-MRSA treatment, for those with a previous history of or risk factors for MRSA, and for those with severe infection or systemic signs and symptoms. Empirical therapy for infection with β -hemolytic streptococci is likely to be unnecessary under these circumstances.

The duration of therapy for skin and soft tissue infections has not been well defined, although no differences in outcome were observed in adult patients with uncomplicated cellulitis receiving 5 versus 10 days of therapy in a randomized, controlled trial.⁵⁶ In the Food and Drug Administration licensing trials for complicated skin and soft tissue infections, patients were typically treated for 7 to 14 days. However, in the outpatient setting of uncomplicated infections, 3 to 5 days of antibiotic therapy is reasonable but should be individualized on the basis of the patient's clinical condition and response to treatment. Accordingly, a return wound inspection or primary care follow-up is an important component of the care plan.

Patients with a history of IVDU who have an abscess and fever require parenteral antibiotic therapy after blood has been drawn for culture, until bacterial endocarditis can be ruled out.⁵² Additionally, patients who have extensive cellulitis or are clinically septic require immediate IV antibiotics, as well as aggressive surgical drainage of any significant abscess. By administering IV ampicillin/sulbactam (2 g/1 g) every 6 hours, Talan and colleagues⁵³ achieved 100% eradication of pathogens from major abscesses in hospitalized IV drug users and non-drug users.

Therapeutic Antibiotics

In contrast to prophylaxis before surgery, the routine use of therapeutic oral antibiotics after I&D of simple cutaneous abscesses in otherwise healthy patients who are not immunocompromised appears to have no value, and their empirical use cannot be scientifically supported. Llera and Levy⁵⁴ performed a randomized, double-blind study to compare the outcomes of patients treated with a first-generation cephalosporin after the drainage of cutaneous abscesses in the ED with those who received a placebo. They found no significant difference in clinical outcome between the two groups and concluded that antibiotics are unnecessary for abscesses in individuals with normal host defenses. This is in agreement with several previous studies.⁵⁷⁻⁵⁹ One study found that, although the use of trimethoprim-sulfamethoxazole (TMP-SMX) did not decrease treatment failure rates, it may help to decrease recurrence of subsequent lesions.⁶⁰ It should be noted that high-risk patients were often excluded from these studies. Immunocompromised patients have not been adequately studied in this situation and are therefore often given antibiotics empirically; but this practice, though common, has not been supported by rigorous prospective studies.

For empirical coverage of CA-MRSA in outpatients with skin and soft tissue infection, oral antibiotic options include the following: clindamycin, TMP-SMX, a tetracycline (doxycycline or minocycline), and linezolid. If coverage of both β -hemolytic streptococci and CA-MRSA is desired, options include the

following: clindamycin alone or the use of TMP-SMX or a tetracycline in combination with a β -lactam (e.g., amoxicillin or cephalexin), or linezolid alone. The use of rifampin as a single agent or as adjunctive therapy for the treatment of skin and soft tissue infections is not recommended.⁵⁵

Facial abscesses should be handled cautiously and checked frequently. Any abscess above the upper lip and below the brow may drain into the cavernous sinus, so manipulation may predispose to septic thrombophlebitis of this system. Treatment with antistaphylococcal antibiotics and warm soaks after I&D has been recommended pending resolution of the process. Areas not in this zone of the face can be treated in a manner similar to that used for other cutaneous abscesses.

A relatively unstudied but a common and currently accepted strategy for patients with soft tissue infections (especially CA-MRSA infections) that are borderline, by clinical judgment, for hospital admission and therapeutic IV antibiotics, is to administer a single dose of an IV antibiotic in the ED, followed by oral antibiotics and close outpatient follow-up. When a CA-MRSA infection is likely, IV vancomycin or linezolid is a reasonable option. Oral linezolid may be as effective as the IV form.

Prophylactic Antibiotics

Prophylaxis for Endocarditis

The precise risk for endocarditis after I&D of a cutaneous abscess remains unknown, and it is difficult to predict in which patients an infection will develop and which particular therapeutic procedures subject the patient to the highest risk for infection. However, bacteremia clearly occurs with manipulation of infected tissue, and mortality rates are substantial for MRSA-associated endocarditis (30% to 37%).^{61,62} Given this risk, it is reasonable that patients at highest risk for cardiac complications related to transient bacteremia be pretreated with appropriate antibiotics within 1 hour preceding the procedure.⁶³⁻⁶⁵

Guidelines issued by the American Heart Association (AHA) in 2007 recommend antibiotic prophylaxis for procedures involving the respiratory tract, infected skin, or infected musculoskeletal tissue only in patients with cardiac conditions that carry the highest risk for an adverse outcome from infective endocarditis.⁶⁵ These conditions are listed in [Box 37.1](#). Most skin infections are polymicrobial, but only staphylococci and β -hemolytic streptococci are likely to cause infective endocarditis. Therefore the therapeutic regimen should include an agent active against these organisms, such as an antistaphylococcal penicillin or a cephalosporin. For patients who cannot tolerate a β -lactam or if MRSA is suspected, vancomycin or clindamycin can be substituted.

Two clinical situations deserve special mention. First, because of the frequent incidence of valvular damage in IV drug users, prophylactic antibiotics may be indicated before I&D of abscesses in these patients; however, no standards exist. It is prudent to inquire about previous endocarditis or auscultate for a heart murmur if IV drug abuse is suspected or known and administer antibiotics under these circumstances. Second, any patient with a documented history of endocarditis must receive prophylactic antibiotics before the I&D procedure.

Cutaneous abscesses may result from active endocarditis and prophylactic antibiotics may obscure subsequent attempts to identify the causative organism. With this in mind, two or three blood cultures (aerobic and anaerobic) should be

BOX 37.1 Cardiac Conditions With the Highest Risk for Adverse Outcome From Endocarditis

- Prosthetic cardiac valve or prosthetic material used in valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD)^a
 - Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or a device, whether placed via surgery or catheter intervention, during the first 6 months after the procedure^b
- Repaired CHD with residual defects at the site of or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
- Cardiac transplantation with the development of cardiac valvulopathy

^aExcept for the conditions listed previously, antibiotic prophylaxis is no longer recommended for any other form of CHD.

^bProphylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis, *Circulation* 116:1736, 2007.

considered before antibiotic therapy for those at risk for endocarditis. Patients with a diagnosis of mitral valve prolapse have traditionally been included for treatment with prophylactic antibiotics, but the indication for this is unclear and antibiotic prophylaxis for uncomplicated mitral valve prolapse is no longer part of the AHA guidelines.⁶⁶

Kaye⁶⁷ suggested prophylaxis only for patients who have a holosystolic murmur secondary to mitral valve prolapse.

Prophylaxis for Bacteremia in Other Conditions

Conflicting results have been reported from the few studies investigating the relationship between I&D of cutaneous abscesses and bacteremia. For example, in 1985 Fine and associates⁶⁸ concluded that I&D of cutaneous abscesses is often accompanied by transient bacteremia. They compared blood culture results from specimens obtained before and at 1, 5, and 20 minutes after I&D procedures in 10 patients with soft tissue infections. None of the cultures of blood obtained before I&D were positive; however, six patients had at least one positive culture after the procedure. Eleven of the 30 postprocedure cultures yielded growth. In contrast, in 1997 Bobrow and coworkers⁶⁹ concluded that I&D of a localized cutaneous abscess is unlikely to result in transient bacteremia in afebrile adults. Their study included 50 patients with localized cutaneous abscesses. Blood samples were collected before and at 2 and 10 minutes after I&D. In addition, specimens from the wound were collected after drainage. None of the blood cultures were positive, even though 64% of the wound cultures were positive, primarily for *S. aureus*. Bobrow and coworkers⁶⁹ noted that prophylactic antibiotics should be given to patients at high risk for bacterial endocarditis. In a discussion of the differences between these findings and those reported by Fine and associates,⁶⁸ Bobrow and coworkers⁶⁹ noted that Fine and associates' cultures were obtained from indwelling, heparinized IV catheters, a practice that allows ample opportunity for con-

tamination. Furthermore, half the patients in Fine's group had perirectal abscesses, and if these abscesses involved mucosal surfaces, the risk for bacteremia was potentially increased.⁶⁸

Immunocompromised patients may benefit from the prophylactic administration of antibiotics in preparation for I&D of cutaneous lesions. In contrast to patients with risks for endocarditis, immunocompromised patients are at risk for septicemia secondary to brief bacteremia. IV drug users have a high incidence of diseases associated with human immunodeficiency virus (HIV),^{65,70,71} and the treating clinician must anticipate various degrees of immunodeficiency among them. Because no specific standard of care exists, clinical judgment must guide the use of antibiotics in these situations.

No specific guidelines have been offered for the antibiotic regimen to be used before I&D of infected cutaneous tissue in patients at risk for conditions other than endocarditis. The choice of antimicrobial agent is based on the organism anticipated to cause the bacteremia. Although the location of the abscess will give some clue to the organism involved, most abscesses contain multiple strains of bacteria. Not all bacteria are potent pathogens, so their mere presence does not predict their role in subsequent morbidity. Because *Staphylococcus* continues to be the most common cause of cutaneous abscesses, a broad-spectrum antistaphylococcal drug is indicated. Prophylaxis can consist of a single IV dose given half an hour before I&D. A first-generation cephalosporin or penicillinase-resistant penicillin is a good initial choice. Vancomycin may also be considered. Others may prefer cefazolin (Ancef [GlaxoSmithKline, Research Triangle Park, NC], Kefzol [Eli Lilly and Co Indianapolis, IN]), 1 g intravenously, for adults. This regimen covers staphylococcal and streptococcal species, many gram-negative organisms, and many anaerobes.

Although it has not been studied, it is reasonable to also give antibiotics before I&D to all patients who will subsequently be administered therapeutic antibiotics. The ideal duration of therapeutic antibiotics is unknown. As a general guideline, immunocompromised patients should receive antibiotics for 5 to 7 days and immunocompetent patients for 3 to 5 days after the procedure, depending on the severity of the condition and their clinical response at follow-up.

RECURRENT INFECTIONS

The first-line approach to the prevention of recurrent soft tissue infections is education regarding personal hygiene and appropriate wound care. Patients should be directed to keep wounds covered with clean, dry bandages. Maintain good personal hygiene with regular bathing and frequent hand washing with soap and water or an alcohol-based hand gel, especially after touching the wound or items that came in contact with the wound. Avoid reusing or sharing personal items that have contacted the infected area.

Environmental hygiene measures should be considered in patients with recurrent skin and soft tissue infections in the household or community setting. Focus cleaning efforts on high-traffic surfaces (i.e., surfaces that come in frequent contact with skin each day, such as counters, doorknobs, and toilet seats) that may contact bare skin or uncovered infections.

An approach to individual treatment of recurrent CA-MRSA soft tissue infections is outlined in [Box 37.2](#).

Oral antimicrobial therapy is recommended for the treatment of active infection only and is not routinely recommended for

BOX 37.2 Strategies to Eradicate CA-MRSA Carrier States in Patients With Recurrent CA-MRSA Soft Tissue Infections

Recurrent CA-MRSA soft tissue infections have been linked to a carrier state in affected individuals, with the nose and skin areas being colonized. It may be difficult to totally or permanently eradicate colonization, and there are no proven methods to accomplish this. The following strategies have been used in an attempt to eradicate the carrier state in individuals with recurrent CA-MRSA soft tissue infections. The appropriate time to implement these procedures is not known, but it would be reasonable to institute first-line techniques if more than two to three episodes of proven CA-MRSA infection are documented.

FIRST-LINE

Apply 1 cm of mupirocin (Bactroban [GlaxoSmithKline]) ointment (an intranasal form is available) to the anterior nares three times a day for 7 days,^a plus

Daily total body wash with (4%) chlorhexidine (Hibiclens [Mölnlycke Health Care US, LLC, Norcross GA]) for 5-7 days.^b

SECOND-LINE

Obtain specimens for culture to ascertain sensitivity to various antibiotics.

Repeat mupirocin and chlorhexidine as above.

Rifampin, 300 mg twice a day, plus trimethoprim-sulfamethoxazole DS or doxycycline (100 mg) twice a day for 1-2 weeks.^c

Note: For multiple recurrent infections, consider consultation with an infectious disease expert.

^aMay cause burning, pruritus, dry membranes, and erythema. Avoid long-term use. Do not substitute bacitracin.

^bMay cause skin and eye irritation. Apply for 5 minutes and then rinse thoroughly.

^cDo not use rifampin alone because resistance may develop. It can cause an orange color of urine and tears and stain contact lenses. Adjust the dose for patients with renal impairment. Do not use in those with impaired hepatic function.

CA-MRSA, Community-acquired methicillin-resistant *Staphylococcus aureus*.

decolonization. In the case of multiple recurrent infections, consider consulting an infectious disease expert.

I&D PROCEDURE

Procedure Setting

Definitive I&D of soft tissue abscesses can be performed in either the ED or the operating room (OR). When abscesses are drained in the ED, some centers prefer to use a special area to avoid contamination of general treatment rooms, but protocols vary greatly (Box 37.3).

The choice of the locale for the procedure depends on a number of important factors. The location of the abscess may dictate management in the OR. Large abscesses or abscesses located deep in soft tissues require a procedure involving a great degree of patient cooperation, which might be achieved only under general or regional anesthesia. Proximity to major neurovascular structures, such as in the axillae or antecubital

Figure 37.5 Equipment required for incision and drainage. Most items can be found in a routine suture kit. The scalpel, culture swab, and packing material need to be gathered separately.

fossa, may necessitate specific management. Infections of the hand (with the exception of distal finger infections) have traditionally been managed in the OR because of the many important structures involved and the propensity for limb-threatening complications.

Lack of adequate anesthesia is the most common factor limiting I&D in the ED. The current increased use of ED procedural sedation (see Chapter 33) has changed previous OR cases to ones that can be managed well in the ED. If the clinician believes that the abscess cannot be fully incised and drained because of inadequate anesthesia, the patient should be taken to the OR for management under general anesthesia. In addition to limiting proper drainage, it is inhumane and unethical to subject a patient to extreme pain when alternatives are available.

Equipment and Anesthesia

A standard suture tray provides adequate instruments if a scalpel and packing material are added (Fig. 37.5). Although sterility is impossible during the procedure, one should avoid contamination of surrounding tissue. Some clinicians prefer to use an obligatory skin scrub with an antiseptic solution, but the value of this step is dubious. Most clinicians use nonsterile gloves while draining pus, but practices vary.

It is often quite difficult to achieve local anesthesia by direct infiltration because of the poor function of local anesthetic agents in the low pH of infected tissue. Furthermore, distention of sensitive structures by a local injection is quite painful and hence poorly tolerated by most patients. Skin anesthesia is usually possible, but total anesthesia of the abscess cavity itself cannot generally be achieved. If a regional block can be performed (see Chapters 29-32), this type of anesthesia is preferred. Alternatively, a field block may be used. It should be noted that infected tissue is very vascular and local anesthetics are therefore absorbed quickly. Strict adherence to maximum safe doses of local anesthetics is required.

The skin over the dome of an abscess is often quite thin, thus making skin anesthesia difficult. If a 25-gauge needle is used carefully, one can frequently inject the dome of the abscess

BOX 37.3 Abscess Drainage by the Loop Drainage Technique

Historically, drainage of an abscess has involved the creation of a large skin incision to ensure adequate initial drainage of purulent material, followed by filling the abscess cavity with packing to promote continued drainage. The loop drain technique, an old technique now undergoing renewed interest, confers several advantages over the classic I&D. There are no packing changes, smaller incisions result in better cosmesis, and incisions drain as long as the loop is in place. This technique, though perhaps counterintuitive to classic teaching, provides excellent results for abscesses that previously would have been subjected to traditional incision, drainage, packing, and repacking protocols.

WHAT TYPE OF DRAIN TO USE

The original article describing this technique used a silicone vessel loop, a small Penrose drain, or a sterile rubber band. A readily available product is a vessel loop used by surgeons (Fig. 37.13, step 1).

TECHNIQUE

Step 1: Make a small (5–10 mm) incision with a No. 11 scalpel blade at the periphery of the abscess but still within its borders (see Fig. 37.13, step 2). Make the first incision where the abscess is pointing or already draining. Then probe the cavity with a hemostat and break up loculations (see Fig. 37.13, step 4). Pus should flow out of this puncture incision.

Step 2: With the hemostat inside the abscess cavity, find the opposite edge of the abscess cavity and position the tip of a hemostat underneath the area where you will make the second incision (see Fig. 37.13, step 5). Tent the skin from underneath. Make another stab with a No. 11 scalpel blade over the hemostat tip. Slide the tip of the hemostat through the new incision. At this stage, you should have two small incisions with a hemostat going into one, tunneling through the abscess cavity, and coming out of the other incision. There should be a maximum separation between the two incisions of up to 4 cm. If the abscess is larger than this, you can place more loops, depending on the shape of the abscess cavity.

Step 3: Using the hemostat that has traversed the cavity, grab the end of the loop drain and pull it back through the wound (see Fig. 37.13, steps 7 and 8). There should be a long end of the loop drain exiting each incision.

Step 4: Tie the two ends of the drain together without tension. Too much tension is painful and can necrose the skin between the incisions. One way to avoid excessive skin tension is to place a syringe between the skin and the drain while you are tying it (see Fig. 37.13, step 9). Tie the knots flush with the syringe; when the syringe is pulled away there will be a loosely placed loop that will exert no tension on the incision sites. A finger should be able to be passed between the skin and loop. The drain is going to be slippery, so make about five knots. Tie the last two very tightly by stretching the loop almost to the breaking point. Trim the ends of the drain (see Fig. 37.13, step 10). An option at this point is to irrigate the abscess cavity through the stab incision. Cover the operative site with gauze as drainage will continue.

DISCHARGE INSTRUCTIONS

With the dressing removed and the loop still in place, the patient should bathe or shower twice a day for the first 3 days to promote continued drainage. Change the dressing at least twice daily or whenever saturated. Gently pull the loop back and forth once or twice a day to help keep the wound open.

WHEN TO REMOVE THE DRAIN

Remove the drain when the discharge stops and cellulitis improves. Simply cut the loop and pull it out. The loop is generally removed in approximately 5–10 days but may be removed sooner with a small abscesses or rapid healing. The patient now has only two small puncture sites that will heal over rather than a large scar that must heal by secondary intention.

From Tzoraides SS, Pearl RH, Stanfill AB, et al: Incision and loop drainage: a minimally invasive technique for subcutaneous abscess management in children, *J Pediatr Surg* 45:606–609, 2010.

subcutaneously. Without moving the tip of the needle, the anesthetic solution spreads over the dome through the subcutaneous layers into the surrounding skin and provides excellent skin anesthesia. If the needle is in the proper plane (best accomplished by holding the syringe parallel rather than perpendicular to the skin), the surrounding skin blanches symmetrically during infiltration without having to reposition the needle (Fig. 37.6, step 2). In an extremely anxious or uncomfortable patient, judicious use of preoperative sedation (see Chapter 33) with IV opioids and sedatives or with nitrous oxide makes the procedure easier for both the patient and clinician. Ketamine, propofol, or a combination of these drugs is a popular option in the ED setting.

Some clinicians recommend the use of topical ethyl chloride or Fluori-Methane spray (Gebauer Company, Cleveland, OH) for the initial skin incision, but although this is an attractive concept to patients, the pain relief offered by these agents is variable and fleeting. Ethyl chloride is also highly flammable. These vapocoolant sprays may be useful to provide momentary anesthesia for injection of a local anesthetic or for the initial

skin incision if the injection or incision is made immediately after blanching of the skin. In general, however, these agents are of minimal benefit as a stand-alone anesthetic agent for all but the smallest of superficial abscesses (e.g., purulent folliculitis).

Incision

One should make all incisions conform with skin creases or natural folds to minimize visible scar formation (Fig. 37.7). Care should be taken in areas such as the groin, the posterior aspect of the knee, the antecubital fossa, and the neck so that vascular and neural structures are not damaged.

A No. 11 or 15 scalpel blade, held perpendicular to the skin, is used to nick the skin over the fluctuant area, and then a simple linear incision is carried the total length of the abscess cavity (see Fig. 37.6, step 3). This will afford more complete drainage and facilitate subsequent breakup of loculations. Attempting to drain an abscess with an inadequate incision is counterproductive and makes packing changes more difficult.

Incision and Drainage

1 Identify and confirm the location of the abscess. This patient has a pilonidal abscess, which is found at the superior portion of the gluteal cleft.

2 Anesthetize the region. Use a 25-gauge needle to inject the dome of the abscess. Hold the needle parallel to the skin during injection. Blanching will occur as the anesthetic spreads.

3 Use an 11-blade scalpel to make a linear incision over the total length of the abscess cavity. If possible, the incision should conform to skin creases or natural folds.

4 Culture the purulent drainage.

5 Probe the depth of the abscess and use a hemostat to break open loculations. This can be painful; inject additional anesthetic if needed through the cut skin edges and into the deeper tissues.

6 Irrigate the abscess cavity to assist with removal of residual debris.

7 Loosely pack the abscess cavity with gauze wick. The purpose of the packing is to keep the incision open, which allows continued drainage of the cavity. Avoid overpacking the abscess.

8 Place an absorbent gauze dressing over the packed abscess. Arrange for follow-up care, which usually entails a repeat exam in 1 to 3 days.

Figure 37.6 Incision and drainage. Packing the cavity with gauze is a common intervention but this procedure has not been proven to be of significant value. Routine culturing and irrigation are optional and left to the discretion of the clinician.

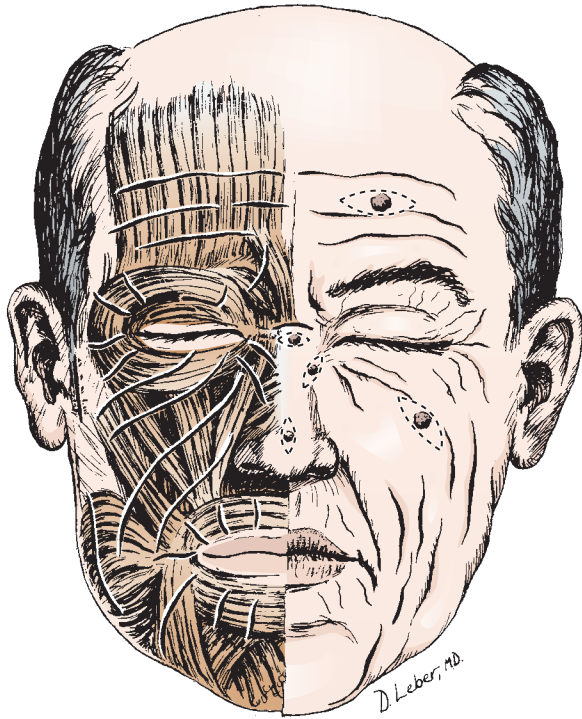

Figure 37.7 Relationship of the elective lines of tension in the face to the underlying mimetic musculature. Only in the lower eyelid are these lines not perpendicular to the muscles. The left side of the drawing shows the use of this principle when common facial lesions are excised or a facial abscess is drained. (From Schwartz SI, Lilliehei RC, editors: *Principles of surgery*, ed 2, New York, 1974, McGraw-Hill. Reproduced with permission.)

Figure 37.8 A simple linear incision is preferred over an X-shaped or crosshatched incision. In this case, a cutaneous postsurgical scalp abscess was drained by an X incision and the tips of the flap necrosed, which left a slowly healing, full-thickness wound.

Avoid using cruciate (X-shaped) or elliptical skin incisions for routine treatment of cutaneous abscesses. The tips of the flaps of a cruciate incision may necrose and result in an unsightly scar (Fig. 37.8). A timid “stab” incision may produce pus but is not generally adequate for proper drainage. The scalpel is used only to make the skin incision and is not used deep in the abscess cavity.

Exceptions regarding aggressive incision are abscesses in cosmetic areas, in areas under significant skin tension (e.g., extensor surfaces), and in areas with extensive scar tissue (e.g., sites of multiple previous drainage procedures). In these special circumstances, a stab incision or simple aspiration alone may be attempted initially, with the goal of limiting tissue injury and resultant scar formation. Use of this less aggressive approach requires that the patient be counseled that multiple decompressions (e.g., via needle aspiration) or delayed aggressive I&D may be required. The abscess will need to be reassessed in 24 to 48 hours to determine whether additional intervention is needed.

Wound Dissection

Following a standard incision, the operator should probe the depth of an abscess to assess its extent and ensure proper drainage by breaking open loculations (see Fig. 37.6, step 5). An ideal instrument for this procedure is a hemostat, optionally wrapped in gauze (or a cotton swab for small abscesses), which is placed into the abscess cavity and spread and manipulated throughout the cavity (Fig. 37.9). Traditionally, the operator’s gloved finger has been suggested as an ideal way to assess the depth of the abscess cavity and to break up loculations, but this is a potentially dangerous practice that should be avoided unless it is certain that the abscess contains no sharp foreign body. Of particular concern is an abscess caused by skin-popping of IV drugs. These abscesses occasionally harbor broken needle fragments (see Fig. 37.9D and E). In addition, patients who engage in this practice have a high incidence of hepatitis and HIV infection. Clinicians are often surprised at the depth or extent of abscesses discovered during probing. Sharp curettage of the abscess cavity is not usually required and may produce bacteremia. Although tissue probing is generally the most painful aspect of the technique and total local anesthesia is difficult to attain, this portion of the procedure should not be abbreviated. If pain persists, additional local anesthetic can be administered through the cut skin edges and into deeper tissues to provide additional anesthesia (Fig. 37.10A). If the procedure is limited because of pain, use of appropriate analgesia or anesthesia is mandated. Failure to adequately pack the abscess on the first visit makes follow-up packing changes more problematic.

A blunt-ended suction device can be used to extract copious pus from large or deep abscesses while also assisting in breakup of loculations (see Fig. 37.10B).

Wound Irrigation

Following the breakup of loculations, some clinicians advocate copious irrigation of the abscess cavity with normal saline to ensure adequate removal of debris from the wound cavity (see Fig. 37.6, step 6). Though seemingly beneficial, irrigation of the abscess cavity has not been experimentally demonstrated to significantly augment healing or affect outcome, and hence may be eschewed.⁷² Hyperemic tissue may bleed profusely, but the bleeding usually stops in a few minutes if packing is used. Abscesses of the extremities can be drained with the use of a tourniquet to provide a bloodless field.

Packing and Dressing

Multiple studies, most from countries outside the United States, suggest that primary suture closure of incised and drained

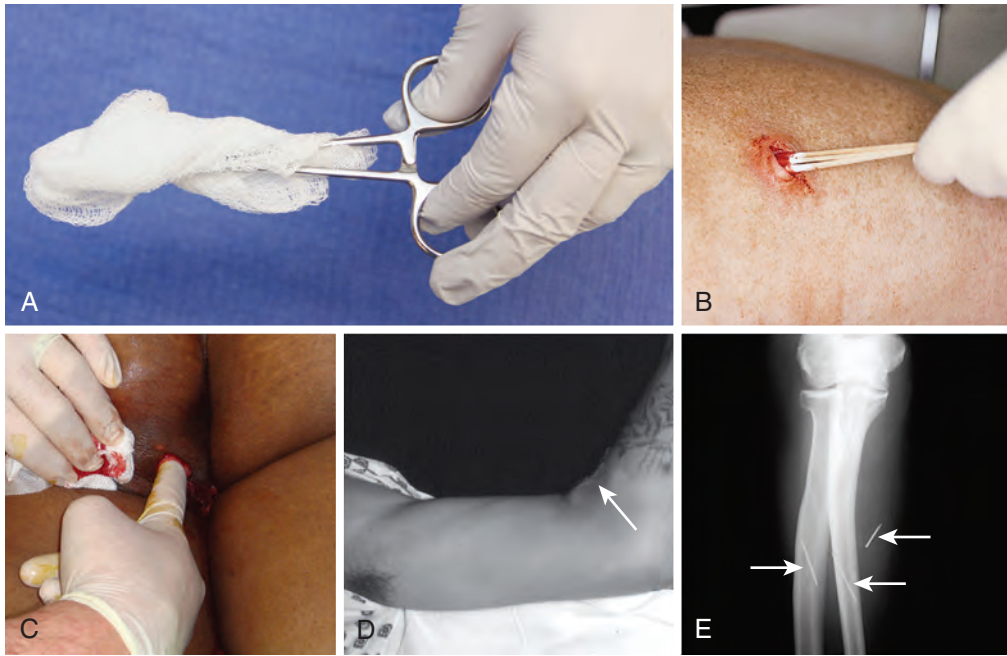

Figure 37.9 Options for wound dissection. **A**, A hemostat wrapped with gauze is an ideal instrument to break up loculations. **B**, Alternatively, cotton-tipped swabs can be used. **C**, Traditionally, fingers have been used to identify and open the cavity and this abscess would likely not harbor a foreign body. However, this practice must be avoided if there is any chance of a foreign body. **D**, This intravenous drug user had an abscess (*arrow*) in the antecubital fossa. After the incision, the clinician attempted to break up the loculations with his finger. **E**, When a radiograph was obtained, three needle fragments (*arrows*) were found embedded in the wound. The patient was positive for human immunodeficiency virus and claimed no knowledge of the presence of the needles. Instead of using a finger, break up loculations with an instrument.

abscesses results in faster healing than after packing and secondary closure, and results in similarly low abscess recurrence rates. Many of the reported cases involved abscesses in the anogenital region, a site teeming with bacteria. Acute superficial abscesses have been managed with incision, curettage, and primary suture closure without antibiotics or packing, which is safe and cost-effective. This clinical approach is not currently in wide practice in the United States.⁷³

Although the specific technique and the clinical value of routine packing of abscesses have not been well studied, packing is a traditional intervention and is often performed in the ED. Some, however, advocate that packing is neither needed nor beneficial for easily drained abscesses, and the intervention adds to cost and patient discomfort. Although most studies evaluating the necessity of wound packing have been small, there does not appear to be evidence of increased recurrence of abscesses when not packed. There is no proven benefit to routine packing of drained cutaneous abscesses as it does not appear to prevent recurrence of abscesses or to decrease further intervention at follow-up.⁷³

As noted earlier, some advocate curettage and irrigation of the abscess cavity and then primary suture closure, without packing. Overall, it appears reasonable to avoid packing of small, easily drained abscesses. The loop drainage technique described hereafter is evidence that formal packing is not a prerequisite for abscess healing. Hence, clinical judgment, common sense, and individualized treatment based on the particular scenario should prevail. Simply stated, no packing recommendation is universally accepted, but the procedure is likely overused.

When used, a loose packing of gauze or other material is placed gently into the abscess cavity to prevent the wound margins from closing and to afford continued drainage of any exudative material (see Fig. 37.6, step 7). The packing material should make contact with the cavity wall so that on removal, gentle débridement of necrotic tissue will occur spontaneously. A common error is to attempt to pack an abscess too tightly with excessive packing material. In essence, the pack merely keeps the incision open, and its main purpose is not to absorb all drainage as a dressing accomplishes this goal. Care must be exercised to ensure that the packing does not exert significant pressure against the exposed tissue and lead to further tissue necrosis. Some prefer to use plain gauze, some use gauze soaked in saline or povidone-iodine, and some use gauze impregnated with iodine (iodoform). For large abscess cavities, gauze pads (without cotton backing) are ideal packing material (Fig. 37.11). If gauze pads are used, the number of pads placed in the wound should be counted and charted. Ideally, the corner of each pad should exit from the wound. The clinician must ensure that all gauze pads will be removed when the packing is changed or discontinued. More commonly, thin (0.6 to 1.2 cm) packing strip gauze, either plain or iodoform, is used. The iodoform gauze may sting the patient for a few minutes after it is inserted. Packing, especially packing strips containing iodine, will be radiopaque on a plain radiograph. If a foreign body is considered, a radiograph should be obtained before packing. The value of antibiotic-impregnated gauze is uncertain.

An absorbent gauze dressing should be placed over the packed abscess, or if an extremity is involved, a lightly wrapped circumferential dressing should be used (see Fig. 37.6, step 8).

Figure 37.10 **A**, If pain persists while an abscess is being drained, pull the skin open and inject additional anesthetic into the subcutaneous tissue under direct vision. **B**, This large abscess is draining copious pus. A tonsil suction device is used to both break up loculations and extract pus. Note the copious pus in the tubing (*arrows*).

Generous amounts of dry gauze are used over the packing to soak up any drainage or blood. The affected part should be splinted if possible, and elevation should be routine. The dressing and splint should not be disturbed until the first follow-up visit. Drainage relieves most of the pain of an abscess, but postoperative analgesics may be required.

After treatment, packing is often changed periodically (Fig. 37.12A). Most patients require a repeated visit to the clinician for packing change, but if the original packing is to be removed and not replaced (as with a paronychia or hair follicle abscess), selected patients may remove the packing and perform their own wound care totally at home. Motivated patients can provide total follow-up, and a cotton-tipped applicator swirled in the base of the wound once or twice a day for a few days can replace formal packing (see Fig. 37.12B).

FOLLOW-UP EXAMINATION

A drained abscess should be reevaluated in 1 to 3 days, depending on a number of factors. Most lesions are reevaluated 48

Figure 37.11 Wound packing. **A**, The traditional packing material is 1/4-inch to 1/2-inch gauze, plain or with iodoform. **B**, A 4-cm × 4-cm gauze pad soaked in povidone-iodine (Betadine [Purdue Products L.P., Stamford, CT]) can be used to pack a large abscess, but be careful to avoid losing or forgetting about packing material in the base of a large abscess. Use an instrument to introduce the packing into the bottom of the abscess. Use only enough gauze to keep the incision open and avoid tight packing. Some clinicians do not use packing at all for easily drained abscesses, and the value of packing is questionable and is not an absolute standard. See the discussion about the vessel loop abscess drainage technique (see also Fig. 37.13).

hours after the procedure, with the first but possibly the only packing change occurring at this time. Some wounds warrant closer monitoring. Diabetic patients or other patients with impaired healing capacity, mental impairment, or physical disabilities may require a home care nurse or hospital admission for more frequent wound care and packing changes. Wounds that are at high risk for complications, such as those about the face or hands or those with significant cellulitis, require close follow-up depending on the specific scenario. The patient should be encouraged to play an active role in wound care. During the first follow-up visit, compliant and able patients should be taught to change the packing and dressing. If this is anatomically impossible, a friend or family member can be instructed in the technique. If long-term packing or complicated wound care is required, referral to wound care centers rather than multiple repeated ED visits may be more practical.

The technique for changing packing material is usually one of personal preference. It should be emphasized that patients often fear a repeated visit and expect significant pain with subsequent wound care, especially if the initial I&D was difficult. Therefore the specifics of packing change should be addressed

Figure 37.12 Wound check. **A**, Packing gauze is removed from the abscess on the first wound inspection. If drainage is present, the abscess may be repacked. **B**, Small abscesses can be cleaned with a cotton swab swirled in the cavity, which is left open. This care can be continued at home.

before release home after the initial drainage procedure. Ideally, the initial procedure will have been accomplished without undue pain to allay subsequent fears. Some clinicians suggest that an oral opioid be taken 30 to 40 minutes before the next visit or the use of local anesthesia or parenteral analgesia if significant pain is anticipated. Removal of packing material is frequently painful, but if the packing is moistened with saline before removal, it may be less traumatic. If the original incision was of the proper length, loculations were adequately removed, and packing was adequate, subsequent packing changes will be considerably easier. Once the packing is removed, the wound is inspected for residual necrotic tissue. The cavity may be irrigated with saline before replacing the pack if significant exudate is present, but this is not often required because the packing absorbs most debris.

The frequency of packing or dressing changes is also clinically guided. Some wounds require multiple packing changes, whereas other wounds require only the initial packing. For most facial abscesses, the packing should be removed after only 24 hours, at which time warm soaks should be started. Wounds large enough to require repeated packing should be repacked at least every 48 to 72 hours (occasionally daily for the first few visits) until the drainage stops or healing continues in a deep-to-superficial direction.

In general, once healthy granulation tissue has developed throughout the wound and a well-established drainage tract

is present, packing may be discontinued. The patient should then be instructed to begin warm soaks of the wound. Gentle hydrostatic débridement may be performed by the patient in the shower at home: the patient holds the skin incision open and directs the shower or faucet spray into the abscess cavity. Appropriate dressing changes should then follow until healing is completed. When all signs of infection (e.g., erythema, drainage, pain, and induration) have resolved and healthy granulation tissue is present, the patient may be discharged from medical care.

SPECIFIC ABSCESS THERAPY

Folliculitis, Furuncles, and Carbuncles

Folliculitis, furuncles, and carbuncles are common ED presentations in healthy patients with no specific predisposing risk factors, due to chronic colonization with a *Staphylococcus* bacterium. Those in close contact with infected individuals are also at increased risk for similar infections. The pathogenesis of staphylococcal disease is a complex host-bacterium interaction. *S. aureus* can invade the skin by way of a hair follicle or any open wound. This can lead to destruction of the local tissue followed by vasodilation of the blood vessels, increasing the blood flow to the affected area, which is called *hyperemia*. Subsequently, an exudative reaction occurs, with polymorphonuclear cell invasion. The process will extend, following the path of least resistance, and form an abscess. The abscess may then extend and form sinus tracts. Eventually dissemination may occur through invasion of blood vessels, leading to infection of other organ systems including osteomyelitis, meningitis, and endocarditis.^{2,74}

Inflammation of a hair follicle caused by bacterial invasion is known as folliculitis. Folliculitis is a common inflammatory skin syndrome of the young and middle-aged, but can be observed in all age groups. The underlying pathogenic mechanisms are unclear, but microbial involvement has been suggested.⁷⁵ Staphylococci, especially *S. aureus*, are mainly cultured from inflamed lesions and pustules^{76–78} but fungal involvement (e.g., *Malassezia* species) has also been documented.^{79–81}

Pseudomonas aeruginosa is a rare cause of folliculitis. *Pseudomonas* folliculitis can develop after contact with contaminated water from swimming pools, hot tubs, and spa baths.⁸²

Fungal folliculitis may be seen solely or in conjunction with *Staphylococcus* in individuals who use antibacterial antibiotics, oral corticosteroids, immunosuppressive treatments, topical steroids, have hyperhidrosis, or are obese.⁸³ Treatment generally consists of warm compresses to the affected area and antimicrobial soaps. If multiple sites are involved systemic antibiotics may be required. Recurrence may warrant repeat treatment along with chlorhexidine baths and bacitracin to the nares.

Furuncles, or “boils,” are acute circumscribed abscesses of the skin and subcutaneous tissue that usually involve the hair follicles (Fig. 37.14). They are most frequently seen on the face, neck, buttocks, thigh, perineum, breast, and axilla. Carbuncles are groups of interconnected furuncles, most frequently seen at the base of the neck where the skin is thickest. The thickness of the skin leads to lateral extension. *S. aureus* is the most common organism seen. Large carbuncles can cause systemic symptoms and complications. A common risk factor for carbuncles is diabetes. These large carbuncles often

Vessel Loop Method of Incision and Drainage

1 Instead of traditional gauze packing, a sterile silicone loop is used. This is commonly referred to simply as a “vessel loop” and is readily available from the operating room (this device is used by vascular surgeons).

2 After sterile preparation and anesthetic infiltration, make a small (5–10 mm) incision at the periphery of the abscess. If possible, make the incision where the abscess is already pointing, noted by the white arrow.

3 Express as much pus as possible from the incision. Obtain cultures if clinically indicated.

4 Use a hemostat to probe the abscess cavity and break up loculations.

5 Probe with the hemostat to find the opposite edge of the abscess cavity. Position the tip of the hemostat underneath the area of the second incision, tent the skin, and make another stab incision over the hemostat tip.

6 Optionally irrigate the cavity with a syringe and plastic intravenous catheter.

7 Place the hemostat through the cavity so that it exits the second incision. Grab the end of the vessel loop (arrow).

8 Pull the vessel loop through the abscess cavity so that it exits through the first incision.

9 Tie the two ends of the vessel loop together. To avoid excessive skin tension, tie the loops over a syringe. Tie at least five knots, as the loop material is slippery. Tie the last two knots tightly, by stretching the loop almost to the breaking point.

10 Remove the syringe, and then trim the ends of the vessel loop. Note that it is not tied tightly against the skin. Refer to the text for information on discharge instructions and loop removal.

Figure 37.13 Vessel loop method of incision and drainage. (For more details, refer to: McNamara WF: An alternative to open incision and drainage for community-acquired soft tissue abscesses in children, *J Pediatr Surg* 46:502–506, 2011; Ladd AP: Minimally invasive technique in treatment of complex, subcutaneous abscesses in children, *J Pediatr Surg* 45:1562–1566, 2010; and Tsoarides SS, Pearl RH, Stanfill AB, et al: Incision and loop drainage: a minimally invasive technique for subcutaneous abscess management in children, *J Pediatr Surg* 45:606–609, 2010.)

Figure 37.14 **A**, *Staphylococcus aureus* is a common cause of folliculitis, although other bacteria such as *Pseudomonas* may be responsible. Treatment consists primarily of local measures such as warm compresses and antibacterial soaps and ointments. **B**, Furuncles are circumscribed abscesses of the skin and subcutaneous tissue that usually involve a hair follicle. **C**, A carbuncle is a complicated abscess on the nape of the neck. It is very common in diabetics. Carbuncles are usually caused by *S. aureus*, including community-acquired methicillin-resistant *S. aureus*. Because of its many crypts, loculations, and intercommunicating small abscesses, treatment by simple incision and drainage is often not readily curative. When fluctuance is appreciated, incision is indicated. One should avoid multiple small incisions because tissue circulation may be compromised. Antibiotics may augment healing of this abscess, but wide surgical excision may be required. (**A**, from Weston WL, Lane AT, Morelli JG, editors: *Color Textbook of Pediatric Dermatology*, ed 4, St. Louis, 2007, Mosby; **B**, from Long SS, Pickering LK, Prober CG, et al: *Principles and Practice of Pediatric Infectious Diseases Revised Reprint*, ed 3, Philadelphia, 2009, Churchill Livingstone.)

require widespread surgical excision rather than simple I&D. Systemic therapy may be indicated in patients with widespread lesions, systemic symptoms, or in immunosuppressed patients. Pedicure-associated nontuberculous mycobacteria has been reported. This is believed to be associated with the foot baths used and suboptimal cleaning methods.⁸⁴

Most cases of recurrent staphylococcal skin infections are caused by autoinfection from skin lesions or nasal reservoirs. Treatment is directed at prevention, through eliminating the organisms. This can be accomplished by the application of bacitracin to the nares, chlorhexidine baths, and good hygiene. If unsuccessful, then systemic oral antistaphylococcal treatment is required, usually for 2 to 3 weeks. Close contacts often require treatment as well.^{2,85,86}

S. aureus can cause suture abscesses. A suture abscess is often misdiagnosed as a wound infection, but in fact it is a local nidus of inflammation, infection, or both caused and potentiated by suture material. Such an abscess usually appears after sutures have been in place for 3 to 5 days, with single or multiple discrete areas of erythema and tenderness being noted at the site where the suture penetrates the skin. Simply removing the suture (a drop of pus may be expressed) and providing warm compresses and topical antibiotic ointment is generally all that is required. Wide opening of the wound and systemic antibiotics are seldom required. When the suture is buried, a small incision should be followed by probing the wound with a small hook or bent needle (see [Chapter 35](#)) to snare the suture for removal.

Hidradenitis Suppurativa

HS is a chronic, relapsing, inflammatory follicular occlusive disease process that affects the apocrine sweat glands in the axilla, the inguinal region,⁸⁷ and the perineum ([Fig. 37.15](#)). Its prevalence is 1% to 4% in industrialized countries; most affected individuals are young women.⁸⁸⁻⁹¹ The condition results from follicular inflammation and subsequent occlusion of the apocrine ducts by keratinous debris, which leads to ductal dilation, inflammation, and rupture into the subcutaneous area. The clinical manifestations vary, ranging from recurrent inflamed nodules and abscesses to draining sinus tracts and bands of severe scar formation. The associated pain, malodor, drainage, and disfigurement that accompany HS contribute to a profound psychosocial impact of the disease on many patients. Dysregulation of the immune response is thought to play a role, with some studies showing a response to immunosuppressive agents.^{92,92a} Occlusion of the hair follicle predisposes to secondary bacterial infection and subsequent abscess formation. In its early stages, it is indistinguishable from a simple furuncle. Progression and recurrence, however, lead to the distinctive appearance of multiple foci coupled with areas of induration and inflammation that are in various stages of healing. This chronic process can create draining fistulous tracts, often involving large areas that are not amenable to simple I&D procedures (see [Fig. 37.15C](#)).⁸⁶

Genetic factors appear to be an important contributor in HS.^{91,93} A hormonal impact has been suggested by observations

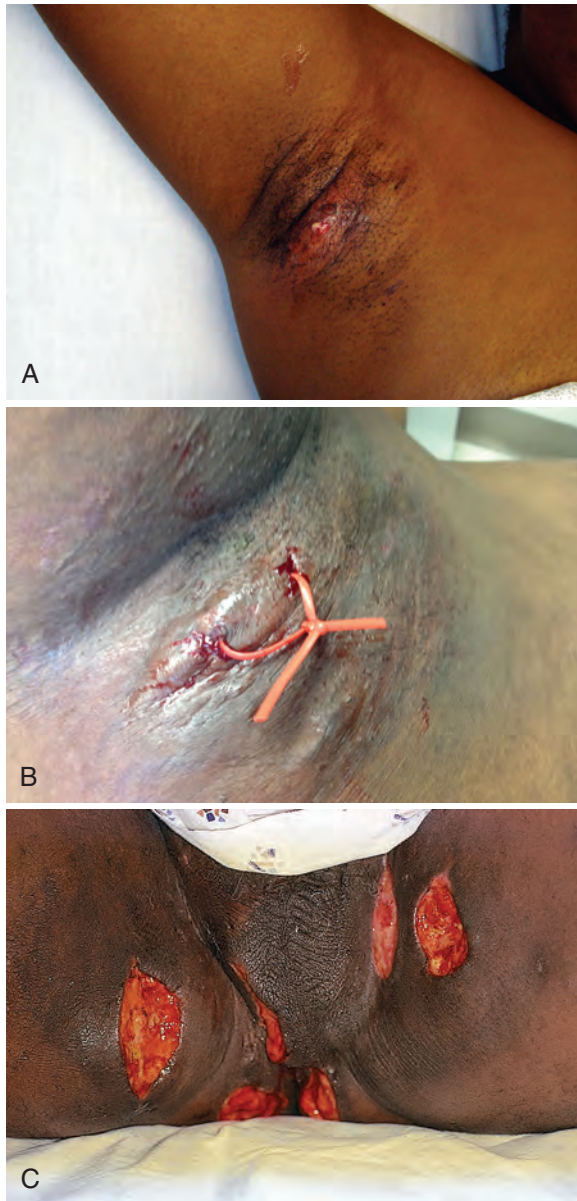

Figure 37.15 **A**, Axillary abscesses are common and recurrent. Community-acquired methicillin-resistant *Staphylococcus aureus* is an increasing cause. **B**, Vessel loop drainage of an axillary abscess. **C**, Hidradenitis suppurativa of the groin or axilla is a complicated series of abscesses that may not be amenable to simple incision and drainage. In this patient with involvement of the groin, extensive surgery was required to excise recurrent infection.

of the rarity of HS in prepubertal children and improvement in HS during treatment with anti-androgenic agents.⁹³⁻⁹⁷

Other factors thought to be related include obesity and smoking. In a French case-control study of 302 clinically assessed patients with HS and 906 controls, 76% of the patients with HS versus 25% of the controls were current smokers. Additionally, a body mass index (BMI) of 30 or greater was present in 21% of patients with HS versus only 9% of controls, and a BMI between 25 and 29 was present in 22% of HS patients versus 17% of controls.⁹⁸ Environmental factors including antiperspirants and shaving⁹⁹ were implicated in the past, but later studies have not found any association.¹⁰⁰

Bacterial cultures of specimens from hidradenitis suppurativa lesions are frequently sterile or reflect organisms seen in other soft tissue abscesses. *Staphylococcus* is the most commonly isolated organism,¹⁰⁰ with *E. coli* and β -hemolytic streptococci being other important pathogens. In the perineal region, enteric flora are often found. Many of these abscesses have multiple isolates, and anaerobic bacteria are frequently cultured. CA-MRSA is an increasing cause of such abscesses.

Clinical manifestations may be influenced by gender. Primary sites of involvement in women are the groin, upper inner thigh, axilla, chest, and the buttocks or gluteal clefts.^{101,102} In men, primary sites of involvement are the groin or thigh, axilla, perineal or perianal regions, and buttocks or gluteal cleft.¹⁰¹⁻¹⁰³ Both sexes regularly show involvement in nonintertriginous skin, particularly at sites of skin compression and friction. Belts, waistbands, and brassiere straps or bands are also common locations.

Multiple disorders have been associated with HS including diabetes, obesity, dyslipidemia, hypertension, cardiovascular disease, Crohn's disease, and acne vulgaris. Long-standing, poorly controlled HS may lead to significant physical and emotional consequences such as strictures and contractures,¹⁰⁴ lymphatic obstruction, lymphedema of limbs and genitalia, malaise, depression, suicide, and long-term effects of chronic suppuration including anemia, hypoproteinemia, amyloidosis, infectious complications (lumbosacral epidural abscess, sacral bacterial osteomyelitis), arthritis, squamous cell carcinoma, and anemia.¹⁰⁵⁻¹⁰⁷

Multiple therapeutic approaches exist for the management of HS. Any fluctuant area requires drainage, as described in the section on **I&D Procedure**. In patients with extensive cellulitis, a broad-spectrum, antistaphylococcal antibiotic should be used. Unfortunately, HS cannot be cured with localized I&D and/or antibiotics. If I&D is required for relief of a secondary abscess, it should be made clear to the patient that this procedure does not cure the underlying disease.¹⁰⁸ The chronic nature of the disease produces multiple areas of inflammation and subcutaneous fistulous tracts that induce routine recurrences. The patient must be informed of this unfavorable prognosis and should be referred to a dermatologist or surgeon for long-term care.

Milder forms of the disease are initially treated with conservative measures. Many different approaches have been tried, with only limited degrees of success. Few controlled studies of treatment strategies have been performed. Patients are often counseled to lose weight, stop smoking, avoid skin trauma, wear light clothing, refrain from shaving, stop using scented deodorants, and improve personal hygiene. The benefits of these efforts are unknown. Topical clindamycin is often utilized as a first-line therapy for mild HS. A randomized 3-month trial supported its efficacy for mild inflammatory lesions and demonstrated the relative safety and tolerability of this regimen.¹⁰⁹ Oral antistaphylococcal antibiotics are most commonly used, with varying results.¹¹⁰ Retrospective reviews looking at the efficacy of combination therapy (clindamycin and rifampin) have been promising, with some patients experiencing long-term remission, although diarrhea is a common side effect.^{111,112} There have been reports of success with topical clindamycin,¹⁰⁹ hormone therapy in females,¹¹³ and laser therapy.¹¹⁴ Finally, immunosuppressive therapy with tumor necrosis factor- α inhibitors (infliximab, adalimumab, and etanercept)¹¹⁵⁻¹¹⁷ has been successful in treating a few intractable cases.

Advanced stages of the disease are managed by wide or local excision. Recurrence is more likely with smaller excisions than wider excisions.¹¹⁸ Delayed closure^{119,120} may offer better results, but this has not been directly compared with primary closure. Wide excision may warrant skin grafting.¹²¹

Breast Abscess

Breast abscesses are localized collections of pus in the breast tissue. They can occur in lactating (14%) and nonlactating breasts (86%).¹²² They occur more commonly in African Americans, obese individuals, and smokers. They are caused by normal skin bacteria that enter through a break or crack in the skin, usually the nipple (Fig. 37.16). The infection becomes established in parenchymal tissue and causes pain, swelling, and localized hyperthermia. In its early stages, when cellulitis predominates, a breast abscess can be difficult to diagnose. In equivocal cases, antibiotics may be curative. Cellulitis may progress to frank abscess formation. Women with a significant breast abscess can be quite ill and appear toxic.

The estimated incidence of inflammatory processes of the breast (mastitis) in lactating women ranges from 2% to 33%.¹²³ In lactating women the infection is usually precipitated by milk stasis after weaning or missed feedings and usually occurs in the first 6 weeks of breastfeeding or during the weaning phase. The cause is usually bacterial invasion through a cracked or abraded nipple by *S. aureus*, including MRSA, or streptococci originating from the mouth of the nursing child.^{124–126} Manifestations include redness, heat, pain, fever, and chills. Treatment consists of antistaphylococcal antibiotics, continued breast emptying with a breast pump, and application of heat. During treatment it is important to encourage continued breast emptying to promote drainage. Nursing can be continued with the noninfected breast.¹²⁷ Breast abscesses in nonlactating women are more common. People at risk are smokers and diabetics. These are also risk factors for recurrence. In addition, abscesses may be a complication of nipple piercing or breast implants inserted under appropriate medical care,¹²⁸ as well as via illicit cosmetic

Figure 37.16 Breast abscess. These abscesses are more common in nonlactating than in lactating women. Initial treatment recommendations call for ultrasound-guided needle aspiration and antibiotics, as opposed to traditional incision and drainage. Multiple aspirations may be required. (From Bland KI, Copeland EM III, editors: *The Breast*, ed 4, Philadelphia, 2009, Saunders.)

procedures.^{129,130} Most primary breast abscesses are caused by *S. aureus*, with MRSA becoming increasingly prominent.¹³¹

Less prominent pathogens include strains of *Streptococcus pyogenes*, *E. coli*, *Bacteroides*, *Corynebacterium* species, coagulase-negative staphylococci (e.g., *Staphylococcus lugdunensis*), *P. aeruginosa*, *Proteus mirabilis*, and anaerobes.¹³⁰ Mixed flora are more commonly found in recurrent abscesses.¹³¹

In the setting of nonsevere infection, in the absence of risk factors for MRSA, outpatient therapy may be initiated with dicloxacillin or cephalexin, pending culture results.¹³¹ In the setting of β -lactam hypersensitivity, clindamycin may be used. If the community prevalence of MRSA is high, treatment with clindamycin or TMP-SMX should be considered. In the setting of severe infection, empiric inpatient therapy with vancomycin should be initiated.

Ultrasound-guided needle aspiration, as opposed to formal I&D, is becoming the standard of care for most breast abscesses. Multiple aspirations may be required. When repeat aspirations are required, hospitalization may be the best way to facilitate treatment. When compared with I&D, aspiration causes less scarring, does not interfere with breastfeeding, and does not require procedural sedation.¹³³ Christensen and associates¹³⁴ recommended that ultrasound-guided needle drainage replace surgery as first-line treatment of uncomplicated puerperal and nonpuerperal breast abscesses. Emerging treatment parameters are ultrasound-guided needle aspiration for abscesses less than 3 cm in diameter and ultrasound-guided catheter drainage for abscesses 3 cm in diameter or larger.¹³⁵ Ultrasound images of breast abscesses appear as inhomogeneous, hyperechoic masses (Fig. 37.17). Repeat aspiration daily or every other day helps to achieve complete resolution, with a mean of 3.5 aspirations being required.¹³⁵ Surgical drainage is warranted in the setting of compromise to the overlying skin and in cases in which the abscess is not responding to needle aspiration and antibiotics.^{134,135}

Recurrent abscesses are a common, troublesome complication after traditional treatment with I&D and antibiotics.^{138,139} Fortunately, the reported recurrence rate associated with ultrasound-guided aspiration or drainage procedures is quite low.^{140,141} Patients with persistent recurrences should be managed by a surgeon for total excision of the involved area.

Although a breast abscess is rarely a harbinger of malignancy, it could be the initial manifestation of a metastatic process.^{140,142} After needle aspiration or catheter drainage, send the aspirate for culture and cytologic examination, and perform a postdrainage mammogram and ultrasound to evaluate for underlying or coexistent malignancy.¹⁴¹

A breast abscess in a male is an unusual occurrence, so consider malignancy and underlying bone or joint infection in these cases (see Fig. 37.2A and B).

Pilonidal Abscess

Pilonidal sinuses are common malformations that occur in the sacrococcygeal area (Fig. 37.18). The cause of the sinus formation is unclear, and the malformation may occur during embryogenesis. Although pilonidal sinuses are present from birth, they are not usually manifested clinically until adolescence or the early adult years. Pilonidal cyst formation is thought to be secondary to blockage of a pilonidal sinus. The blockage is most commonly the result of hair in the region, and the lesion may in part be a foreign body (hair) granuloma. The result of this obstruction is repeated soft tissue infection,

Figure 37.17 Longitudinal images of ultrasound-guided drainage of an abscess in the lower inner quadrant of a 27-year-old woman's right breast 8 weeks after delivery. **A**, Well-defined, slightly loculated, inhomogeneous hypoechoic abscess measuring 6 cm × 4 cm. Dots extend across the abscess, with the cursor at one margin of the abscess. **B**, Pigtail catheter (7 Fr) containing a trocar (arrows) in the abscess cavity. **C**, After removal of the trocar and aspiration of 70 mL of pus. The parallel lines represent the walls of the catheter (arrows). (From Ullitzsch D, Nyman MKG, Carlson RA: Breast abscess in lactating women: US-guided treatment, *Radiology* 232:904, 2004.)

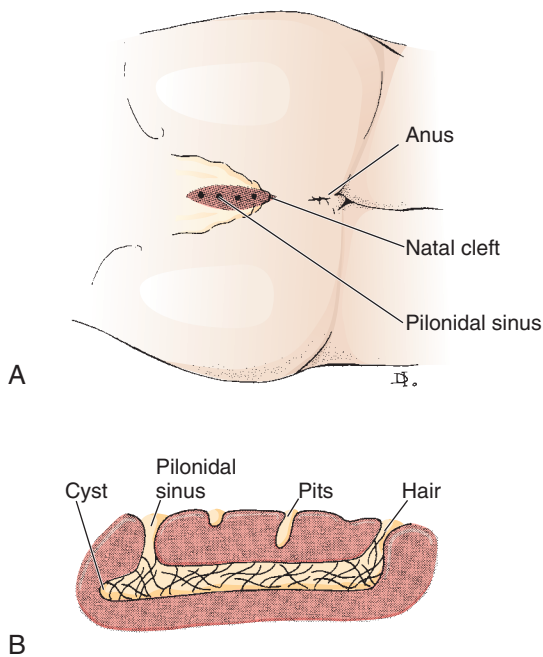

Figure 37.18 Pilonidal sinus. **A**, Sinuses occur in the midline, some 5 cm above the anus in the natal cleft. **B**, Longitudinal section showing sinuses and pits. (From Hill GJ II, editor: *Outpatient Surgery*, ed 3, Philadelphia, 1988, Saunders. Reproduced with permission.)

followed by drainage and partial resolution, with eventual reaccumulation. Pilonidal abscess formation most frequently affects young adults with a 2:1 male to female ratio. The sinuses and cysts are lined with stratified squamous epithelium and, after excision, may be found to contain wads of hair and debris. When cultured, pilonidal abscesses generally yield mixed fecal flora with a preponderance of anaerobes.¹⁴³ The specific mechanism for the development of pilonidal disease is unclear, although hair and inflammation are contributing factors.¹⁴⁴⁻¹⁴⁶

As a person sits or bends, the natal cleft stretches, traumatizing hair follicles and thus creating pores. The pores collect debris and serve as a fertile environment for roots of hairs to lodge and become embedded. As the skin is drawn taut over the natal cleft with movement, negative pressure is created in the subcutaneous space drawing hair deeper into the pore, and the friction causes the hairs to form a sinus. Pilonidal disease typically develops in people with deep natal clefts. Subsequently, hairs become ingrown, bacteria invade, and an abscess develops in the sacrococcygeal region. At the current time, CA-MRSA infections are not common.

Patient presentation is highly variable. They may be completely asymptomatic with just a pilonidal cavity and sinus, or present with acute infection and drainage, or even chronic inflammation with drainage. There may even be multiple areas of drainage. Patients with a pilonidal abscess will seek care for back pain and local tenderness. On examination the area is found to be indurated. Frank abscess formation may not be appreciated as sometimes the abscess is deep. One will usually see barely perceptible dimples or tiny openings at the rostral end of the gluteal crease (Fig. 37.19). A hair or slight discharge may be noticed at the opening. The discharge will usually be purulent or bloody. One may find a more caudal cyst or abscess, possibly with a palpable sinus tract connecting the two. The sinus and cyst may be draining chronically, or they may become infected as the size increases and blockage occurs.¹⁴⁷

Treatment of an acutely infected cyst is the same as previously discussed for any fluctuant abscess: all hair and pus should be removed, and the lesion should be packed (see Figs. 37.6 and 37.13). The abscess cavity may be quite large and thus necessitate a lengthy incision to ensure complete drainage. The incision should be made laterally, off-midline, or over the area of maximal fluctuance. A retrospective study looked at 48 patients who had undergone lateral incisions and matched them with 48 patients who had undergone midline incisions. Those who had undergone midline incisions took approximately 3 weeks longer to heal than those drained with a lateral incision.¹⁴⁸ In general, reported median healing times after I&D vary between 12 and 63 days.^{149,150} The area may be repacked

Figure 37.19 Pilonidal abscess. An erythematous, indurated, fluctuant, and tender mass is found at the superior gluteal cleft. Small dimples or openings (*arrow*) can be seen on the surface of the abscess. Incision and drainage of pus, debris, and hair is an appropriate emergency department intervention, but these tend to recur and may require additional surgical treatment.

at 2- to 4-day intervals as an outpatient procedure, although some prefer to discontinue packing after the first week. Antibiotic therapy is not generally required.

An I&D, however, is not the definitive procedure for pilonidal disease, as recurrence rates range from approximately 20% to 55%.^{146,151}

In a retrospective review of 73 consecutive patients with a first episode of acute pilonidal abscess treated by I&D, 42 (58%) healed primarily, with a median time to healing of 5 weeks; 9 of the 42 developed recurrence of pilonidal disease at a median follow-up of 60 months.¹⁴⁴ The overall cure rate following I&D was 45%. The patient should be referred to a general surgeon for removal of the cyst and sinus after the inflammatory process has resolved. Small abscesses may be incised and drained as an outpatient procedure performed under local anesthesia, but the disease process is often extensive, and general anesthesia may be required to achieve complete drainage. The extent of the cyst cavity and the volume of pus encountered on initial incision can be surprising.

Closure strategies for these potentially large wounds vary. Primary closure is associated with faster wound healing and a quicker return to work, but a delayed closure is associated with a lower likelihood of recurrence.¹⁵³

Antibiotics are not commonly needed when treating these abscesses. They are reserved for concurrent surrounding cellulitis. However, patients with underlying immunosuppression, MRSA, concurrent systemic illness, or at high risk for endocarditis should be considered for ancillary antimicrobial prophylaxis in conjunction with surgical management.¹⁵²

Perirectal Abscesses

Most anorectal infections originate in the cryptoglandular area located in the anal canal at the level of the dentate line. Abscesses within these glands can penetrate the surrounding sphincter and track in a variety of directions, with larger abscesses occurring within the perianal, intersphincteric, ischiorectal, and supralelevator spaces. A small number of anorectal abscesses have a noncryptoglandular cause such as Crohn's disease, atypical

infection (e.g., tuberculosis, lymphogranuloma venereum), malignancy, or trauma.¹⁵⁴

The prevalence of anal abscesses in the general population is probably much higher than seen in clinical practice as the majority of patients with symptoms referable to the anorectum do not seek medical attention. It is estimated that there are approximately 100,000 cases per year in the United States.¹⁵⁵ The mean age for presentation of anal abscess and fistula disease is 40 years (range 20 to 60 years).¹⁵⁶⁻¹⁵⁹ Adult males are twice as likely to develop an abscess and/or fistula compared with women.^{155,159}

Perirectal infections can range from minor irritation to fatal illness. Surprisingly, clandestine infections often occur in diabetics. Successful management depends on early recognition of the disease process and adequate surgical therapy. Small abscesses can initially be managed on an outpatient basis with simple I&D, described previously. Because of the morbidity and mortality associated with inadequate treatment of these conditions, patients with large and deep abscesses should be promptly admitted to the hospital for evaluation and treatment under general or spinal anesthesia (Fig. 37.20).

It is important to understand the anatomy of the anal canal and the rectum to appreciate the pathophysiology of these abscesses and their treatment (Fig. 37.21). The mucosa of the anal canal is loosely attached to the muscle wall. At the dentate line, where columnar epithelium gives way to squamous epithelium, there are vertical folds of tissue called the rectal columns of Morgagni that are connected at their lower ends by small semilunar folds called anal valves. Under these valves are invaginations termed anal crypts. Within these crypts are collections of ducts from the anal glands. These glands are believed to be responsible for the genesis of most, if not all perirectal abscesses. These glands often pass through the internal sphincter but do not penetrate the external sphincter.

The muscular anatomy divides the perirectal area into compartments that may house an abscess, depending on the direction of spread of the foci of the infection (Fig. 37.22).^{160,161}

The circular fibers of the intestinal coat thicken at the rectum-anus junction to become the internal anal sphincter. The muscle fibers of the levator ani fuse with those of the outer longitudinal fibers of the intestinal coat as it passes through the pelvic floor. These conjoined fibers are connected by fibrous tissue to the external sphincter system, which consists of three circular muscle groups.

Pathophysiology

As described previously, the anal glands are mucous-secreting structures that terminate in the area between the internal and external sphincters. It is believed that most perirectal infections begin in the intersphincteric space secondary to blockage and subsequent infection of the anal glands. Normal host defense mechanisms are overwhelmed, and this results in invasion and overgrowth by bowel flora.¹⁶²

If the infection spreads across the external sphincter laterally, an ischiorectal abscess is formed. If the infection dissects rostrally, it may continue between the internal and external sphincters and give rise to a high intramuscular abscess. The infection may also dissect through the external sphincter over the levator ani to form a pelvirectal abscess.¹⁶³

When infection of an anal crypt extends by way of the perianal lymphatics and continues between the mucous membrane and the anal muscles, a perianal abscess forms at the anal orifice. A perianal abscess is the most common variety of perirectal

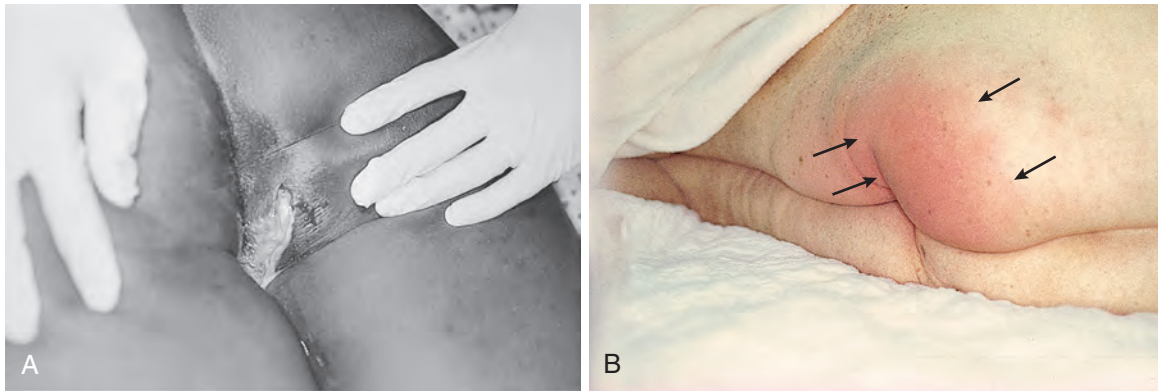

Figure 37.20 Perirectal abscess. **A**, If a perirectal abscess spontaneously ruptures and drains, formal incision, drainage, and packing should still be performed. **B**, A deep, poorly localized perirectal abscess of this size simply cannot be adequately drained in the emergency department (ED). *Arrows* outline the area of induration. This patient requires extensive drainage under general anesthesia. A computed tomography scan may further evaluate the location of the abscess. Broad-spectrum intravenous antibiotics may be started in the ED before definitive surgical intervention. A stab incision in the ED to initiate drainage is also optional, especially if definitive operating room treatment is delayed.

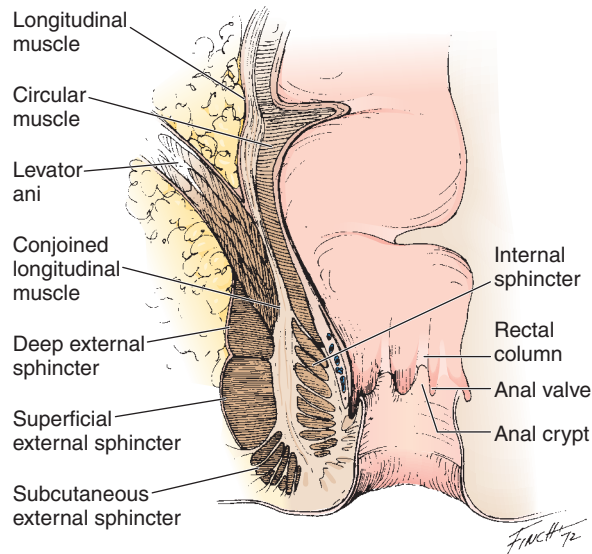

Figure 37.21 Schematic coronal section of the anal canal and rectum. (From Schwartz SI, Lilliehei RC, editors: *Principles of Surgery*, ed 2, New York, 1974, McGraw-Hill. Reproduced with permission.)

Figure 37.22 Classification of perirectal abscesses. 1, Perianal. 2, Ischiorectal. 3, Intersphincteric. 4, High intramuscular. 5, Pelvirectal. (From Hill GJ II, editor: *Outpatient Surgery*, ed 3, Philadelphia, 1988, Saunders. Reproduced with permission.)

infection. A perianal abscess lies immediately beneath the skin in the perianal region at the lowermost part of the anal canal. It is separated from the ischioanal space by a fascial septum that extends from the external sphincter and is continuous with the subcutaneous tissues of the buttocks. The infection may be small and localized or it may be very large, with a wall of necrotic tissue and a surrounding zone of cellulitis.² Perianal abscesses may be associated with a fistula-in-ano. A fistula-in-ano is an inflammatory tract with an external opening in the skin of the perianal area and an internal opening in the mucosa of the anal canal. A fistula-in-ano is usually formed after partial resolution of a perianal abscess, and its presence is suggested by recurrence of these abscesses with intermittent drainage. The external opening of the fissure is usually a red, elevated piece of granulation tissue that may exhibit purulent or serosanguineous drainage on compression. In many cases the tract can be palpated as a cord. Patients with anal fistulas should be referred for definitive surgical excision.¹⁶³

Ischioanal abscesses are fairly common. They are bounded superiorly by the levator ani, inferiorly by the fascia over the perianal space, medially by the anal sphincter muscles, and laterally by the obturator internus muscle. These abscesses may commonly be bilateral, and if so, the two cavities communicate by way of a deep postanal space to form a “horseshoe” abscess.²

Intersphincteric abscesses are less common. They are bounded by the internal and external sphincters and may extend rostrally into the rectum, thereby separating the circular and longitudinal muscle layers.

Causes of perirectal abscesses other than the cryptoglandular process have been documented but are fairly rare. It is believed that hemorrhoids, anorectal surgery, episiotomy, or local trauma may cause abscess formation by altering the local anatomy and thus destroying natural tissue barriers to infection.^{164,165} Perirectal abscesses may serve as a portal of entry for organisms responsible for necrotic soft tissue infections such as Fournier’s gangrene.¹⁶⁶

Physical and Laboratory Findings

A perianal abscess is not generally difficult to diagnose. The severe throbbing pain in the perianal region is acute and

aggravated by sitting, coughing, sneezing, and straining. There is swelling, induration, tenderness, and a small area of cellulitis in proximity to the anus. Rectal examination of a patient with a perianal abscess reveals that most of the tenderness and induration are located below the level of the anal ring. Deeper abscesses may be difficult to localize and identify. Computed tomography is often the first imaging study, given its ready availability. The sensitivity of computed tomography for anorectal abscesses, however, is only 77%.¹⁶⁷ Therefore, when clinical suspicion is high, magnetic resonance imaging should also be considered.

Patients with ischiorectal abscesses have fever, chills, and malaise, but at first there is less pain than with a perianal abscess. Initially on physical examination, one will see an asymmetry of the perianal tissue; later, erythema and induration are apparent. Digital examination reveals a large, tense, tender swelling along the anal canal that extends above the anorectal ring. If both ischiorectal spaces are involved, the findings are bilateral.

Patients with intersphincteric abscesses usually have dull, aching pain in the rectum rather than in the perianal region. No external aberrations of the perianal tissues are noted, but tenderness may be present. On digital examination one frequently palpates a soft, tender, sausage-shaped mass above the anorectal ring; if the mass has already ruptured, the patient may give a history of passage of purulent material during defecation.^{165,168}

Diagnosis of pelvirectal abscesses may be very difficult. Usually, fever, chills, and malaise are present, but because the abscess is so deeply seated, few or no signs or symptoms are present in the perianal region. Rectal or vaginal examination may reveal a tender swelling that is adherent to the rectal mucosa above the anorectal ring.

Laboratory findings do not always aid in the diagnosis. Kovalcik and colleagues¹⁶² found that less than 50% of their patients had a white blood cell count greater than $10.0 \times 10^9/L$. Cultures of perirectal abscesses usually show mixed infections involving anaerobic bacteria, most commonly *B. fragilis* and gram-negative enteric bacilli. MRSA, though less common, should also be considered in endemic areas.¹⁶³

Treatment

Successful management of perirectal abscesses depends on adequate surgical drainage. Complications from these infections may necessitate multiple surgical procedures, prolong hospital stays, and result in sepsis and death. Bevans and associates¹⁶⁴ retrospectively studied the charts of 184 patients who were treated surgically over a 10-year period. These patients were evaluated primarily to identify factors that contributed to morbidity and mortality. Initial drainage was performed under local anesthesia in 38% of the patients and under spinal or general anesthesia in 62%. The authors identified three key factors in those with excessive morbidity and mortality: (1) delay in diagnosis and treatment, (2) inadequate initial examination or treatment, and (3) associated systemic disease. They believed that the only way to effectively examine and adequately drain all but superficial well-localized perirectal abscesses was under spinal or general anesthesia. This assessment was supported by evidence of an increased incidence of recurrence, sepsis, and death in patients treated under local anesthesia. Drainage of deep abscesses under local anesthesia generally does not allow drainage of all hidden loculations. In addition, local anesthesia is not adequate for the treatment of associated pathologic conditions.

Small, well-defined perianal abscesses without deeper perirectal involvement are the only perirectal infections that lend themselves to outpatient therapy. All other perirectal abscesses should be drained in the OR. The result of I&D is almost immediate relief of pain and rapid resolution of infection. Indications for inpatient drainage are failure to obtain adequate anesthesia, systemic toxicity, extension of the abscess beyond a localized area, or recurrence of a perianal abscess. Recurrence may be caused by the presence of a fistula-in-ano.

Drain a perianal abscess through a cruciate incision because if a simple linear incision is used, the abscess cavity has a propensity to close prematurely without adequate drainage. With either technique, make an incision over the area that is most fluctuant. If a simple linear incision is used, lightly pack the abscess cavity for at least 24 hours to ensure adequate drainage. It is extremely painful to probe a perianal abscess and to break up loculations, so liberal analgesia is advised and conscious sedation should be considered. Advise the patient to begin sitz baths at home 24 hours after surgery. Replace the packing at 48-hour intervals until the infection has cleared and granulation tissue has appeared. This usually occurs within 4 to 6 days. Cultures are generally not required in the treatment of an anal abscess as antibiotics are not generally needed. Cultures and antibiotics may be useful to distinguish between a cryptoglandular abscess (typically due to colonic flora) and an abscess of the perianal skin (typically due to staphylococcal species). Cultures may also be useful in patients who would typically be treated with antibiotics, including those with valvular heart disease, immunosuppression, extensive cellulitis, and diabetes; patients who have been on multiple courses of antibiotics; patients with pain out of proportion to findings, who may have an unusual pathogen (e.g., immunocompromised patients); and patients with leukemia or lymphoma who may have unusual or resistant bacteria.

Use of de Pezzer catheters in anorectal abscesses has been described as an alternative to traditional incision and packing. In a series of 91 patients treated in this manner, Kyle and Isbister¹⁶⁵ found equivalent rates of subsequent fistula surgery, less need for general anesthesia, and a shorter postoperative hospital stay than in patients treated with traditional incision and packing. Beck and coworkers¹⁶⁹ reported successful use of catheter drainage in 55 patients with an ischiorectal abscess. Because of the complexity of ischiorectal abscesses, this technique is probably best left to the surgeon who is providing ongoing care.

Perirectal abscesses are currently recognized as a fairly common cause of fever in granulocytopenic patients. These abscesses have a different bacteriologic profile: *P. aeruginosa* organisms are isolated most frequently. These patients are initially seen later because pain develops later in the course, and fever may be the first manifestation. Therefore any patients who are granulocytopenic with vague anorectal complaints, especially those with fever, should be examined carefully for perirectal abscesses. Any abscess that is found should be drained immediately under appropriate anesthesia, and extensive IV antibiotic coverage should be initiated.

Infected Sebaceous Cyst

A common entity that appears as a cutaneous abscess is an infected sebaceous cyst. Such infections are increasingly being caused by MRSA. Sebaceous cysts, caused by obstruction of sebaceous gland ducts, can occur anywhere on the body. The

Sebaceous Cyst Excision

1 This patient has an infected sebaceous cyst on the posterior of the earlobe (*arrow*). These lesions are typically tender, fluctuant, subcutaneous masses, often with overlying erythema.

2 Drain the cyst as you would a typical abscess. The thick sebaceous material must be expressed manually, because it is too thick to drain spontaneously.

3 Sebaceous cysts differ from simple abscesses in that they have a distinct capsule with a pearly white appearance (*arrow*). This capsule must be removed to prevent recurrence. This may be done initially or on a return visit once the inflammation has subsided.

4 Appearance of the cavity after excision of the capsule. Treat the lesion as you would any other abscess, with wound packing and timely follow-up care.

Figure 37.23 Excision of an infected sebaceous cyst. Loop drainage is not applicable to this abscess due to the need for capsule removal.

cyst becomes filled with a thick, cheesy, sebaceous material, and the contents frequently become infected. Sebaceous cysts can be quite large and may persist for many years before they become infected. When infected, they appear clinically as tender, fluctuant subcutaneous masses, often with overlying erythema.

The initial treatment of an infected sebaceous cyst is simple I&D (Fig. 37.23). The loop drainage technique may not be suited for this abscess. The thick sebaceous material must be expressed because it is too thick to drain spontaneously. An important difference exists between infected sebaceous cysts and other abscesses. A sebaceous cyst has a definite pearly white capsule that must be excised to prevent recurrence. Traditionally, in the presence of significant inflammation it is preferable to drain the infection initially and remove the shiny capsule on the first follow-up visit or at a later visit, when it can be more easily identified. Alternatively, the entire cyst can be removed during the initial incision. At the time of capsule removal, the edges are grasped with clamps or hemostats, and

the entire capsule is removed by sharp dissection with a scalpel or scissors. After excision of the capsule, the area is treated in the same manner as a healing abscess cavity. Simple drainage without excision of the capsule often leads to recurrence.

Kitamura and colleagues¹⁷⁰ reported a randomized study of 71 patients treated by either traditional I&D or primary resection of the cyst, followed by irrigation and wound closure. In this study, the patients treated by primary resection had faster healing, fewer days of pain, and less scarring.

Paronychia

Paronychia is an infection localized to the area around the nail root (Fig. 37.24). It is a common infection, probably caused by frequent trauma to the delicate skin around the fingernail and the cuticle. These type of infections have also been linked to “insults” induced by nail cosmetics (mechanical trauma, irritant reactions, and allergic reactions)¹⁷¹ and to a number of occupations (e.g., hair cutting and meat handling).¹⁷² When

a minor infection begins, the nail itself may act like a foreign body. Usually, the infectious process is limited to the area above the nail base and underneath the eponychium (cuticle), but occasionally, it may spread to include tissue under the nail as well and form a subungual abscess. *Staphylococcus* is the most common cultured organism from these lesions; however, anaerobes and numerous gram-negative organisms may be isolated.¹⁷³ Paronychia in children is often caused by anaerobes, and is believed to be the result of finger sucking and nail biting. Occasionally, a group A β -hemolytic streptococcal infection will develop in a paronychia in a child with streptococcal pharyngitis who engages in thumb sucking.^{174,175} Paronychia involving CA-MRSA has been reported.^{176,177} Paronychia has also been reported in association with antiretroviral therapy

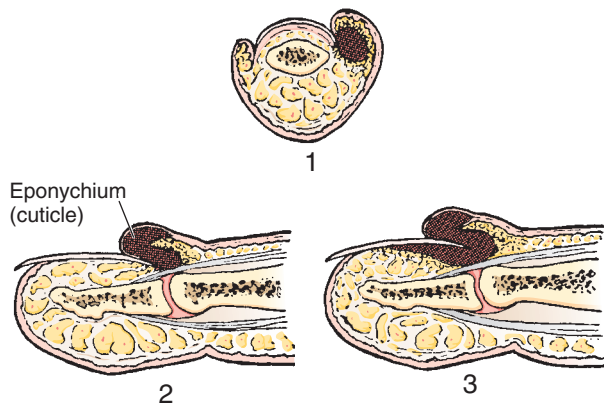

Figure 37.24 Paronychia. 1, Abscess at the side of the nail. 2, The infection has extended around the base of the nail. It has raised the eponychium but has not penetrated under the nail. 3, End stage of paronychia, with a subeponychial and subungual abscess. (From Wolcott MW, editor: *Ferguson's Surgery of the Ambulatory Patient*, ed 5, Philadelphia, 1974, Lippincott. Reproduced with permission.)

for HIV infection^{178,179} and with use of epidermal growth factor inhibitors.¹⁸⁰

A paronychia appears as a swelling and tenderness of the soft tissue along the base or the side of a fingernail (Fig. 37.25). Pain, often around a hangnail, usually prompts a visit to the ED. The infection begins as a cellulitis and may form a frank abscess. If the nail bed is mobile, the infectious process has extended under the nail, and a more extensive drainage procedure should be performed. Although no comparative trials of surgical management versus oral antibiotics have been performed,¹⁸¹ some general guidelines for the management of paronychias have become established in clinical practice. If soft tissue swelling is present without fluctuance, treatment consists of frequent warm soaks (three times a day) and a short course of oral antibiotics. Topical antibiotics with or without topical corticosteroids have also been used.¹⁸² Incision will be of little value at the early cellulitic phase. Antibiotic treatment of localized infection is summarized in Table 37.1. If significant cellulitis is present, a broad-spectrum antistaphylococcal antibiotic (cephalosporin or semisynthetic penicillin) may be tried.

When a definite abscess has formed, drainage is usually quickly curative. A number of invasive operative approaches have been suggested. Actual skin incision or removal of the nail is rarely required, and neither procedure should be the initial form of treatment. One can invariably obtain adequate drainage by simply lifting the eponychial fold away from the nail matrix to allow the pus to drain. This is usually curative because a paronychia is not a cutaneous abscess per se, but rather a collection of pus in the potential space between the cuticle and the proximal end of the fingernail. Drainage may be accomplished after a digital nerve block is performed. After softening the eponychium by soaking, advance a No. 11 scalpel blade, scissors, or a 21- to 23-gauge needle parallel to the nail and under the eponychium at the site of maximal swelling (Fig. 37.26). When using the needle approach, some patients

Figure 37.25 Paronychia in various degrees of severity. **A**, Paronychia of the index finger. In this early stage of abscess formation, the collection is limited to the lateral nail fold (arrow). **B**, More advanced paronychia of the great toe. The abscess has spread around the base of the nail and lifted the eponychium (arrows) but has not yet spread under the nail. There is associated cellulitis on the distal portion of the toe. **C**, Even more advanced paronychia, with subungual extension (black arrow) and cellulitis extending up the finger and onto the dorsum of the hand (white arrow). This patient required removal of the nail and intravenous antibiotics.

TABLE 37.1 Common Hand Infections, Usual Offending Organisms, and Appropriate Therapeutic Regimens

CONDITION	MOST COMMON OFFENDING ORGANISMS	RECOMMENDED ANTIMICROBIAL AGENTS	COMMENTS
Paronychia	Usually <i>Staphylococcus aureus</i> or streptococci; <i>Pseudomonas</i> , gram-negative bacilli, and anaerobes may be present, especially in patients with exposure to oral flora	First-generation cephalosporin or antistaphylococcal penicillin; if anaerobes or <i>Escherichia coli</i> are suspected, oral clindamycin (Cleocin) or a β -lactamase inhibitor such as amoxicillin-clavulanate potassium (Augmentin)	I&D should be performed if infection is well established If infection is chronic, suspect <i>Candida albicans</i> Early infections without cellulitis may respond to conservative therapy
Felon	<i>S. aureus</i> , streptococci	First-generation cephalosporin or antistaphylococcal penicillin	I&D should be performed if infection is well established Oral antibiotic therapy is usually adequate
Herpetic whitlow	Herpes simplex virus	Supportive therapy	Antivirals may be prescribed if infection has been present for <48 hr For recurrent herpetic whitlow, suppressive therapy with an antiviral agent may be helpful Consider antibiotics if secondarily infected I&D is contraindicated

I&D, Infection and drainage.

Adapted from Clark DC: *Common acute hand infections*, Am Fam Physician 68:167, 2003.

may tolerate the procedure without the need for digital blockade. Pus escapes rapidly, with immediate relief of pain. A tourniquet placed at the base of the finger may limit bleeding and aid the clinician in determining the exact extent of the infection during the drainage procedure.

If more than a tiny pocket of pus is present, fan the knife tip or needle or spread the scissors under the eponychium while keeping the instrument parallel to the plane of the fingernail (see Fig. 37.26, steps 5 and 6). When a large amount of pus is drained, slip a small piece of packing gauze under the eponychium for 24 hours to provide continual drainage. Given the prevalence of MRSA, cultures are generally indicated. Antibiotics are frequently prescribed, although they are not essential if drainage is complete or the surrounding area of cellulitis is minimal. An alternative to systemic antibiotics is to keep the operative site bathed in antibiotic ointment. After the anesthesia has worn off, start the patient on frequent soaks in warm tap water at home. In most cases the patient may easily remove the packing. At 24 to 36 hours, soak the finger in warm water and pull the gauze out; a repeated visit to a clinician is not required if healing is progressing, but follow-up examinations should always be encouraged. Once the packing is removed, cover the area with a dry, absorbent dressing. Apply an antibiotic ointment periodically to the site for several days.

An alternative technique, called the *Swiss roll technique*, was described by Pabari and colleagues¹⁸³ for severe, acute paronychia with a run-around or contiguous infection of both nail folds. With a No. 15 scalpel blade pointing away from the nail bed, make an incision on both sides of the nail fold. The nail fold, after thorough irrigation with saline, is then rolled proximally over nonadherent dressing, like a swiss roll, and sutured to the skin with a nonabsorbable dressing. Apply a finger dressing. Remove the sutures in 48 hours and unfold the nail fold back to its original position to allow it to heal by

secondary intention.¹⁸³ The authors argue that this technique spares the nail plate and allows rapid healing, although no controlled studies have compared this technique with simple incision followed by packing gauze described previously.

If the infection has produced purulence beneath the nail (subungual abscess), remove a portion of the nail or trephinate the nail to ensure complete drainage. As an alternative to nail removal, place a hole in the proximal part of the nail with a hot paper clip or a portable electrocautery device. Make a large opening or multiple holes to ensure continued drainage.

The proximal portion of the nail is involved in most cases. After a digital block has been performed under sterile conditions, proximal subungual collections can be managed by bluntly elevating the eponychium to expose the proximal edge of the nail. Elevate the proximal third of the nail from the nail bed and resect it with scissors. Leave the distal two thirds of the nail in place to act as a physiologic dressing and to decrease postoperative pain (Fig. 37.27). If purulence is found below the lateral edge of the nail, gently elevate the affected part and excise it longitudinally.¹⁸⁴ Exercise care during this procedure to avoid damage to the nail matrix. Place a wick of gauze beneath the eponychium for 48 hours to ensure continued drainage.

Most paronychias resolve in a few days, and one to two postoperative visits should be scheduled to evaluate healing and reinforce home care. For compliant patients with a small paronychia, home care alone may suffice after the initial drainage. Clinical infection lasting longer than a few weeks should prompt evaluation for osteomyelitis of the distal phalanx, a well-known but rare complication of even a properly drained paronychia.

Patients occasionally come to the ED complaining of a chronic, indolent paronychial infection. These seldom respond to ED intervention. Frank purulence is rarely present, and

Paronychia Drainage

In selected patients the procedure can be completed without anesthesia. After softening the eponychium by soaking, advance a No. 11 scalpel blade under the eponychium parallel to the nail.

Pus escapes rapidly, with immediate relief of pain. Antibiotics are not required for minor cases. Instruct the patient to frequently soak the digit in warm water at home.

Many patients, especially those with a large paronychia, will require a digital block before the procedure. (See Chapter 31 for details on digital blocks.)

Lift the eponychial fold away from the nail. Here, the blunt side of a No. 15 blade is being used. No sharp incision is required; simply lifting the eponychium away from the nail is sufficient.

Pus will readily escape as the fold is lifted.

Keep the scalpel parallel to the nail and continue to lift the eponychium to release all the pus. Place a small piece of packing gauze under the eponychium for 24 hours, encourage warm soaks, and prescribe antibiotics if cellulitis is present.

Figure 37.26 Paronychia drainage.

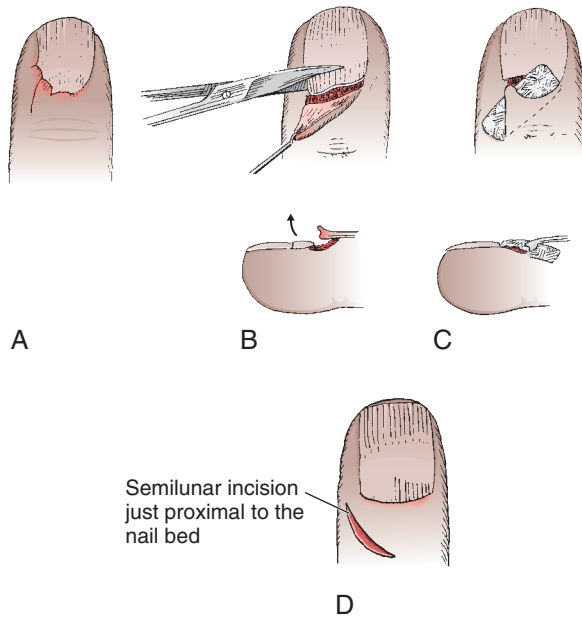

Figure 37.27 A–C, Aggressive treatment of recurrent paronychia or subungual abscess includes removal of a portion of the proximal part of the nail and incision of the eponychium. **D**, Some physicians prefer to use a semilunar incision proximal to the eponychium rather than directly incising and potentially injuring the cuticle permanently. These aggressive therapies are seldom required and are not first-line interventions.

conservative treatments are often unsatisfactory. Many causes of this frustrating condition have been described, including fungal, bacterial, viral, and psoriatic conditions. Screen patients for malignancy if they have chronic paronychia that is unresponsive to therapy.¹⁸⁵ Meticulous hand care, oral and topical antimicrobial medications, topical corticosteroids, and, occasionally, aggressive surgical intervention have been suggested.¹⁸⁶ Refer these patients to a dermatologist or hand surgeon because of the prolonged treatment required.

Herpetic Whitlow

Herpetic whitlow is an extremely contagious infection of the distal phalanx caused by herpes simplex virus (type 1 or 2) (Fig. 37.28). Herpes infection of the hand predominantly presents in a bimodal age distribution: children younger than 10 years of age and young adults between 20 and 30 years of age. In children, herpetic whitlow tends to be associated with gingivostomatitis caused by herpes simplex 1, whereas adults most commonly harbor herpes simplex 2. Inoculation occurs through a discontinuity in the skin.¹⁸⁷ Health care providers exposed to oral secretions (e.g., dental hygienists and respiratory therapists) and patients with other herpes infections are most commonly infected.^{188,189} After a 2-day to 2-week incubation period, an infected individual may experience prodromal signs and symptoms such as fever, malaise, lymphadenitis, and axillary lymphadenopathy. In the affected finger the infection is characterized by tenderness, followed by throbbing or burning pain (out of proportion to the findings on physical examination), edema, and erythema. Vesicles containing clear, bloody, or cloudy fluid form and mark the most infectious stage of the process. Vesicles may coalesce to form a bulla. Viral vesicles

Figure 37.28 Herpetic whitlow. Clinical findings include pain out of proportion to the results of examination, erythema, and vesicular lesions. Herpetic whitlow may be confused with paronychia. However, incision and drainage is contraindicated because it may lead to bacterial superinfection. (From Habif TP: *Clinical Dermatology*, ed 5, St. Louis, 2009, Mosby.)

typically involve the digits but can also involve other areas of the hand.¹⁹⁰ The lesions are usually quite painful but are self-limited and resolve in 2 to 3 weeks. Unlike bacterial infections the pulp space is soft and not tense. The treatment of herpetic whitlow is conservative. Drainage of herpetic whitlow is contraindicated as it may induce a secondary bacterial infection and delay healing.^{188,191} Treatment is symptomatic and consists of splinting, elevation, and analgesia as needed. Oral antiviral agents effective against herpes infections (acyclovir, famciclovir, or valacyclovir) can shorten the course of the disease if given early. Infection recurs in 30% to 50% of cases, but the initial infection is usually the most severe. Acyclovir, 200 mg taken orally three to four times a day, can decrease recurrence rates.¹⁸⁹

Consideration must be given to preventing spread of the infection. An occlusive dressing decreases the chance of viral transmission, but health care providers with herpetic whitlow should limit and perhaps even refrain from patient contact, especially until all lesions have crusted over and viral shedding has stopped.^{192,193} Compliance with universal precautions will decrease the likelihood of patient-to-provider transmission.

Felon

A felon is an infection of the pulp of the distal end of the finger (Fig. 37.29). The usual cause is trauma with secondary invasion by bacteria. A felon may develop in the presence of a foreign body, such as a thorn or a splinter, but often a precipitating trauma cannot be identified. Finger-stick felons are common in diabetic patients. An important anatomic characteristic of this area is that many fibrous septa extend from the volar skin of the fat pad to the periosteum of the phalanx; these septa subdivide and compartmentalize the pulp area. When an infection occurs in the pulp, these structures make it a closed-space infection. The septa limit swelling, delay pointing of the abscess, and inhibit drainage after incomplete surgical decompression. Pressure may increase in the closed space and initiate an ischemic process that compounds

Figure 37.29 A well-developed felon. In this advanced case the patient had little pain at initial evaluation. The distal phalanx was almost completely resorbed because of pressure, inflammation, and chronic osteomyelitis. This infection is extensive and warrants consultation with a hand specialist.

the infection. The infection can progress to osteomyelitis of the distal phalanx, septic arthritis, and flexor tenosynovitis. Although the septa may facilitate an infection in the pulp, they also provide a barrier that protects the joint space and tendon sheath by limiting proximal spread of the infection.

In most cases the offending organism is *S. aureus*, but mixed infections and gram-negative infection may also occur. A study looking at the bacteriology of hand infections over an 11-year period found that of 159 hand infections, 48 (30%) harbored CA-MRSA, the incidence of CA-MRSA increased by 41% per year, and IV drug use and felon infections in particular were risk factors for CA-MRSA.¹⁸⁴ These changing patterns, along with the often protracted course of felons and concern for osteomyelitis, make this one of the few soft tissue infections in which culture may be helpful.

A patient in whom a felon is developing will describe a gradual onset of pain and tenderness of the fingertip. In a few days, the pain becomes constant and throbbing and gradually becomes severe. In the initial stages, physical examination may be quite unimpressive because the fibrous septa limit swelling in the closed pulp space. As the infection progresses, swelling and redness become obvious. Occasionally, one may elicit point tenderness, but frequently, the entire pulp space is extremely tender. The patient characteristically arrives with the hand elevated over the head because the pain is so intense in the dependent position. Cessation of pain indicates necrosis and nerve degeneration.

During the early stages of cellulitis, a felon may be controlled by treatment consisting of elevation, oral antibiotics (see [Box 37.2](#)), and warm water or saline soaks. For more developed felons, proper treatment consists of early and complete I&D.¹⁸⁸ Antibiotics alone are not curative once suppuration has occurred. Delaying surgery may result in permanent disability and deformity.

A minor felon can usually be drained on an outpatient basis after the application of a digital nerve block. A long-acting anesthetic (bupivacaine) will prolong the anesthesia. A tourniquet (1.25-cm Penrose drain) applied proximally can be used to allow an incision into a bloodless field. Surgical drainage

must be performed carefully to avoid injury to nerves, vessels, and flexor tendons. Most felons can be managed with a limited procedure, but many surgical options have been advocated, none of which has been proved to be superior for all circumstances.¹⁸⁸ Traditional incisions (“hockey stick” or “fish mouth”) have a propensity for complications such as sloughing of tissue and postoperative fat pad anesthesia or instability and are rarely used. The preferred initial treatment is a simple longitudinal incision over the area of greatest fluctuance,^{194,195} 3 to 5 mm distal to the distal interphalangeal joint. The incision may be made laterally or along the volar surface ([Fig. 37.30A](#)), although injury to the sensory nerve or digital artery is more of a concern with the lateral incision given its proximity to these structures. Frank pus may be encountered during incision, but usually only a few drops are expressed. One more often drains a combination of necrotic tissue and interstitial fluid. A foreign body should be sought even if the history is not known. A potential drawback to an incision in the middle of the fat pad is the production of a scar in a very sensitive and commonly traumatized area. The incision must not extend to the distal interphalangeal crease because of the danger of injuring the flexor tendon. The subcutaneous tissue is bluntly dissected with a hemostat to provide adequate drainage. A gauze pack may be placed in the wound for 24 to 48 hours to ensure continued drainage. Recurrent or more severe infections may require a more aggressive approach by a hand specialist. Follow-up recommendations for patients with a diagnosis of felon should include referral to a hand surgeon.

No matter which incision is made, it must not be carried proximal to the closed pulp space because of the danger of entrance into the tendon sheath or the joint capsule. A snug dressing, splinting, elevation, and adequate opioid analgesics are prerequisites for a successful outcome. Most felons are treated empirically with antibiotics for at least 5 days. A broad-spectrum cephalosporin is a reasonable choice pending cultures (if done). Antibiotics effective against CA-MRSA should also be considered given its increasing incidence. MRSA infections can be treated with vancomycin, 1 g twice a day, or linezolid and may require weeks until resolution.¹⁹⁶ Oral linezolid may allow outpatient treatment.

The patient should be rechecked in 2 to 3 days. On the first postoperative visit, perform a digital block and remove the packing if present. Irrigate the incision copiously with saline and remove any additional necrotic tissue. If there is continued drainage at this time, replace the drain for 24 to 48 hours, but it can usually be removed and a dressing reapplied. Soaking may be advised. At the first revisit, check the sensitivities of the bacterial cultures and make a decision to continue or change antibiotics.

Some clinicians advocate radiographic evaluation for retained foreign bodies at the initial visit, as well as a baseline evaluation of the bone for subsequent evaluation of osteomyelitis. Other clinicians reserve radiographs for wounds not showing significant improvement in 5 to 7 days. Evidence of osteomyelitis, however, may not be found radiographically for several weeks after the appearance of the lesion. Persistent infections necessitate more radical I&D and may require IV antibiotics. After adequate drainage, osteomyelitis may respond surprisingly well to outpatient antibiotic therapy, with almost complete regeneration of bone being achieved if the I&D procedure has been adequate.

Difficult or persistent cases require evaluation and care by a hand surgeon. In these cases, early consultation is advisable

Felon Drainage

The preferred initial incision for draining a felon is made directly into the area of most fluctuance (1). More aggressive incisions should be reserved for complicated cases because they have greater morbidity and require more complicated wound care. The unilateral longitudinal approach is a good first choice. Some prefer a similarly located through-and-through incision (see below).

A fat pad incision is generally avoided but can be acceptable for localized infections. They may be associated with a painful scar in an area that is often traumatized. The transverse fat pad incision should avoid the digital nerves (2), and the longitudinal fat pad incision should avoid the flexor tendon (3).

A

This patient has an extensive paronychia (arrow) but did not seek medical attention.

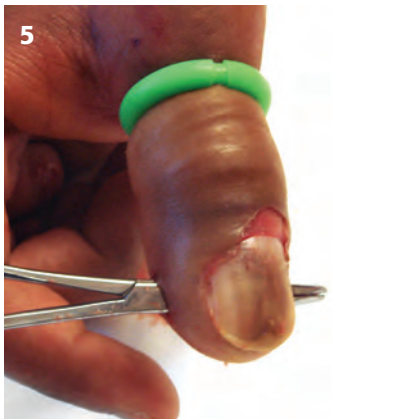

The infection has spread volarly and progressed to a felon. Drainage of both areas is required.

The eponychium is lifted, which resulted in immediate drainage of large quantities of pus.

A hemostat is placed under the eponychium to facilitate complete evacuation of the pus.

To drain the felon, a through-and-through incision is made on the volar side. A hemostat is used to break up loculations in the fat pad and then to grab gauze for a pull-through pack.

The gauze pack is pulled through the incision and left in place for 24 to 48 hours to ensure continued drainage.

B

Figure 37.30 Felon drainage. For a felon the authors prefer the through-and-through drainage procedure shown in **B**. Antibiotics should be used postoperatively. Culture can aid in the selection of long-term antibiotics, but most initially cover for community-acquired methicillin-resistant *Staphylococcus aureus*.

Figure 37.31 Subungual hematoma. **A**, Subungual hematoma with a totally blackened nail bed. Do not remove this intact nail, even though the nail bed is lacerated, or there is a total hematoma and underlying minor tuft fracture. In this example, blood accumulated only under the nail, not in any paronychia areas. **B**, Subungual hematoma of the great toe after dropping a heavy object on the foot (a common injury).

to avert catastrophic complications such as loss of function or amputation.

Subungual Hematoma

Subungual hematomas are typically caused by hitting a fingertip with a hammer, slamming a finger in a door (Fig. 37.31), or dropping a weight on a foot. Patients present with terrible throbbing pain that increases with the pressure under the nail. There is an associated blue-black discoloration under the affected nail, indicative of the hematoma. The source of the pain is pressure in a contained space, pressing against nerve fibers and not from the soft tissue injury or bony injury alone.

Subungual hematomas may be simple (i.e., the nail and nail fold are intact) or accompanied by significant injuries to the nail fold and digit. The nail matrix is the tissue under the base of the nail that permits nail growth and migration. Its longitudinal fibers anchor the dermis to the periosteum of the distal phalanx.¹⁹⁷ The matrix begins 7 to 8 mm under the proximal fold, and its distal end is the white crescent called the lunula. Scarring of the matrix, as occurs with nail trauma, can disrupt nail growth and lead to nail deformity or permanent loss of the nail. When describing the injury, the clinician should estimate the percentage of nail bed that is affected by the hematoma and discuss associated trauma to the nail margins or surrounding tissue. The examination should include tests of the extensor and flexor tendons, of circulation by capillary refill, and of the sensitivity of the area.¹⁹⁸

If fracture of the distal phalanx is suspected (e.g., if the fingertip is unstable or the mechanism of injury suggests a fracture), obtain anteroposterior and lateral x-ray films. Radiographs can help differentiate tendinous from bony mallet-type injuries. Crush injuries are associated with three types of distal phalanx fractures: longitudinal, transverse, and comminuted. If the fracture is angulated, displaced, unstable, or intraarticular or involves a third or more of the articular surface, refer the patient to a hand surgeon.¹⁹⁹ Because trephination in patients with a distal phalanx fracture theoretically converts a closed fracture into an open one, there is concern about infectious and cosmetic complications. In the two studies that

examined this possible association,^{200,201} with fracture subsets totaling 26, no infections occurred. These studies suggest that the presence of an underlying fracture does not contraindicate nail trephination for fear of causing infection. There are no data supporting the routine use of prophylactic antibiotics following trephination if an underlying fracture is present.

Subungual hematomas should be trephinated if they are acute (less than 24 to 48 hours old), are not spontaneously draining, are associated with intact nail folds, or are painful. After 48 hours, most subungual hematomas have clotted and trephination is typically not effective.

Nail removal is unnecessary, even if there is an underlying distal phalanx fracture, as long as the nail margins and nail are intact.^{202,203} If the nail is split, avulsed or disrupted, or a nail bed laceration extends to the skin, the nail should be removed and the underlying nail bed repaired (see further discussion in Chapter 35). Simple trephination of an uncomplicated subungual hematoma, even if it involves the entire subungual area, results in a good outcome functionally and cosmetically.²⁰⁴ Trephination should also be considered if the hematoma covers more than half the intact nail or if it is smaller but painful.

Prophylactic antibiotics are not necessary for patients with uncomplicated subungual hematomas that have been trephinated. An underlying tuft fracture does not mandate antibiotic prophylaxis. For more serious injuries, a slight risk for infection exists, but in most cases rigorous wound cleaning and careful soft tissue repair constitute adequate treatment.^{205,206}

Methods of Trephination

All methods of trephination require aseptic technique. Clean the nail thoroughly and place the digit in a sterile field. Follow universal precautions because the fluid under the nail is under pressure and can spurt.²⁰⁷ Ensure that adequate analgesia has been achieved. Anesthesia is not always required, but a digital block can be used to calm an anxious patient and is commonly performed.

An 18- or 21-gauge needle can be rotated between the thumb and the index finger while gentle pressure is applied so that the sharp end of the needle corkscrews through the nail.²⁰⁷ When using a needle, the “give” is harder to feel, so

the clinician should proceed slowly until blood is drawn. Because the hole made with a needle is small, a second hole may be required.

An alternative needle-based approach is being used by a group of Turkish dermatologists. Kaya and associates²⁰⁸ use extra fine, 29-gauge insulin syringes for evacuation of hematomas. After the nail is trimmed, the needle is inserted parallel to the nail plate and advanced to the distal edge of the hematoma. This technique is especially effective for small hematomas of the second, third, and fourth toenails, which are hard to trephine.

A No. 11 scalpel blade can be used to score and then cut through the affected nail. This approach is painful for the patient because the hole is usually larger than required.

Hot cautery is the most common form of trephination and is usually done with a paper clip which has been straightened and heated in a flame (Figs. 37.32 and 37.33). Place the hot end on the nail above the center of the hematoma and apply gentle pressure until the nail is breached and the hematoma expressed. A give is felt as the instrument passes through the nail. Stop the pressure at this point to avoid damage to the nail bed. Blood exits rapidly, and the blackened nail regains its normal color (see Fig. 37.33, step 3). The blood usually remains fluid for 24 to 36 hours and can easily be expressed with slight pressure. Multiple holes may be needed for continued drainage. Do not use hot cautery trephination on artificial nails because they are flammable.²⁰² Hot cautery with a paper clip is easy to perform, but hematomas treated in this way tend to reform. It has also fallen out of favor secondary to the need of using an open flame in front of the patient. In addition, most paper clips are made of aluminum, which is difficult to sufficiently heat to penetrate the nail. A portable hot-wire electrocautery unit can be used, but it is difficult to obtain an adequate drainage hole without adapting the instrument

(see Fig. 37.33). It can be modified to burn a larger hole by “fattening” the end of the wire loop and rotating the device slowly as the nail is penetrated or by removing a small rectangle of nail. In addition to being convenient, the cautery device is desirable because the wire stays hotter longer, thereby enhancing nail penetration.

The PathFormer (Path Scientific, Carlisle, MA) is a relatively new device that allows controlled nail trephination (“mesoscission”) and therefore minimizes patient discomfort during the procedure.²⁰⁷ It uses electrical resistance in the nail bed as feedback to stop and retract the drill when it penetrates the nail plate. The nail bed, with its blood supply and nerve endings, is not disturbed.

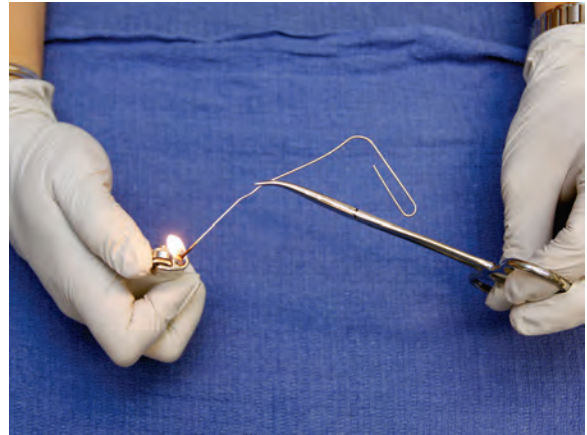

Figure 37.32 A straightened paper clip, held with a hemostat and heated with a flame, can be used for hot cautery trephination.

Nail Trephination

1 This patient has a painful subungual hematoma and requires trephination. Cleanse the area with antiseptic prior to trephination. Anesthesia with a digital block can optionally be used.

2 Place the hot cautery device (here, a disposable cautery pen) over the center of the hematoma and apply gentle pressure. A “give” is felt and blood is rapidly expressed as the hematoma is released. Multiple holes may be required.

3 Successful trephination is demonstrated by relief of pain and return of the normal color of the nail bed.

Figure 37.33 Nail trephination.

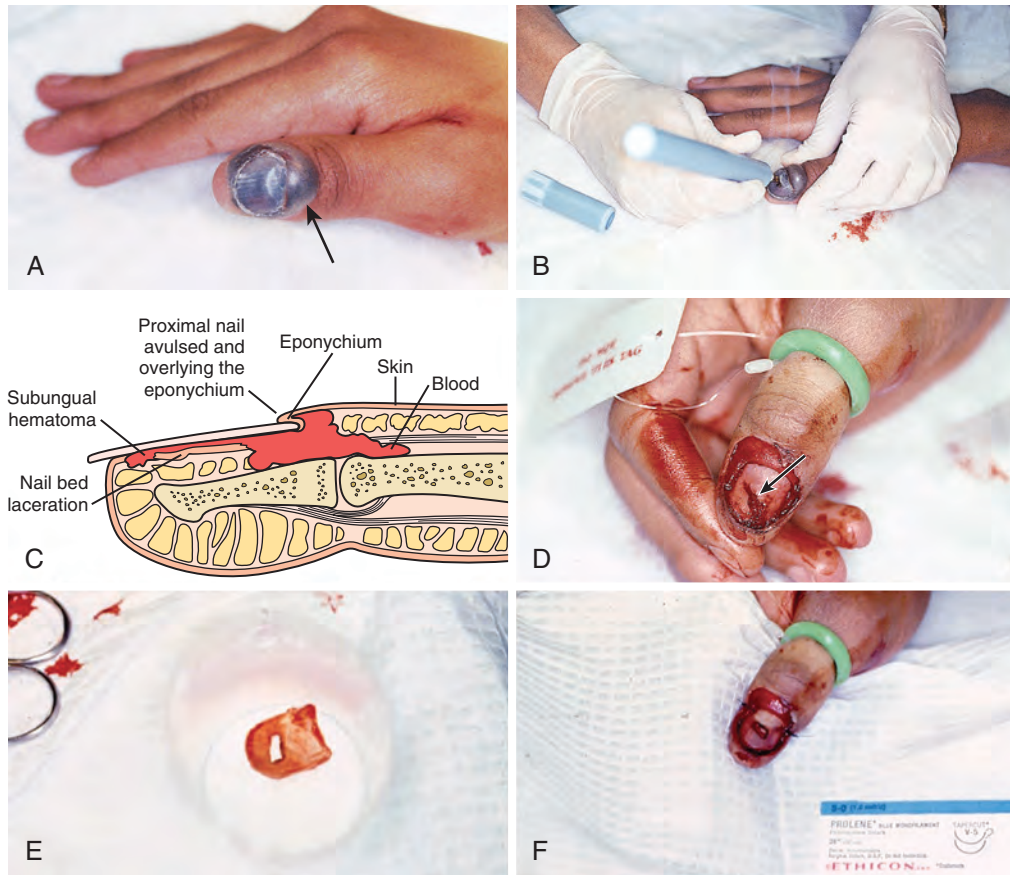

Figure 37.34 Complicated subungual hematoma. **A**, This patient slammed his finger in a car door and sustained acute flexion of the distal phalanx and a crush injury. It appears to be a simple subungual hematoma, but note the blood in the paronychial space (*arrow*). There is communication between the nail bed laceration and the eponychium. **B**, All the blood did not drain when the nail was trephined. **C**, Blood accumulated in this area because the base of the fingernail has been avulsed from its origin and now lies between the eponychium (cuticle) and skin. This is appreciated when the skin is débrided. Note the white avulsed base of the fingernail just under the skin. The closed nature of the injury causes the confusion. **D**, With the nail removed, the nail bed laceration (*arrow*) can be seen and repaired. **E** The old trephined nail; **F**, this can now be replaced and sutured in its original position to keep the eponychial space open, or the space can be packed with gauze for a few weeks to discourage scar formation and subsequent nail deformity. Note the drainage hole in the original nail.

Outcome

It is difficult to predict the fate of the fingernail after drainage of a subungual hematoma. Obviously, there must be a nail bed laceration if bleeding occurs, but with a stable nail bed, repair is unnecessary. Even if a small tuft fracture is present, most do well with simple drainage. Some patients will lose the nail, but if the nail root or nail bed is not significantly disrupted and the nail remains implanted, a normal-appearing nail is the usual final result.

After a hematoma has been drained, the nail should be cleaned thoroughly and a dry dressing applied. Patients should be advised to keep the digit dry for 2 days. Any fracture should be splinted and given appropriate follow-up at a surgical clinic.

Conditions With a Similar Appearance

One condition that may be mistaken for a simple subungual hematoma is closed avulsion of the base of a fingernail occurring in conjunction with a subungual hematoma from a nail bed

laceration. A common mechanism is slamming a finger in a car door, which causes sudden flexion of the distal phalanx in conjunction with a crush injury of the nail bed. The nail itself is usually stable, so generally no repair of the nail bed appears to be required. However, if the subungual hematoma extends past the confines of the nail bed, such as in the paronychial space (under the skin of the cuticle), there must be a communication between the nail bed and this space. This produces a paronychial hematoma, with blood occupying the space where pus would be located in an infectious paronychia (**Fig. 37.34**). When this condition is present, the avulsed proximal portion of the fingernail overlies the nail fold of the cuticle but is appreciated only after the overlying skin is opened. Open reduction (replacement) of the nail must be performed. The replaced nail often grows normally, but a lost or deformed nail is possible. Repair of the nail bed laceration is optional at this juncture but may not be required if the nail is stable. Once the injury is anatomically aligned, splinting and soaking

follow as for a simple subungual hematoma. These injuries rarely become infected, and there is no evidence that the prophylactic use of antibiotics is necessary.

Subungual hematomas can also be a manifestation of diseases such as Kaposi's sarcoma and melanoma. These conditions should be considered when no trauma has occurred and the findings on physical examination are not consistent with a simple subungual hematoma.

Burn Care Procedures

Anthony S. Mazzeo

Two million people suffer a burn-related injury every year in the United States. The American Burn Association (ABA) estimates that almost 500,000 of these patients received medical evaluation and treatment in 2014 and approximately 40,000 required hospitalization.¹ According to the 2014 National Burn Repository,² patients who suffer burn injuries are predominately male (69%), and their mean age is 32 years old. Children younger than 5 years account for 19% of burns, and patients older than 60 years account for an additional 13%. Seventy-four percent of all burns involve less than 10% of the total body surface area (TBSA). Nearly 80% of all burns are caused by flame or fire or by scalds, with scald injury occurring most in children younger than 5 years.

Overall, the incidence of burn injury has declined in recent decades and advances in medical care have improved the morbidity and mortality of burn patients.^{2,3} Enhancements in resuscitation, surgical and anesthetic techniques, intensive care, infection control, nutrition, and metabolic support have all contributed to dramatic improvements in the survival, preservation of body function, physical appearance, and emotional outcomes of patients with this injury. The initial care provided to burn patients by emergency medical providers can improve outcomes by preventing the conversion of superficial burns to deep burns requiring surgery and by improving the long-term functional and cosmetic outcomes of the affected tissues.

The classification of burns is based on three criteria⁴: depth of skin injury, percentage of TBSA involved, and source of injury (thermal, chemical, electrical, or radiation). The seriousness of a burn injury is determined by the characteristics and temperature of the burning agent, the duration of exposure, the location of the injury, the presence of associated injuries, and the age and general health of the victim (Table 38.1).

The ABA defines minor burns as uncomplicated partial-thickness burns involving less than 5% TBSA in children (<10 years old) or the elderly (>50 years old), less than 10% TBSA in adults, or full-thickness burns less than 2% TBSA.⁵ Moderate or major burns include injuries that involve a greater TBSA, as well as burns in areas of specialized function, such as the face, hands, feet, and perineum. More serious burns also include those caused by a high-voltage electrical injury or those with associated inhalation injuries or other major trauma.

Throughout the course of history, clinicians have experimented with burn therapies to relieve pain and promote healing. Many treatment regimens and home remedies have been successful, largely because minor burns generally do well with a modicum of intervention and commonsense wound care. Although little has changed in the care of minor ambulatory burns over the past 3 decades, treatment of major burns has significantly improved, including the development of sophisticated burn centers, increased knowledge of burn wound physiology, and prevention of infection.

WOUND EVALUATION

Emergency clinicians should be aware that the depth of a burn wound cannot always be determined accurately on clinical grounds alone at initial evaluation and that burn injury is a dynamic process that may change over time, particularly during the 24 to 48 hours after the burning process has been arrested. It is common, for example, for a seemingly minor or superficial burn to appear deeper on the second or third return visit (Fig. 38.1). This phenomenon is not a continuation of the burning process that can be altered by clinician intervention but is considered to be a pathophysiologic event related to tissue edema, dermal ischemia, or desiccation.⁶

Estimating Burn Depth

The depth of a burn has historically been classified by degree.⁷ First degree involves the epidermis only, second-degree (or partial-thickness) burns extend into the dermis, and third-degree (or full-thickness) burns destroy the entire skin. An additional fourth degree is sometimes used to describe injuries to the underlying muscle, tendon, or bone (Fig. 38.2).

First-degree burns involve the epidermis only (Fig. 38.3A). The skin is reddened but is intact and not blistered. This injury ranges from mildly irritating or even pruritic to exquisitely painful. Minor edema may be noted. Causes include ultraviolet light (as in sunburn) and brief thermal “flash” burns. First-degree burns may blister within 24 to 36 hours, and the patient should be warned about this possibility. Frequently, the epidermis may flake or peel within 5 to 10 days. Healing occurs spontaneously, usually without scarring.

Second-degree burns involve the epidermis and extend into the dermis to include the sweat glands and hair follicles. Superficial second-degree burns involve only the papillary dermis (see Fig. 38.3B). These burns are pink, moist, and extremely painful. Blisters are common and the skin may slough. The burn blanches with pressure, and mild to moderate edema is common. Hair follicles often remain intact. Superficial second-degree burns are the most common burns seen in the emergency department (ED). The usual causes are scalds, contact with hot objects, or exposure to chemicals. Barring infection or repeated trauma, these burns heal spontaneously and without scarring in approximately 2 weeks. These areas may be sensitive to sunburn, windburn, and skin irritation for months after the original injury has healed.

Deep second-degree burns involve the reticular dermis and appear mottled white or pink (see Fig. 38.3C). There is obvious edema and sloughing of the skin, and any blisters are usually ruptured. Blanching is absent. These burns are not generally painful initially and may have decreased sensation, but pressure may be perceived. Within a few days, however, these burns can become exquisitely painful. This type of burn may be converted to a full-thickness injury by further trauma or infection.

Third-degree burns result from complete loss of the dermis and may extend into subcutaneous (SQ) tissue (see Fig. 38.3D). These burns usually appear dry, pearly white, or charred. They are initially painless, with a leathery texture. Circumferential third-degree burns on an extremity or the torso cause a loss of elasticity that may impair the circulation or ventilation and necessitate an escharotomy.

Fourth-degree burns extend deeply into SQ tissue, muscle, fascia, or bone (see Fig. 38.3E). These burns are

TABLE 38.1 Characteristics of Burns, by Depth

CLASSIFICATION OF BURN	ETIOLOGY	APPEARANCE	SENSATION	TIME TO COMPLETE HEALING	SCARRING
First Degree					
Superficial epidermal layers	Sunburn, other UV exposure Short flash flame burns	Dry, red Blanches with pressure	Present May be quite painful	3–7 days	No
Second Degree					
Varying depth, blisters, or bullae formation					
Dermal appendages spared (e.g., sweat glands, hair follicles)					
Includes entire epidermis and some portion of the dermis					
Superficial partial thickness	Water scald Longer flash burn	Blisters, peeling skin Blanches with pressure Skin red and moist under blisters	Painful Exposure to air and temperature painful	7–21 days	Unusual if no infection and proper follow-up Pigment change may be seen Burned area may be sensitive to frostbite, windburn, and sunburn for many months Itching may be problematic for weeks after healing
Deep partial thickness	Flame Water immersion Oil, grease, hot foods (e.g., soup)	Variable color Wet or waxy dry, does not blanch Blisters easily removed, skin peeling off	Pressure only	>21 days	Severe; risk for contracture
Third Degree					
Loss of all skin elements, thrombosis and coagulation of vessels	Flame, steam, oil grease Immersion, scald Caustic chemical, high voltage	Leathery appearance, white or charred, dry, inelastic; blanching with pressure May be present under blisters	Deep pressure only	Never heals Requires grafting	Very severe, high risk for contracture

UV, Ultraviolet.

Modified after Clayton MC, Solem LD: No ice, no butter: advice on management of burns for primary care physicians, *Postgrad Med* 97:151, 1995; Morgan ED, Bledsoe SC, Barker J: Ambulatory management of burns, *Am Fam Physician* 62:2015, 2000.

Figure 38.1 It may be difficult to accurately assess the depth or severity of a burn on the first visit. **A**, This full-thickness burn will not heal without a skin graft. **B**, This blistered hot water burn is probably second degree, but full-thickness burns can develop under blisters. **C**, At 2 weeks, a second-degree burn and a small area of third-degree burn (*arrows*).

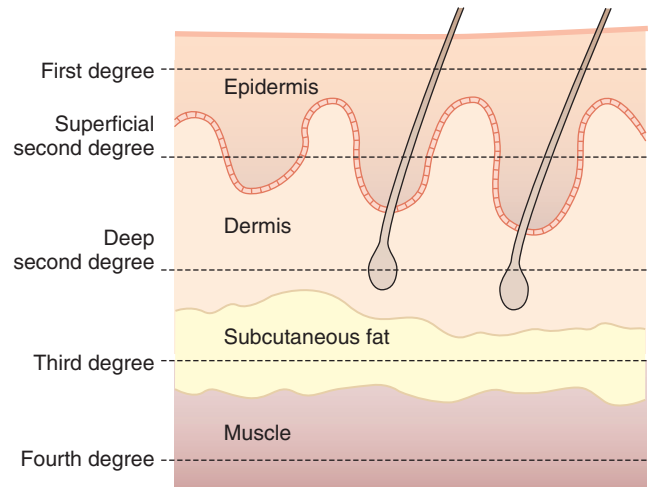

Figure 38.2 Depths of a burn. First-degree burns are confined to the epidermis. Second-degree burns extend into the dermis (dermal burns). Third-degree burns are full thickness through the epidermis and dermis. Fourth-degree burns involve injury to underlying tissue structures such as muscle, tendons, and bone. (From Townsend CM, Beauchamp RD, Evers BM, et al., editors: *Sabiston textbook of surgery*, ed 19, St. Louis, 2012, Saunders.)

Figure 38.3 Depth of thermal injury. **A**, Patient with sunburn on the lower extremity (a superficial or first-degree burn with associated blisters on the anterior tibial surface). **B**, Partial-thickness injury of the hand (superficial second-degree burn). **C**, Partial-thickness injury extending beyond the subcutaneous layers (deep second-degree burn). **D**, Full-thickness (third-degree) burn. **E**, Full-thickness injury with extensive tissue loss (fourth-degree burn). (From Davis PJ, Cladis FP, Motoyama EK, editors: *Smith's anesthesia for infants and children*, ed 8, St. Louis, 2011, Mosby.)

TABLE 38.2 American Burn Association's Grading System for Burn Severity and Disposition of Patients^a

Criteria	Type of Burn		
	Minor	Moderate	Major
Criteria	<10% TBSA burn in adult <5% TBSA burn in young or old <2% full-thickness burn	10%–20% TBSA burn in adult 5%–10% TBSA burn in young or old 2%–5% full-thickness burn High-voltage injury Suspected inhalation injury Circumferential burn Concomitant medical problem predisposing the patient to infection (e.g., diabetes, sickle cell disease)	>20% TBSA burn in adult >10% TBSA burn in young or old >5% full-thickness burn High-voltage burn Known inhalation injury Any significant burn involving the face, eyes, ears, hands, feet, genitalia, or joints Significant associated injuries (e.g., fracture, other major trauma)
Disposition	Outpatient management	Hospital admission vs. higher-level, structured outpatient care	Consider referral to a burn center ^b

^aBurn, partial-thickness or full-thickness burn, unless specified; young, patient younger than 10 years; adult, patient 10 to 50 years of age; old, patient older than 50 years.

^bDecision to refer to a burn center is according to physician judgment on a case-by-case basis. The above list are guidelines set by the ABA for consideration for referral. TBSA, Total body surface area (percentage) affected by the injury.

Adapted with permission from hospital and prehospital resources for optimal care of patients with burn injury: *Guidelines for development and operation of burn centers: American Burn Association, J Burn Care Rehabil 11:98, 1990; with additional information from Hartford CE: Care of outpatient burns. In Herndon DN, editor: Total burn care, Philadelphia, 1996, Saunders p 71.*

characteristically caused by contact with molten metal, flame, or high-voltage electricity.

A more practical method of classifying burns is to describe them as either superficial or deep because this approach defines both treatment and prognosis. In general, first- and second-degree burns are considered partial-thickness burns, whereas third- and fourth-degree burns are full-thickness burns. As such, superficial burns involve the papillary dermis, with its rich vascular plexus, and the epidermis, which permits spontaneous healing by reepithelialization from the dermal appendages, including hair follicles, sebaceous glands, and sweat glands. This usually occurs within 2 weeks with minimal scarring. Superficial burns appear wet, pink, and blistered and blanch with pressure. They are painful. Deep burns involve the reticular dermis and SQ fat and generally lack sufficient epithelial appendages for spontaneous healing. If healing does occur, it will occur slowly and produce unstable skin, hypertrophic scarring, and contracture. Deep burns are best treated by excision and skin grafting. The initial appearance of deep burns ranges from cherry red, mottled, white, and nonblanching to leathery, charred, brown, and insensate (Table 38.2).

Although bedside evaluation of very superficial or deep wounds presents little diagnostic difficulty, clinical assessment of a mid-dermal or “indeterminate” burn is accurate only approximately two-thirds of the time.⁸ Even though it is useful to initially characterize the extent of the burn, it must be noted that the early appearance of a burn wound may not accurately reflect the true extent of the soft tissue injury. Reexamination and follow-up are critical because burn wounds may change during the 24 to 72 hours following injury. Indeterminate burns may eventually heal spontaneously, or they may convert to deeper wounds requiring excision and skin grafting (see Fig. 38.1).

Estimating Burn Size

Calculating burn size is necessary to determine treatment plan, fluid requirements, and aids in prognosis. It is important for

the emergency provider to accurately estimate the burn size. Note that first-degree burns do not count in the calculation of total burn surface area when utilizing fluid resuscitation formulas. Overestimating the burn size is a common error, especially in children. Several formulas are available to estimate TBSA in burn patients. In 1944, Lund and Browder published the now famous Lund-Browder chart (Fig. 38.4).^{9,10} In their landmark paper, they used direct measurements and body surface area formulas to produce a chart that clinicians can use to estimate %TBSA. Burn centers typically utilize the Lund-Browder chart for estimating burn size.¹¹ The initial Lund-Browder chart was developed from human anatomic studies derived from 11 adults (3 women and 8 men) and produced a unisex chart. A 2004 study involving 60 volunteers determined that the Lund-Browder chart significantly underestimates the size of chest burns in large-breasted women. The investigators developed a table that incorporates a correction using brassiere cup size.¹²

The simplest method for estimating TBSA in adults is the “rule of nines.” This formula was developed in the late 1940s by Pulaski and Tennon, who observed that the percentage of each body segment was approximately a multiple of nine (Fig. 38.5).¹³ Similar formulas for children adjust estimates for their disproportionately large head surface area. However, in a study of obese patients it was determined that this formula underestimates %TBSA of the legs and torso and overestimates %TBSA of the arms and head. The authors suggested replacing the “rule of nines” with a “rule of fives” for obese patients heavier than 80 kg.

The size of a burn can also be estimated by using the patient's hand as representing approximately 1% TBSA. With this method, the hand is a rectangle. However, two studies using planimetry have determined that the hand actually represents from 0.5% to 0.78% of a patient's TBSA.¹⁴

Regardless of the method used, it is important for the emergency provider to take time to quantify the %TBSA as accurately as possible. It should be reemphasized that

AGE	Birth-1 yr	1-4 yr	5-9 yr	10-14 yr	15 yr	Adult
Head	19	17	13	11	9	7
Neck	2
Ant trunk	13
Post trunk	13

B BODY AREA

Figure 38.4 Lund-Browder charts. **A**, The Lund-Browder charts are somewhat more accurate than the rule of nines in estimating the total body surface area (TBSA) burned. **B**, Proportion of TBSA of individual areas according to age. When compared with adults, children have larger heads and smaller legs. Other areas are relatively equivalent throughout life. The rule of nines is not accurate in determining the percentage of TBSA burned in children.

fluid recommendations based on %TBSA DO NOT include first-degree burns in the %TBSA, rather they are based on %TBSA of second- and third- (and fourth-) degree burns. Including first-degree burns in the calculation of %TBSA results in an overestimate of the total burned areas, and is a common error.

HISTOPATHOLOGY OF BURNS

One thermal wound theory describes three zones of injury in burns (Fig. 38.6)¹⁵:

1. Zone of coagulation: dead, avascular tissue that must be débrided.

2. Zone of stasis: injured tissue in which blood flow is impaired. Desiccation, infection, or mechanical trauma may lead to cell death.
3. Zone of hyperemia: minimally injured, inflamed tissue that forms the border of the wound. The hyperemia usually resolves within 7 to 10 days but may be mistaken for cellulitis.

Histologically, full-thickness burns are characterized by confluent vascular thrombosis involving arterioles, venules, and capillaries. Edema secondary to loss of microvascular integrity results not only from the effects of direct thermal injury but also from the release of vasoactive mediators. The increase in vascular permeability is linked to activation of complement and release of histamine. Histamine increases catalytic activity

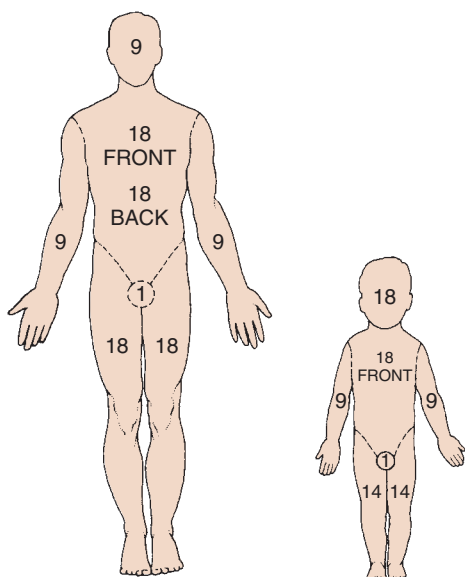

Figure 38.5 The “rule of nines.” The rule of nines is a rough estimate of the total body surface area (TBSA) burned. Note that adults and children are different. This formula frequently overestimates the extent of a burn in clinical practice. As a rough guide, the area covered by the individual’s palm is approximately 1.25% TBSA. See Fig. 38.4 for a more accurate method of determining TBSA burned in children.

Figure 38.6 Zones of injury after a burn. The zone of coagulation is the portion that is irreversibly injured. The zones of stasis and hyperemia are defined in response to the injury. (From Townsend CM, Beauchamp RD, Evers BM, et al., editors: *Sabiston textbook of surgery*, ed 19, St. Louis, 2012, Saunders.)

of the enzyme xanthine oxidase, with resultant production of hydrogen peroxide and hydroxyl radicals. These by-products increase the damage to dermal vascular endothelial cells and result in progressive vascular permeability.¹⁶

The cellular debris and denatured proteins of the eschar provide a milieu that supports the proliferation of microorganisms. The devitalized tissue (eschar) sloughs spontaneously, usually as a result of the proteolytic effect of bacterial enzymes. The greater the degree of wound bacteriostasis, the greater the delay in sloughing.

Partial-thickness burns result in incomplete vascular thrombosis, usually limited to the upper dermis. The dermal circulation is restored gradually, generally over a period of several days, thus resulting in a significant interval of relative ischemia. The eschar in deep partial-thickness burns is thinner than in a full-thickness burn and sloughs as a result of reepithelialization rather than bacterial proteolysis.

OUTPATIENT VERSUS INPATIENT CARE

One of the first steps in minor burn care is to select patients for whom outpatient care is appropriate. For patients determined to require inpatient care, the decision to admit or transfer the patient depends on the burn care capabilities of the initial treating facility. Guidelines set forth by the ABA¹⁷ regarding criteria for referral to a burn center are listed hereafter. Burn injuries that should be considered for referral to a burn center include the following:

1. Partial thickness burns greater than 10% TBSA
2. Burns involving the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma in which the burn injury poses the greatest risk for morbidity or mortality after emergency or surgical stabilization of the traumatic injuries. In such cases if the trauma poses the greatest immediate risk, the patient’s condition may be stabilized initially in a trauma center before transfer to a burn center. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention

Note, the previously-mentioned guidelines are not absolute clinical mandates and clinical judgment and patient characteristics may allow certain patients listed in these categories to be treated appropriately without transfer to a burn center.¹⁸ If in doubt, the decision to admit a patient with an acute burn injury is rarely inappropriate. Candidates who can be considered for outpatient treatment are generally adults and children meeting the ABA criteria for minor burn criteria. Burns usually better managed initially on an inpatient basis are large or deep burns involving the hands, face, feet, neck, or perineum; burns resulting from abuse or attempted suicide; burns occurring in association with other trauma or inhalation injuries; and chemical or electrical burns.

Patients who are at risk for poor outcomes with even minor burns include patients with concomitant medical problems such as diabetes mellitus, peripheral vascular disease, congestive heart failure, and end-stage renal disease; patients taking steroids or other immunosuppressive agents; patients who are very young or very old; those who are mentally impaired or have drug and alcohol dependency; homeless persons; those who are malnourished; and patients without a sufficient home support system. Whereas very minor burns in these patients may still be treated appropriately in the outpatient setting, inpatient treatment might be necessary in these circumstances even though the burn might be considered “minor” by ABA criteria. Other admission considerations include pain control, the ability to return for follow-up care, the degree of incapacity, the ability to receive wound care at home, and the overall social situation; all should influence the final decision of whether admission or transfer is warranted.¹⁹

BOX 38.1 General Approach to Blisters With Minor Burns

IF TREATED LESS THAN 48 HOURS AFTER THE BURN

1. Leave all intact blisters alone.
2. If blisters have ruptured, treat them as dead skin and débride them completely.
3. Needle aspiration of blisters is not advised.

ON FOLLOW-UP OR MORE THAN 48 TO 72 HOURS AFTER THE BURN

1. Débride large (>6 cm in diameter) intact blisters and all blisters that have ruptured. Large, firm blisters on the palms and soles may be left intact longer. Do not aspirate blisters.
2. Do not débride small or spotty blisters until they break or until 5 to 7 days after the burn.

FIVE TO 7 DAYS AFTER THE BURN

1. Débride all blisters completely.

**All blisters and burned skin are débrided in the presence of infection. Note: Multiple approaches to blisters are acceptable, and practice varies considerably.*

Note: Intact blisters provide significant pain relief. Be prepared for an exacerbation of pain immediately after débridement. Prophylactic analgesia is recommended.

Additional guidelines that can guide emergency providers in determining the need for admission following an acute burn injury include the following:

1. *Patients requiring intravenous (IV) access.* Following a burn there is an immediate capillary leak of plasma-like fluid that can last for 18 to 24 hours. In burns involving greater than 20% TBSA, the leak occurs in both burned and nonburned tissues. If not replaced, this fluid loss can lead to hypovolemic shock and renal failure. IV fluid resuscitation is indicated for all patients with second- and third-degree burns greater than 10% TBSA, in patients younger than 10 or older than 50 years, and for burns greater than 20% TBSA in all other age groups.
2. *Anticipated surgery.* Deep burns are best treated by early surgical excision and skin grafting. This permits faster wound healing, provides more stable skin, and reduces contractures. Hospital admission facilitates wound care and preparation for surgery.
3. *Respiratory problems.* Patients with respiratory distress requiring oxygen therapy and those suspected of inhaling toxic fumes or vapors should be admitted for observation or intubation and for mechanical ventilation (Box 38.1). Direct bronchoscopic evaluation of the airway may assist in the evaluation and diagnosis of tracheobronchitis or pneumonitis from a smoke inhalation injury.
4. *Need for special nursing care.* Specialized wound care, dressings, and nursing care are often required for burns involving the face, hands, feet, perineum, and genitalia and may best be treated on an inpatient basis if outpatient care is not feasible or ideal based on the case specifics. Patients unable to care for themselves or those lacking family and friends able to assist them may also require admission.
5. *Special burn injuries.* Chemical injuries are often more severe than the initial examination would suggest. Unlike thermal burns, tissue destruction may continue many hours after injury. Patients with chemical injuries should be admitted

Figure 38.7 This patient suffered from circumferential third-degree burns on the arm, and compartment syndrome developed. Escharotomy was required.

whenever the injuries are of indeterminate depth, affect a large area, or are deep and require surgical excision or if there are systemic manifestations of chemical toxicity or when the chemical responsible for injury requires a specific antidote. Swelling from deep circumferential burns may constrict the chest or limbs and result in compartment syndrome. Such burns should be monitored frequently to determine the potential need for escharotomy or fasciotomy (Fig. 38.7). Whenever the patient's condition prevents a reliable clinical examination, direct measurement of compartment pressures can provide an objective measurement of intracompartmental pressure and assist in the decision to perform these surgical procedures (see Chapter 54). Adult and pediatric patients with extensive burn injuries that require fluid resuscitation with large volumes of crystalloid should be monitored closely for the development of abdominal compartment syndrome.²⁰ Patients with mechanical burns involving large areas of skin loss or with significant frostbite injuries are often admitted for specialized wound care and parenteral pain management. Patients with certain electrical injuries may require admission for cardiac monitoring, specialized wound care, or IV fluids.

PROCEDURE

Emergency Treatment

Home or field treatment and ED care overlap. Initial treatment of a thermal injury begins immediately following the burn. If safe to do so, patients should be rapidly removed from the source of injury. Flames are extinguished by smothering the fire with a blanket, jacket, or equivalent item; by dousing the fire with water; or by using a chemical fire extinguisher. Most chemical injuries are best treated by irrigating the affected area with copious quantities of clean water. Patients with electrical injuries are removed from contact with the electrical source as soon as it is safe to do so.

Cooling is most beneficial for small burns if started within 3 minutes of injury and possibly of additional benefit if continued for the first few hours after the burn. Doing so has been shown to reduce pain significantly and can limit tissue damage by decreasing thromboxane production. When cooling a burn

Figure 38.8 To cool a burn that cannot easily be immersed in water, cover the area with unfolded gauze pads that have been soaked in room-temperature saline. Continue to frequently soak the gauze with cool saline or tap water drawn up in a syringe. Adding a few ice chips to the liquid is helpful, but do not cover the burn with ice. Towels are generally too bulky for this procedure. Narcotics are the best way to control pain in any burn, and should be used liberally.

wound, it is important to avoid hypothermia or freezing of tissue because this may deepen the injury.²¹ At home or in the field, room-temperature or cold tap water irrigation, immersion, or compresses (20°C to 25°C) will provide some pain relief without the risk of further injuring burned tissues and inducing hypothermia, which can occur with iced solutions (Fig. 38.8).^{22,23} Placing ice on a burn should not be done. Sterile dressings are not required for field treatment; a moist towel or nonadherent sheet may be used. Nonmentholated shaving cream makes an excellent temporary covering for out-of-hospital use if a dressing is not available.²⁴ Home remedies, such as butter or Vaseline, are best avoided but are probably benign.²⁵ Remove jewelry and gross debris in the field if possible.

Initial Care of Major Burns

Major burns require the specialized resources of a burn center. In such cases, emergency providers should initiate the resuscitation, consult the burn center for referral, and transfer the patient as soon as practically possible. Initial resuscitation should follow standardized trauma protocols, including a primary and secondary survey, and provide immediate interventions directed at airway management, breathing, and cardiovascular support, as needed. IV catheters can be inserted initially through burned skin when unburned sites are unavailable. Early IV access permits the administration of resuscitative fluids, medications, and parenteral narcotics to relieve the pain. Patients with burns exceeding 20% TBSA should receive IV fluid resuscitation with lactated Ringer's (LR) solution based on various available formulas. LR solution is preferred because large saline infusions will produce hyperchloremic acidosis. One need not use bolus fluid resuscitation as fluids are lost via capillary leak and via the raw skin, and significant fluid loss does not occur within the first hour.

Historically, the Parkland or Brooke formulas have been used to estimate fluid needs. It should be noted that the 2011 Advanced Burn Life Support (ABLS) Manual specifies that research has shown that the Parkland formula's $4 \text{ mL/kg} \times \% \text{TBSA}$ formula commonly results in excessive edema formation and over-resuscitation.¹¹ Whether this is because first-degree burns may have been erroneously included in the %TBSA or other reasons is unclear. For adults the ABLS advises a total of $2 \text{ mL LR} \times \text{body weight in kilograms} \times \% \text{ second- and third-degree burns}$ in the first 24 hours. For pediatric patients

BOX 38.2 ABA ABLs Initial Fluid Recommendations for Burn Patients in First 24 Hours

1. Lactated Ringer's (LR) is the fluid of choice.
2. Estimate %TBSA (count second and third degree only)
3. Obtain actual body weight in kilograms.
4. Utilize appropriate formula as detailed below:
 - **Adults with Thermal and Chemical Burns:**
 $2 \text{ mL LR} \times \text{patient's body weight in kg} \times \% \text{TBSA}$ (second and third degree only)
 - **Children 14 years or younger and body weight of less than 40 kg**
 $3 \text{ mL LR} \times \text{child's weight in kg} \times \% \text{TBSA}$ (second and third degree only)-add normal maintenance fluid to the fluid requirements, consider including dextrose in maintenance fluids for infants and young children who may rapidly deplete glycogen stores, particularly for those 2 years and younger.⁹⁷
 - **Adult patients with High Voltage Electrical Injuries**
 If there is evidence of deep tissue injury or red pigments in urine use:
 $4 \text{ mL LR} \times \text{patient's body weight in kg} \times \% \text{TBSA}$ (second and third degree only)
5. Infuse half of the calculated 24-hour fluid needs in the first 8 hours following the burn. Infuse the second half of the 24-hour fluid needs in the next 16 hours (hours 9–24)
6. Increase or decrease the fluid rate based on the patient's urine output (and pigment). Adjust fluids to maintain urine output at 0.5 mL/kg per hr in adults and 1 mL/kg per hr in children.

ABA, American Burn Association; ABLs, advanced burn life support; TBSA, total body surface area.

(under age 14 and weight less than 40 kg), the ABLs advises a total of $3 \text{ mL LR} \times \text{body weight in kilograms} \times \% \text{ second- and third-degree burns}$ in the first 24 hours. It should be noted that 24 hours starts at the time of the burn and not the time medical care begins. After the total amount is calculated, fluids should be administered as a constant infusion rather than by bolus administration. Half of the calculated fluid requirement should be given in the first 8 hours and the remaining half provided over the following 16 hours (Box 38.2). Lastly, these fluid quantities are guidelines and urine output monitoring will assist in adjusting the rate or volume to meet the target outputs of 0.5 mL/kg per hour for adults and 1 mL/kg per hour for children weighing under 40 kg. According to the ABA, Foley catheter placement is advised in major burns to accurately monitor urine output.

More recently, the US Army Institute of Surgical Research has advocated a simpler formula for estimating hourly fluid requirements in burn patients. This simpler formula may be more useful for prehospital providers or ED resuscitation (Box 38.3). The formulas estimate hourly fluid requirements and must be adjusted up or down to achieve a urine output of 0.5 to 1.0 mL/hr. Insertion of a Foley catheter is usually necessary to accurately measure hourly urine output.

Patients exposed to carbon monoxide should have carboxy-hemoglobin levels measured and empirically receive 100% oxygen. The duration of oxygen administration will depend on the level and symptoms of the individual patient, but often

BOX 38.3 Simplified ED Burn Fluid Resuscitation: the Rule of 10

1. Estimate burn size (%TBSA) to the nearest 10.
2. %TBSA \times 10 = initial fluid rate in mL/hr (for adult patients weighing 40 to 80 kg).
3. For every 10 kg above 80 kg, increase the rate by 100 mL/hr.

ED, Emergency department; TBSA, total body surface area.

From Chung KK, Salinas J, Renz EM, et al: Simple derivation of the initial fluid rate for the resuscitation of severely burned adult combat casualties: in silico validation of the rule of 10, *J Trauma* 69:S49–S54, 2010.

require 6 hours or more. Once considered a traditional empirical treatment, there is no evidence-based proven benefit from hyperbaric oxygen therapy for carbon monoxide poisoning. A Cochrane review (<http://www.summaries.cochrane.org/CD002042>) concluded that there is insufficient evidence to support the use of hyperbaric oxygen for the treatment of patients with carbon monoxide poisoning. The Cochrane review of published trials found conflicting, potentially biased, and generally weak evidence regarding the usefulness of hyperbaric oxygen for the prevention of neurologic injury. Per an evidence-based analysis, existing randomized trials do not establish whether the administration of hyperbaric oxygen to patients with carbon monoxide poisoning reduces the incidence of adverse neurologic outcomes. Because there may still be advocates of hyperbaric oxygen therapy, consultation with a local hyperbaric center is reasonable in certain cases, but it is not standard that this intervention be routinely implemented. Critically ill and pregnant patients are still often offered hyperbaric treatment, but controversy over the efficacy and safety persists even for these subgroups.

Cyanide is released from mattress fires and burning of upholstery. Patients suspected of having been exposed to significant levels of cyanide and manifesting symptoms should receive hydroxocobalamin (Cyanokit [Meridian Medical Technologies, Inc., Columbia, MD]). If not available, the Cyanide Antidote Package may be used despite lack of proven benefit of this traditional cyanide therapy. It is reasonable to empirically administer hydroxocobalamin or the sodium thiosulfate portion of the cyanide kit to burn victims in coma or to those exhibiting metabolic (lactic) acidosis after smoke exposure.

In addition to the logical increased mortality with larger areas of TBSA involved, the mortality of patients with burns is also increased when concomitant inhalation is present. The Baux Score was developed a half-century ago by Professor Serge Baux to estimate the mortality of burns.²⁶ This score was updated in 2010 using data from the National Burn Registry to include the effect of inhalation injury to mortality (Box 38.4).²⁷ In short, the original Baux score became outdated because advances in care of the burn victim which has improved the mortality of patients. The modified Baux score is now more accurate for modern burn survival rates.

Burn patients have an impaired ability to regulate their core body temperature and will quickly become hypothermic if untreated. Core temperature should be measured frequently, and active and passive warming strategies should be implemented to prevent hypothermia from developing. This can include minimizing exposure by covering patients with sheets and blankets, warming IV fluids, warming the room, or applying radiant or convective warming systems. In anticipation of

BOX 38.4 Baux Score and Modified Baux Score to Predict Mortality in Burn Injury

Original Baux Score: % Mortality = Age + %TBSA

Modified Baux Score: % Mortality = Age + %TBSA + 17*(Inhalation Injury, Yes=1, No=0)

Plot of the observed mortality versus the group midpoint computed within 10 groups of the revised Baux score.

From Baux S: Contribution a l'Etude du traitement local des brulures thermiques etendues, Paris, 1961, *These*; Osler, et al: Simplified estimates and probability of death after burn injuries: extending and updating the Baux score, *J Trauma Inj Crit Care* 68(3):690–697, 2010.

transfer to a burn center or before surgical consultation, remove any wet cooling dressings that may have been applied initially and cover the wounds with dry gauze dressings.

Initial Care of Minor Burns

Prompt cooling of the burned part is an almost instinctive response and is one of the oldest recorded burn treatments, having been recommended by Galen (AD 129–199) and Rhazes (AD 852–923).⁶ In the ED, room-temperature or cold tap water irrigation, immersion, or compresses (20°C to 25°C) are optimal in obtaining pain relief and providing some measure of protection for burned tissues without the problems of hypothermia that iced solutions can cause.^{10,12} If not done before ED treatment, immediate cold water immersion may still have some ability to limit the extent of a burn and will provide significant pain relief. It is acceptable to add a few ice chips to the water, but packing the wound in ice must be avoided.

All involved clothing and jewelry (such as rings), along with any gross debris, should be removed from the burned area. Chemical burns involving the skin or eyes require prolonged tap water irrigation. The burn should otherwise be covered with a moist, sterile dressing. In the ED and prehospital phase, appropriate analgesics, usually narcotics, are the best way to control pain and should not be forgotten in the initial phase of burn care. The burned area may be immersed immediately in room-temperature water or covered with gauze pads soaked in room-temperature water or saline (see Fig. 38.8). The gauze may be kept cool and moist to provide continued pain relief; the patient will let the clinician know when additional cooling is desired. Many clinicians use sterile saline for cooling, but it has no proven benefit over tap water, even when the skin is broken. It is acceptable to add ice chips to water or saline to lower the temperature. As stated previously, immersion of burned tissue in ice or ice water should be avoided because ice immersion increases pain and risks frostbite injury or systemic hypothermia.

BOX 38.5 Advantages of Prompt Burn Cooling

Limit extent of thermal damage
 Reduction or cessation of pain
 Elimination of local hyperthermia
 Inhibition of postburn tissue destruction
 Decreased edema
 Reduced metabolism and toxin production

The potential benefits of burn cooling are listed in [Box 38.5](#). Because most patients with minor burns seek medical attention after initial self-instituted prehospital cooling, it is unlikely that the clinician can favorably affect the burned tissue with any intervention in the ED. With the exception of pain relief and removal of debris, the primary benefits of burn cooling are probably experienced only if the burn is cooled promptly, within the first 3 minutes after injury, thus making home care important.^{28,29} Minor burns are considered tetanus prone, and tetanus toxoid should be administered if patients are unsure of their tetanus immunization status or when it has been more than 10 years since the last immunization. Nonimmunized patients should receive tetanus toxoid and immunization with subsequent boosters in accordance with current guidelines.

Outpatient Care of Minor Burns

Minor burns are generally those that will heal spontaneously and do not require surgery or specialized wound care. These wounds are not associated with immunosuppression or hypermetabolism, nor are they highly susceptible to infection, a quality associated with larger burns.^{30,31} Treated conservatively, most minor burns will heal without significant scarring. Many complications seen with minor burns are thought to result from overtreatment rather than undertreatment. Examples include the use of dry dressings that can adhere to newly forming skin and secondary infections from the overzealous use of topical or systemic antibiotics.

The most important characteristic of a dressing is that it controls fluids within the wound. Burn dressings that keep the surface of the wound moist and avoid pooling of fluids will speed healing.³² The best material for this purpose is a generous amount of simple dry gauze applied over a nonadherent dressing or topical preparation. The outer layer of dressing should be porous to permit evaporation of water from the absorbent dressing material. Some clinicians prefer to eschew a nonadherent portion of the dressing so that subsequent dressing removal aids in minor débridement. Wound preparation and basic bandaging should include the following steps ([Fig. 38.9](#)):

1. Cleanse the burned area gently with a clean cloth or gauze and a mild antibacterial wound cleaner such as chlorhexidine, and irrigate the wound with saline or water. It is not necessary to shave the hair in or around the wound. There is no benefit to vigorously washing a minor wound with strong antiseptic preparations (such as povidone-iodine [Betadine, Purdue Products L.P., Stamford, CT] and others).³¹
2. Although some authors recommend leaving blisters intact, most sources advise that providers débride blisters and sloughed skin initially by peeling the devitalized skin from the wound ([Fig. 38.10A–C](#)). Blisters can be opened with scissors and forceps. If necessary, provide analgesia for any painful débridement. On the initial débridement, attempt

to remove only grossly devitalized tissue. Additional débridement of the wound can take place, if needed, during subsequent follow-up visits when the wound has matured.

3. Consider applying a layer of antibiotic cream or ointment such as 1% silver sulfadiazine (Silvadene [Pfizer Inc., New York, NY]) or bacitracin directly to the wound (see [Fig. 38.10D](#)).
4. Apply fine-mesh gauze or commercial nonadherent gauze such as Adaptic or petrolatum gauze impregnated with 3% bismuth tribromophenate (Xeroform [DeRoyal, Powell, TN]) to the burn wound.
5. Cover and pad the wound with loose gauze fluffs. If fingers and toes are involved, pad the web spaces and the digits individually and separate them with strips of gauze (see [Figs. 38.9D](#) and [38.10E and F](#)). Wrap the entire dressing snugly (but not tightly) with an absorbent, slightly elastic material such as Kerlix (Medtronic, Minneapolis, MN).
6. Instruct the patient to elevate the affected limb to prevent swelling, which may cause delayed burn conversion or wound infection.

Open Burn Care

Following cleansing of the wound with chlorhexidine soap and débridement of blisters and any loose skin, wounds that are not amenable to a dressing, such as those on the face, can be managed initially by the application of a bland topical antibiotic such as bacitracin. The wound can be washed two or three times per day, followed by reapplication of the topical agent. This is the preferred method for managing burns on the face and neck.

Burn Dressings**Biologic Dressings**

Biologic dressings are natural tissues, including skin that consists of collagen sheets containing elastin and lipid. They are not routinely used in the emergency care of minor wounds and are primarily treatment options in burn centers. The benefits of biologic dressings include a reduction in surface bacterial colonization, diminished fluid and heat loss, avoidance of further wound contamination, and prevention of damage to newly developed granulation tissue. Examples of biologic dressings include cadaveric human skin and commercially available porcine xenograft or collagen sheets.

Synthetic Dressings

Synthetic dressings are manufactured in various forms. Film-type dressings have a homogeneous structure and are usually polymers. Because these dressings are nonpermeable, problems with retention of wound exudates have occurred. Some second-generation dressings have been developed to address these problems. These products include Tegaderm (3M Medical, St. Paul, MN), Vigilon (Bard Medical, Covington, GA), DuoDERM (ConvaTec, Bridgewater, NJ), Biobrane (Smith & Nephew), Op-Site (Smith & Nephew, Inc., Andover, MA), Acticoat (Smith & Nephew), Aquacel products (ConvaTec, Greensboro, NC), and TransCyte (Advanced Tissue Sciences, La Jolla, CA).^{32–33a} These preparations have theoretical benefits under certain circumstances, but are not proven to have superior performance over simple gauze dressings for minor outpatient burns. These products are most often used by burn centers and have little applicability for minor burns in patients discharged from the ED. For patients admitted or transferred to a burn center, simple gauze dressings are appropriate. Some

Figure 38.9 Outpatient burn dressing of the hand. Patients with serious hand burns should be admitted to the hospital, but minor burns can be treated in the outpatient setting. **A**, After the application of an antibiotic ointment or a dry, nonadherent dressing, separate the fingers with fluffs in the web spaces and **B**, enclose the entire hand in a position of function (here with the help of a roll of Kerlix). **C**, If the wrist is involved, a removable plaster splint may be applied over the dressing. **D**, The result of a minor burn involving the hand when the fingers were not wrapped individually. Initially, there were only a few blisters, but this patient now has second-degree skin loss because of an improper burn dressing that caused maceration of normal skin between the fingers. Not only were the fingers incorrectly wrapped together in one gauze wrap, but the first wound check was also incorrectly scheduled in 6 days, too long for the first wound inspection of a hand burn.

burn centers prefer that topical agents not be applied before transfer so that the full extent of the burn can be assessed immediately.

Specific Clinical Issues in Minor Burn Care **Analgesia**

Pain is a critical feature of any burn injury. Relief of pain by the appropriate and judicious use of narcotic analgesics is of the utmost importance in the initial care of all burn patients. Prehospital narcotics are very appropriate when standard contraindications do not exist. Analgesia should be provided before extensive examination or débridement is performed. Inadequate analgesia is probably the most common ED error in the treatment of burn injuries, especially when burns occur in children. Parenteral narcotic analgesics have been erroneously relegated to pain control only for major burns, but it is suggested that narcotics be generously administered in the initial treatment of even minor painful burns.

Parenteral opioids (e.g., fentanyl, 1 to 2 $\mu\text{g}/\text{kg}$, or morphine, 0.1 to 0.2 mg/kg) are usually required, especially if painful

procedures such as débridement and dressing changes are planned. We prefer to use IV opioids (occasionally supplemented with a short-acting benzodiazepine such as midazolam) for all painful procedures. For complicated débridement or dressing changes adequate analgesia is a minimum requirement with some patients requiring procedural sedation (see [Chapter 33](#)).

Regional or nerve block anesthesia is an excellent alternative when practical, and if feasible, nitrous oxide analgesia may be used. Ketamine may also be a reasonable alternative. Oral opioids may be inadequate for the initial treatment of significant pain but can be used for continued outpatient analgesia. Local anesthetics may be injected in small quantities when appropriate, such as for the débridement of a deep ulcer or other small burn. Topical analgesics have no role in burn care. A properly designed dressing will do much toward preventing further discomfort after release home; however, home burn care and dressing changes may be quite painful. For this reason, an adequate supply of an oral opioid analgesic should be provided, and responsibility in analgesic use should be encouraged.

Figure 38.10 Débridement and dressing of a blistering burn. **A**, Exactly when to débride burn blisters is controversial and probably of no consequence to the final outcome (see text), although blisters often thin after the first 24–48 hours and are therefore easier to débride at that time. Eventually, however, all dead tissue must be removed. **B** and **C**, The easiest and quickest way to débride blisters is to grasp the dead loose skin with dry 4- × 4-inch gauze and pull it off quickly rather than with slow meticulous instrument techniques. Provide analgesia that is appropriate for the clinical condition. **D**, Apply an appropriate ointment to the denuded tissue. (Silvadene [Pfizer] is shown here, but bacitracin can also be used.) **E** and **F**, The débridement itself is not especially painful, but when the underlying tissue is exposed, pain increases. Hence, dress the burn quickly after débridement.

Pruritus

Postburn pruritus is one of the most common and distressing complications of burn injury and is estimated to affect 87% of burns.³⁴ It typically develops in the subacute phase and is therefore not a common issue for the emergency provider in

the acute treatment phase. Despite the limited literature on the treatment of postburn pruritus, available therapies include oral antihistamines, topical antihistamines, and topical moisturizers. The use of topical therapies should be withheld until sufficient wound healing has occurred.

Edema

Minor burns lead to immediate inflammation mediated by the release of histamine and bradykinins, which cause localized derangements in vascular permeability with resultant burn wound edema. This edema may be harmful in several ways. First, the increase in interstitial fluid increases the diffusion distance of oxygen from capillaries to cells and thereby increases hypoxia in an already ischemic wound. Second, the edema may produce untoward hemodynamic effects by a purely mechanical mechanism: compression of vessels in muscular compartments. Third, edema has been associated with the inactivation of streptococidal skin fatty acids, thus predisposing the patient to burn cellulitis.^{35,36}

Successful management of burn edema hinges on immobilization and elevation. Most patients are unfamiliar with the medical definition of elevation and are not aware or convinced of its value. Patient education in this regard is critical; however, certain burns (e.g., burns in dependent body areas) are prone to edema despite everyone's best intentions. It is for this reason that lower extremity burns in general and foot burns in particular are prone to problems. Major burns of the hand should be elevated while the patient is still in the ED. This is most readily accomplished by hanging the injured hand from an IV pole with a stockinette to support the bandaged hand (Fig. 38.11).

Use of Topical Preparations and Antimicrobials

Minor burns result in insignificant impairment of normal host immunologic defenses, and burn wound infection is not usually a significant problem. Topical antimicrobials are often used; however, some believe that these agents may actually impair

wound healing.³⁶ Although the procedure is of unproven value, many clinicians routinely use antibiotic creams or ointments on even the most minor burns. Most patients expect some type of topical concoction, so a discussion of their use—or nonuse—is prudent.

Topical antimicrobials were designed for the prevention and care of burn wound sepsis or wound infection, primarily in hospitalized patients with major burns, and there is no convincing evidence that their use alters the course of first-degree burns and superficial partial-thickness injuries. As noted, the burn dressing is the key factor in minimizing complications in all burns. Nonetheless, topical antimicrobials are often soothing to minor burns, and their daily use prompts the patient to look at the wound, assess healing, perform prescribed dressing changes, or otherwise become personally involved in the care. Keep in mind that if a topical antimicrobial is used, its effectiveness is decreased in the presence of proteinaceous exudate, thus necessitating regular dressing changes if the antimicrobial benefit of topical therapy is to be realized. In reality, once-daily dressing changes are most practical and are commonly prescribed, and no data indicate that this regimen is inferior to more frequent dressing changes.

All full-thickness burns should receive topical antimicrobial therapy because the eschar and burn exudate are potentially good bacterial culture media and deep escharotic or subescharotic infections may not be easily detected until further damage is done. All deep partial-thickness injuries likewise benefit from the application of a topical antimicrobial. As stated, this intervention can await definitive therapy in a burn unit.

Criteria for choosing a specific topical agent include its *in vitro* and clinical efficacy, toxicity (absorption), superinfection rate, ease and flexibility of use, cost, patient acceptance, and side effects. It is important to note that no firm scientific data convincingly support the use of any specific topical antimicrobial for minor outpatient burns.

Specific Topical Agents

Silver Sulfadiazine (Silvadene, Pfizer). This poorly soluble compound is synthesized by reacting silver nitrate with sodium sulfadiazine. It is the most commonly used topical agent for outpatients, and it is well tolerated by most patients (Fig. 38.12A; also see Fig. 38.10D). It has virtually no systemic effects and moderate eschar penetration, and it is painless on application. Although silver sulfadiazine is commonly used, its popularity is waning. It must be applied daily and the thick white cream can be difficult to remove. There are no well designed studies confirming improved burn healing or a reduced rate of infection with silver sulfadiazine. It may impede reepithelialization and should be stopped when this occurs. Hence, many burn specialists prefer plain bacitracin ointment as the topical of choice because of its cost, equal efficacy, and good patient acceptance.

Silver sulfadiazine is available as a “micronized” mixture with a water-soluble white cream base in a 1% concentration that provides 30 mEq/L of elemental silver. It does not stain clothes, is not irritating to mucous membranes, and washes off with water. It may be used on the face, but such use may be cosmetically undesirable for open treatment. It should not be used near the eyes. Its broad gram-positive and gram-negative antimicrobial spectrum includes β -hemolytic streptococci, *Staphylococcus aureus* and *Staphylococcus epidermidis*, *Pseudomonas* spp., *Proteus* spp., *Klebsiella* spp., Enterobacteriaceae, *Escherichia coli*, *Candida albicans*, and possibly herpesvirus hominis.

Figure 38.11 Begin elevation of a burned hand in the emergency department. After a hand dressing is applied, suspend the arm from an intravenous pole with stockinette. A plaster or fiberglass splint may also be incorporated into the dressing.

Figure 38.12 **A**, The most popular topical burn preparation is Silvadene (Pfizer) cream. Though commonly used on minor burns, it probably has little beneficial effect on healing, and minor burns rarely become infected. Nonetheless, Silvadene is a standard intervention that at least causes the patient to look at the burn and become involved in dressing changes. **B**, Some clinicians suggest inexpensive neomycin-free topical antibiotic ointments, such as bacitracin or bacitracin-polymyxin B sulfate (Polysporin, Johnson & Johnson) for all outpatient burns. They are commonly used on face and neck burns. These are preferred because contact dermatitis can occur from the neomycin portion of some topical agents, as depicted in the photograph.

One downside of silver sulfadiazine is that it often interacts with wound exudate to form a pseudomembrane (pseudoeschar) over partial-thickness injuries. This pseudomembrane is often difficult and painful to remove. Removing the pseudomembrane is necessary to monitor the wound state and facilitate reepithelialization.

Except for term pregnancy and in newborns (i.e., because of possible induction of kernicterus), there are no absolute contraindications to the use of silver sulfadiazine. Allergy and irritation are unusual, although there is potential cross-sensitivity between silver sulfadiazine and other sulfonamides.

Other Topical Preparations. Mafenide acetate (Sulfamylon, Mylan Institutional Inc., Rockford, IL), gentamicin, povidone-iodine, and silver nitrate are products that have been replaced with newer topicals, but they are mentioned for historical interest. These products are not typically used in modern burn therapy, although they are generally acceptable alternatives for specific indications.

BROAD-SPECTRUM ANTIBIOTIC OINTMENTS. Many nonprescription topical antimicrobials are used for minor burn therapy despite a paucity of data attesting to specific benefits. Included are bacitracin zinc ointment, polymyxin B–bacitracin (Polysporin, Johnson & Johnson, New Brunswick, NJ). These are all soothing, cosmetically acceptable for open treatment (such as on the face), and effective antiseptics under burn dressings. Some researchers caution against agents containing neomycin because of a potential for sensitization (see Fig. 38.12B). Though commonly applied by patients without adverse effects, we advise against the use of topicals that contain neomycin (Neosporin, Johnson & Johnson) because of the potential for contact dermatitis. The authors suggest plain bacitracin or Polysporin ointment as the routine topical agents for most burns, although Silvadene is a very acceptable, albeit more expensive alternative.

ALOE VERA CREAM. Aloe vera cream is commercially available in a 50% or higher concentration with a preservative. It exhibits antibacterial activity against at least four common burn wound pathogens: *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *S. aureus*, and *Klebsiella pneumoniae*. Heck and coworkers and others^{37,38} compared a commercial aloe vera cream with silver sulfadiazine in 18 patients with minor burns. Healing times were found to be similar, and there was no increase in wound colonization in the aloe vera group in comparison to patients treated with silver sulfadiazine. Other authors have promulgated the use of aloe gel preparations for minor burns.³⁸ Aloe vera cream is an acceptable, inexpensive option for open or dressed outpatient care of minor burns.

HONEY. Honey has long been advocated as an inexpensive and effective topical treatment for minor outpatient burns. The physicochemical properties of honey (osmotic effect, pH) give this substance the antibacterial and antiinflammatory properties that support its use. It may be superior to silver sulfadiazine with regard to minor burn wound healing. Honey is not widely used, but it has been promulgated as a safe, effective, and inexpensive dressing for the outpatient management of burn wounds.^{39–41}

CORTICOSTEROIDS. High-potency topical steroid preparations have no beneficial effects on the rate of healing or limitation of scarring of thermal burns. Though probably not harmful in most cases, their use is not supported.⁴²

FOLLOW-UP CARE OF MINOR BURNS

The specifics of outpatient follow-up of minor burns are controversial and often based on clinician preference and personal bias rather than on firm scientific data. Follow-up should be individualized for each patient and should be based on the reliability of the patient, the extent of the injury, the frequency and complexity of dressing changes, and the amount of discomfort anticipated during a dressing change. Depending on the characteristics of the patient and the resources available to them as an outpatient follow-up plans may include primary care physician rechecks, follow-up at wound care center, home health visits by wound care team, or even return to an ED or “fast-track” setting. Outpatient physical therapy departments or wound care centers often have excellent facilities to monitor outpatient burns with clinician oversight.

Figure 38.13 Providing patients with burn dressing material on discharge encourages proper home care. Dispensing only limited supplies of the items may enhance compliance with follow-up visits.

If a topical antibiotic agent is used, the dressing should be changed daily with removal and reapplication of the topical preparation. The wound should be rechecked by a clinician after 2 to 3 days and periodically thereafter, depending on wound size, compliance, healing, and other social issues. If a dry dressing is chosen, follow-up every 3 to 5 days is usually adequate. The purpose of any burn dressing changes or home care regimen is defeated if the patient cannot afford the material or is not instructed in the specifics of burn care. Many EDs supply burn dressing material on patient release. A complete pack includes antibiotic ointment or cream, gauze pads (fluffs), an absorbent gauze roll, a sterile tongue blade to apply the cream, and tape (Fig. 38.13). Providing limited supplies of the items necessary for dressing changes may enhance compliance with follow-up if the patient has to return for additional supplies. Writing a prescription and merely stating that the dressing should be changed daily may not be sufficient.

Daily home care can be performed by the patient with help from a family member or visiting nurse (Box 38.6). The dressing may be removed each day and the burn area gently washed with a clean cloth or a gauze pad, tap water, and a bland soap. Sterile saline and expensive prescription soaps are not required. A tub or shower is an ideal place to gently wash off burn cream. The affected area may be put through a gentle range of motion during dressing changes. After the burn is cleaned, the patient inspects it in the hope that complications can be recognized and prompt further follow-up. After complete removal of the old cream, a new layer is applied with a sterile tongue blade and covered with absorbent gauze.

If the undermost fine-mesh gauze of a dry dressing is dry and the coagulum is sealed to the gauze, the patient should allow the dressing to remain and simply reapply the overlying gauze dressing. If the wound is moist and macerated, the fine-mesh gauze should be removed and the wound cleaned and re-dressed. The patient should be instructed to not remove dry adherent fine-mesh gauze from the underlying crust. When epithelialization is complete, the crust will separate, and the gauze can be removed at that time.

In the postacute phase, dryness in healing skin may be treated with mild emollients such as Nivea (Beiersdorf, Inc.,

BOX 38.6 How to Change a Burn Dressing at Home: Patient Instructions

1. Take pain medicine $\frac{1}{2}$ hour before dressing change if you find dressing changes to be painful.
2. If the burn is on the hand, foot, or other areas that are difficult to reach, have someone help you.
3. Have all materials available. Gloves may be worn.
4. Remove the dressing and rinse off all burn cream or ointment with tap water, under a shower, or in the bathtub. The area can be gently washed with mild soap and a clean cloth or gauze pads.
5. Look at the burn and assess the healing, blistering, and amount of swelling. Note any signs of infection.
6. Gently exercise the area through range of motion.
7. Apply the burn ointment with a sterile tongue blade.
8. Cover the cream with fluffed-up gauze.
9. Wrap the area in bulky gauze.
10. Repeat this dressing change daily.

Norwalk, CT), Vaseline Intensive Care Lotion (Chesebrough Ponds, Inc., Greenwich, CT), or other readily available over-the-counter skin care moisturizing lotions. Natural skin lubrication mechanisms usually return by 6 to 8 weeks.³⁰ Excessive sun exposure should be avoided during wound maturation because this may lead to hyperpigmentation. When the patient is outdoors, sun avoidance strategies should be used, or at the very least, a commercially available sunblock should be applied. Exposure of the recently healed burned area to otherwise minor trauma (chemicals, heat, sun) may result in an exaggerated skin response. Pruritus is common and may be treated with oral antihistamines or a topical moisturizing cream.

Outpatient Physical Therapy for Burn Care

When the hospital's outpatient physical therapy department or wound care center is equipped to treat minor burns, it is prudent to consider this option as a means of longitudinal follow-up. Many centers make available daily or periodic burn treatment consisting of dressing changes, whirlpool débridement, and range-of-motion exercises. An additional advantage is that medically trained personnel evaluate the burn daily, thereby decreasing clinician visits and enabling identification of problems before serious complications develop. Similar services are available in many areas where providers visit the patient in their home to perform wound/burn care.

Burn Wound Healing

Burn wound healing differs from healing of other soft tissue wounds.⁴ The duration is variable but is often proportional to burn depth. Within 1 to 3 weeks and following the initial inflammatory response, neovascularization of the burn occurs and is accompanied by fibroblast migration. Collagen production begins but it is often deposited randomly, thereby leading to scar formation. Reepithelialization follows collagen deposition. The persistence of necrotic tissue and eschar in the wound will impede all aspects of healing. The extent of scar formation is related directly to healing time. Wound healing that occurs

in fewer than 16 days often results in decreased scar formation.⁴ Proper wound débridement is also associated with faster wound healing and minimizes scar formation.

Healing of superficial burns occurs by reepithelialization from the wound edge and from residual dermal elements containing epithelial cells. This process generally requires 10 to 14 days. After healing, the initial epithelial layer is often fragile and is easily reinjured. The application of bland, lanolin-containing creams for 4 to 8 weeks after initial healing may reduce dryness and cracking of the healing wound.

Deep burns lack residual dermal elements within the wound and heal by reepithelialization from the wound edge. Healing is slow and often unsatisfactory; it frequently takes longer than 3 weeks, and an unstable epithelium is produced that is prone to hypertrophic scarring and contractures. This is a particular problem in burns that extend across joints and limit motion. Burns that take longer than 2 to 3 weeks to heal are also prone to infection, which may be reduced by using topical antimicrobial agents. Deep wounds should be referred for surgical consultation and generally require early excision, grafting, and physical therapy.

SPECIAL MINOR BURN CARE CIRCUMSTANCES

Blisters

Management of blisters in minor burns is controversial. In reality, there is little one can do wrong when it comes to a clinical approach to blisters in minor burns (Fig. 38.14). Management arguments are generally theoretical or based on local tradition; the ultimate outcome of a minor burn is rarely determined by how one treats blisters. Intact blisters do offer some pain control and a physiologic dressing that rarely becomes infected; however, most large blisters spontaneously rupture after 3 to 5 days and eventually require débridement. When the integrity of the blister is breached, the fluid becomes a potential culture medium. Clinical choices for blister management include débridement (immediate and delayed) or simply leaving the blister intact. In general, ruptured blisters should be débrided. Needle aspiration of blisters should NOT be performed as this may increase the risk of infection.

Some studies suggest that intact burn blisters may allow reversal of capillary stasis and less tissue necrosis.⁴ Madden and colleagues⁴³ showed that burn exudate (as contained within intact blisters) is beneficial in stimulating epidermal cell proliferation.

Swain and associates⁴⁴ demonstrated that the density of wound colonization with microorganisms was much lower in minor burns with blisters left intact. They also found that 37% of patients with aspirated blisters (not recommended) experienced a reduction in pain versus none of those whose blisters were unroofed. Other investigators believe that undressed wounds with débrided blisters are subject to additional necrosis secondary to desiccation, which can convert a partial-thickness burn to a full-thickness injury.⁵ Finally, intact blisters clearly provide some pain relief, as evidenced by the sudden increase in pain immediately after débridement. Increased pain should be anticipated and analgesia offered as appropriate when débridement is necessary. We suggest the steps listed in Fig. 38.10 as a general approach to burn blisters.^{4,5,43-45}

Figure 38.14 It is difficult to do anything wrong with minor burn blisters, and many regimens are acceptable. Blister aspiration is not supported. Eventually, however, any unroofed blisters will have to be débrided. **A**, An expeditious and relatively painless way to débride a burn is to use a dry gauze pad to grasp the dead skin and **B**, peel it off. Meticulous instrument débridement is often time-consuming and stressful to the patient. Be aware that pain occurs when air comes in contact with the débrided skin, and prophylactic analgesia should therefore be provided. Large burns can be débrided under procedural sedation.

Minor Burn Infections

Prophylactic systemic antibiotics are not warranted in the routine treatment of outpatient burns. It may be difficult to separate the erythema of the injury or healing process from cellulitis, but minor burns rarely become infected, with infection rates being well under 5%.⁴⁶ There are bacteria on the skin at all times; normal skin usually harbors nonvirulent pathogens such as *S. epidermidis* and diphtheroids. Therefore, all burns are contaminated but not necessarily infected. Because thermal trauma results in coagulative necrosis, burn wounds contain a variable amount of necrotic tissue which, if infected, acts much as an undrained abscess and prevents access of antibiotics and host defense factors.

The microbial flora of outpatient burns varies with time after the burn. Shortly after injury, the burn becomes colonized with gram-positive bacteria such as *S. aureus* and *S. epidermidis*. After this period there is a gradual shift toward inclusion of gram-negative organisms, 80% of which originate from the patient's own gastrointestinal tract.⁶ Common organisms seen on days 1 to 3 include *S. epidermidis*, β -hemolytic streptococci, *Bacillus subtilis*, *S. aureus*, enterococci, *Mima polymorpha*, *Enterobacter* spp., *Acinetobacter* spp., and *C. albicans*. One week after the burn these organisms may be seen along with *E. coli*, *P. aeruginosa*, *Serratia marcescens*, *K. pneumoniae*, and *Proteus vulgaris*.

Anaerobic colonization of burn wounds is rare unless there is excessive devitalized tissue, as occurs with a high-voltage electrical injury.⁴⁷ For this reason, routine anaerobic cultures are generally unnecessary in an assessment of infective organisms that produce minor infections.

A healing burn may produce leukocytosis and a mild fever in the absence of infection, especially in children. Early (days 1 to 5) burn infections are generally caused by gram-positive cocci, especially β -hemolytic streptococci. Streptococcal cellulitis is characterized by marked spreading erythema extending outward from the wound margins. Despite the plethora of organisms and the presence of some gram-negative pathogens in superficial burn cultures, standard gram-positive cellulitis coverage is appropriate initial therapy in most cases.

Effective topical treatment at the time of initial burn care and subsequent dressing changes is meant to delay bacterial colonization, maintain the bacterial density of wounds at low levels, and produce a less diverse wound flora. Because outpatient management of burns should be attempted only when the risk for infection is minimal, the use of systemic antibiotics is unnecessary for minor burns, even in the setting of delayed treatment, diabetes, and steroid use.⁴⁶ Unnecessary antibiotic use may select for resistant organisms. Antibiotics in the management of minor burns have been recommended for patients undergoing an autograft procedure.⁴⁹ There are no data on the use of antibiotics as prophylaxis for patients with burns in the setting of valvular heart disease.

In minor burn care, wound cultures are not required or recommended. It is useless, for example, to culture blister fluid in a patient who arrives for emergency care immediately after a thermal injury. Cultures are necessary only when overt infection develops, especially when it occurs when a topical or systemic antibiotic is being used. Cultures may also be of benefit when the infected wound is old, when hygiene is poor, or when there are preexisting abrasions nearby.⁵⁰ Although they may adequately reflect wound flora, falsely sterile cultures are relatively frequent. In general, superficial cultures do not reflect deep burn flora and provide no quantitative information.

Sterile wound biopsy for culture is most satisfactory for the assessment of intraescharotic, subscharotic, or invasive infections and allows quantification of bacterial flora.

Foot Burns

Despite their relatively small surface area, foot burns tend to heal poorly, usually because of excessive edema; therefore, they are generally considered major burns. Foot burns are the most common burn category to fail outpatient therapy, and subsequently require admission and inpatient care (Fig. 38.15). Zachary and coworkers⁵¹ reported on a series of 104 patients with foot burns. In no patient admitted on the day of injury did burn cellulitis develop; in contrast, 27% of delayed-admission patients had cellulitis. Their study also noted a higher incidence of hypertrophic scarring with the need for skin grafting in the delayed-admission group. Overall, fewer days of hospitalization were required for the initially admitted group.

Specific problems in the care of foot burns include pain, wound drainage, difficulty changing dressings without help, inability of even motivated patients to comply with the requirements for elevation, and prolonged convalescence. The benefits of hospital admission include splinting, intensive local burn care, physical therapy, and bed rest with elevation, which

Figure 38.15 Burns of the feet are special burns that require careful evaluation and an individualized treatment plan, even if the burn surface area is relatively small. It is difficult for many patients to provide ideal burn care at home when the feet are involved. **A**, It is tempting to initially treat a seemingly minor superficial second-degree foot burn in an outpatient setting, but the patient's compliance and social situation must be ideal for a successful outcome. Unless home health care, a wound care center, or other similar arrangements are available to the patient, hospitalization may be most prudent until these arrangements can be solidified. **B**, Example of a foot burn that is a potential disaster, in this case because of late treatment of a diabetic patient.

minimizes edema. For these reasons, initial admission should be considered for all but the most minor of foot burns. Close outpatient follow-up wound checks are required for those foot burns that are most appropriate for outpatient care.

Hand Burns

Because of its functional significance, burns involving the hand can result in significant functional loss even when the TBSA burned is small. Losing the use of one or both hands can become seriously disabling and affect the patient's activities of daily living regardless of whether the cause of the loss is a burn dressing, the late onset of scar contractures, or loss as a result of amputation.⁵²

As with other burns, the depth and extent of the burn determine the severity of the injury. The entire surface of one hand represents only 2.5% TBSA, yet even small burns can cause a disproportionate loss of function. Deep partial- or full-thickness hand burns, even if quite small, often warrant referral for early excision and grafting to limit scarring and maintain function. The skin on the dorsum of the hand is thinner than that on the palm and is more susceptible to burn injury so it must remain flexible to allow finger motion. Any exposed tendon or bone, such as may be seen with an electrical burn, constitutes a true fourth-degree injury, and either flap closure or amputation is required to heal the wound.

Many of the issues complicating outpatient management of foot burns are relevant to the care of hand burns. After initial burn cooling, the wound should be gently cleansed with mild soap. Any loose skin or ruptured blisters should be gently debrided, rinsed, patted dry, and covered with a topical antimicrobial agent and a nonadherent, bulky gauze dressing. The fingers should be carefully separated and bandaged individually. Small, intact blisters that do not interfere with hand function should be left intact to serve as a biologic dressing. Elevation of the hand is very important in the first few days after a burn injury to minimize edema. Deep partial- or full-thickness burns on the dorsum of the hand should be splinted^{53,54} after bandaging to avoid the development of contractures or a boutonnière deformity.

Hospital admission or burn center referral should be considered for all significant hand burns, particularly full-thickness injuries and circumferential burns involving the digits (Fig. 38.16). If outpatient treatment is appropriate, the patient should have appropriate follow-up, must be given comprehensive instructions, and should have the resources available to perform daily dressing changes and range-of-motion exercises of the fingers and wrist during these dressing changes. An initial follow-up visit should occur in 48 to 72 hours, but the patient should be encouraged to return if burn cellulitis, worsening pain, fever, or lymphangitis develops. Ideally, the patient should be seen twice in the first week after injury and then, if clinically appropriate may be reduced to once a week until the burn is healed.

Figure 38.16 This badly burned hand requires referral to a surgeon or burn center and should not be definitively handled in the emergency department. Note the very tight ring (*arrow*).

Facial Burns

Facial burns commonly result from unexpected ignition flash burns (e.g., from a stove, oven, or charcoal grill) or from car radiator accidents (Fig. 38.17A and B).^{55,56} Facial burns from these sources usually do well, but singeing of facial hair, significant edema, and pain often result. However, facial burns from these causes may produce airway problems and might require skin grafting. Singed nasal hairs or any sign of significant heat exposure to the face should prompt an evaluation of airway injury, which may result in airway compromise at a time later than the initial incident (see Fig. 38.17C).

Concurrent globe or corneal injury is quite rare because of protective blinking reflexes. If the eye is burned, it is usually in the setting of a life-threatening concomitant burn injury.⁵⁷ Burns involving the eyelids can cause significant scarring. Fluorescein staining and slit-lamp examination should be performed to confirm or exclude the diagnosis of corneal injury (Fig. 38.18). Treatment of a corneal injury can involve irrigation, topical ophthalmic antibiotics, and consideration of eye patching versus protective soft contact lens (see Chapter 62). Referral to an ophthalmologist is usually prudent. Facial burns are otherwise treated in the usual fashion and with an open (no dressing) technique. Patients are instructed to wash their face two or three times a day with a mild soap and then apply a thin layer of antibiotic ointment, such as bacitracin zinc. Car radiator burns result from the combination of a hot liquid and steam burn (see Fig. 38.17B). Antifreeze exposure to skin does not produce a caustic injury, nor is it systemically absorbed. Neck burns are treated similarly.

A flash burn in a patient smoking cigarettes while using nasal oxygen causes a facial burn that is not uncommonly seen in the ED (see Fig. 38.17D). These burns may involve the nose and lips, may have melted plastic particles on the skin or in the nose, and can be quite painful. Although such patients generally do well, facial burns can make the continued use of nasal cannula oxygen problematic until healing takes place. Though not generally an inhalation burn issue, careful evaluation of the upper airways and assessment of lung function are prudent. Many patients using oxygen are relatively immunocompromised. They may not be able to tolerate even minor physical insults and have fragile conditions that require careful evaluation, short-term observation in some cases, and close follow-up for delayed healing and infection. Hospitalization for burn care and general supportive measures may be prudent for all but minor burns in this patient population. Minor burns can be treated on an outpatient basis in an open fashion with topical ointments, such as bacitracin.

All patients with head or neck burns should be evaluated carefully for a concomitant inhalation injury. Such patients may have direct evidence of injury, such as oral burns, blisters, soot, or hyperemia and a history of being in an enclosed space, or have indirect evidence, such as dyspnea, wheezing, arterial hypoxemia, or an elevated carboxyhemoglobin level. The definitive diagnostic test for inhalation injury is fiberoptic bronchoscopy.⁵⁸ Flash ignition burns involving the face do not pose a problem with carbon monoxide poisoning, and although inhalation injuries generally do not occur with minor flash ignition burns, airway management should remain a consideration.

Inpatient care should be considered for all patients with significant facial burns. Outpatient pain control may be difficult in those with facial burns, the degree of edema may be difficult

Figure 38.17 **A**, Flash burns on the face from lighting a gas stove. These burns are painful and may cause edema, but they usually do well. Note the singed facial hair. The eyes are usually protected by rapid reflex blinking, and carbon monoxide poisoning and pulmonary burns are not an issue. Most can be handled in the outpatient setting with bacitracin ointment and no dressing. Pain control may be problematic unless opioids are prescribed. **B**, Facial and neck burns when a radiator cap was removed and the victim was sprayed with steam and hot antifreeze. **C**, This patient has a severe facial burn with smoke inhalation, as evidenced by soot in the pharynx and singed nasal hairs. Tracheal intubation is in the near future for this patient. **D**, A flash burn in a patient who was smoking a cigarette while using nasal oxygen.

Figure 38.18 A thermal burn of the cornea. Note the opacified, “heaped-up” appearance of the epithelium. (From Kanski JJ, editor: *Clinical diagnosis in ophthalmology*, St. Louis, 2006, Mosby.)

to predict, and home care can be problematic. There are no universally agreed standards for admission versus outpatient treatment of facial burns.

Corneal contact burns, as from accidental contact with a curling iron, are often manifested rather dramatically as opacified, “heaped-up” corneal epithelium (see Fig. 38.18). Despite their appearance, the end result is usually excellent. Treatment is the same as for a corneal abrasion.⁵⁹

Abuse of Children and Elderly Individuals

Recognition of the possibility of deliberate abuse by burning in the pediatric and geriatric populations is essential. In addition, children younger than 2 years have a thinner dermis and a less well-developed immune system than adults do. Elderly patients (>65 years) likewise tolerate burns poorly. These two populations are the most prone to abuse, often by family members (Fig. 38.19). For these reasons, both these groups of patients often require inpatient care.²³

Figure 38.19 Burns can be a manifestation of child abuse, spouse abuse, or abuse of the elderly. **A**, Abuse burns from contact with a hot metal grate as a result of a child allegedly falling. **B**, This burn was the result of spouse abuse caused by throwing hot soup during an argument. Domestic abuse is often denied initially, but the delayed arrival at the hospital was a clue. **C**, Burns of the face and neck are common when a toddler pulls hot liquid from a stove. This case was never proved to be child abuse, but burns in young children are often due to abuse, especially if they are in atypical places. Although the body surface area of this burn is relatively small, the patient's age and the burn's location, coupled with the possibility of child abuse, require that this child be hospitalized. **D**, This infant received a severe blistering sunburn at the beach despite being in the shade most of the day. Reflection of sunlight from the sand and water can injure the delicate skin of an infant, who should have sunscreen applied. **E**, Self-inflicted cigarette burns in a psychiatric patient.

The majority of abused children are 18 to 36 months old, and for unknown reasons, the majority are male.³⁶ Immersion burns are a common type of abuse and are characterized by circumferential, sharply demarcated burns on the hands, feet, buttocks, and perineum. Cigarette burns and burns from hot objects such as irons should be obvious. Contact burns on “nonexploring” parts of the child also warrant suspicion. A delay in seeking treatment may be a tip-off that a burn resulted from abuse. In older populations, the presence of confirmed self-inflicted burns such as cigarette burns suggests psychiatric disease (see Fig. 38.19E).

Burns in Pregnancy

There is little information in the literature concerning the special problems of pregnant burn victims. Ying-bei and Ying-jié⁶⁰ reported on 24 pregnant burn patients representing a wide range of burn severity. Complications of the burn injuries included abortion and premature labor, although all patients in this series with burns covering less than 20% TBSA did well and delivered living full-term babies.

Because the resistance of pregnant women to infection is lower than that of nonpregnant women, control of burn wound infection is paramount. Gestational age appears to have no direct bearing on prognosis. Silver sulfadiazine cream should be avoided near term because of the potential for kernicterus.

SPECIFIC BURNING AGENTS

Hot Tar Burns

Asphalt is a product of the residues of coal tar and is commonly used in roofing and road repair. It is kept heated to approximately 450°F. When spilled onto the skin, the tar cools relatively rapidly, but the retained heat is sufficient to produce a partial-thickness burn. Fortunately, full-thickness burns are unusual. Cooled tar is nonirritating and does not promote infection. When cooled tar is physically removed, the adherent skin is usually avulsed (Fig. 38.20). Careless removal of the tar may inflict further damage on burned tissues. Agents such as alcohol, acetone, kerosene, or gasoline have been used to remove the tar, but these are flammable and may cause additional skin damage or a toxic response secondary to absorption.

There is no great need to meticulously remove all tar at the first visit. Obviously devitalized skin can be débrided, but adherent tar should be emulsified or dissolved rather than manually removed (Fig. 38.21). Polyoxyethylene sorbitan (Tween 80 [Sigma-Aldrich Corp., St. Louis, MO] or polysorbate 80) is the water-soluble, nontoxic, emulsifying agent found in Neosporin and several other topical antibiotic creams. Note that the cream formulations, not the ointments, contain the most useful tar dissolvers. The creams contain a complex mixture of ethers, esters, and sorbitol anhydrides that possess excellent hydrophilic and lyophilic characteristics when used as nonionic, surface-active emulsifying agents. With persistence, most tar can be removed (emulsified) on the initial visit, although this may be unnecessary as previously detailed.

Another household product (De-Solv-It [Orange-Sol Blending and Packaging, Inc., Chandler, AZ] multiuse solvent) also appears logical for topical ED use.^{50,61} De-Solv-It has a surface-active moiety that wets the chemical's surface and emulsifies

Figure 38.20 A, There is no compelling reason to remove all tar on the first visit. Physical removal of cooled tar usually results in avulsion of the underlying skin. Skin that is obviously loose should be débrided, but adherent tar is best liquefied with an emulsifying agent. Neomycin cream, not ointment, is a suggested emulsifier, but others are acceptable (see text). Final removal may be delayed for several days to permit loosening of the tar. Frequent dressing changes and application of an emulsifying agent can be performed by the patient to remove the tar over a period of a few days. B, This extremity was covered with an emulsifying agent and with gauze, and the residual tar was washed off easily 36 hours later.

tar and asphalt. Because De-Solv-It is itself a petroleum-based solvent, it should be applied only briefly, and the operator should wear gloves and protective eyewear during application. It should be used only for external exposure to tar or asphalt. After removal, the skin should be cleansed gently and dressed appropriately.

Many clinicians instead prefer to emulsify the majority of tar on an outpatient basis. A generous layer of polysorbate-based ointment can be applied under a bulky absorbent gauze dressing. The patient is then released home, and the residual tar is easily washed off after 24 to 36 hours (see Fig. 38.20B). Several dressing changes may be required. Once the residual tar is removed, the wound is treated as any other burn (see Fig. 38.21).

Shur-Clens (ConvaTec), a nontoxic, nonionic detergent, also works well for tar burn wound cleansing, as do mineral oil, petrolatum, and Medi-Sol (Orange-Sol), a petroleum-citrus

Figure 38.21 A, Tar stuck to the face can B, be emulsified with various agents and a lot of patience and persistence. Fortunately, tar burns are not usually full-thickness burns.

Chemical Burns

Chemical burns generally occur in the workplace, and the offending substance is usually well known. More than 25,000 chemicals currently in use are capable of burning the skin or mucous membranes. Commonly used chemical agents capable of producing skin burns are shown in [Box 38.7](#).

Injury is caused by a chemical reaction rather than a thermal burn.⁶² Reactions are classified as oxidizing, reducing, corrosive, desiccant, vesicant, or protoplasmic poisoning. The injury to skin continues until the chemical agent is physically removed or exhausts its inherent destructive capacity. The degree of injury is based on the strength, concentration, and quantity of the chemical; duration of contact; location of contact; extent of tissue penetration; and mechanism of action.

Immediate flushing with water is recommended for all chemical burns, with the exception of those caused by alkali metals. Flushing serves to cleanse the wound of unreacted surface chemical, dilute the chemical already in contact with tissue, and restore lost tissue water. Leonard and colleagues⁶³ clearly demonstrated that patients receiving immediate copious water irrigation for chemical burns had less full-thickness burn injury and a 50% or greater reduction in hospital stay. Flushing should be thorough and may require at least 30 minutes (or as much as 2 hours) for maximal benefit, depending on the nature of the chemical.

Acid and Alkali Burns

Chemical burns cause progressive tissue damage until the chemical is inactivated or removed. Acids damage tissue by coagulation necrosis, a process that limits the depth of penetration into tissue. Alkalis react with lipids in skin and result in liquefaction necrosis. This process permits penetration of the chemical into tissues until neutralized. Thus, exposure to alkali is more likely to produce deep tissue wounds. Skin exposed to caustic substances should be decontaminated aggressively until neutralized and the resulting wounds considered deep until demonstrated otherwise.

Desiccant acids, such as sulfuric acid, create an exothermic reaction with tissue water and can cause both chemical and thermal injury. With extensive immersion injuries, acids may be absorbed systemically, thereby leading to systemic acidosis and coagulation abnormalities.

Chemical burns may be excruciatingly painful for long periods. Discomfort can be out of proportion to what one might expect from the perceived depth or extent of the burn. When caring for a chemical burn, the emergency care team should remove all potentially contaminated clothing. Any dry (anhydrous) chemical should first be brushed off the patient's skin. The involved skin should then be irrigated with large amounts of water under low pressure. Any remaining particulate matter should be carefully débrided during irrigation.

Strong alkali burns may require irrigation for 1 to 2 hours before tissue pH returns to normal. Some recommend that if the burn continues to feel “slippery” or tissue pH has not returned to normal after extensive irrigation, chemical neutralization may be helpful.^{64,65} Given that any heat of neutralization will be carried away with the irrigation solution,⁶⁶ prompt irrigation with a dilute acid (e.g., vinegar, or 2% acetic acid) may hasten neutralization and patient comfort.

Contact Burns From Wet Cement

The major constituent of Portland cement, an alkaline substance, is calcium oxide (64%), combined with oxides of silicon, aluminum, magnesium, sulfur, iron, and potassium. There is considerable variability in the calcium oxide content of different grades of cement, with concrete having less and fine-textured masonry cement having more.⁶³ The addition of water exothermically converts the calcium oxide to calcium hydroxide ($\text{Ca}[\text{OH}]_2$), a strongly corrosive alkali with a pH of 11 to 13. As the cement hardens, the calcium hydroxide reacts with ambient carbon dioxide and becomes inactive.

Both the heat and the $\text{Ca}(\text{OH})_2$ produced in this exothermic reaction can result in significant burns. Because of its low solubility and consequent low ionic strength, long exposure to $\text{Ca}(\text{OH})_2$ is required to produce injury. This usually occurs when workers spill concrete into their boots or kneel in it for a prolonged period. The burn wound and the resultant protein denaturation of tissues produce a thick, tenacious, ulcerated eschar. Concrete burns are insidious and progressive. What may appear initially as a patchy, superficial burn might in several days become a full-thickness injury requiring excision and skin grafting.⁶⁷ The pain associated with these burns is often severe and more intense than the appearance of the wound might suggest (Fig. 38.22). Interestingly, many workers are not warned of the dangers of prolonged contact with cement, and because the initial contact with cement is usually painless, exposure may not be realized until the damage is done.

Treatment is as follows. Remove any loose particulate cement or lime, usually by brushing off, remove contaminated clothing, and irrigate the wound copiously with tap water (the pH of the effluent is tested and irrigation continued if the effluent is still alkaline). Apply compresses of dilute acetic acid (vinegar) to neutralize the remaining alkali and provide relief of pain after irrigation. Apply antibiotic ointment to the eschar during the early postburn period.

Sutlains ointment (Travase, Flint Pharmaceuticals, Deerfield, IL) is often recommended because it contains proteolytic enzymes that help speed eschar separation, but any common topical burn preparation is acceptable. The depth of burns from wet cement can be difficult to assess in the first several days. If it becomes apparent that the burns are full-thickness burns, early excision and skin grafting are recommended.

Cement burns should be differentiated from cement dermatitis, which is far more common. The latter is a contact sensitivity reaction, probably from the chromates present in cement. The contact dermatitis can initially be treated as a superficial partial-thickness burn.

Air Bag Keratitis and Thermal Burns

Safety legislation has mandated increased use of air bags to protect automobile occupants in the event of collision. Burns from air bags can be thermal, friction, or chemical (Fig. 38.23). The automobile air bag is a rubberized nylon bag that inflates on spark ignition of sodium azide to yield nitrogen gas, ash,

Figure 38.22 Alkali burns from wet cement develop insidiously, are extremely painful, and are frequently full-thickness injuries. They are most common **A**, on the feet when cement leaks over the top of the boots or **B**, from kneeling in wet cement while working. The alkali can penetrate clothing.

Figure 38.23 A burn on the forearm from a first-generation air bag can be a combination of friction and chemicals. They are usually minor.

and a small amount of sodium hydroxide. Within seconds, the superheated air is vented, and this can produce a thermal burn if it contacts an extremity, the face, or the upper part of the torso.^{7,68,69} If the air bag ruptures, the alkaline contents of the bag are dispersed as a fine, black powder that usually causes no problems unless the eyes are exposed. Patients with eye exposure exhibit clinical evidence of a chemical keratoconjunctivitis, including photophobia, tearing, redness, and decreased visual acuity. Tear pH is usually elevated, and there may be particulate matter in the fornices.⁷⁰

The severity of an ocular alkaline burn is related to the duration of exposure and the concentration and pH of the chemical. For this reason, prompt, copious irrigation of the eyes with frequent assessment of tear pH is essential to prevent or minimize the injury (see [Chapter 62](#)). A rising pH suggests that trapped particulate matter is releasing additional chemical. Corneal edema and conjunctival blanching are signs of serious injury and can necessitate immediate ophthalmologic consultation.

Hydrocarbon Burns

Hydrocarbons are capable of causing severe contact injury by virtue of their irritant, fat-dissolving, and dehydrating properties. Cutaneous absorption may cause even more dangerous systemic effects. Gasoline, the usual agent involved, is a complex mixture of C₄ to C₁₁ alkane hydrocarbons and benzene; the hydrocarbons appear to be the major toxic agent. Lead poisoning caused by either absorption through intact skin or burns from exposure to leaded gasoline have been reported previously but are currently quite rare because unleaded gasoline has virtually replaced the leaded version for most purposes.⁷¹

The depth of injury is related to the duration of exposure and the concentration of the chemical agent. Gasoline immersion injuries resemble scald burns and are usually partial thickness.⁷² Occasionally, gasoline-injured skin exhibits a pinkish brown discoloration, possibly related to dye additives. A common source of gasoline exposure is motor vehicle collisions in which a comatose patient has been lying in a pool of gasoline.

The lungs are the usual site of systemic absorption and are often the only major route of excretion. The resultant high pulmonary concentrations may lead to pulmonary hemorrhage, atelectasis, and acute respiratory distress syndrome. To treat hydrocarbon burns, remove contaminated clothing, administer prolonged irrigation or soaking of the contaminated skin, débride significant burns caused by lead-containing gasoline (to reduce systemic lead absorption), and apply topical antibiotic ointments.

Phenol Injury

Phenol is a highly reactive aromatic acid alcohol that acts as a corrosive. Carboic acid, an earlier term for phenol, was noted to have antiseptic properties and was used as such by Joseph Lister in performing the first antiseptic surgery. Hexylresorcinol, a phenol derivative, is in current use as a bactericidal agent. Phenols, in strong concentrations, cause considerable eschar formation, but skin absorption also occurs and can result in systemic effects such as central nervous system depression, hypotension, hemolysis, pulmonary edema, and death. Interestingly, phenol acts differently from other acids in that it penetrates deeper in a dilute solution than in a more concentrated form.⁶² Therefore, irrigation with water is suboptimal for phenol burns, but, because water is commonly and readily available, it is frequently used for irrigation.

Full-strength polyethylene glycol (PG 300 or 400) is more effective than water alone in removing phenolic compounds and should be obtained and used after water irrigation has begun. Polyethylene glycol is nontoxic and nonirritating and may be used anywhere on the body. When immediately available, polyethylene glycol can be used to remove the surface chemical before water irrigation (and chemical dilution) is begun.

Hydrofluoric Acid Injury

Hydrofluoric acid (HFA) is one of the strongest inorganic acids known; it has been widely used since its ability to dissolve silica was discovered in the late 17th century.⁷³ Currently, HFA is used in masonry restoration, glass etching, and semiconductor manufacturing; for control of fermentation in breweries; and in the production of plastics and fluorocarbons. It is also used as a catalyst in petroleum alkylating units. It is available in industry as a liquid in varying concentrations up to 70%. It is also readily sold in home improvement and hardware stores. Significant concentrations of HFA are present in many home rust removal products, aluminum brighteners, automobile wheel cleaners, and heavy-duty cleaners in concentrations of less than 10%. Despite its ability to cause serious burns, unregulated and poorly labeled HFA products are recklessly used on a regular basis in the home and in small businesses. The public and many clinicians are generally unaware of the potential problems with this acid ([Fig. 38.24](#)).

Although HFA is quite corrosive, the hydrogen ion plays a relatively insignificant role in the pathophysiology of the burn injury. The accompanying fluoride ion is a protoplasmic poison that causes liquefaction necrosis and is notorious for its ability to penetrate tissues and cause delayed pain and deep tissue injury. This acid can penetrate through fingernails and cause nail bed injury. With home products, the unwary user does not realize that the substance is caustic until the skin (usually the hands and fingers) is exposed for a few minutes to hours, at which time the burning begins and becomes progressively worse. At this point the damage is done and the absorbed HFA cannot be washed off. With higher-strength industrial products, symptoms are almost immediate.

The initial corrosive burn is due to free hydrogen ions; secondary chemical burning is due to tissue penetration of fluoride ions. Fluoride is capable of binding cellular calcium, which results in cell death and liquefaction necrosis. The ionic shifts that result, particularly shifts of potassium, are believed to be responsible for the severe pain associated with HFA burns.

In high concentrations, the fluoride ions may penetrate to bone and produce demineralization. Exposure of skin to concentrated HFA involving as little as 2.5% TBSA can lead to systemic hypocalcemia and death from intractable cardiac arrhythmias; it has been calculated that exposure to 7 mL of anhydrous HFA (HFA gas) is capable of binding all the free calcium in a 70-kg adult.^{74,75} Hyperkalemia and hypomagnesemia can also develop. If the hands are exposed, the acid characteristically penetrates the fingernails and injures the nail bed and cuticle area. As with most caustics, the pain is generally out of proportion to the apparent external physical injury. HFA burns produce variable areas of blanching and erythema, but blisters or skin sloughing are rarely seen initially. Skin necrosis and cutaneous hemorrhage may be noted in a few days.

Immediate treatment should begin with copious irrigation with water. Another approach is to wash the area with a solution

Figure 38.24 A, Initially, this very painful hydrofluoric acid burn of the thenar and hypothenar eminence appeared minimal. B, Despite infiltration with calcium gluconate, a deep burn developed 3 days later.

of iced magnesium sulfate (Epsom salts) or a 1:500 solution of a quaternary ammonium compound such as benzalkonium chloride (Zephiran, Sanofi-Synthelabo Inc., New York, NY) or benzethonium chloride (Hyamine 1622, Sigma-Aldrich). Magnesium and calcium salts form an insoluble complex with fluoride ions, thus preventing further tissue diffusion. Though frequently recommended, topical preparations are often ineffective in limiting injury or controlling pain.

If there is no or only minimal visible evidence of skin injury and minimal pain, the burn may be dressed with topical calcium gluconate paste. This is not commercially available in the United States but is easily compounded in the pharmacy by mixing 3.5 to 7 g of pulverized calcium gluconate with 5 oz of a water-soluble lubricant such as K-Y jelly. This will form a thick paste with a calcium gluconate concentration of 2.5% to 5.0%. Some have suggested dimethyl sulfoxide as a vehicle to aid in skin penetration of the calcium. Plastic wrap (e.g., Saran Wrap, SC Johnson, Racine, WI) is used over a standard dry burn dressing to cover the calcium paste on the limbs. A vinyl or rubber glove filled with the paste can be used to cover

the fingers and hands. Completely re-dress the wound and reapply the paste every 6 hours for the first 24 hours. As with most topical treatments of HFA burns, calcium gluconate is only minimally effective in relieving pain, and its value is probably overestimated in the literature.

A digital or regional nerve block with long-acting bupivacaine is an excellent way to provide prolonged pain relief if the hands are involved, but this does nothing to ameliorate the injury. In most cases, oral opioids are required. If bullae or vesicles have formed, they should be débrided to decrease the amount of fluoride present, and the wound should then be treated as any partial-thickness burn. Burns with HFA of less than 10% strength will heal spontaneously, usually without significant tissue loss, but pain and sensitivity of the fingertips may persist for 7 to 10 days. In addition, the fingernails may become loose.

The presence of significant skin injury or intense pain implies penetration of the skin by fluoride ions. This scenario is particularly common with exposure to HFA solutions in concentrations of 20% or greater, but tissue injury can occur with prolonged exposure to less concentrated products.

Initial treatment of a more concentrated exposure begins as described earlier and includes immediate débridement of necrotic tissue to remove as much fluoride ion as possible.⁷⁶ After débridement, inject a 10% solution of calcium gluconate (note: avoid calcium chloride for tissue injections) intradermally and subcutaneously with a 30-gauge needle about the exposed area, using approximately 0.5 mL per square centimeter of burn. Pain relief should be almost immediate if this therapy is adequate. Because the degree of pain is a measure of the effectiveness of treatment, the use of anesthetics, especially by local infiltration, may be deleted if the burn is on the arm or leg. HFA can penetrate fingernails without damaging them. Soft tissue can be injected without prior anesthesia, but if the fingertips or nail beds are involved, they may be injected after a digital nerve block has been performed (Fig. 38.25). Before anesthesia and injection of calcium, the patient can outline the affected areas with a pen to ensure accurate injection of the antidote (see Fig. 38.25C). Although some investigators recommend that the fingernails be removed routinely, we strongly advise against this unless the nails are very loose or there is obvious necrosis of the nail bed. Fingers are best injected with a 25- or 27-gauge needle (a tuberculin syringe works well).⁶⁵ Nails frequently become loose in a few days, but they often return to normal and do not require removal, particularly when lower-concentration nonindustrial products are involved.

Although infiltration of calcium gluconate is somewhat effective, the technique has certain limitations. Injections are painful, and the calcium gluconate solution itself causes a burning sensation. Because of the volume restrictions, not enough calcium may be delivered to bind all the free fluoride ions present. For example, 0.5 mL of 10% calcium gluconate contains 4.2 mg (0.235 mEq) of elemental calcium, which will neutralize only 0.025 mL of 20% HFA.

Several authorities have advocated intraarterial calcium infusions in the treatment of serious HFA burns of the extremities.^{77,78} Though very effective, this technique is not recommended for burns secondary to dilute HFA (i.e., concentrations <10%) because the morbidity is usually quite mild. When using this technique, 10 mL of 10% calcium gluconate is diluted in 50 mL of a 5% dextrose and water solution. The dilute solution is administered by slow infusion into an arterial catheter. It is unclear which artery best delivers the calcium

Figure 38.25 **A**, Hydrofluoric acid (HFA) burns of the fingertips are extremely painful despite minimal clinical findings; initially only hyperemia and minor ecchymosis are apparent. HFL can penetrate the intact fingernail and produce a significant injury to the nail bed. **B**, The area of burn can be injected with calcium gluconate minimally diluted with plain lidocaine. Using a small-gauge needle, generously infiltrate the entire area of the burn. **C**, Before performing digital block anesthesia to painlessly infiltrate the fingertips with calcium gluconate, ask the patient to outline the painful areas with a felt-tipped marker to ensure accurate placement of the antidote. In the treatment of HFA burns, topical therapy is often ineffective. Calcium gluconate may be injected subcutaneously with a 25- to 27-gauge needle into the nail bed via the fat pad under a digital nerve block. Do not remove fingernails routinely if burns are mild, such as those seen with household products containing less than a 10% concentration of the acid. Intraarterial calcium infusions are often quite successful in relieving pain and limiting necrosis. **D**, Combine the calcium gluconate with a small amount of lidocaine for injection.

to injured tissues. If only the radial three digits are involved, probably only the radial artery needs to be cannulated. Otherwise, a percutaneous catheter is inserted into the brachial artery. However, some investigators have advocated use of the radial artery in all cases, and because the arterial supply of the hand is interconnected, this may be a reasonable recommendation.⁷⁹ The radial artery is usually more easily cannulated than the brachial artery. When arterial access has been accomplished, the solution is infused slowly over a 4-hour period. At this point the catheter is left in place and the patient is observed. If pain returns at any time over the next 4 hours, the infusion is repeated. If the patient is pain free over the 4-hour observation period, the burn is dressed and the patient is released home. This technique may be initiated in the ED, but many clinicians are reluctant to cannulate an artery and infuse calcium in the

ED. Such patients require hospitalization or burn center referral for further evaluation and observation.

Advantages of the intraarterial method are elimination of the need for painful SQ injections and avoidance of the volume limitations of the SQ route while providing substantially more calcium to neutralize the fluoride. Disadvantages of intraarterial calcium therapy include the possibility of local arterial spasm (which can be treated with vasodilators such as phentolamine or removal of the catheter), local arterial injury or thrombus, and the long duration of treatment required.

Infusing calcium into the general venous circulation is of no benefit for HFA burns. Some authors have advocated the use of regional IV calcium gluconate, similar to the method used with the Bier block for regional anesthesia (see [Chapter 32](#)).⁸⁰ Case reports have noted variable success, but this technique

has neither been well studied nor rigorously compared with other options. This method would be useful only for upper extremity burns. To perform regional calcium therapy, place an IV catheter in the dorsum of the hand on the involved extremity. Partially exsanguinate the arm by elevation, wrapping with an elastic bandage, or both. Apply a Bier block tourniquet or a heavy-duty blood pressure cuff to the burn and inflate it to 20 to 30 mm Hg above the systolic pressure to stop blood flow to and from the arm. Because slow deflation of a regular blood pressure cuff may thwart success of the procedure, using this specialized tourniquet is recommended. Then, dilute 10 mL of 10% calcium gluconate with 30 to 40 mL of saline, and infuse the solution into the venous catheter. Keep the solution in the arm by keeping the tourniquet on for 20 to 30 minutes. Some patients cannot tolerate arm ischemia for this period, thus limiting the effectiveness of this procedure. Theoretically, the calcium diffuses out of the venous system and into the injured tissues. After 20 to 30 minutes, deflate the cuff to restore normal circulation to the extremity. It may require 10 to 20 minutes after deflation of the tourniquet before the patient experiences relief of pain. This procedure is safe, but its efficacy is variable.

HFA burns involving the eye are potentially devastating injuries that deserve special mention. Ophthalmologist referral is mandatory. Ocular exposure to liquid or gaseous HFA will result in severe pain, tearing, conjunctival inflammation, and corneal opacification or erosion. Complications include decreased visual acuity, globe perforation, uveitis, glaucoma, conjunctival scarring, lid deformities, and keratitis sicca. Optimal therapy for ocular HFA burns, other than initial irrigation, is unknown. Irrigation may be performed with water, isotonic saline, or magnesium chloride.⁸¹ We advise copious saline irrigation. Topical antibiotics and cycloplegics, along with light pressure patching, are also recommended. The use of topical steroids has been advocated by some to lessen corneal fibroblast formation, but other attempted therapies such as subconjunctival injections of calcium gluconate and ocular irrigation with quaternary ammonium compounds have been associated with additional injury.⁸²

Chromic Acid Injury

Chromium compounds are used extensively in industry, mainly in metallic electroplating. Chromic acid is commonly used in concentrated solutions containing up to 25% sulfuric acid. It causes sufficient skin damage to allow absorption of the toxic chromium ion if intensive irrigation is not undertaken immediately. Heated (60°C to 80°C) chromic acid makes the problem of chromium absorption much worse.

Dichromate salts containing hexavalent chromium are the most readily absorbed and the most toxic because they can cross cell membranes. The mortality rate from these burns is very high if the burn exceeds 10% TBSA. Chromium absorption leads to diarrhea, gastrointestinal bleeding, hemolysis, hepatic and renal damage, coma, encephalopathy, seizures, and disseminated intravascular coagulation.

To treat, immediately excise the burned tissues to lessen the total body dichromate burden. Wash wounds with a 1% sodium phosphate or sulfate solution and dress them with bandages soaked in 5% sodium thiosulfate solution. These actions reduce the hexavalent chromium ion to the less well absorbed trivalent form.⁸³

Institute chelation therapy with ethylenediaminetetraacetic acid (EDTA) and give IV sodium thiosulfate and ascorbic acid.

Hemodialysis, peritoneal dialysis, or exchange transfusion may be indicated.

Phosphorus Burns

White phosphorus is a translucent, waxy substance that ignites spontaneously on contact with air. For this reason, it is usually stored under water. It is used primarily in fireworks, insecticides, rodenticides, and military weapons.

Phosphorus causes both thermal burns from the flaming pieces and acid burns from the oxidation of phosphorus to phosphoric acid. The burns classically emit a white vapor with a characteristic garlic odor.⁸⁴

Treat these burns first by immersion in water. Débride any gross debris. Wash the wound with a 1% copper sulfate solution, which reacts with the residual phosphorus to form copper phosphate. Copper phosphate appears as black granules, which allow for easy débridement. After débridement, remove the residual copper with a thorough water rinse, dress the wound, and treat it as any other burn.

Elemental Alkali Metal Burns

The commonly encountered alkali metals (sodium, lithium, and potassium) are highly reactive with water and with water vapor in the air and produce their respective hydroxides with liberation of hydrogen gas. Therefore, water should never be used for extinguishing or débriding the metal. A class D fire extinguisher or plain sand may be used to smother the fire, followed by the application of mineral oil or cooking oil to isolate the metal from water and allow safe débridement. Then, treat the burn as an alkali burn.

Magnesium burns in a less intense fashion but otherwise acts as other alkali metals do. These burns may be particularly injurious, however, because if all the metallic debris is not removed, the small ulcers that form will slowly enlarge until they become quite extensive.

The initial topical treatment of unusual chemical burns is outlined in [Table 38.3](#).

Electrical Burns

Electrical burn wounds occur when energy traveling through the body across a potential difference is converted to heat. This energy has the ability to destroy deep tissues, including muscles, tendons, and nerves ([Fig. 38.26](#)). In addition, electrical injuries can arise from the arc produced when electricity passes through the air and from flames caused by the ignition of clothing. Electrical injuries from high-voltage or high-current sources (> 1000 V and > 5000 mA) are more likely to result in deep soft tissue damage, whereas low voltage or low current (< 1000 V and 5 to 60 mA) causes less soft tissue damage but is more likely to result in cardiac arrhythmias.⁸⁵

TEN and SJS

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are severe blistering diseases. They are primarily associated with the intake of medications that cause apoptosis of keratinocytes, which results in the separation of large areas of skin at the dermal-epidermal junction and produces the appearance of a scald. More than 200 medications have been associated with this condition, although infections and immunizations have also been associated. A major factor in improving outcomes has been high-quality intensive support and trained

nursing care with expertise in wounds. Thus these disorders are ideally suited to treatment at burn centers.

The distinction between TEN and SJS is one of extent, with lesions occupying less than 10% TBSA qualifying as SJS (Fig. 38.27) and lesions involving greater than 30% TBSA being called TEN (Fig. 38.28); when the extent of involvement lies between 10% and 30%, an intermediary term is coined, SJS-TEN overlap. These disorders are rare with an annual

Figure 38.27 Stevens-Johnson syndrome (SJS). Purpuric macules became bullous. Note the inflammation of the conjunctivae and lips. By definition, in SJS the lesions occupy less than 10% of total body surface area (TBSA). (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology*, ed 4, St. Louis, 2011, Saunders.)

incidence of 0.4 to 1.2 and 1.2 to 6.0 per million persons, respectively, and are more common in females and the elderly.⁸⁶ Patients at risk are those who are severely immunocompromised (e.g., human immunodeficiency virus [HIV] infection, lymphoma). Death occurs on average in every third patient with TEN. More than 200 drugs, including antibiotics (particularly sulfonamides), nonsteroidal antiinflammatory drugs, and anticonvulsants, have been implicated.

Various theories exist to explain the precise sequence of molecular and cellular events responsible for the development of TEN. The 1- to 3-week interval between the onset of TEN and the commencement of drug therapy favors an immune etiology. Cytotoxic T cells are seen in cutaneous lesions, and it is hypothesized that necrolysis is due to their recognition of complexes between drug metabolites and major histocompatibility complex class I molecules on the surface of keratinocytes. Exfoliation is due to the death of keratinocytes via apoptosis, and data suggest that the latter is mediated by interaction of the death receptors, transmembrane proteins, Fas, and its ligand FasL. This activates the proteolytic cascade (caspases), which leads to cellular disintegration.⁸⁷ Evidence has shown upregulation of FasL in patients with TEN.

Clinical Features

TEN and SJS are usually characterized by fever, corneal irritation, and painful swallowing (representing oral mucocutaneous involvement). These symptoms can precede the rash by 1 to 3 days. In more than 99% of patients, erythema and erosions of the buccal, ocular, and genital mucosa develop and are painful. Diagnosis may require skin biopsy as the condition might be difficult to clinically differentiate from other conditions such as staphylococcal scalded skin syndrome or other dermatologic emergencies. The epithelium of the respiratory tract is involved in 25% of cases of TEN, and gastrointestinal lesions can occur. The skin lesions first appear as erythematous, dusky red, or purpuric macules, irregular in size and shape, that tend to coalesce. Nikolsky's sign (blistering following pressure with the finger) may be evident. A gray appearance of the macule heralds necrosis of the epidermis, which soon separates from the dermis and leaves a raw painful area. Wound infections

Figure 38.28 Toxic epidermal necrolysis. **A**, Detachment of large sheets of necrolytic epidermis (>30% total body surface area) led to extensive areas of denuded skin. A few intact bullae are still present. **B**, Hemorrhagic crusts with mucosal involvement. **C**, Epidermal detachment of the palmar skin. (From Bologna JL, Jorizzo JL, Rapini RP, editors: *Dermatology*, ed 3, St. Louis, 2012, Saunders.)

(*S. aureus* and *P. aeruginosa*) and fluid and electrolyte loss often follow. Death is mainly due to sepsis, acute respiratory distress syndrome, and multiorgan failure. Reepithelialization and healing of wounds can occur within 3 weeks but may be prolonged. There are, however, late sequelae such as scarring and pigmentary abnormalities, as well as serious ophthalmic complications (e.g., symblepharon, conjunctival synechiae, entropion), which can range from sicca syndrome to blindness.

Management

Initial management of TEN requires immediate discontinuation of all medications, including antibiotics, if there are no signs of infection. Supportive care is similar to that required in the treatment of thermal burns. Depending on the body surface area involved patients may require the resources of a Burn Center that has dermatology consultants available. Medical attention is paid to correction of fluid and electrolyte abnormalities, renal insufficiency, nutrition, and sepsis. Involvement of respiratory mucosa may warrant intubation and ventilation. The wounds are carefully débrided and a biopsy specimen is taken to confirm the diagnosis. Regular hydrotherapy and topical antimicrobials are used to decrease infection. Silvadene and mafenide are best avoided because they may be implicated in causing the disorder, but alternative dressings include the various silver products (e.g., Acticoat, Smith & Nephew), as well as bacitracin and Xeroform (DeRoyal). Synthetic dressings such as Biobrane (Smith & Nephew) and biologic materials, including allograft, have all been used with various success.⁸⁸

Regular examination by an ophthalmologist is also recommended. The eyelids should be cleansed daily and followed with a daily application of antibiotic ointment. Attention to oral hygiene is also mandatory because oral lesions are common. Several case reports and uncontrolled series suggest the utility of specific therapies for the treatment of TEN/SJS; however, thus far there are no strong evidence-based standards to promote any particular therapy. Studies have included cyclosporine, cyclophosphamide, IVIG, plasmapheresis, and *N*-acetylcysteine, but these therapies are not established as standard of care. The use of systemic corticosteroids remains controversial, and they may even increase mortality. Promising results were shown with the use of IV immunoglobulins that contain antibodies

TABLE 38.4 Scorten Score for Predicted Mortality in TEN^a

RISK FACTOR	0	1
Age	<40 years	≥40 years
Malignancy	No	Yes
Heart rate	<120	≥120
Serum BUN (mg/dL)	<27	>27
%BSA involved	<10%	>10%
Serum bicarbonate (mEq/L)	≤20	<20
Serum glucose (mg/dL)	<250	>250
NUMBER OF RISK FACTORS	MORTALITY RATE	
0–1	3.2%	
2	12.1%	
3	35.3%	
4	58.3%	
5 or more	90%	

^aScorten Scale as reported in article by Bastuji-Garin S, Fouchard N, Bertocchi M, et al: SCORTEN: a severity-of-illness score for toxic epidermal necrolysis, *J Invest Dermatol* 115(2):149–153, 2000.

against Fas that can block the binding of Fas with FasL, but recently granulysin has been identified as the most important of known mediators for SJS & TEN.⁹⁰ Importantly, subsequent research has not demonstrated a significant mortality advantage for patients using either high- or low-dose IVIG compared with patients treated with supportive care only, so IVIG is not currently established as standard of care therapy.

Mortality of TEN approaches 30% on average, depending on stage of diagnosis at presentation, supportive measures, age, and comorbidities. A modified scoring system for patients

Figure 38.29 Frostbite. Initial management includes rapid rewarming in a water bath (temperature of 40°C to 42°C) for 15 to 30 minutes. Hemorrhagic blisters should be left intact; white or clear blisters may be débrided. Avoidance of refreezing is imperative.

with TEN has been published by Bastuji-Garin and colleagues that predicts the mortality of these patients⁹¹ (Table 38.4). Although rarely useful for the emergency provider, this scoring system and predicted mortality may aid in the collaborative decision to hospitalize at a non-burn center or arrange for transfer to a burn center.

Frostbite

Frostbite is the result of exposure to low environmental temperatures (Fig. 38.29). The formation of ice crystals within extracellular fluid causes direct cellular injury and cellular dehydration through transmembrane osmotic shifts. In addition, a secondary vascular effect of cooling leads to endothelial damage and progressive dermal ischemia.⁹²

Initial management of acute frostbite should entail determination of the core temperature and a full physical examination. The frostbitten part should be rapidly rewarmed in a water bath (temperature of 40°C to 42°C) with adequate analgesia for 15 to 30 minutes. Treatment of deep injury consists of elevation of the injured part to control edema, adequate analgesia, splinting, and the application of topical antibiotics. Traditionally, white blisters are débrided. They generally represent superficial injury, and débridement is thought to be beneficial because it helps in the removal of thromboxane A₂ and prostaglandin F_{2α}. Hemorrhagic blisters, however, are said to represent deeper injury and are best left intact to protect tissues against desiccation. The use of antithromboxane drugs such as aspirin or ibuprofen has been shown to be useful, as has the application of aloe vera. The avoidance of refreezing is critical to reduce complications. Patients should be educated on this important precaution. Premature amputation should be avoided but may be necessary for definitive closure. Long-term consequences include a predilection for future frostbite, vasospastic syndromes, and cold hypersensitivity.

Radiation Burns

Accidents involving ionizing radiation are not common, but when they occur, the clinical findings may range from erythema to charring of the superficial layers of skin. Whole-body

exposure of more than 100 rad causes acute radiation syndrome within hours of exposure. This is characterized acutely by nausea, vomiting, diarrhea, fever, fatigue, and headache. The symptoms may resolve transiently during a latent period only to recur as hematopoietic, gastrointestinal, or vascular complications.^{93,94}

EMERGENCY ESCHAROTOMY

Full-thickness burns result in an eschar that is inelastic and may become restrictive and result in compartment syndrome. Intracellular and interstitial edema can develop and progress, both because of fluid resuscitation and as a direct result of transcapillary extravasation of fluid from the thermal injury. As the soft tissues become edematous and pressure rises under the unyielding eschar, first venous and then lymphatic, capillary, and ultimately arterial flow to the underlying and distal unburned tissue may be compromised. Full-thickness and extensive partial-thickness circumferential extremity burns are most likely to impede peripheral blood flow. Circumferential chest burns may restrict chest wall movement and impair ventilation, and circumferential neck burns may result in tracheal obstruction. In such cases, immediate escharotomy may be indicated.

On occasion, because of high-volume fluid resuscitation, noncircumferential and deep partial-thickness burns require surgical decompression to prevent the complications of nerve or muscle damage. Once signs and symptoms of vascular impairment are present, the clinician must act quickly to prevent tissue hypoxia and cellular death. This pathophysiology may be manifested within a time frame that requires an emergency clinician to intervene. Clinical assessment of tight compartments may be aided by measurements such as capillary refill, Doppler signals, pulse oximetry, and direct measurement of compartment pressures. Escharotomy, when required, is usually performed within the first 2 to 6 hours of a burn injury. The need for non-burn specialists to identify the need for and perform an adequate escharotomy is illustrated by the report of Brown and associates,⁹⁵ who found that 44% of pediatric burn cases were inadequately decompressed before arrival at a referral burn unit.

It is not standard of care that emergency clinicians be skilled in emergency escharotomy, nor can it be expected that this procedure will be done in the ED. The technique is described here for circumstances when escharotomy must be performed by a non-burn specialist.

Indications

The indications for escharotomy are based on clinical examination, compartment pressure, or both. A high index of suspicion and a low threshold for intervention are essential for a successful outcome. Skin temperature and palpation of pulses are unreliable and imprecise indicators of the adequacy of circulation because of peripheral vasoconstriction and local edema. A patient with circulatory embarrassment significant enough to warrant escharotomy may complain of deep aching pain, progressive loss of sensation, or paresthesias, but these parameters are difficult to quantitate in a severely burned, sedated, or mechanically ventilated patient. However, motor activity and peripheral pulses may remain intact despite severe underlying muscle ischemia. In the series by Brown and associates,⁹⁵ peripheral pulses were present in 74% of the limbs that required decompression. Muscle compartments with pressures in excess of 30 mm Hg should be decompressed. Measurements should be taken before and after escharotomy to ensure adequate decompression.

In a patient with absent distal arterial flow (as determined with a Doppler ultrasonic flow meter) but otherwise adequate blood pressure, immediate escharotomy is indicated. Bardakjian and coworkers⁹⁶ suggested that an oxygen saturation below 95% in the distal end of the extremity as demonstrated by pulse oximetry (in the absence of systemic hypoxia) is also a reliable indicator of the need for emergency escharotomy.

Technique of Escharotomy

Because full-thickness burns are insensate to pain and involve coagulation of superficial vessels, no anesthesia is needed. Patients with deep partial-thickness burns may still possess pain sensation, and escharotomy may be performed with local anesthesia or systemic analgesia. A properly executed escharotomy releases the eschar to the depth of SQ fat only. This results in minimal bleeding, which can be controlled with local pressure or electrocautery. These incisions, even though life or limb saving, represent potential sources of infection for the burn patient and should be treated as part of the burn wound. The wounds should be loosely packed with sterile gauze impregnated with an appropriate topical antimicrobial such as silver sulfadiazine cream. Fasciotomy, which involves a deeper incision, may be needed for thermal or electrical burns.

Limbs

Under sterile conditions, incise the lateral and medial aspects of the involved extremity with a scalpel or electrocautery 1 cm proximal to the burned area and 1 cm distal to the involved area of constricting burn (Fig. 38.30). Carry the incision through the full thickness of skin only and this should result in immediate separation of the constricting eschar to expose SQ fat. Because joints are areas of tight skin adherence and potential vascular impingement, incisions should cross these structures (Fig. 38.31). Take care to avoid vital structures, such as the ulnar nerve at the elbow, the radial nerve at the wrist, the superficial peroneal nerve near the fibular head, and the posterior tibial

Figure 38.30 Escharotomy. **A**, Patients with deep, nearly circumferential or circumferential chest wall burns may require escharotomy to facilitate ventilation. If performed properly, escharotomy of the torso will markedly enhance compliance. **B**, Properly performed escharotomy will result in immediate improvement in extremity blood flow. (From Vincent JL, Abraham E, Moore FA, et al., editors: *Textbook of critical care*, ed 6, St. Louis, 2011, Saunders.)

Figure 38.31 Preferred sites for escharotomy incisions. Dotted lines indicate the escharotomy sites. Bold lines indicate areas where caution is required because vascular structures and nerves may be damaged by escharotomy incisions. (From Davis JH, Drucker WR, Foster RS, et al: *Clinical surgery*, St. Louis, 1987, Mosby.)

artery at the ankle. In circumferential burns of the feet, if escharotomy is indicated, extend the incision to the great toe medially and the little toe laterally. In circumferential burns of the hands in which escharotomy is indicated, extend the incisions to the thenar and hypothenar aspects of the hands (see Figs. 38.30 and 38.31). Softening of the compartment, improved distal tissue perfusion, return of sensation, Doppler flow signal strength, and oximetry values indicate adequate release.⁹⁶

Chest

Full-thickness circumferential chest or upper abdominal burns may impair respiration. Nearly all these patients are expected to be intubated and mechanically ventilated. Evidence of the need to release the eschar is increased airway pressure or an inability to ventilate. Escharotomy of the chest wall should extend from the clavicle to the costal margin in the anterior axillary line bilaterally, while avoiding breast tissue in females. This may be joined by transverse incisions to result in a chevron-shaped subcostal incision (see Fig. 38.30).

Neck

Neck escharotomy should be performed laterally and posteriorly to avoid the carotid and jugular vessels.

Penis

Penile escharotomy is performed midlaterally to avoid the dorsal vein.

Complications

Complications of escharotomy include bleeding, infection, and damage to underlying structures. Complications of inadequate decompression include muscle necrosis, nerve injury (such as footdrop), and even amputation of the limb. Systemic complications of inadequate decompression include myoglobinuria and renal failure, hyperkalemia, and metabolic acidosis.

CONCLUSION

Patients with circumferential or nearly circumferential burns should be evaluated for the risk of developing compartment syndrome and deep tissue ischemia. Emergency clinicians should not hesitate to perform an escharotomy before transfer of the patient to a burn center if there is evidence of reduced limb perfusion or impaired ventilation.

Gastrointestinal Procedures

CHAPTER 39

Esophageal Foreign Bodies

David W. Munter

Patients with foreign bodies (FBs) lodged in the esophagus commonly present to the emergency department (ED) for evaluation and treatment. Though most commonly accidental, FBs may sometimes be swallowed purposefully. Patients may have a sensation of a recently passed FB, minor irritation, life-threatening airway obstruction, or other significant complications. Because of the anatomic and physiologic features of the esophagus, FBs in this area of the gastrointestinal (GI) tract present unique clinical issues to the clinician.

GENERAL FEATURES

Anatomy

The esophagus is a muscular tube 20 to 25 cm in length. There are three anatomic areas of narrowing in which FBs are most commonly entrapped: in the upper esophageal sphincter, which consists of the cricopharyngeus muscle; in the midesophagus at the crossover of the aortic arch; and in the lower esophageal sphincter (LES) (Fig. 39.1). The LES is the narrowest point of the esophagus and the entire GI tract.

Epidemiology

There are almost 100,000 cases of FB ingestions reported annually in the United States, and they are the eighth most common cause of calls to poison control centers.¹ Patients with retained esophageal FBs generally fall into one of the following categories: pediatric patients, psychiatric patients, prisoners, and adults who either are edentulous or have underlying esophageal pathology.

Children account for 75% to 85% of esophageal FBs seen in the ED, with the peak incidence occurring at the age of 18 to 48 months.¹⁻⁷ The incidence is equal in boys and girls. Inquisitive children frequently place objects in their mouth and unintentionally swallow them. As a result, children most commonly ingest coins, but they also swallow buttons, marbles, beads, screws, and pins.^{2,4,5,7-10} Unlike adults, children who

have entrapped, accidentally swallowed FBs do not normally have underlying esophageal disorders.¹¹ However, this is not the case in children with esophageal meat or food impaction, and these patients will need further evaluation for underlying esophageal disease,^{10,12,13} the most common of which is eosinophilic esophagitis (55%), or stricture (27%).¹⁴

Patients with an anatomic abnormality of the esophagus or a motor disturbance are more prone to FB entrapment.^{9,12,15} Anatomic abnormalities include strictures, webs, rings, diverticula, and malignancies. Motor disturbances include achalasia, scleroderma, and esophageal spasm. Adults who have dentures or underlying esophageal anatomic or motor abnormalities may accidentally ingest food boluses, chicken bones, fish bones, glass, toothpicks, fruit pits, or pills while in the act of eating.

Prisoners and psychiatric patients ingest a wide variety of objects, some of which may be quite unusual: spoons, razor blades, pins, nails, or practically any other object.⁹ Patients who intentionally ingest foreign objects frequently ingest more than one, with an average of 4 to 5.¹⁶

Complications

Impacted FBs of the esophagus must be removed or dislodged. The time frame under which this mandate must be carried out varies widely and depends on many circumstances. In general, however, the esophagus does not tolerate FBs well or for prolonged periods because it is prone to pressure, edema, necrosis, infection, and eventually perforation. FBs can transit the esophagus in a matter of seconds or minutes or may adhere to the mucosa. Retained objects may become less symptomatic after time, and the clinician must resist the urge to allow esophageal FBs to “pass by themselves” or “dissolve.” Once FBs become stuck in the mucosa, they may become less symptomatic, but they rarely pass on their own. The one exception may be children with coins or other smooth round FBs such as small marbles, especially those lodged at the LES. Approximately one third of these objects may pass spontaneously within 24 hours, and some authorities have advocated an observational approach, although this tends to be more poorly accepted by parents.^{10,17-20} Button batteries must be immediately removed because of the risk of rapidly occurring esophageal erosion and perforation.

The literature is replete every year with a wide array of case reports and small reports of series of complications that can arise from retained esophageal FBs (Box 39.1), including benign mucosal abrasions, lacerations, esophageal stricture, and necrosis from corrosive agents such as button batteries. Esophageal perforation²¹⁻²⁶ can lead to life-threatening conditions such as retropharyngeal abscess,²⁷ mediastinitis, pericarditis, pericardial tamponade,²⁸ pneumothorax, pneumomediastinum,

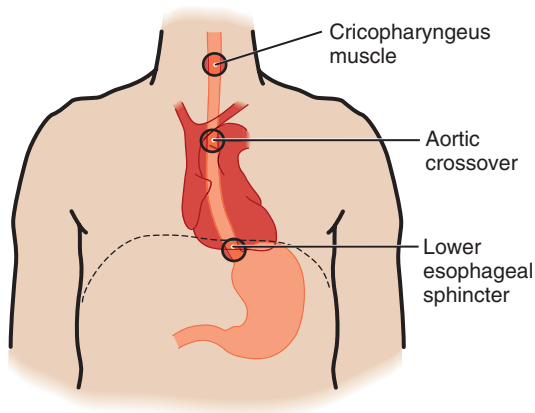

Figure 39.1 Blunt esophageal foreign bodies are most commonly lodged at one of three anatomic areas of narrowing: the cricopharyngeus muscle, the level of the aortic crossover, and the lower esophageal sphincter.

BOX 39.1 Complications of Esophageal FBs

- Airway compromise secondary to tracheal compression
- Aspiration pneumonia
- Esophageal necrosis
- Esophageal perforation
- Esophageal stricture
- Failure to thrive
- Mediastinitis
- Mucosal abrasion
- Paraesophageal abscess
- Pericardial tamponade
- Pericarditis
- Pneumothorax
- Pneumomediastinum
- Retropharyngeal abscess
- Tracheoesophageal fistula
- Vascular injury, including aortic perforation
- Vocal cord paralysis

FB, Foreign body.

tracheoesophageal fistula, and vascular injuries, including injuries to the subclavian vein and aorta.^{29,30} Complications are more common when FBs are entrapped for longer than 24 hours^{6,24,31,32} and when they are sharp.^{4,6,7,33}

Clinical Findings

Esophageal FB impaction is usually an acute condition, particularly in adults who have a clear history of ingestion. Children also commonly remember an ingestion, but some will have a vague history or symptoms. As many as one third of children with proven esophageal FBs are asymptomatic on initial evaluation^{4,5,7,10,34,35}; therefore a high index of suspicion is indicated, especially in children who were seen with an object in their mouth that subsequently disappeared. This is particularly true if transient coughing or gagging occurred, even though the actual ingestion was not witnessed. Poor feeding, irritability, fever, stridor, cough, wheezing, and aspiration can all be caused

TABLE 39.1 Level of Entrapment of Esophageal FBs

Lower esophageal sphincter	12	68

FB, Foreign body.

by an underlying esophageal FB in a child, especially a young infant.^{4,5,12,35}

Dysphagia is a common initial complaint with esophageal FBs. Drooling is suggestive of high-grade obstruction, and complete inability to handle oral secretions is a sign of total obstruction. Infants with a clandestine esophageal FB can exhibit wheezing or a chronic cough. They may appear to have bronchospasm and may be treated for asthma by a number of clinicians before an FB is suspected. Stridor from an FB can mimic epiglottitis.

The esophagus is well innervated proximally, and patients can typically accurately localize FBs in the oropharynx or upper third of the esophagus. However, scratches or abrasions of the esophagus can create a persistent FB sensation. Upper esophageal FBs often cause gagging or vomiting. In rare cases, an upper esophageal FB can impinge on the trachea, especially in children, and mimic infection by inducing wheezing, stridor, or frank respiratory distress. The lower two thirds of the esophagus is not as well innervated, and FBs in this location typically cause vague symptoms of discomfort, fullness, or nonlocalizing pain. Swallowed coins that lodge in the lower part of the esophagus in children may cause no overt symptoms until feeding is attempted.

The location of retained esophageal FBs is related to age and areas of physiologic narrowing of the esophagus (Table 39.1). Children more typically have objects entrapped in the upper part of the esophagus at the level of the cricopharyngeus muscle, whereas adults more commonly have entrapment at the LES.^{4,5,19,36}

Evaluation

The most useful aspect of the evaluation is the history. The time of the ingestion, size and shape of the ingested object, and any current symptoms should be ascertained. Findings on physical examination are frequently normal in patients with esophageal FBs, unless complete obstruction is present. In this case they will be drooling, spitting, and unable to handle oral secretions. Even though a patient may be asymptomatic at initial encounter, transient coughing or gagging should raise the index of suspicion for an esophageal FB. Examination of the oropharynx, neck, respiratory system, cardiac system, and abdomen is essential in the evaluation of potential complications.

After attending to life-threatening conditions such as airway compromise, the goal of ED evaluation is to localize the FB to determine what, if any, interventions need to be undertaken to remove it or assist its transit into the stomach. Once an FB passes into the stomach, it has a greater than 90% likelihood of passing through the entire GI tract without any further problems.³³ Even irregular, and seemingly dangerous FBs will often transit the entire GI tract with relative ease.

RADIOLOGY OF ESOPHAGEAL FOREIGN BODIES

Background

Radiographic imaging of a patient with a suspected esophageal FB is a common practice and is particularly useful for detecting radiopaque FBs. Traditionally, an inability to quickly identify the object by physical examination encouraged the use of plain radiography in an attempt to verify and localize the retained FB. However, the limitations of plain radiography require that other diagnostic approaches also be considered.

Indications

Essentially every patient with a suspected esophageal FB warrants radiographic evaluation with some exceptions, including those patients who have an obvious complete obstruction with an inability to manage their secretions. These patients need endoscopy to relieve the obstruction. If there is any question of aspiration, a chest x-ray may be indicated. Patients with a history of sharp, nonradiopaque FBs such as toothpicks will also need urgent endoscopy. If there has been a delay in presentation in the case of a sharp FB and there are any signs of infection such as fever or chest pain, computed tomography (CT) may be indicated to evaluate for perforation or mediastinitis. Finally, those patients with an FB sensation that is visualized in the upper pharynx on exam and removed may forego radiographs. In nonverbal patients, including preschool children and those who are demented or debilitated, maintain a low threshold for screening radiography in cases with a suspicious history. Examples include a child seen with an object in the mouth that “disappeared” or a patient with symptomatology suggestive of an esophageal FB, such as drooling, gagging, or unexplained respiratory symptoms.

Plain Radiographs

Plain radiographs reliably verify and localize radiopaque FBs such as glass and metal of sufficient size, and are indicated as the main method of radiologic evaluation for these objects.

When used, a complete oropharyngeal radiographic series includes the nasopharynx to the lower cervical vertebra in both lateral and anteroposterior views. Optimum-quality radiographs are mandatory. Patients should be positioned upright with the neck extended and the shoulders held low. Use of a soft tissue technique enhances the discrimination of weak radiopaque FBs. Phonation of “eeee” during radiography prevents motion artifact from swallowing, distends the hypopharynx, and enhances soft tissue landmarks. As previously mentioned, FBs are most frequently entrapped at one of three locations of physiologic narrowing in the esophagus: the cricopharyngeus muscle (Fig. 39.2), the aortic crossover (Fig. 39.3), and the LES (Fig. 39.4). Objects that become lodged in the middle portion of the esophagus most likely represent esophageal pathology, such as stricture related to tumor or eosinophilic esophagitis.

Posteroanterior (PA) and lateral views of the chest are used to evaluate the remainder of the esophagus. Both projections are indicated to identify multiple objects and FBs visible in only one plane. Esophageal FBs typically lie in the vertical plane and are differentiated from airway bodies or calcifications by their location posterior to the tracheal air column on lateral radiographs. As a rule, flat objects such as coins perch in the

Figure 39.2 Posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the cricopharyngeus muscle. This is the most common area of the esophagus to harbor a coin in children. Coins remaining in the upper tract are usually removed unless there is a steady progression with observation. This coin would probably be symptomatic in an infant and cause respiratory distress, drooling, wheezing, and possibly stridor. *Note:* The chance of spontaneous passage is approximately 20% to 25%.

Figure 39.3 Posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the aortic crossover. *Note:* The chance of spontaneous passage is approximately 20% to 25%.

Figure 39.4 Posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the lower esophageal sphincter. Coins in this area are most likely to pass and be favorably manipulated by medication (see [Table 39.2](#)). *Note:* The chance of spontaneous passage is approximately 25% to 60%; chances increase with prolonged observation. (From Waltzman ML, Baskin M, Wypij D, et al: A randomized clinical trial of the management of esophageal coins in children, *Pediatrics* 116:614, 2005; and Soprano JV, Fleisher GR, Mandl KD: The spontaneous passage of esophageal coins in children, *Arch Pediatr Adolesc Med* 153:1073, 1999.)

coronal plane in the esophagus and in the sagittal orientation in the trachea. Intraesophageal air and air-fluid levels represent indirect evidence of esophageal obstruction, and may aid in the verification of radiopaque FBs. Soft tissue swelling, extraluminal air, and aspiration pneumonitis can occasionally help identify complicated impactions radiographically.

In children, a film from the nasopharynx to the anus is frequently obtained to allow visualization of the entire nasopharynx, throat, and esophagus, in addition to the abdomen in case the FB has passed into the stomach or beyond. Radiation exposure can be minimized if adult-sized radiograph cassettes are used. Swallowed coins or other FBs may become lodged in the nasopharynx, usually after gagging or vomiting, and could be missed if this area is not included on the radiograph. In adults, if neck or chest films are negative, abdominal films are sometimes obtained for reassurance of the presence of the FB in the stomach.

Unfortunately, many ingested FBs are nonopaque, including nonbony food, plastic, wood, and aluminum. The visibility of low-opacity FBs can be improved using low-dose radiography, especially in neck films.^{37,38} Some pull tabs from beer cans may be seen if oriented in the coronal plane. A metal detector has been reported to help localize radiolucent aluminum pull tabs.^{39,40} Calcification of fish and chicken bones is often incomplete, but cooking alters the structure of bones and makes them radiolucent on plain films. The degree of bony calcification varies with the fish species and between different samples of

the same species, thus preventing useful guidelines.⁴¹⁻⁴³ For these reasons, plain films provide little substantive evidence in the majority of cases of fish or chicken bone dysphagia. Plain radiographs detect only 25% to 55% of endoscopically proven bones, and carry a high rate of false-negative and false-positive interpretations.^{38,41-43} Because of the lack of diagnostic value for detecting bones, many clinicians do not routinely order plain radiographs and instead initially opt for CT in cases in which radiographic evaluation is required.^{38,42,44-46}

Plain radiography of the neck is limited by the radiographic properties of ingested materials and the complicated anatomy of the upper aerodigestive tract. The base of the tongue, palatine and lingual tonsils, vallecula, and piriform recesses are common regions for entrapment of small, sharp objects, and deserve careful interpretive attention ([Fig. 39.5](#)). Superimposition of the mandible contributes to suboptimal resolution of this region on lateral neck films. Calcified airway cartilage often masquerades as FBs and contributes to false-positive rates as high as 25%.⁴¹ Normal ossification of airway cartilage begins in the third decade and progresses with age. The typical curvilinear contour and well-defined margins of bony FB fragments may help distinguish them from normal laryngeal calcifications. The orientation of bony FBs is variable. The C6 vertebra approximates the level of the cricopharynx, a common site of FB impaction. Increased prevertebral soft tissue width, air within the cervical esophagus, and soft tissue emphysema are rare indirect findings that may help identify radiolucent objects.⁴⁷

Computed Tomography

CT of the neck and mediastinum is an easy, rapid, cost-effective, and accurate noninvasive means of detecting or excluding esophageal FBs ([Fig. 39.6](#))^{38,41,44-46,48} and has garnered support in the setting of suspected FB entrapment.^{38,46} CT further excels at localization and characterization of the impacted FB and identification of associated complications, such as perforation.^{24,38,46} CT has a sensitivity and accuracy of 97% and 98%, respectively, for the diagnosis of esophageal FBs compared to a sensitivity and accuracy of 47% and 52%, respectively, for plain films.³⁸ CT provides improved diagnostic utility for fish bone FBs over plain radiography when obtained either with or without barium enhancement.^{41-44,48} The sensitivity of CT can be improved with 3D reformations. These allow better visualization of the FB and any esophageal injury.³⁸ Use of CT in patients in whom clinical suspicion for a retained FB is high has the potential to reduce the number of unnecessary endoscopies.⁴⁸

The use of intravenous (IV) contrast with CT is not indicated, unless there is concern for an inflammatory process (abscess, peritonitis, fistula formation), or vascular injury (aortic or caval perforation). Use of oral contrast with CT in the setting of suspected FB remains controversial.^{20,38} If used, it can impair visualization on endoscopy. Use of oral contrast is generally reserved for those rare cases where either esophageal perforation is suspected (water-soluble media should be used), or a nonradiopaque FB is suspected and the radiologist wants a small amount of contrast to “outline” the potential FB.³⁸

Contrast-Enhanced Esophagograms

Background

A contrast-enhanced esophagogram is a test that is almost never indicated in the ED as a routine intervention to evaluate

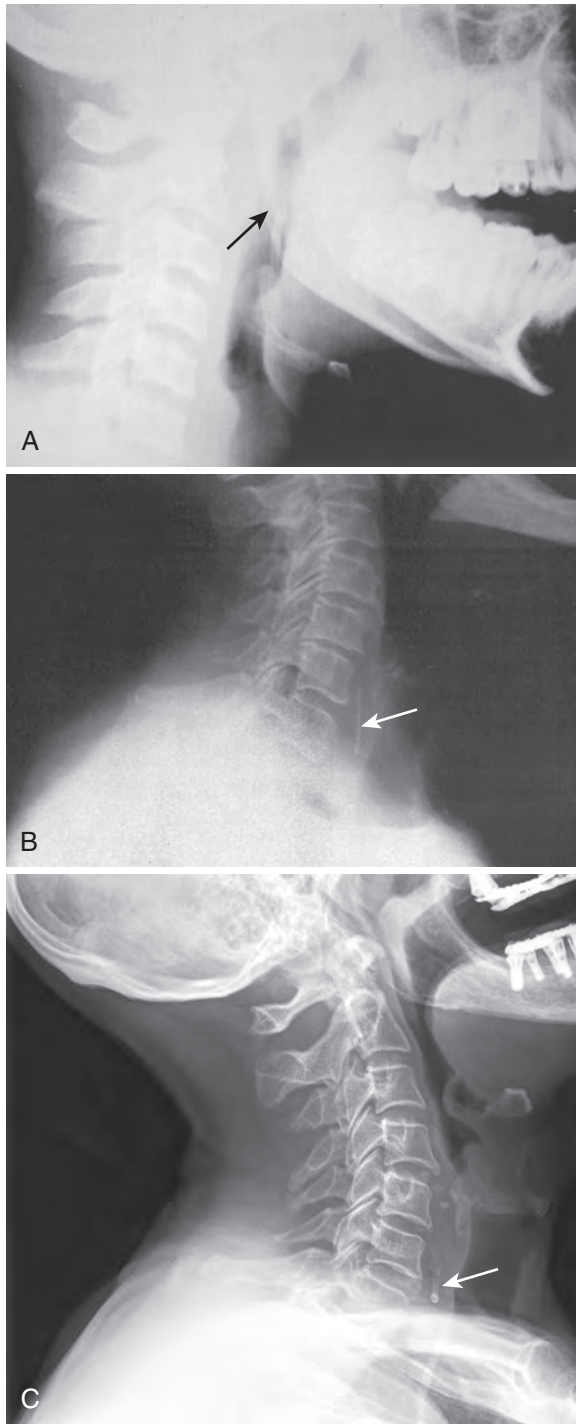

Figure 39.5 **A**, Lateral neck radiograph showing a chicken bone (*arrow*) lodged in the pharynx with associated soft tissue swelling. Plain radiographs have poor diagnostic accuracy for detecting bones in the esophagus, and they are often eschewed in favor of a computed tomography scan if radiographic evaluation is deemed necessary. **B**, A chicken bone in the proximal end of the esophagus (*arrow*), where it is more readily seen on a radiograph. **C**, Another example of a chicken bone in the proximal end of the esophagus (*arrow*).

for an esophageal FB. It has largely been replaced by CT and endoscopy for evaluation of FBs. This technique uses swallowed contrast material to help identify the presence and location of an impacted radiolucent FB, the degree of obstruction, any underlying anatomic abnormalities, and the presence of perfora-

Figure 39.6 Computed tomography scan demonstrating an esophageal foreign body.

tion. Contrast material (barium) may interfere with the detection and extraction of FBs at endoscopy, and may increase the risk for aspiration pneumonitis. Therefore routine, serial contrast-enhanced esophagograms after negative plain radiography in patients with known or suspected FBs are unnecessary for diagnostic purposes in most cases. Selective use is reasonable, but CT or endoscopy are interventions with a better and more cost-effective yield. The American Society for Gastrointestinal Endoscopy guidelines suggest “avoiding contrast radiographic examinations” before endoscopic removal.²⁴ The rare indication in the ED would be a questionable FB or perforation where the radiologist or consultant requests the procedure to “outline” a possible FB to better visualize it, or to evaluate for leakage of contrast material.

Procedure

Esophagograms couple voluntary ingestion of an enteric contrast agent (Gastrografin [Bracco Diagnostics Inc., Monroe Township, NJ] or barium) and plain radiography. Immediately after ingestion, erect and horizontal radiographs are performed at right-angle projections (PA and lateral, or right and left anterior oblique). In addition to anatomic abnormalities, radiolucent FBs may be identified by contrast delineation or filling defects within the contrast column (Fig. 39.7).

The initial choice of contrast agent is debated and should be individualized according to the threat of aspiration and perforation. Water-soluble Gastrografin is indicated first in most cases of suspected perforation because it causes less mediastinal inflammation when extravasated; however, it can give rise to severe chemical pneumonitis if aspirated, and is relatively contraindicated in patients with complete esophageal obstruction. Patients without evidence of complete esophageal obstruction are instructed to swallow progressively larger aliquots of contrast agent up to approximately 50 mL. If these films are normal, the procedure is repeated with half-strength and then full-strength barium to delineate small esophageal injuries. Note that water-soluble contrast material (Gastrografin) causes more pulmonary reaction than barium does when inadvertently aspirated, and should be used in small aliquots if aspiration or complete esophageal obstruction is a concern.

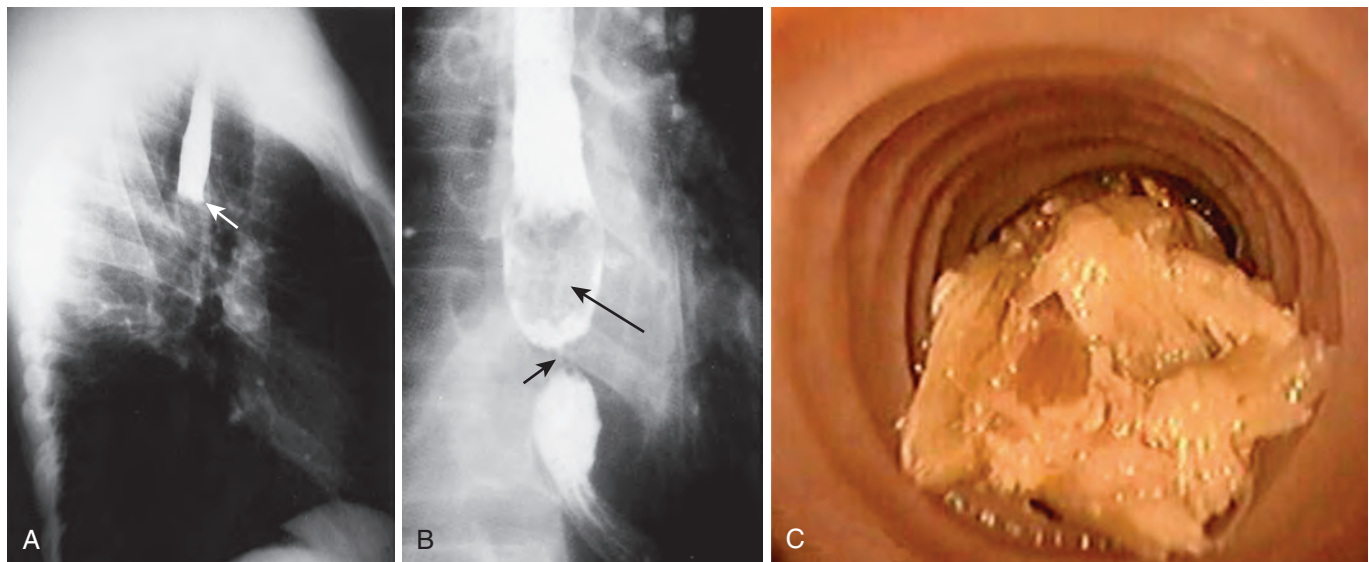

Figure 39.7 A, Barium swallow demonstrating complete esophageal obstruction in the proximal to midportion of the esophagus (*arrow*). B, Barium esophagogram demonstrating a large piece of meat (*long arrow*) lodged above an esophageal stricture (*short arrow*). Many patients with lodged meat have underlying esophageal pathology. C, A bolus of meat seen in the distal end of the esophagus with an endoscope. The scope provides a means for removal and esophageal evaluation simultaneously. This young person had a ringed esophagus as his pathology.

TABLE 39.2 Summary of Recommendations for Esophageal Foreign Bodies^{10,20,38,50}

FOREIGN BODY TYPE	LOCATED IN THE ESOPHAGUS	LOCATED IN STOMACH OR BOWEL
Coin	Remove within 24 hours if still present	Stomach—x-ray weekly Remove if no progression within 3–4 weeks
Button battery	Remove emergently	Stomach—repeat x-ray in 2 days Past pylorus—repeat x-ray in 3–4 days
Magnet	Remove all magnets within endoscopic reach (proximal duodenum or stomach)	Remove all magnets within endoscopic reach (proximal duodenum or stomach). Daily x-ray to assess progression
Sharp object	Remove emergently endoscopically	Remove all objects >2.5 cm wide or 6 cm long that are within endoscopic reach (proximal duodenum or stomach) urgently. Daily x-ray to assess progression
Blunt object	Remove endoscopically within 24 hours	Remove all objects >2.5 cm wide or 6 cm long that are within endoscopic reach (proximal duodenum or stomach). Weekly x-ray

Barium interferes with endoscopy and should not be used when endoscopy is anticipated.

Follow-up Radiographs

Often FBs are visualized in the stomach, or procedures performed in the ED (described later) result in the FB moving into the stomach. A variety of organizations have proposed recommendations for how to manage FBs in the stomach and intestines (Table 39.2).

Conclusions

Diagnostic radiography for esophageal FBs is indicated in almost all cases with the exception of those with a complete obstruction where there is no concern for aspiration. Plain radiographs clearly assist the clinician in several situations: (1) screening of children, adults with dementia, and nonverbal patients with a history or symptoms suspicious for purposeful or inadvertent FB ingestion that can be assumed to be radiopaque; and (2) localization of known radiopaque FBs to clarify

the necessity for and means of FB extraction. Conversely, attempts to verify radiolucent FBs, including bones, by plain radiography are often misleading. CT is more accurate and sensitive than plain films in diagnosing FBs, and in most cases, contrast is not needed.

VISUALIZATION OF ESOPHAGEAL AND PHARYNGEAL FBs

Patients with an FB sensation in their oropharynx typified by a “fish bone” or “chicken bone” sensation need to have some form of visualization of their oropharynx performed as part of the physical examination. The three procedures are direct pharyngoscopy, which is simply direct visualization or examination using a tongue blade with a light source that may be a pen light, wall light, or head light; indirect laryngoscopy, which involves using a handheld mirror reflecting a light to allow visualization of the epiglottis, vallecula, arytenoids, arytenoid folds, and vocal cords (a procedure that requires experience and a cooperative patient); or nasopharyngoscopy, a procedure using a flexible nasopharyngoscope. If an FB is visualized (Fig. 39.8), it should be removed with forceps and the oropharynx carefully reexamined for any injury or additional FB. All three of these procedures are discussed in detail in Chapter 63.

ESOPHAGOSCOPY

Esophagoscopy is the definitive diagnostic and therapeutic procedure for impacted esophageal FBs.^{10,13,24} Although esophagoscopy is not a procedure performed by the emergency provider, its proper role in the ED evaluation of FBs must be understood. With esophagoscopy, the provider can document the presence and location of the FB along with any underlying lesion. The clinician can then remove the object and reevaluate the esophagus after removal of the FB to rule out perforation or underlying pathology. Esophagoscopy may be necessary

Figure 39.8 An esophageal foreign body (arrow) seen on nasopharyngoscopy.

even if a radiologic contrast-enhanced study does not reveal complete obstruction because plain radiographs are not always conclusive.^{24,49} Esophagoscopy may be necessary to exclude predisposing pathology or resultant perforation, even when symptoms presumed to be caused by an esophageal FB have resolved.

Esophagoscopy is the preferred method for removal of sharp or pointed objects such as bones, open safety pins, and razors. In the case of sharp objects prone to causing esophageal perforation, intravenous antibiotics should be administered before the procedure. Endoscopy is the preferred way to remove an impacted meat bolus and to evaluate for possible esophageal pathology at the same time. Esophagoscopy is also indicated for an FB retained for more than 24 to 48 hours, both to remove it and to examine for esophageal wall erosion or perforation. Esophagoscopy is the only appropriate removal technique for multiple or large esophageal FBs. This technique is also indicated for patients with an FB proved to have passed into the stomach and for those who have persistent symptoms possibly caused by esophageal wall injury. Flexible endoscopic procedures can usually be performed without general anesthesia, even in most children.^{10,13} The success rate of flexible endoscopy in patients with retained esophageal FBs exceeds 96%.^{10,50}

Traditionally, esophagoscopy is up to 10 times more expensive than other maneuvers, such as Foley catheter removal or esophageal bougienage (described later),^{17,50–53} largely because of charges for the surgical suite, but it has a higher success rate than the other two techniques. ED removal of esophageal FBs in children by experienced endoscopists, while the child is under conscious or deep sedation administered by the emergency provider, has been described.⁵⁴ In selected cases this approach can shorten the interval to completion of the procedure and reduce expense.

ESOPHAGEAL PHARMACOLOGIC MANEUVERS

Background

As the LES is the narrowest portion of the entire GI tract, most FBs that reach the stomach eventually move through the GI tract without further problems. Because a large number of entrapped esophageal FBs are lodged at the LES, especially in adults, several therapeutic maneuvers have been proposed to assist transit into the stomach, including pharmacologic relaxation of the LES. In theory, agents that promote smooth muscle relaxation should improve mobility through the LES. Although many clinicians use pharmacologic adjuncts for all esophageal FBs, objects lodged at the LES will probably benefit most from such interventions. Nonspecific pain relief, anxiolysis, vomiting, and spontaneous passage over time may account for the success attributed to many pharmacologic manipulations of esophageal FBs as there is little scientific evidence that any of these agents offer any benefit over placebo.

Indications and Contraindications

The indication for pharmacologic relaxation of the LES is the presence of a smooth or blunt FB such as a coin or food bolus. Angulated, abrasive, or sharp FBs should not be treated with pharmacologic modalities but instead should be removed by esophagoscopy. Analgesics and sedatives are routinely indicated if pain is present or the patient is excessively anxious.

Glucagon

Pharmacology

Glucagon was historically a prototype for the spasmolytic agents. Glucagon theoretically relaxes esophageal smooth muscle and decreases LES resting pressure. Glucagon has no effect on the upper third of the esophagus, a common site of coin impaction in children, where striated muscle is present and some voluntary control is operative. It only minimally affects the middle third of the esophagus. Peristalsis is not affected by glucagon. Results with glucagon have been mixed, and the only randomized study, done in children, showed no better results than those achieved with placebo.⁵⁵ Nonrandomized studies in adults showed that glucagon is approximately equivalent to placebo, with a 33% success rate.^{56,57} A meta-analysis has also shown no benefit over placebo.⁵⁸ However, its use is still advocated by some authorities such as the American Society for Gastrointestinal Endoscopy²⁰ “as an acceptable option” as long as it does not “delay definitive endoscopic removal of a food impaction.” Likewise, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition has stated that glucagon “may be considered in patients with distal esophageal impactions” or in “facilities where endoscopic care is not readily available.”¹⁰ As glucagon has little downside and emergency providers may be asked to administer it by their consultants for esophageal food impactions, it is reasonable to understand its use despite lack of scientific evidence for efficacy.

Indications and Contraindications

Glucagon is used for smooth FBs or food impactions at the LES that are suspected because of a patient’s complaint of pain or “something stuck” in the lower part of the chest or epigastrium. The clinical diagnosis is usually straightforward, especially if complete esophageal obstruction is present and the patient is unable to tolerate oral secretions. Glucagon is

not effective in relieving upper and middle esophageal obstruction, and it is not widely recommended for use in children. In addition, glucagon is not usually effective in patients with fixed fibrotic strictures or rings at the gastroesophageal junction. Glucagon is contraindicated if the patient has an insulinoma, pheochromocytoma, Zollinger-Ellison syndrome, hypersensitivity to glucagon, or a sharp esophageal FB.

Administration of Glucagon

The therapeutic dose is 0.25 to 2 mg administered intravenously (Table 39.3) over a period of 1 to 2 minutes in a seated patient, although one study found that in normal subjects 1 mg of glucagon provides no significant additive benefit over 0.5 mg. The patient is given water orally within 1 minute after the injection of glucagon to stimulate normal esophageal peristalsis; this helps push the food through the relaxed LES into the stomach. Glucagon has a rapid onset and short duration of action: GI smooth muscle relaxes within 45 seconds, and its duration of action is approximately 25 minutes. If no results are seen within 10 to 20 minutes, a second administration of 0.25 to 2 mg may be tried. Success rates are higher when glucagon is combined with gas-forming agents or even carbonated beverages.^{59,60} It is recommended that a small volume of some oral fluid be routinely given to enhance the activity of glucagon.

Complications

Glucagon is associated with a few minor side effects. If administered too rapidly, it causes nausea and vomiting. Therefore adult patients must be alert and mobile enough to avoid aspiration. Occasionally vomiting dislodges the impacted food bolus. Theoretically, there is a risk for rupture of the obstructed esophagus during induced emesis, so slow injection is preferred to minimize this side effect.

Administration of glucagon is also associated with dizziness. Mild elevation of blood glucose levels is also common but not

TABLE 39.3 Recommended Pharmacologic Therapies for Esophageal FBs

CLASS AND AGENTS	SITE OF ACTION	DOSE AND ROUTE	ADVERSE EFFECTS
Spasmolytics			
Glucagon	LES	1–2 mg IV ^a	Nausea, vomiting, hyperglycemia, hypersensitivity
Nitroglycerin	Body and LES	0.4–0.8 mg SL ^b	Hypotension, tachycardia, bradycardia
Nifedipine	LES	5–10 mg SL ^c	Hypotension, tachycardia <i>Use with caution</i>
Gas-Forming Agents			
Tartaric acid	Distal and proximal	15 mL tartaric acid (18–20 g/100 mL) ^d	Vomiting, increased intraesophageal pressure
Sodium bicarbonate	Distal and proximal	15 mL sodium bicarbonate (10 g/100 mL) ^d	Vomiting
Carbonated beverage	Distal and proximal	100 mL PO	Increased intraesophageal pressure

^aMay be repeated once or used in conjunction with nitroglycerin.

^bOne to 2 inches of nitroglycerin paste applied under an occlusive dressing may be an alternative.

^cA capsule is punctured, chewed, held in the mouth for 3 minutes, and then swallowed. Because of *hypotension*, a 5-mg dose may be used in the elderly. *Do not use if the patient has cardiovascular disease, is hypotensive, or has also recently been given nitroglycerin.*

^dAlternatively, dissolve 2 to 3 g tartaric acid and 2 to 3 g sodium bicarbonate in 30 mL water.

FB, Foreign body; IV, intravenously; LES, lower esophageal sphincter; PO, per os (orally); SL, sublingually.

of clinical concern, and blood glucose levels do not need to be monitored. No fatalities have been reported. Although theoretically glucagon can stimulate release of catecholamine in patients with pheochromocytoma and can induce hypoglycemia from reflex release of insulin with an insulinoma, these endocrine tumors are rare. Nonetheless, precipitation of either profound catecholamine or insulin reactions with the use of glucagon should direct a workup for these underlying tumors.

Further Evaluation and Therapy

If the patient experiences relief of symptoms after the administration of glucagon, a postprocedure radiograph or contrast-enhanced study may be obtained to confirm passage of a radiopaque object, but this is not mandatory (Fig. 39.9). Adult patients with successful FB passage into the stomach may also be discharged home, but careful follow-up should be obtained to rule out coexistent esophageal pathology because a significant number of patients (65% to 80%) will have underlying esophageal disorders.¹⁵ Pediatric patients with food boluses lodged in the esophagus also have a high rate of underlying esophageal disease and need referral for further evaluation; this is not the case for accidentally swallowed FBs in children.^{10,12} If glucagon fails to produce relief of the symptoms or resolve

Figure 39.9 This patient had meat impacted in the distal end of the esophagus, which is clearly visible on the “before” contrast-enhanced esophagogram (arrow). He was treated successfully with simultaneous administration of glucagon and an effervescent sodium bicarbonate drink. On the “after” esophagogram, the contrast material can be seen flowing down the distal end of the esophagus and into the stomach (arrows). (Note: Gastrografin contrast medium was used in this study.) This patient will require endoscopy post removal to evaluate for underlying esophageal disease.

the radiograph findings, its use does not preclude other methods from being used.

Nitroglycerin and Nifedipine Pharmacology

Both sublingual nitroglycerin and nifedipine have been used in a manner similar to glucagon to relieve LES tone and allow the passage of a distal esophageal FB.⁶¹ Although these two agents have been used less than glucagon for the treatment of esophageal FBs, both are useful for the relief of chest pain associated with esophageal smooth muscle spasm and may be administered concurrently with glucagon. Nifedipine, conversely, significantly reduces LES pressure without changing contraction amplitudes in the body of the esophagus. Thus nitroglycerin may relieve partial or complete obstruction of the middle or lower part of the esophagus secondary either to intrinsic esophageal disease or to simple FB impaction; and nifedipine, like glucagon, is most likely to succeed when the bolus is lodged at the gastroesophageal junction.

Indications and Contraindications

Similar to clinical indications for the use of glucagon, any patient with an impacted smooth esophageal FB, especially a food bolus, may be a candidate for nitroglycerin or nifedipine (or both). In addition, similar to the mode of action of glucagon, neither of these agents is expected to relax a fixed fibrotic stricture or ring at the gastroesophageal junction.⁶² Nevertheless, because both agents have a relatively benign side effect profile, if the patient has no contraindication to their use, they may be tried with or without previous documentation of the distal esophageal obstruction with a contrast-enhanced study. Contraindications to their use include a history of allergic reactions, a sharp esophageal FB, hypovolemia, and hypertension.

Use and Complications

Doses of 1 or 2 (0.4 mg) sublingual nitroglycerin tablets, 1 to 2 inches of nitroglycerin paste, or 5 to 10 mg of nifedipine have been reported.⁶¹ Some patients with esophageal FBs may have some degree of dehydration because of the inability to swallow liquids or their own saliva. These patients may be prone to hypotension from the vasodilation associated with the use of either agent. Ideally, rehydration should precede therapy with these agents. *Do not* use both agents simultaneously. The smaller dose of nifedipine is suggested in the elderly or those with cardiovascular disease.

Further Evaluation and Therapy

As with the use of glucagon, if nitrate therapy fails to produce relief of the symptoms or resolve the radiographic findings, its use does not preclude trying another method. If a patient experiences symptomatic relief, a postprocedure radiograph may be obtained to confirm passage of a radiopaque object, but this is not mandatory. Adult patients may be discharged home, but careful follow-up should be obtained to rule out coexistent esophageal pathology because a significant number of patients will have underlying esophageal disorders.

Gas-Forming Agents

Pharmacology

The use of gas-forming agents for the treatment of distal esophageal food impaction, especially meat boluses, was first described in 1983.⁶³ The combination of tartaric acid solution

followed immediately by a solution of sodium bicarbonate or even carbonated beverages has been reported. In theory, use of this acid-base mixture or a carbonated beverage may produce sufficient carbon dioxide to distend the esophagus, relax the LES, and push impacted food through the gastroesophageal junction into the stomach.⁶⁴

Indications and Contraindications

Gas-forming agents are indicated for the relief of smooth distal esophageal FB impaction, with or without prior FB confirmation by a radiographic study (see Fig. 39.9). They are often given to patients with food impaction or retained coins. Although gas-forming agents are more likely to succeed with distal esophageal impactions, they have also been successful in relieving obstructions in the proximal part of the esophagus. Concurrent administration of spasmolytic agents may improve the effectiveness of gas-forming agents.

Use and Complications

A solution of 15 mL of tartaric acid (18.7 g/100 mL), followed by 15 mL of a sodium bicarbonate solution (10 g/100 mL), or 1.5 to 3 g of tartaric acid and 2 to 3 g of sodium bicarbonate dissolved in 15 mL of water can be used.⁶⁵ Carbonated beverages (100 mL) have also been successful in the transit of FBs into the stomach⁶⁴ and are more readily available in the ED. Many patients with esophageal FB impaction have been noted to retch after receiving gas-forming agents, which theoretically puts patients at risk for esophageal trauma, including rupture. Gas-forming agents should not be given to patients with impactions of greater than 6 hours' duration, or to patients with chest pain that might be indicative of an esophageal injury.

Further Evaluation and Therapy

As with the use of glucagon, nitroglycerin, or nifedipine, even if administration of the gas-forming agent is successful, as judged by relief of symptoms, follow-up evaluation is necessary to determine the underlying esophageal abnormality that potentially led to the FB impaction.

Papain

The use of papain, a proteolytic enzyme used commercially as a meat tenderizer, is NOT recommended for treatment of an esophageal food FB. The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition states that it "is contraindicated."¹⁰ Papain is not currently recommended because of the unacceptable risk for complications and the availability of safer, more effective interventions. It has been associated with esophageal injuries, pulmonary edema, and hemorrhages.⁶⁵ There is one published report of a retrospective series with no complications from using this agent,⁶⁶ but the preponderance of data and expert opinion would weigh against its use in the ED.

REMOVAL OF ESOPHAGEAL FBs IN THE ED

In the United States the most prevalent method for removing FBs lodged in the esophagus is referral for removal under direct visualization via endoscopy, normally done in either an endoscopy suite or operating room under sedation. Endoscopy is costly^{17,50,51,53,67} and time-consuming, and if the patient is being seen after hours, the procedure requires additional personnel to come into the hospital to care for the patient.

With procedural sedation becoming more common in EDs, procedures to remove lodged esophageal FBs, when appropriate, are becoming more common. Currently three procedures are used in the ED to remove FBs lodged in the esophagus, and these are somewhat dependent on the type and location of the FB. These procedures include Magill forceps removal, Foley catheter removal, and esophageal bougienage. Each will be described separately. Another strategy, "watchful waiting," is reserved for single, smooth, asymptomatic FBs (usually coins) typically at the LES in children and will also be discussed.

Magill Forceps Removal of Esophageal FBs

Background

In children, the most common accidentally ingested FB is a coin, and the most common location for the FB to be lodged is at the cricopharyngeus muscle (Fig. 39.10). Given these facts, when children have a single coin at the level of the cricopharyngeus muscle confirmed by radiographs, they are candidates for Magill forceps removal. The procedure requires sedation (see Chapter 33), and thus all airway equipment must be available, in addition to monitoring equipment and expertise in its use. In centers that are using this procedure, success rates have ranged from 95% to 100%.⁶⁸⁻⁷¹ All centers reporting this procedure used sedation and visualization with a laryngoscope or video-assisted system. The procedure was performed rapidly, usually in less than a minute.^{68,71} Complications were rare and typically consisted of minor bleeding or vomiting. In the one center that intubated patients before the procedure, complications were higher and associated with the intubation.⁷⁰ Magill forceps removal seems to be ideally indicated for stable children with a coin at the cricopharyngeus muscle in a facility that is well equipped and staffed and experienced in managing procedural sedation and airways in children.

Figure 39.10 A coin lodged at the level of the cricopharyngeus muscle in a 2-year-old toddler.

Procedure (Fig. 39.11)

1. Ensure that adequate procedural sedation and appropriate monitoring are both implemented (refer to [Chapter 33](#)). Place the patient supine on the stretcher with the head slightly extended in the “sniffing position.”
2. Insert the laryngoscope or video-assisted laryngoscope. Suction as necessary.
3. Visualize the upper part of the esophagus, where the FB is normally lodged.
4. Grasp the FB with the Magill forceps and then slowly remove it.
5. Visualize the esophagus after removal for any injuries such as erosion or bleeding.
6. Recover the patient from procedural sedation.

Aftercare

No specific aftercare is necessary if no complications have occurred from the procedure. If there is any evidence of esophageal injury, the patient needs to be referred to gastroenterology immediately. Children who ingest FBs are at risk for future ingestions, with the “repeat offender” rate being as high as 18% to 20%.³³

Foley Catheter Removal of Esophageal FBs**Background**

Foley catheter removal of esophageal FBs was first described in the thoracic surgery literature in 1966⁷² and in the emergency medicine literature in 1981.⁷³ The technique has essentially been unchanged since the first reports and is now used by emergency providers, radiologists, otolaryngologists, and general surgeons.^{74–77} The classic patient for this technique is a small child who is brought to the hospital shortly after swallowing a coin that is documented by radiography, but the procedure may be used for a wide variety of smooth FBs in patients of all ages. Success rates for Foley catheter removal of FBs have been cited from 85% to 100%, with complication rates of 0% to 2%.^{75,77–80} Many of the reported complications were caused by nasal insertion of the catheter, and complication rates are lower when the catheter is inserted orally and at centers that perform the procedure frequently. Foley catheter extraction of FBs costs significantly less than endoscopy.^{17,67} Fluoroscopic assistance may be preferable, but it is not essential. Whether the procedure is performed in the ED or the radiology department, equipment and personnel

Magill Forceps Removal of Esophageal Foreign Body

1

Ensure that adequate procedural sedation and appropriate monitoring are implemented. Place the patient in the supine position with the head slightly extended in the “sniffing position.”

2

Insert the laryngoscope or video-assisted laryngoscope. Suction as necessary. Visualize the upper part of the esophagus, where the foreign body is normally lodged.

3

Grasp the foreign body with the Magill forceps, and then slowly remove the foreign body.

4

After removal, visualize the esophagus for any injury such as erosion or bleeding. Recover the patient from procedural sedation.

Figure 39.11 Removal of an esophageal foreign body with Magill forceps.

capable of emergency pediatric airway management must be present.

Indications

Recently ingested smooth, blunt objects that are radiographically opaque are most suitable for balloon catheter extraction. Recently ingested FBs carry little likelihood of causing pressure necrosis, perforation, or other significant injury; however, 24 to 48 hours' duration of impaction should be the upper limit for consideration of this technique.^{32,67}

Coins are particularly amenable to Foley manipulation, but food boluses and button batteries have also been extracted successfully.⁷³ Radiographically opaque objects are most easily located with plain radiographs. Radiolucent objects can be manipulated, but uncertainty about location mandates contrast-enhanced esophagography.

Contraindications

Contraindications to catheter removal of esophageal FBs include total esophageal obstruction, as manifested by an air-fluid level on a plain radiograph or contrast-enhanced esophagogram or when patients are unable to handle oral secretions. The presence of a total obstruction prevents passage of the tip of the catheter

distal to the FB. Esophageal perforation and airway distress, as recognized by the typical symptoms and signs, require immediate surgical consultation and preclude blind esophageal manipulation. The presence of multiple esophageal FBs also precludes use of the Foley catheter. Sharp, irregularly shaped FBs should not be removed with this technique because esophageal perforation or laceration can result, and the balloon may burst during the procedure. Finally, lack of expertise or equipment to handle an airway problem arising during the procedure is a contraindication.

Procedure (Fig. 39.12)

1. Coach the patient on the procedure. Topical oropharyngeal anesthesia may be used (although this increases the risk for aspiration). Light sedation may be used.
2. Place the patient in the Trendelenburg, lateral decubitus, or prone position.
3. Insert an uninflated catheter (10 to 16 Fr in children) so that the tip is past the FB (as visualized on fluoroscopy or as estimated on radiographs).
4. Fill the catheter balloon slowly with 3 to 5 mL of saline or contrast material (if fluoroscopy is used). Stop inflating the balloon if the patient complains of increased pain.

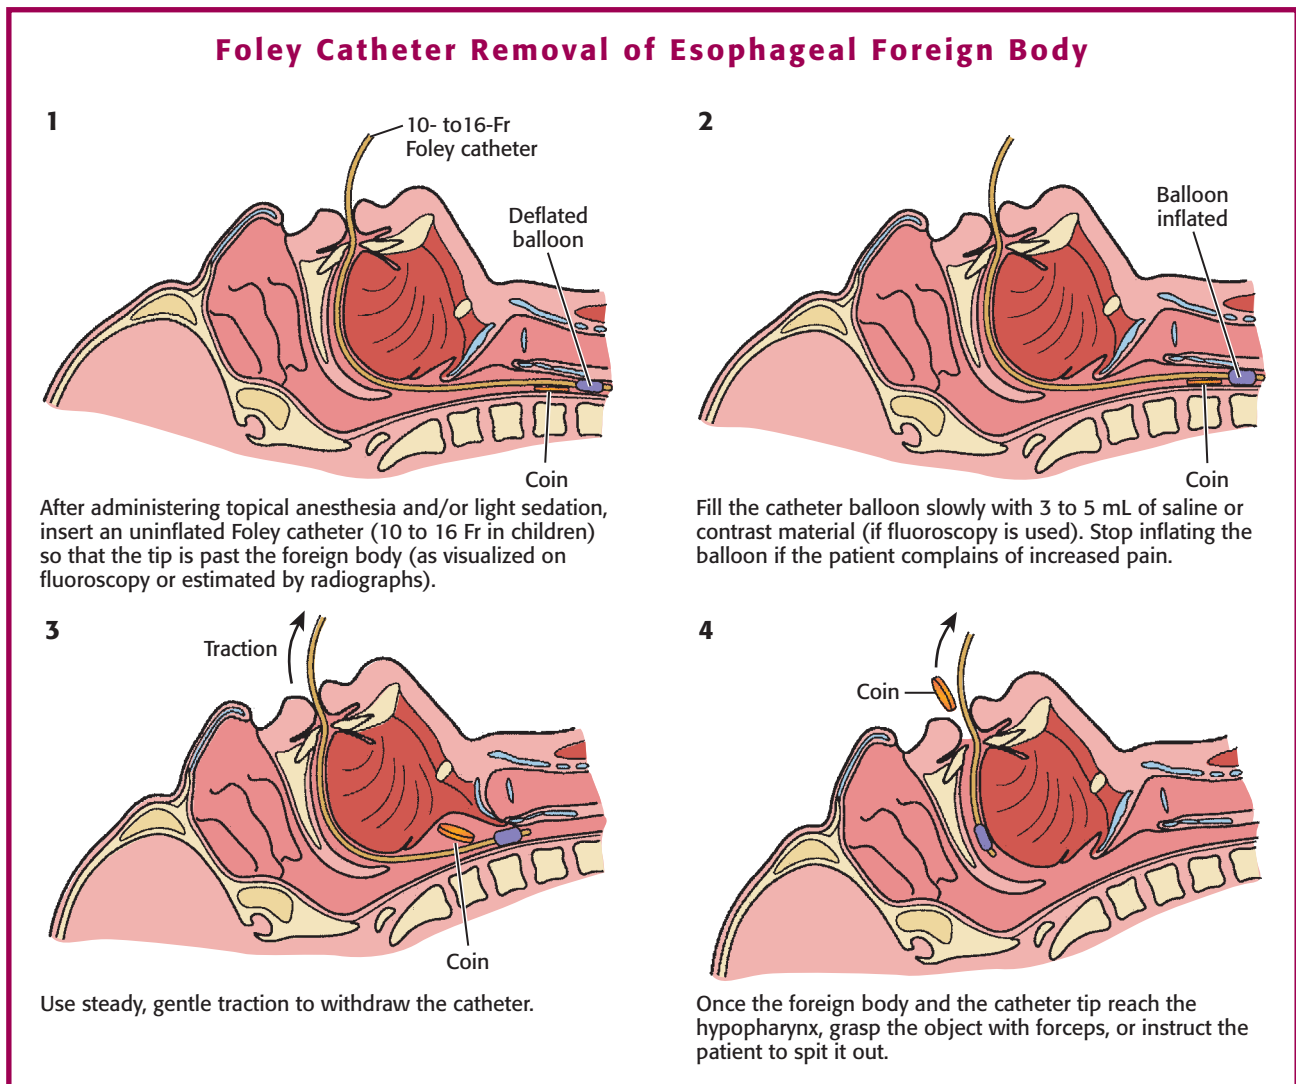

Figure 39.12 Removal of an esophageal foreign body with a Foley catheter.

5. Use steady, gentle traction to withdraw the catheter.
6. Once the FB and the tip of the catheter reach the hypopharynx, grasp the object with forceps, or instruct the patient to spit it out.
7. Obtain another radiograph to ensure that multiple FBs were not present.
8. If the catheter slips by the FB, reinsert the catheter, inflate it with an additional 2 to 3 mL of fluid, and make one additional attempt at withdrawal.
9. If fluoroscopy is not used and no FB is retrieved, another radiograph should be obtained because 10% to 20% of the time the FB will pass distally into the stomach.

Complications

Complication rates of 0% to 2% have been reported.^{75,77–81} Many complications (nosebleeds or displacement of the FB into the nose) have been related to nasal insertion of the catheter. Complication rates are lower when the catheter is inserted orally and generally lower at centers that perform the procedure frequently. No deaths have been reported. Laryngospasm and aspiration are rare complications. Failure to either remove the object or displace it into the stomach occurs in approximately 2% to 10% of carefully selected patients,^{75,79,80} but success rates are lower in adults or patients with underlying esophageal disorders.⁸⁰

Aftercare

Children who have an FB removed successfully with a Foley catheter need no further follow-up if they remain asymptomatic. If the FB was moved into the stomach, clinical follow-up should be adequate to verify movement of gastric FBs through the alimentary tract. Discharge instructions should include warnings about the potential symptoms of GI obstruction, perforation, and hemorrhage. Parents of children who swallow coins can be instructed to watch for coins in their stool. Adults with esophageal FBs that have been removed successfully must be referred for evaluation of possible esophageal pathology, as should children with food impactions. Should an FB remain lodged in the esophagus, immediate referral for endoscopy is necessary.

Esophageal Bougienage

Background

Displacement of esophageal FBs into the stomach can be done with nasogastric or orogastric tubes or via esophageal bougienage. Esophageal bougienage is a technique for dislodging impacted esophageal coins by blind mechanical advancement of the coin into the stomach, a procedure first described in 1965.⁸² The technique has greater than a 95% success rate with essentially no reported complications when used for the proper indications.^{50–53,81,83,84} Rates as high as those with endoscopy have been reported.^{67,83} Furthermore, bougienage is unrivaled in overall cost-effectiveness because it is approximately 10% of the cost of endoscopic removal.^{50–53}

This technique does not allow visualization of the esophagus or retrieval of the object. There have traditionally been warnings against forceful advancement of esophageal FBs, but growing evidence verifies the efficacy and safety of blind esophageal bougienage as first-line therapy for coin ingestions in properly selected patients. Although early articles suggested that esophageal bougienage should be performed exclusively by pediatric surgeons, the technique is easily mastered and used by emergency clinicians.^{50,51,53,83,84}

Indications and Contraindications

Strict patient selection is paramount for successful and uncomplicated bougienage. The criteria have changed little since initially proposed and define a group in whom a round, smooth object can be forcibly passed into the stomach with little risk.^{50,51} Although many swallowed objects meet this description, only coins hold clear supportive evidence in the literature. Because many patients with impacted food or meat have underlying esophageal pathology, we do not suggest that it be used in the ED for this condition. Selection criteria are the following: a single, smooth FB lodged less than 24 hours in a patient with no respiratory distress or history of esophageal disease, including previous FBs, or surgery. The FB should be likely to pass beyond the stomach without complications. The procedure is contraindicated in patients who do not satisfy all the criteria. It is important to ascertain the duration of esophageal impaction to avoid performing the procedure when there may be underlying esophageal injury. Plain radiographs are indicated to verify coin location and the absence of multiple esophageal bodies. Preprocedure esophagograms are not required.

Procedure (Fig. 39.13)

1. Coach the patient (and parents) on the procedure. Place the patient in an upright position.
2. Achieve topical anesthesia with gargled 2% to 4% viscous lidocaine, atomized 2% lidocaine, or topical benzocaine spray.
3. Flex the patient's head, open the mouth, and ask the patient to protrude the tongue. Use a tongue blade if necessary. In some patients a bite block may be needed; several tongue blades can be taped together for this purpose.
4. Pass a well-lubricated, appropriately sized bougie (Table 39.4) posteriorly along the roof of the mouth and caudally to the hypopharynx.
5. The patient may gag momentarily; ask the patient to swallow and gently pass the dilator past the cricopharyngeus muscle.
6. Ask the patient to phonate while passing the bougie at this point.
7. Once past the cricopharyngeus, extend the head to enable the bougie to pass distally to the stomach with little resistance.
8. Withdraw the bougie after a single pass.
9. Terminate the procedure immediately if pain or resistance to advancement is encountered.
10. Obtain a postprocedure x-ray to ascertain passage of the coin into the stomach.

Complications

Gagging and self-limited nonbloody vomiting are not uncommon after the procedure and may reveal the dislodged coin. Patients may experience a residual FB sensation for several hours. Pulmonary aspiration and inadvertent passage into the airway are potential complications. Likewise, traumatic pharyngeal and esophageal injury, ranging from mild self-limited bleeding to frank esophageal perforation with concomitant infection, are possible but rare.

Aftercare

Plain radiographs of the chest and abdomen are indicated to verify passage of the FB into the stomach and to check for any potential complications. Discharge asymptomatic patients with appropriate precautions, including the need to return if

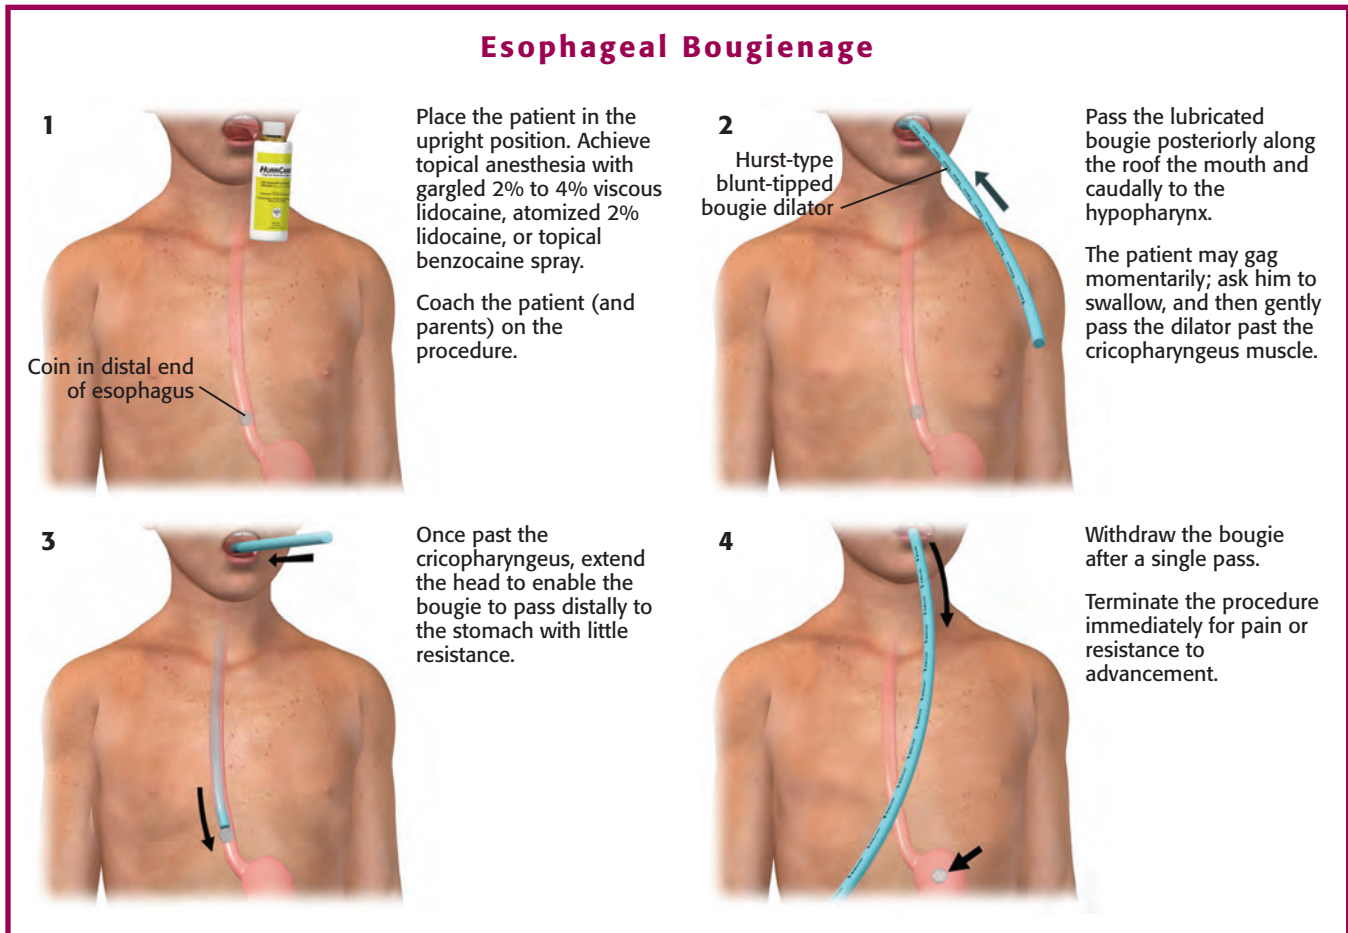

Figure 39.13 Esophageal bougienage.

TABLE 39.4 Hurst Dilator Size by Age for Esophageal Bougienage⁵⁰

PATIENT AGE	HURST DILATOR SIZE
1 to 2 years	28 F
2 to 3 years	32 F
3 to 4 years	36 F
4 to 5 years	38 F
5 years or older	40 F

signs of respiratory compromise, chest or abdominal pain, dysphagia, hematemesis, persistent vomiting, or other concerns are present. Follow-up abdominal radiographs may be performed to document passage of the coin if it is not identified in feces within 1 week.

SPECIAL SITUATIONS

Childhood Coin Ingestion

Coins are the most commonly ingested objects by preschool-age children. In most cases the ingestion is quickly realized by a

caretaker, and in the majority of cases the coins pass uneventfully.⁸⁵ Rarely, an esophageal coin can be clandestine for many weeks or months and produce a variety of vague respiratory or GI symptoms.⁸⁶ In addition, many coin ingestions are not witnessed,³⁵ so maintain a high index of suspicion for children with dysphagia, drooling, or crying, who may have esophageal FBs, most likely coins.

Most coins pass from the esophagus to the stomach with only transient symptoms. The child may be in pain for a few minutes as the coin migrates, but on arrival at the ED, the child is often asymptomatic. Coins that remain in the esophagus are likely to, but do not always, produce continued symptoms (e.g., drooling, pain, dysphagia, and refusal to eat or drink). Rarely, esophageal coins can cause airway distress by external compression of the trachea and simulate an asthmatic attack. Coins below the diaphragm are asymptomatic, and the presence of pain or symptoms requires further evaluation. Coins in the trachea produce immediate and obvious respiratory distress.

Although up to 44% of children with esophageal coins may be asymptomatic, and up to two thirds of coins will be in the stomach at the time of ED evaluation, it is prudent to obtain plain radiographs in all children with a suggestive history.³⁴ In most cases a single film that includes the pharynx, esophagus, and stomach will suffice to prove or exclude an ingested coin (Fig. 39.14). Another advantage of obtaining radiographs is to rule out multiple FB ingestions, which are not uncommon in children.⁸⁷ Only a single PA chest film is needed to prove

Figure 39.14 For children who are suspected of having ingested a coin, a single radiograph that includes the pharynx, esophagus, and stomach will usually suffice to prove or exclude an ingestion. Here, the child swallowed a souvenir penny, which is seen in the region of the aortic crossover.

the presence of a coin, but a lateral projection is also suggested. If the flat surface of the coin is seen (see Figs. 39.2 to 39.4), this orientation ensures an esophageal position. If the edge of the coin is seen, this orientation suggests that it has traversed the vocal cords, but a coin in the airway is not subtle and produces obvious distress. It is advisable to also routinely obtain a lateral radiograph to determine whether multiple coins are stacked on top of each other (Fig. 39.15).

Once a coin's presence has been documented, a decision concerning removal must be made. The approach varies and there is no agreed standard. Overall, approximately 25% of coins will pass spontaneously, even if the coin is located proximally. Observation for 8 to 16 hours is a reasonable approach for asymptomatic children if the ingestion has taken place within 24 hours. Coins in the upper and middle third of the esophagus are less likely to pass spontaneously, and some prefer to remove them as soon as the diagnosis is made.¹⁹ Coins in the distal end of the esophagus will pass spontaneously in one third to one half of patients within 24 hours.^{34,88,89}

The decision regarding management of these patients depends on various factors: clinician comfort and experience with removal techniques, local protocols and procedures developed by the medical staff of each institution, and comfort level of the caretakers with various therapeutic options. Regardless of the approach, a radiograph should be taken just before removal to ensure that spontaneous passage has not occurred.

One suggested protocol (Fig. 39.16) involves radiologically localizing the coin, and if the child is symptomatic, immediately

removing the coin. If the patient is asymptomatic, the coin may be removed immediately, or the patient may be observed either as an inpatient or at home. If the child is asymptomatic, one common practice is to allow the child to drink a carbonated beverage and eat a small amount of soft food in the ED, wait approximately 1 to 2 hours, and obtain another radiograph. If sent home with an asymptomatic retained FB, the patient is allowed to eat or drink but should be rechecked in 12 to 24 hours with the knowledge that up to 50% of asymptomatic coin FBs will pass into the stomach spontaneously.^{19,34,90} Both the American Society for Gastrointestinal Endoscopy and the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition recommendations for impacted esophageal coins in children state that asymptomatic coins in the esophagus may be observed up to 24 hours before removal.^{10,20}

The techniques of Magill forceps removal, esophageal bougienage, and Foley catheter removal have been described earlier. All are options for single coins present in the esophagus for less than 24 to 48 hours. Another option for coins impacted at the LES is pharmacologic relaxation of the sphincter to aid passage into the stomach, although scientific evidence for efficacy is lacking. The most common method to remove esophageal coins in use today is esophagoscopy.

Approximately two thirds of ingested coins are in the stomach at the time of first investigation, and such patients can be released home safely to allow almost certain spontaneous passage with a normal diet. Spontaneous passage of a coin from the stomach to the anus usually requires 3 to 7 days. There is no need for routine cathartic use. Parents should be advised to check the stool for the coin and return for repeated radiographs if the coin is not found in 1 to 2 weeks. Most coins are passed unknowingly by the patient. Any abdominal discomfort or distention warrants reevaluation in the ED. If a follow-up radiograph demonstrates a persistent coin in the intestines for more than 3 to 4 weeks, an obstructive lesion may be present, and further evaluation is warranted.

Finally, there are theoretical concerns about US pennies, which contain 97.5% zinc. Theoretically zinc can lead to mucosal ulceration from its caustic nature⁹¹; however, the evidence to date suggests no increased risk from ingested pennies.⁹²

Fish or Chicken Bones in the Throat

Patients who complain of a “bone” in their throat usually arrive at the ED within several hours of the onset of symptoms, and have generally tried a home remedy such as swallowing a piece of bread. These patients are typically able to pinpoint the location of their discomfort and have an FB sensation that is exacerbated by swallowing. Patients who are markedly symptomatic, vomiting, or unable to swallow require definitive therapy. Those with minor complaints may be evaluated safely over a period of a few days, often as outpatients.

In cooperative patients, careful examination of the oropharynx should be done by either direct or indirect laryngoscopy, or both. If the bone is seen, it should be removed with forceps.

If the patient feels pain in the upper part of the throat, special attention is directed to the tonsils because bones often lodge in this area (Fig. 39.17). Strands of saliva may mimic a bone, and small bones may be difficult to see. More commonly, the area of complaint is below the oropharynx. In these patients, indirect laryngoscopy or nasopharyngoscopy should be the

Figure 39.15 **A**, Lateral radiograph of a child showing *four stacked coins* at the same location. A posteroanterior (PA) view suggested a single coin. Multiple swallowed coins are common in children. It is important to obtain both PA and lateral films to ascertain the exact number and location of swallowed coins. **B**, A single coin was seen on the PA chest film, but this lateral film suggests *three coins*. However, they do not seem to be stacked directly on top of each other. This digital radiograph was accidentally exposed three times; in fact, only one coin was swallowed and x-rayed three times during minimal movement.

first step, once again removing the bone if one is seen. This can also be accomplished with local oropharyngeal anesthesia by topical spray and direct visualization with a laryngoscope blade or commercial videoscope blade, and then removal of any bone with forceps.

Most patients with an oropharyngeal FB will not have an easily identified or visualized object on examination. These patients present a diagnostic dilemma for several reasons. Only 17% to 25% of patients complaining of an FB sensation after eating chicken or fish have an endoscopically proven bone present, and only 29% to 50% of endoscopically proven bones are seen on plain films.^{38,41,42,46,93,94} The symptoms in patients with an FB sensation but no FB on endoscopy are believed to be caused by esophageal abrasions.

For these reasons, a two-tiered, but individualized approach to managing these patients is proposed.³³ The patient receives a physical examination and the bone is removed if seen. Carefully examine the tonsils, posterior pharynx, and base of the tongue, which are common places for bones to lodge. If the bone is removed and the symptoms disappear, no further intervention is required and follow-up is instituted as needed. Removal of a bone usually provides immediate and complete relief of symptoms. Persistent symptoms are cause for further evaluation based on individual circumstances.

If no bone is seen on physical examination, the bone may have passed after causing local irritation that persists, or the bone is present and not visualized because of location or consistency. Minor symptoms in the upper part of the throat probably represent persistent local irritation. Minimally symptomatic patients can be discharged and reevaluated in 24 hours. Those with complaints of an FB below the visualized pharynx, or with very bothersome persistent symptoms, should be evaluated with a CT scan of the neck or possibly the chest if the symptoms are distal. Positive scans are an indication for endoscopic removal of the bone. If the CT scan reveals no FB or postbone complication and the patient is stable, the patient is discharged home with follow-up within 24 hours. Patients with oropharyngeal abrasions will usually be asymptomatic at that time. If still symptomatic on follow-up, endoscopy is advocated.

A small bone lodged in the esophagus for a few days is annoying and painful, but it is not generally an emergency. However, impacted bones can cause serious sequelae, often weeks later, and continued complaints cannot be ignored. Importantly, a lodged bone will not dissolve and rarely passes spontaneously once lodged in the mucosa. Referral and possible endoscopy are necessary if complaints persist for more than 2 to 3 days, even if the examination and CT scan are negative.

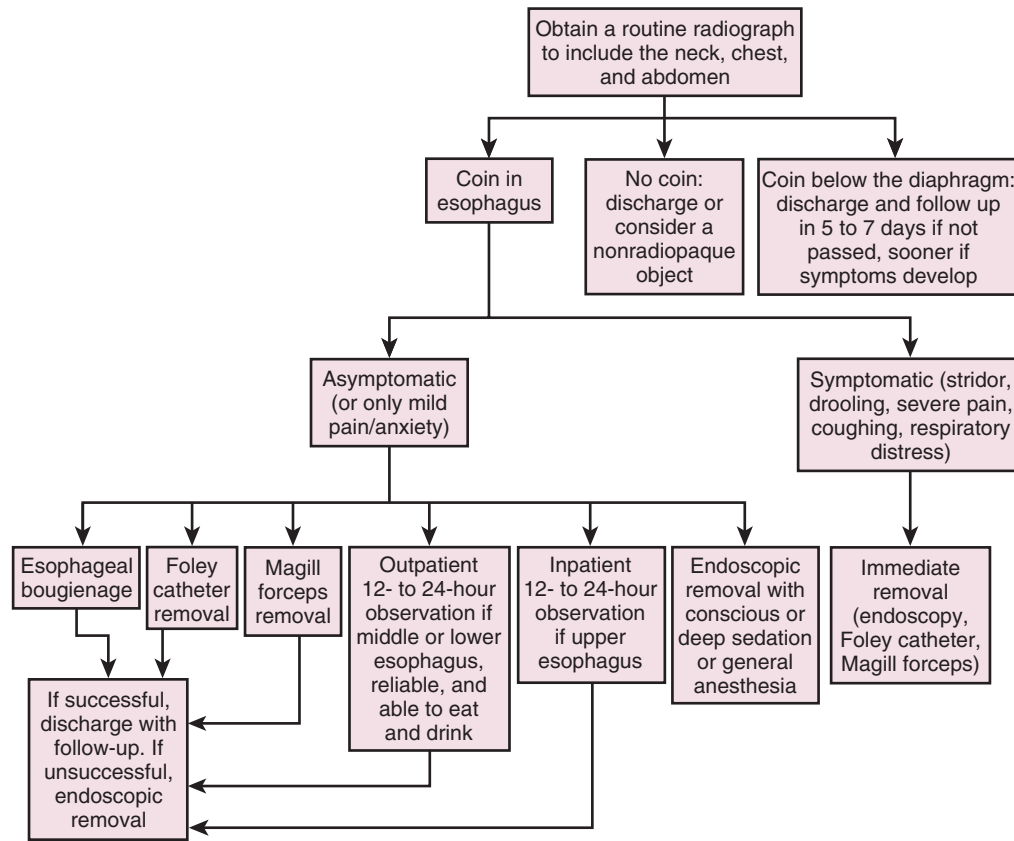

Figure 39.16 Flow diagram outlining an approach to the management of swallowed coins.

Sharp Objects in the Esophagus

Sharp objects cause the majority of complications seen in patients with esophageal FBs. Such objects include tacks, pins, open paper clips, bobby pins, toothpicks, and razor blades (Fig. 39.18). They will not usually pass spontaneously and should be removed urgently. The only appropriate removal technique is under direct visualization with endoscopy. Swallowed dentures or partial plates are a particular hazard in elderly, demented, or mentally challenged patients. Frequently there is no history of such, and patients have a variety of complaints, such as a sore throat or persistent vomiting (Fig. 39.19). Prisoners and psychotic patients are well known to clandestinely swallow multiple bizarre and sharp objects.

Attempts at radiographic localization are appropriate for metallic or radiopaque FBs. Most objects in the stomach, even those considered problematic, will transit the remainder of the GI tract if less than 6 cm in length or 2.5 cm in diameter. If larger than this, consult a gastroenterologist (see Table 39.2). If radiographs show the FB in the esophagus, endoscopic removal is indicated, and attempts to remove such objects in the ED by other methods are not indicated.

Nonradiopaque Objects in the Esophagus

Objects such as toothpicks, aluminum pull tabs from beverage cans, plastic, and food boluses cannot be visualized on plain radiographs and will normally not pass spontaneously. Toothpicks cause a higher percentage of complications than any other type of esophageal FB. As with fish bones, toothpicks

often lodge in the tonsils or posterior pharynx and can be seen on direct vision. The imaging modality of choice is CT. Removal is mandatory and time-sensitive for sharp objects, especially toothpicks.

Impacted Food Bolus

A large bolus of food may become impacted in the esophagus, usually at the LES. This occurs most frequently in the elderly, those intoxicated while eating, or those with dentures. Frequently, underlying esophageal pathology is present such as a stricture or web, even in the young (see Fig. 39.6). Children with an impacted food bolus often have underlying esophageal pathology, and it may occur following prior surgery for congenital esophageal malformations. The diagnosis is usually straightforward, and patients may be in significant distress, gagging, and unable to swallow. A barium swallow may be used to confirm the diagnosis, but this is rarely necessary and is discouraged as it impairs visualization on endoscopy, and in cases of complete obstruction, risks pulmonary aspiration. The American Society for Gastrointestinal Endoscopy suggests avoiding contrast radiographic exams before endoscopic removal of esophageal FBs.²⁰ Proceeding directly to endoscopy appears to be the most reasonable approach. Food boluses may be amenable to pharmacologic relaxation of the LES, but the definitive intervention is endoscopy to both remove the bolus and evaluate the esophagus for pathology.

The most logical ED approach is initial aggressive relief of symptoms (judicious narcotics, sedatives, antiemetics), followed by endoscopic removal. Papain is contraindicated.

Figure 39.17 Many fish bones become impaled in the soft tissues of the upper digestive tract. **A**, This woman felt a bone catch in her throat while eating fish. As is often the case, she was able to consistently localize the foreign body to the right submandibular area, thus suggesting that it could be seen by direct visualization. **B**, With only a tongue blade, local anesthetic spray, and good lighting, a fish bone was found embedded in the tonsil and was easily removed with forceps. Removal provided immediate and total relief, as is usually the case. Strands of saliva can mimic a fish bone, so be careful when probing and grasping. **C**, Fishbone visualized (*arrow*) embedded in a patient's right tonsil. **D** and **E**, This patient felt a fish bone in her left pharynx, and a small bone (*arrow*) was removed from her left tonsil, a common place to find a bone with such symptoms. (**C**, Courtesy Geoff deLaurier, MD, and Jerahme Posner, MD.)

Removal of impacted food is an urgent issue but need not be done immediately on arrival at the ED or in the middle of the night with inadequate resources; endoscopy can wait several hours. Frequently, pain relief and a few hours of relaxation will allow the bolus to slowly pass; if so, follow up with gastroenterology for evaluation of any esophageal pathology is mandatory (this is true for food boluses in patients of any age). Vomiting occasionally dislodges the impaction.

Button Battery Ingestion

Button batteries lodged in the esophagus should be considered an emergency because of the potential for serious morbidity and mortality.^{23,95-97} They must be emergently removed. These batteries range in size from 7 to 25 mm and are radiopaque (**Fig. 39.20**). Batteries appear as round densities, similar to an impacted coin, but some demonstrate a “double-contour” configuration. It is important to distinguish between a coin and a button battery because button batteries require immediate

removal. Batteries consist of two metal plates joined by a plastic seal. Internally, they contain an electrolyte solution (usually concentrated sodium or potassium hydroxide) and a heavy metal such as mercuric oxide, silver oxide, zinc, or lithium.

If ingested, these batteries often lodge in the esophagus. Mechanisms of injury include electrolyte leakage, injury from electrical current, heavy metal toxicity, and pressure necrosis. Of particular concern is the development of corrosive esophagitis or perforation as a result of caustic injury and prolonged mucosal pressure. Though essentially harmless in the stomach and intestines, batteries lodged in the esophagus should be considered an emergency because even new batteries are subject to corrosion and leakage, which can result in mucosal necrosis within a few hours of contact with the esophagus.^{22,23,95,96,98,99}

Esophageal impaction of batteries mandates immediate removal. Options include Magill forceps removal, Foley catheter removal, esophageal bougienage, or esophagoscopy. Esophagoscopy allows direct esophageal evaluation and a more controlled extraction. In addition, the “invasive” nature of

Figure 39.18 **A**, Posteroanterior radiograph of an open safety pin lodged in the upper part of the esophagus. Sharp foreign bodies (FBs) in the esophagus are best removed by endoscopic visualization. **B**, This 10-year-old child was brought to the emergency department (ED) with severe chest pain. No history of an FB was given. Even when the radiograph demonstrated this metallic object in the esophagus, how it got there remained a mystery. Objects such as this are removed under anesthesia with an endoscope, and no ED intervention, except for relief of pain, is indicated.

Figure 39.19 This elderly nursing home patient was seen in the emergency department twice for a sore throat and inability to eat. He had swallowed his partial denture (*arrow*), but this history could not be obtained and the foreign body was discovered when a chest x-ray was taken. Endoscopic removal was indicated.

batteries may lead to rapid edema, thus making the catheter technique more difficult. In some localities rapid transfer of button battery ingestions to trauma centers or referral centers has resulted in much more rapid removal of the batteries.^{100,101}

Once in the stomach, button batteries do not require removal. They may be monitored radiographically to demonstrate passage, with little risk for GI injury or heavy metal poisoning, even if the battery opens^{10,38,46,102} (see [Table 39.3](#)).

Magnets

Swallowed small magnets from toys and household items have become a serious health hazard in children. All such

swallowed magnets within endoscopic reach much be urgently removed.^{10,13,20,103} Some children with complications from multiple magnet ingestion have underlying conditions such as developmental delay or autism, but older children can inadvertently swallow magnets when using them to imitate a pierced tongue. Between 2002 and 2011 there were approximately 1600 magnet ingestions annually in the United States,¹⁰⁴ almost exclusively in children. In 2011 the US Consumer Safety Product Commission issued an alert describing the safety risks from swallowed magnets (<https://www.cpsc.gov/content/cpsc-warns-high-powered-magnets-and-children-make-a-deadly-mix>). These toy magnets are small round strong magnets made from rare earth elements and are much stronger than traditional magnets used to make toys of various shapes, and if multiple magnets are swallowed, they will become adherent inside the bowel ([Fig. 39.21](#)). Multiple magnet ingestion is common, occurring up to 57% of the time.^{105,106} Multiple magnets, especially if ingested at different times, may attract each other across layers of bowel and lead to pressure necrosis, fistula, volvulus, perforation, infection, or obstruction.^{103–107} A piece of bowel may be pinched by two magnets that are swallowed simultaneously and are in different loops of bowel. Hence, suspected magnet ingestion requires urgent evaluation. Radiographs of the neck and abdomen should be obtained to prove magnet ingestion,^{46,107} but radiographs cannot determine whether bowel wall is compressed between the magnets. Identification of magnets that appear to be stacked but slightly separated raises concern for bowel entrapment.

Management of swallowed magnets depends on the timing, location, type, and number of magnets. Because even single magnets have some risk, endoscopic removal is mandated if the magnets are within endoscopic reach. Magnets in the esophagus or stomach should be promptly removed via endoscopy.^{10,13,20} Single magnets passed beyond the stomach can generally be managed conservatively initially, but serial outpatient radiographs should be obtained to confirm that the

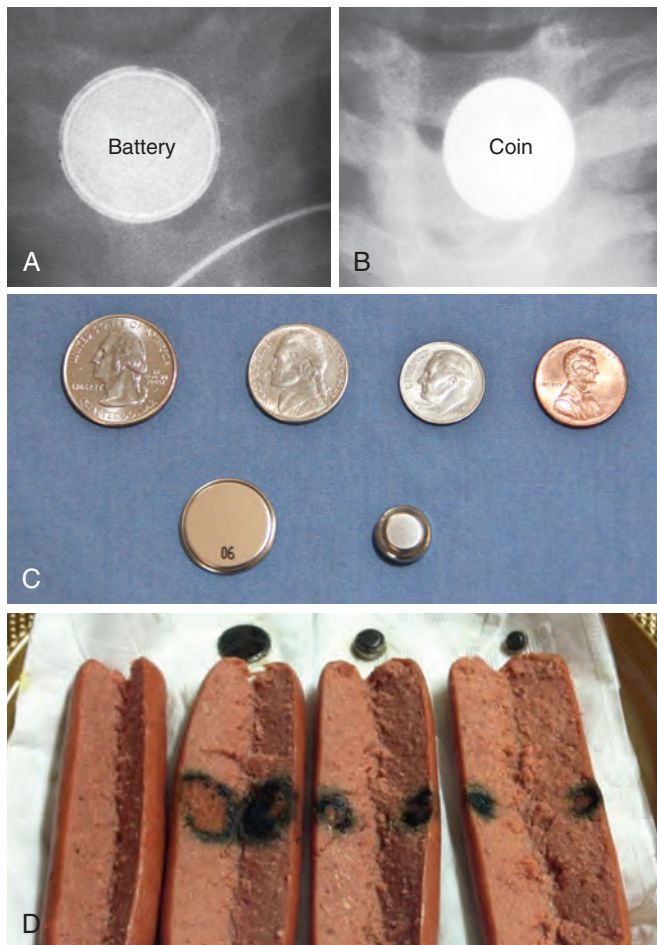

Figure 39.20 Button batteries have a wide range of sizes and can mimic coins on radiographs. Note that the battery (A) has a double-density circular appearance at the border, whereas the coin (B) has a homogeneous density with smooth borders. C, Button batteries range from 7 to 25 mm and are similar in size to coins. D, An example of the potentially rapid, destructive, and caustic power of button batteries in the esophagus. In this model, intact batteries of different sizes were inserted into a hot dog. Larger batteries with greater areas of surface contact caused damage within 30 minutes, and after 3 hours (*image shown*) caustic changes were seen with each of the batteries tested. Immediate removal of all batteries from the esophagus seems prudent. (A and B, From Kost KM, Shapir RS: Button battery ingestion. A case report and review of the literature, *J Otolaryngol* 16:4, 1987. D, Pictures courtesy Adnan Ameer, Rais Vohra, Christian Tomaszewski, and Steve Marcus.)

magnet is progressing through the gastrointestinal tract. Theoretically, the child should be kept away from any magnetic or metallic material (such as metallic buttons or buckles in clothing) until the magnet has passed. Management of patients with multiple magnets beyond endoscopic reach depends on the symptoms and progression. Asymptomatic patients who have swallowed multiple magnets beyond endoscopic reach should be admitted and monitored closely with serial radiographs and physical examination every 4 to 6 hours.¹⁰ Alternatively, magnets can be removed by enteroscopy or colonoscopy if accessible. Symptomatic patients or any patient with multiple magnets that do not progress on serial radiographs should undergo surgery for operative removal of the magnets.^{10,103,107}

Figure 39.21 Buckyballs are strong round toy magnets that when swallowed aggregate strongly in the bowel and may cause intestinal perforation or necrosis if the bowel wall is compressed. They should be removed if in the esophagus or stomach. Careful observation is acceptable for asymptomatic patients with multiple magnets that are not readily removed, but symptomatic patients require surgical removal if bowel pathology is suspected.

The Patient in Distress

Pharyngeal or upper esophageal FBs can cause respiratory distress or respiratory arrest, usually in infants and the elderly. The Heimlich maneuver can be attempted in the prehospital setting or the ED when the situation is appropriate. The first intervention is to ensure an adequate airway, which can be obvious by the situation or may require laryngoscopy or other means of direct visualization. Forceps may be required to remove obstructions under direct vision. Because FBs may mimic multiple other pathologies, the approach to an acutely choking patient is challenging and every situation individual. Upper esophageal FBs can compress the trachea and cause stridor and respiratory compromise; these are indications for immediate removal.

ED Evaluation of FB Sensation in the Throat

FB impactions in the esophagus are usually straightforward, but patients may seek treatment in the ED because of a lump in the throat or difficulty swallowing with no apparent reason or history of FB ingestion. Such complaints require an examination and an investigation based on the clinical encounter and individual circumstances. Complete evaluation of these complaints is beyond the scope of this chapter, but initial modalities available to the clinician to evaluate these complaints are barium swallow, CT, and pharyngoscopy or laryngoscopy. The need for consultation is based on the clinical scenario.

If no cause is suspected by the history or examination, globus pharyngeus may be the causative factor. This may be associated with anxiety or a panic attack. The sensation of a painless

lump in the throat is called globus pharyngeus or globus hystericus. It has many causes other than FBs. Palpate, visualize, or review the anatomic structures in the area: the chin, laryngeal cartilage, cricothyroid cartilage, tracheal rings, sternum, and cricopharyngeal muscle.

FB sensation may be caused by infection, acid reflux, esophageal spasm, esophageal strictures, pill esophagitis, benign and malignant tumors, hiatal hernia, scleroderma, and many other causes. Globus sensations may also persist after an FB

has been completely removed because of mucosal injury. Neurologic causes include botulism, myasthenia gravis, cerebrovascular accident, and amyotrophic lateral sclerosis. If the patient otherwise appears well and is able to drink liquids and keep hydrated, referral to a gastroenterologist as an outpatient is standard.

Nasogastric and Feeding Tube Placement

Leonard E. Samuels

Nasogastric (NG) intubation (Videos 40.1–40.5) is commonly used to evaluate or treat bowel obstruction, ileus, or gastric hemorrhage, preoperatively or postoperatively, or to administer food or medication into the gastrointestinal (GI) tract. Patients with long-term feeding tube complications and those requiring replacement or other manipulation of tubes are frequently seen and treated in the emergency department (ED).

PROPERTIES OF NG AND FEEDING TUBES

Polypropylene is the material most commonly used for Levin and Salem sump NG tubes (Fig. 40.1), but it is too rigid for long-term use as a feeding tube. Polypropylene tubes are less likely to kink than others but are more capable of creating a false passage during placement. Latex (rubber) tubes are moderately firm, require greater lubrication for passage, are relatively thick walled, and induce a greater foreign body reaction than tubes made of other common materials. Latex, especially in latex balloons, deteriorates more rapidly than other materials.¹

Foley catheters are primarily latex, although silicone Foley catheters are available for patients with latex allergies. Silicone

tubes are thin walled, pliable, and nonreactive; however, the walls of silicone tubes are weaker and may rupture if fluid is introduced into a kinked tube.² Polyurethane tubes are nonreactive and relatively durable. Rigidity varies from manufacturer to manufacturer, depending on the thickness of the tube. A stylet may aid in the passage of polyurethane and silicone tubes, but it increases rigidity and the potential for tissue dissection, especially with tubes that have a small distal end-bulb.³ Some feeding tubes have weights, which are usually made of tungsten and are nontoxic if released into the GI tract.

NG TUBE PLACEMENT

Indications and Contraindications

The simplest NG tube is the Levin tube, which has a single lumen and multiple distal “eyes.” The advantage of the Levin tube is its relatively large internal diameter (ID) in proportion to its external diameter. The theoretical disadvantage is that a Levin tube should not be left hooked up to suction after the initial contents of the stomach have been drained because the suction will cause the stomach to invaginate into the eyes of the tube, blocking future tube function and potentially causing injury to the stomach lining. Levin tubes are therefore rarely used in the ED. The Salem sump tube is preferred over the Levin tube for chronic use as a drainage device because it has a separate (blue-colored) channel that vents the distal main lumen to the atmosphere (Fig. 40.2). This vent helps prevent an excessive vacuum from forming at the tip of the tube. Note that both intermittent suction and wall unit vacuum can exceed the venting capacity of the second lumen, so the vacuum setting should be less than 120 mm Hg. The most commonly used size is 16 Fr, although larger and smaller sizes are available.

Nasogastric Tube Placement

Indications

- Decompression of stomach (e.g., obstruction or perforation)
- Reduce incidence and risk of vomiting
- Monitor and evaluate upper gastrointestinal bleeding
- Prolonged ileus
- Administration of medication or oral contrast in a patient unable to swallow
- Detection of transdiaphragmatic stomach herniation

Contraindications

- Midface injury, basilar skull fracture, or coagulopathy (orogastric placement may be a better option)
- History of gastric bypass or lap banding
- Esophageal strictures or alkali injury

Complications

Bleeding	Vomiting/retching
Intracranial placement	Perforation
Pulmonary placement	Sinusitis
Pneumothorax	Aspiration

Equipment

Review Box 40.1 Nasogastric tube placement: indications, contraindications, complications, and equipment.

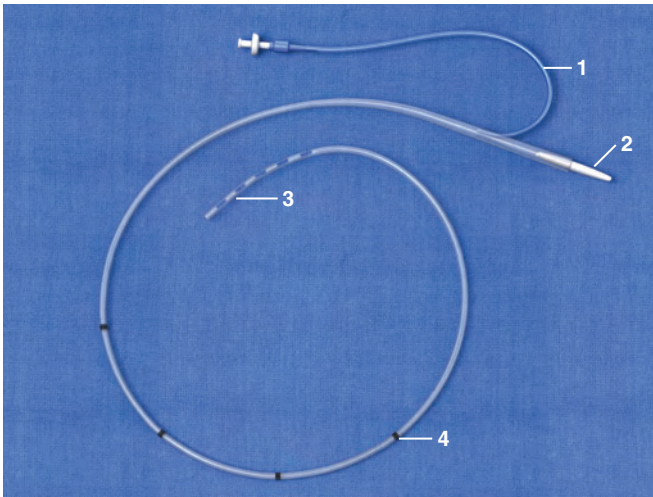

Figure 40.1 Salem sump tube. This tube contains a second lumen that allows venting during continuous suction. 1, Pigtail extension (blue) of the air vent lumen. 2, Connector for attachment of the suction lumen to the vacuum line. 3, Gastric end with suction eyes. 4, Insertion depth markers.

Figure 40.2 Diagram of the Salem sump tube. **A**, General design. **B**, Diagram of the double-lumen principle for suction. (**A** and **B**, Courtesy the Argyle Division of Sherwood Medical, St. Louis, MO.)

The major indication for NG tube placement and suction is to aspirate the stomach contents in patients with gastric bleeding, gastric outlet or intestinal obstruction, gastric or bowel distention, prolonged ileus, or gastric, esophageal, or bowel perforation. Draining the dilated stomach of excessive contents lessens the chance of vomiting and possibly aspiration and provides marked relief of symptoms in patients with intestinal obstruction. The presence or anticipation of depressed mentation potentially justifies NG tube placement to protect

the airway, especially if the stomach is full or vomiting is uncontrolled. Bag-valve-mask ventilation often distends the stomach with air, and a postintubation NG tube can improve ventilation, prevent vomiting, and increase patient comfort. Trauma patients may need an NG tube as part of the evaluation for GI injury or to decompress the stomach before surgery or peritoneal lavage. A radiopaque NG tube may help delineate transdiaphragmatic hernia of the stomach after trauma. A deviated NG tube is a nonspecific sign of traumatic aortic rupture. An NG tube may be used to instill air into the stomach for documentation of a suspected gastric perforation by enhancing visualization of free air under the diaphragm on an upright chest film. In patients unable to swallow, an NG tube may be passed to administer medications or oral contrast material for a computed tomography (CT) scan.

For the evaluation and treatment of upper GI bleeding, indications for NG tubes differ among clinicians, and practices vary widely. Clinical judgement prevails as the best arbitrator, but the true clinical value of an NG tube in patients with GI bleeding is probably less than traditionally promulgated. Although insertion of an NG tube may prompt earlier endoscopy, the procedure has not been demonstrated to improve clinical outcomes.⁴ NG aspiration can help localize bleeding in only a minority of patients with GI hemorrhage. Patients who vomit a significant amount of proven bloody material have had upper GI bleeding; they do not need an NG tube for diagnosis. Such patients are best evaluated by endoscopy, although when a history of bleeding is suspected, stomach aspiration may have a role in diagnosis to confirm the presence of blood. In patients without hematemesis, NG aspiration uncovers less than half the patients with upper GI hemorrhage and thus cannot be used to unequivocally rule out upper GI bleeding. Even a rapidly bleeding duodenal ulcer may not produce blood in the stomach. Some contend that emptying a markedly dilated stomach of blood and stomach contents may reduce the rate of bleeding, but data are lacking. Patients with presumptive upper GI bleeding, which includes those with melena, those younger than 50 years old, and those with a hematocrit lower than 30, need upper endoscopy.^{5,6} Patients passing clots or blood per rectum or those with known previous lower GI bleeding are usually experiencing lower GI bleeding.⁶ Except when frankly bloody fluid is obtained, an NG aspirate is diagnostically unhelpful. Small bits of darkish material, bloody mucus, or positive Gastrocult or guaiac tests probably represent sequelae of the procedure, whereas a clear appearance and negative tests still miss most bleeding distal to the stomach. Patients with a bleeding pattern indicative of a Mallory-Weiss tear may need neither an NG tube nor endoscopy.

NG tubes can provide the earliest indication of high-volume esophageal or gastric bleeding. Although variceal rupture may potentially be caused by insertion of instruments into the esophagus, several studies suggest that passage of an NG tube is generally safe, even in patients with esophageal varices. Use of NG tubes for the evaluation and monitoring of upper GI bleeding should be judicious rather than universal.

Increasingly, the literature suggests that most other causes of vomiting are best controlled with medication. Postoperative ileus ends sooner and patients recover faster without an NG tube after various studied abdominal surgeries.⁵ NG tubes prolong the hospital stay, pain, and hyperamylasemia in those with mild to moderate pancreatitis.^{7,8} Many patients are better off without an NG tube from the point of view of safety, comfort, and speed of recovery.

Figure 40.3 A nasogastric (NG) tube may enter the cranium or facial soft tissues in patients with severe head or facial trauma. Those with a coagulopathy may experience significant bleeding from nasal or pharyngeal trauma during passage of an NG tube. In such cases, a standard NG tube inserted through the mouth (as shown here) may be a better alternative.

In an awake and alert patient with a preserved gag reflex, passage of an NG tube has not been demonstrated to result in significant pulmonary aspiration, even when vomiting occurs during passage. NG tubes are, however, contraindicated in patients with a special predisposition to injury from placement of the tube. Patients with facial fractures who have sustained an injury to the cribriform plate may suffer intracranial penetration with a blindly placed nasal tube.⁹ Severe coagulopathy is a relative contraindication to passage of an NG tube. In patients with a coagulopathy or significant facial or head trauma, passing the desired tube through the mouth may be a better alternative (Fig. 40.3). Patients who have esophageal strictures or a history of alkali ingestion may suffer esophageal perforation. Gagging will decrease venous return and increase cervical and intracranial venous pressure. Comatose patients may vomit during or after NG tube placement. Indwelling NG tubes predispose patients to pulmonary aspiration because of tube-induced hypersalivation, depressed cough reflex, or mechanical or physiologic impairment of the glottis.⁷ Aspiration is also quite common with nasoenteral feedings in debilitated patients, hence the use of a gastrostomy feeding tube for this condition. An NG tube should be avoided when possible in patients who have undergone gastric bypass surgery or lap banding procedures.

Extended irrigation of the stomach with water in a patient with upper GI hemorrhage can lower serum potassium levels,¹⁰ and animal studies suggest that cold water lavage can cause rather than control bleeding.^{11,12} No study has shown irrigation to be effective in the control of bleeding,^{13,14} and vigorous lavage with cold water may lower the body temperature. Erythromycin has been demonstrated to be effective in clearing the stomach for endoscopy,^{15,16} and its success is better substantiated than irrigation.

Equipment

Passage of standard NG or feeding tubes can be messy and may be accompanied by coughing, retching, sneezing, bleeding, and spilled water or stomach fluid. For this reason, both the patient and clinician should be gowned; cleanup may be reduced

if the bib area is covered with a towel and a supply of tissues or washcloths is available. For standard NG tube placement, a piston or bulb syringe (with a catheter slip-tip) should be available. NG feeding tubes should have a compatible 50-mL or 60-mL syringe (some are Luer compatible and others are slip-tip compatible).

Tape torn into 4-inch strips or a commercial NG tube holder (e.g., Suction Tube Attachment Device, Hollister, Libertyville, IL) should be handy for securing the tube after placement. Cotton-tipped applicators and tincture of benzoin may be helpful in securing the tube to the nose if the skin is greasy. Make sure that the feeding tube is designed for duodenal passage if this is desired; such tubes are usually longer than regular feeding tubes.

Procedure

Most NG tubes are placed at the bedside in an awake patient. Explain the procedure to the patient. Written informed consent is not standard. If the patient is alert, raise the head of the bed so that the patient is upright. Place a towel over the patient's chest to protect the gown, and place an emesis basin on the patient's lap.¹⁷ Position the tube (typically a 16- or 18-Fr sump) so that the insertion distance can be estimated, and mark the distance with tape or by noting the markers printed on the proximal end of the tube. A simple method is to measure the tube from the xiphoid to the earlobe and then to the tip of the nose. Then add 15 cm (6 inches) to this number (Fig. 40.4, step 5).¹⁸ It is a common error to fail to estimate the proper length of tube before passage, which can result in the tip of the tube positioned in the esophagus or coiled excessively in the stomach. Check the nares for obstruction. Assess patency by direct visualization, by gentle digital nasal examination, and by having the patient sniff whilst first one and then the other nostril is occluded. Pass the tube down the more patent naris.

Relief of Discomfort

Ameliorate the pain and gagging associated with tube placement by using vasoconstrictors, topical anesthetics, and antiemetics. Because patients rate NG tube placement as very painful, one of the most painful procedures performed in the ED, use these adjuncts whenever time and the clinical situation permit (Fig. 40.5). Spray topical vasoconstrictors, such as phenylephrine (0.5% Neo-Synephrine [Hospira Inc., Lake Forest, IL]) or oxymetazoline (0.05% Afrin [Bayer Healthcare LLC, Whippany, NJ]), into both nares at first in case one side proves to be problematic (see Fig. 40.4, step 2). The nares, nasopharynx, and oropharynx should all be anesthetized at least 5 minutes before the procedure. Gagging is reduced if the pharynx is anesthetized as well as the nose. Combinations of tetracaine, butyl aminobenzoate, and benzocaine (Cetacaine [Cetylite Inc., Pennsauken, NJ]), nebulized or atomized (spray cans or bottles) lidocaine (4% or 10%), and lidocaine gels (2%) are most commonly used. Lidocaine preparations of 10% are most useful. Lidocaine may be nebulized and delivered by face mask with the equipment used to administer bronchodilators to asthmatics (see Fig. 40.4, step 3). This method has been found to be superior to lidocaine spray for reducing gagging and vomiting and increasing the chance of successful passage.^{19,20} Cullen and coworkers concluded that nebulized nasal and pharyngeal lidocaine (4 mL of a 10% solution) reduces the discomfort associated with passage of an NG tube better than placebo and without any lidocaine-related toxicity.²¹

Nasogastric Tube Placement

1 Choose the most patent naris by visual inspection and the sniff test. Alternatively, insert a gloved finger into each nostril to assess patency.

2 Apply a topical vasoconstrictor, such as phenylephrine or oxymetazoline.

3 Anesthetize the naris, nasopharynx, and oropharynx at least 5 minutes before the procedure.

Nebulized lidocaine is ideal because it reduces both nasal and pharyngeal discomfort.

4 Apply 2% viscous lidocaine along the floor of the nasal cavity, and allow it to drip into the nasopharynx and be swallowed.

5 Measure the distance from the tip of the nose to the earlobe to the xiphoid process.

Add another 15 cm to this distance.

Note the total distance on the nasogastric tube markers.

6 Slowly insert the nasogastric tube along the floor of the nostril under direct vision until it passes into the oropharynx.

7 While the patient sips water from a straw, rapidly pass the tube to the predetermined depth. Coordinate tube advancement with the swallowing mechanism to promote easy passage.

8 Assess tube placement with air insufflation and aspiration.

9 Attach the tube to intermittent wall suction.

10 Secure the tube to the nose with tape.

Figure 40.4 Nasogastric tube placement.

Figure 40.5 Insertion of a nasogastric (NG) tube has been termed one of the most painful and unpleasant procedures performed in the emergency department, and it should not be used unless specifically indicated. Whenever possible, some form of topical anesthesia for both the nose and the pharynx should be used at least 5 minutes before passing an NG tube. Merely coating the tube with xylocaine ointment prior to insertion is of no anesthetic value.

After a topical vasoconstrictor and anesthetic are administered, lubricate the tube with viscous lidocaine or lidocaine jelly.²² Lubrication and anesthesia of the nares can be facilitated by using a syringe (without needle) filled with 5 mL of an anesthetic lubricant, such as 2% lidocaine gel (see Fig. 40.4, step 4). Simply putting anesthetic jelly on the tube just before insertion will not provide any anesthesia. Topical anesthetics are generally quite safe, but pay attention to the total dose of anesthetic administered to avoid toxicity.²³ Note that each milliliter of a 10% lidocaine solution contains 100 mg of lidocaine and can be absorbed systemically. In rare cases topical benzocaine has caused methemoglobinemia, even with the relatively small amounts used for endoscopy.²⁴

Although no standard exists and supportive data are sparse, some clinicians administer ondansetron (Zofran [GlaxoSmith-Kline, Research Triangle Park, NC], 4 mg) or metoclopramide (Reglan [Baxter Healthcare Corp., Deerfield, IL], 10 mg) intravenously 5 minutes before passage of an NG tube to potentially reduce nausea and gagging and, secondarily, to improve the pain and prolongation of the procedure that gagging engenders. Metoclopramide may have additional benefits on the discomfort associated with NG tube insertion, unrelated to its antiemetic effects. Ondansetron is preferred for nausea because metoclopramide can cause agitation or facial and tongue spasm, but these effects can be reversed rapidly with the administration of 25 mg diphenhydramine intravenously.

Under direct vision, not blind forcing, insert the tube gently into the naris along the floor of the nose under the inferior turbinate and NOT upward toward the nasal bridge (Fig. 40.6;

Figure 40.6 Endoscopic view of the nasal cavity before and after the application of oxymetazoline nasal spray. The nasogastric tube is passed under the inferior turbinate, which is made more patent after the application of topical vasoconstrictors. The operator should actually look into the nose during insertion to properly guide the tube, not force it blindly. NGT, Nasogastric tube. (From Thomsen T, Setnik G, editors: *Procedures Consult—Emergency Medicine Module*. Copyright 2008, Philadelphia, Elsevier Inc. All rights reserved.)

also see Fig. 40.4, step 6). If mild resistance is felt in the posterior nasopharynx, apply gentle pressure to overcome this resistance. If significant resistance is encountered, it is better to try the other nostril because bleeding or dissection into retropharyngeal tissue may occur if force is used. Once the tube passes into the oropharynx, pause to help the patient regain composure and enhance the chance for cooperation with the rest of the procedure.

If the patient is alert and cooperative, a common option is to ask the patient to sip water from a straw and swallow while you advance the tube into and down the esophagus (see Fig. 40.4, step 7). This may facilitate passage of the tube. Once the tube is in the nasopharynx, flex the patient's neck to direct the tube into the esophagus rather than the trachea. In an intubated, anesthetized, or paralyzed patient, two stacked positive pressure breaths lasting 1 to 2 seconds each via a face mask provide similar relaxation of the upper esophageal sphincter for a brief 4- to 5-second window, and this markedly increases successful tube placement.²⁵

Some gagging during the procedure is common and is not an indication to halt attempts at passage. Withdraw the tube promptly into the oropharynx if the patient has excessive choking, gagging, coughing, a change in voice, or condensation appears on the inner surface of the tube because this indicates the possibility of passage of the tube into the trachea. With the mouth open, inspect the tube in the posterior pharynx to detect coiling or respiratory passage. If the tube is lateral to the midline, this suggests correct position in the esophagus. Once the tube is in the esophagus, advance it rapidly to the previously determined depth. Passing the tube slowly prolongs discomfort and may precipitate more gagging.¹⁷

Confirmation of Tube Placement

Before the NG tube is secured, confirm successful placement by nonradiographic means or by auscultation. Use more than

one method when in doubt because all methods of confirmation have some possibility of error. Radiographic evaluation is the most definitive way to confirm the position of an NG tube, but it is not standard to routinely obtain radiographic confirmation. Radiographs may be more useful in the obtunded patient. Alert and cooperative patients will feel when a tube is entering the trachea or lungs and will be very symptomatic and therefore obviously alert the clinician. Patients who are struggling or have altered sensorium may not give any sign when the tube passes into the lungs, and therefore careful confirmation of placement, usually with radiography, is critical for these individuals. Ultrasound, when successful, is also highly reliable (see [Ultrasound Box 40.1](#)).²⁷

A quick, simple, but unreliable method of confirmation is to insufflate air into the NG tube and auscultate for a rush of air over the stomach (see [Fig. 40.4, step 8](#)). If increased pressure is required to instill the air or if no sounds are heard, the tube may be malpositioned or kinked. Suspect an esophageal location if the patient immediately burps on insufflation. Left pulmonary tubes and tubes which have advanced past the stomach into the small bowel often sound so similar to properly placed tubes that misplacements are not detected.³

Aspiration of stomach contents, especially if pH-tested, is more reliable and can be performed if the tube position is in question. If the pH is less than 4, there is an approximately 95% chance that the tube is in the stomach and nonrespiratory placement is almost guaranteed.²⁸ Although aspirated fluid can occasionally be obtained from the lung or pleural space, the pH should be 5.5 or higher.²⁹ Approximately 4% of correctly placed tubes have aspirates with a pH higher than 5.5. Causes include duodenal reflux, antacids, H₂ blockers, or recent instillation of formula or medications.²⁹

If awake and cooperative, ask the patient to talk. If the patient cannot speak, suspect respiratory placement. Note that with small-bore tubes, patients may still be able to speak despite tracheal placement.³⁰

Once correct tube position is tentatively confirmed, secure the tube. If the patient requires abdominal or chest radiographs for other diagnostic purposes, place the NG tube before obtaining the films. An NG tube deviated to the right may occasionally be seen in patients with traumatic rupture of the aorta, but this is not a reliable indicator.

Securing the Tube

The NG tube is generally secured to the patient with tape attached to both the tube and nose (see [Fig. 40.4, step 10](#)). Excellent purpose-made tape NG holders exist. A butterfly bandage (or tape on each side of the nose) that coils around the NG tube is a typical approach. Clean and prepare the nose and tube with tincture of benzoin if possible. If the tape lets go or requires repositioning, replace both the tape and the tincture of benzoin. It is wise to also secure the tube to the patient's gown so that a tug on the tube will encounter this resistance before pulling on the tape securing the tube to the patient's nose. A rubber band tied around the tube with a slipknot ([Fig. 40.7](#)) and pinned to the gown near the patient's shoulder is effective. It is critical to ensure that the tube is secured in such a way that it does not press on the medial or lateral aspect of the nostril. Necrosis or bleeding can result if a tube is not secured correctly.

When a Salem sump is used, keep the blue pigtail above the level of the fluid in the patient's stomach or the stomach

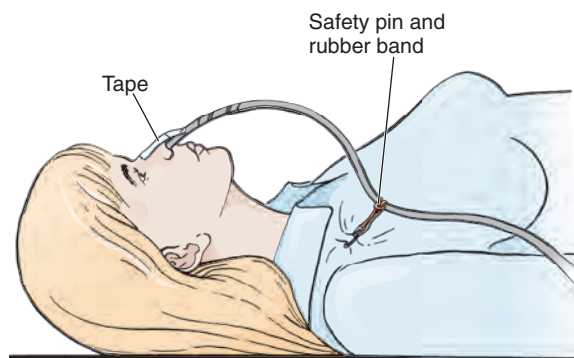

Figure 40.7 Attach the nasogastric tube to the patient's gown with a rubber band and a safety pin so that a tug on the tube pulls the gown and not the tape holding the tube in the patient's nose.

contents may leak back through the vent lumen. If a patient needs to ambulate with a sump tube in place, fit the blue pigtail into the plastic connector at the end of the suction lumen. This creates a closed loop that should not leak.

Placement Issues

If the patient is intubated, deflate the balloon of the endotracheal (ET) tube briefly to allow passage of the NG tube. In a nonintubated unconscious patient, the NG tube is easily misplaced into the pulmonary tree. This complication may be missed during the procedure in cases in which the gag and cough reflexes are suppressed and the patient cannot talk. In addition, the absence of swallowing may prevent successful passage of the tube. In comatose or ventilated patients, several techniques have been studied to aid passage of the NG tube. Using Magill forceps to grip the tube or stenting the end of the tube with a gum bougie passed into the most distal tube eye can help stiffen and control the tube. The combination and sequence of techniques used will depend on the clinician's expertise, the equipment available, and the level of sedation.

If less traumatic strategies fail, an ET tube can be prepared with an ID that is slightly larger than the external diameter of the NG tube. Slit it along its lesser curvature from the proximal end to a point 3 cm from its distal end. Pass the NG tube through a naris into the oropharynx. Visualize the tip of the tube with a laryngoscope, grasp it with Magill forceps, and pull it out of the mouth. Pass the slit ET tube (generally 8 mm in ID) through the mouth into the esophagus.³¹ Alternatively, pass a 7-mm-ID slit ET tube directly through the nose into the esophagus.³² Passage into the esophagus is facilitated by the stiffness of the larger ET tube and does not require active swallowing. Thread the tip of the NG tube into the ET tube and advance it into the stomach ([Fig. 40.8](#)). Remove the slit ET tube from the esophagus. When the distal part of the ET tube is visible, slit the unslit 3-cm distal part with scissors. Remove the ET tube and the NG tube will remain in place.³³ Advance any slack tubing with forceps or pull it back nasally, depending on the final depth required for the NG tube. The technique can also be performed by passing the slit ET tube nasally, which saves the trouble of orally advancing or nasally retracting any slack in the tubing.³³ Make sure that the NG tube can pass into the 7-mm-ID tube and that the ET tube is well lubricated inside and out.

ULTRASOUND BOX 40.1: Assistance in Nasogastric Tube Placement

by Christine Butts, MD

Ultrasound has emerged as a new modality to assist in placement verification of nasogastric tubes, both during the procedure and as a confirmatory test after the procedure.

Place the high-frequency transducer on the patient's neck transversely between the cricoid cartilage and the suprasternal notch, slightly off to the side with the orientation button to the patients' left. (Fig. 40.US1). Obtaining a clear view of the esophagus sometimes involves slight angling of the probe and occasionally even benefits from some minor tracheal manipulation, usually leftward displacement. With these maneuvers, it is probably possible to visualize the esophagus over 90% of the time.²⁶ (Fig. 40.US2)

When the nasogastric tube passes the probe image level, the esophagus acquires a bright echogenic density with posterior shadowing (Fig. 40.US3). The nasogastric tube's strong interaction with the ultrasound may obscure clear visualization of the esophageal wall. A brighter echogenic density is obtained if there is a metal guidewire in the tube, as is common in feeding tubes but not in Salem sump tubes.

Figure 40.US1 Proper positioning of the high-frequency transducer between the cricoid and the suprasternal notch.

Figure 40.US2 Angling of the probe and gentle tracheal (*) manipulation facilitates visualization of the collapsed esophagus (arrow).

If 20 cm of tube has been passed but the esophageal appearance hasn't changed, the tube is likely in the trachea or coiled in the mouth and failing to pass. Sometimes the empty esophagus isn't easily seen, and then it becomes even more important to distinguish the course of the tube and ensure that the tube is in an extratracheal soft tissue

Figure 40.US3 When the nasogastric tube passes the probe, the esophagus becomes brightly echogenic and creates posterior shadowing (arrow). In this image, an endotracheal tube (asterisk) can be visualized in the trachea.

Figure 40.US4 Lateral cross-sectional views may help confirm that the nasogastric tube is clearly outside of the trachea.

ULTRASOUND BOX 40.1: Assistance in Nasogastric Tube Placement—cont'd

Figure 40.US5 Visualization of the nasogastric tube in the stomach (arrow). Note the prominent shadow from the tube.

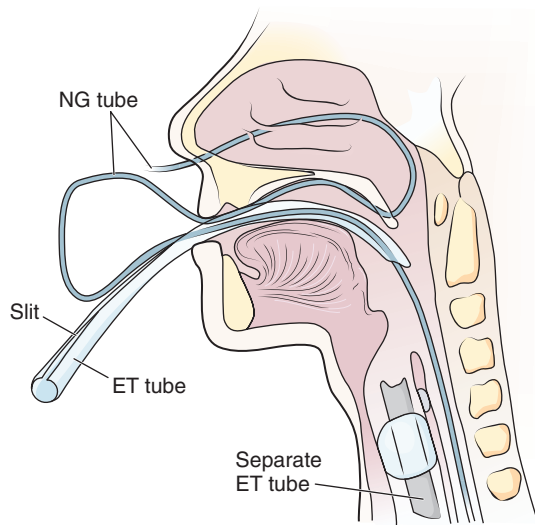

Figure 40.8 Diagrammatic representation of separation of the nasogastric (NG) tube from the guiding endotracheal (ET) tube through the slit in the guiding ET tube. The NG tube has first been passed through the nose and is pulled out through the mouth. The tip of the tube is then threaded into the guiding ET tube to ensure passage down the esophagus. The guiding ET tube is removed from the esophagus before being separated from the NG tube. Note the previous placement of another ET tube in the trachea (partially shown) to avert passage of the guiding ET tube into the trachea. (Modified from Sprague DH, Carter SR: An alternate method for nasogastric tube insertion, *Anesthesiology* 53:436, 1980.)

In a particularly passive, intubated, sedated, unconscious, or toothless patient, guiding the NG tube with fingers into the pharynx is occasionally successful (Fig. 40.9A).³⁴ Displacing the larynx forward by manually gripping and lifting the thyroid cartilage can aid in inserting the tube,³⁵ as can simple jaw elevation. A soft nasopharyngeal airway, well lubricated, is at

space and not in the trachea. A lateral cross-sectional view with the probe pointed across from the side (by sliding the probe around the neck from the original transverse position, as shown in Fig. 40.US4) or oblique angles of the probe may allow the nasogastric tube to be visualized as being clearly outside the trachea.

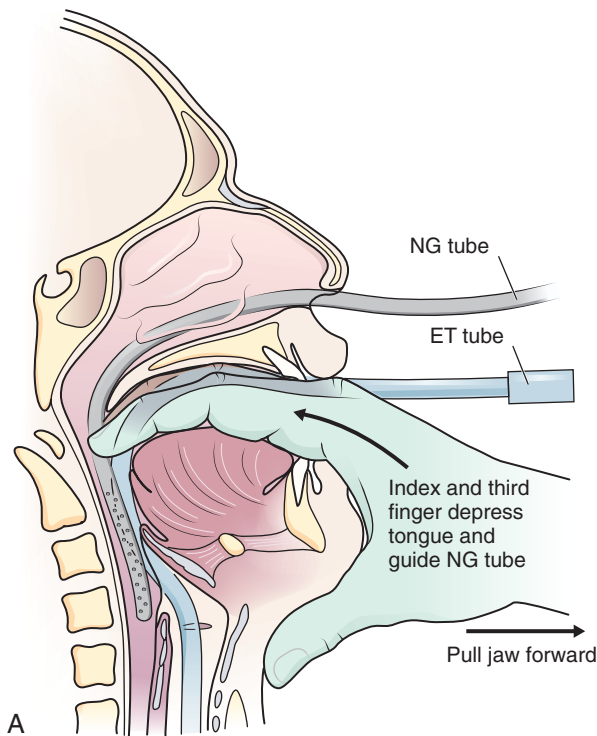

Confirmation of tube placement in the stomach is less reliable, even after successful placement. Place the low-frequency probe over the epigastric area and try to visualize the tube. Fluid can be injected through the tube, creating a visible “foggy” disturbance in the stomach. Such confirmation reliably indicates proper placement, but when absent does not imply the tube must be replaced; rather, alternative confirmatory measures should be employed prior to using the tube for instillation of materials. Visualization of the nasogastric tube in the epigastrium on still shots is possible (Fig. 40.US5). Note that still views of the nasogastric tube in the epigastric region can look similar if the tip is in the stomach, distal esophagus, or proximal duodenum.

times easier to pass nasally than an NG tube, and then the lubricated NG tube can be passed through it. In addition, it affords some protection to the nasal mucosa if multiple attempts at passing the NG tube are necessary or if it is particularly important to minimize bleeding or trauma. Cooling an NG tube increases its rigidity, and coiling it can increase the curvature of the tube, both of which may help pass the tube. Alternatively, the NG tube and larynx can be visualized with a laryngoscope, endoscope, or the GlideScope (Verathon, Bothell, WA) (see Fig. 40.9B).³⁵ Under laryngeal visualization, manipulation and lifting of the jaw and neck flexion can help align the tube for passage under direct vision into the esophagus.

Ultimately, if all other methods fail, place a flexible fiberoptic bronchoscope or esophagoscope into and through the esophagus under direct visualization.³⁶ Thread a guidewire into the stomach. Place the NG tube over the guidewire into the stomach and then remove the guidewire.³⁷

Complications

Complications of standard NG tube placement are similar to the problems noted with placement of an NG feeding tube. The complications related to tube misplacement are discussed in that section. In addition, clinicians placing an NG tube in a patient with neck injuries should be cautious of potentiating cervical spine injuries with excessive motion during passage (especially in association with coughing and gagging in an awake patient). Furthermore, passage of an NG tube in an awake patient with a penetrating neck wound may exacerbate hemorrhage should coughing or gagging result. Particularly serious forms of tube misplacement are pulmonary placement (Fig. 40.10) and intracranial placement (Fig. 40.11). In confusing cases, a CT scan will clarify most misplacement issues (Figs. 40.12 and 40.13). NG tubes, when in place for prolonged periods, are a common cause of innocuous gastric bleeding and gastric erosions.

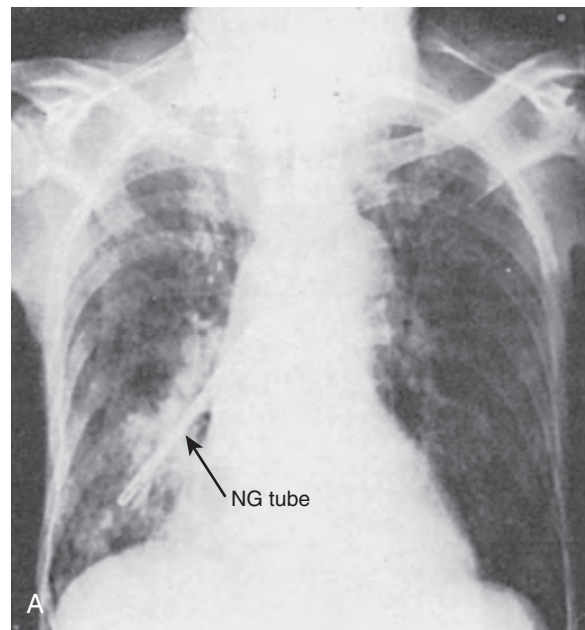

A

B

Figure 40.9 **A**, Passage of a nasogastric (NG) tube through the nose of an intubated patient can be difficult. An endotracheal tube is in the trachea via the mouth. Place the second and third fingers in the posterior pharynx. Depress the tongue with the fingers. Guide the NG tube down the esophagus by passing it through the second and third fingers. Importantly, place the thumb under the jaw and pull the jaw forward. **B**, In this intubated patient, a video laryngoscope (GlideScope, Verathon, Bothell, WA) can be used to manipulate the larynx and visualize the passage of the nasogastric tube.

Tension gastrothorax can develop in patients with an intrathoracic stomach. It can occupy much of the left hemithorax and thus displace the heart and lungs and cause a clinical syndrome identical to tension pneumothorax. Even though successful passage of an NG tube will relieve tension gastrothorax, the high pressures of a tension gastrothorax often develop because torsion of the stomach in the chest prevents egress of air; such torsion may also prevent ingress of the therapeutic NG tube. The condition is rare enough that further emergency therapy is based on case reports rather than substantial series. Relief of tension gastrothorax has been accomplished by transthoracic puncture of the stomach with a

A

B

Figure 40.10 **A**, Levin tube inadvertently placed in the right main stem bronchus; an alveolar infiltrate consistent with early pneumonia is also shown. **B**, Proper position of the nasogastric (NG) tube (arrow) is best verified with a radiograph. (**A**, From Johnson JC: Letter to the editor: back to basics for morbidity-free nasogastric intubation, *JACEP* 8:289, 1979; **B**, from Thomsen T, Setnik G, editors: *Procedures Consult—Emergency Medicine Module*. 16-gauge catheter-over-the-needle device inserted into the second intercostal space in the midclavicular line and then removing the needle. The catheter is left in place attached to intravenous tubing with the distal end under a water seal.³⁸ A single 16-gauge puncture of the stomach is unlikely to leak and cause pleuritis; such punctures have long been used for placement of percutaneous endoscopic gastrostomy (PEG) tubes. Inserting a chest tube into the stomach is not advisable because gastric fluid may leak into the pleural space. Once the tension on the stomach is relieved, it may be possible to pass the NG tube to prevent reoccurrence of the problem. The stomach, no longer tense and wedged in the chest, can twist to allow the tube to pass. Surgical correction of the condition permitting, intrathoracic herniation of the stomach is the definitive treatment to prevent recurrence of tension gastrothorax.

Figure 40.11 Anteroposterior and lateral skull radiographs demonstrate intracranial insertion of a nasogastric tube in a patient with multiple skull fractures. (From Johnson JC: Letter to the editor: back to basics for morbidity-free nasogastric intubation, *JACEP* 8:289, 1979.)

REPLACEMENT OF NASOENTERIC FEEDING TUBES

Indications and Contraindications

The most common indication for replacement of a feeding tube in the ED is unintentional removal of a preexisting feeding tube. In one prospective study, 38% of tubes were removed unintentionally. Although some of these tubes had fallen out or had been coughed out, more than half were pulled out by the patient.³⁹ Tube rupture, deterioration, or clogging may also necessitate replacement. Management of a clogged or nonirrigating feeding tube is discussed in the later section on clogged feeding tubes.

Feeding Tube Site

Three major classes of enteral feeding tubes are in common use and are classified according to the site of insertion. Tubes can enter through the nares (a cervical ostomy) or the abdomen (an abdominal ostomy). Enteral tubes are often categorized by the location of the tip of the tube. Tubes may terminate primarily in the stomach, such as a gastrostomy (G) or PEG tube (Fig. 40.14). They may terminate in the jejunum (J tube) (Fig. 40.15) or in both the stomach and the small intestine (a PEG-J tube). To confuse the issue, some tubes enter the stomach and terminate in the stomach (G tube) or in the proximal part of the small bowel (J tube), whereas others enter the GI tract directly through the wall of the small bowel (J tube). Practically speaking, almost all gastric tubes are PEG tubes. They are placed endoscopically with local anesthesia and without a surgical incision. J tubes that enter the small bowel directly are inserted surgically under general anesthesia, require a surgical incision, and result in a surgical scar at the insertion site. Gastric feeding results in better digestion than intestinal feeding does. Jejunal feeding reduces reflux and aspiration.⁴⁰ Normally, approximately 20% of the gastric antral contents pass into the duodenum, with 80% refluxing back into the body of the stomach for further mixing, so proximal duodenal feeding is of limited benefit in preventing aspiration.^{41,42} If the feeding tube is placed in the antrum of the stomach or in the small bowel, enteral feeding solution passing into the small bowel may not be tolerated and can result in diarrhea and paradoxical decreased nutrition.^{41,42}

Procedure

The clinician should explain the procedure to the patient before passage of the tube. Replacement of a nasoenteric feeding tube requires greater time and effort if the patient is uncooperative or has a physically obstructing lesion. It is generally advisable to restrain the hands of demented, impaired, or otherwise uncooperative patients. Prepare the nares before passage of the tube using the procedure for primary NG tube placement. If a feeding tube stylet is used, lubricate and insert it into the feeding tube before introducing it into the naris. Tube stylets can be lubricated with water-soluble jelly. If using the Dobhoff, Entri-Flex (Biosearch [Biosearch, Branchburg, NJ.]), or another tube with preapplied lubricant, you may need to activate the lubricant with a 5-mL flush of water. Never allow the stylet to protrude beyond the end of the feeding tube because these stiff, small-diameter wires have the capacity to scratch the esophagus and allow the creation of a false passage. The stylet may lock into position on the tube at the proximal end and should be properly secured.

When the patient is uncooperative or cannot drink, introduce 5 to 15 mL of water into the mouth or into the proximal end of the feeding tube with a syringe; this may induce swallowing and facilitate passage of the tube. Although the patient may not swallow for several minutes, wait for swallowing because this may mean the difference between a coiled or pulmonary tube placement and successful passage.

Confirmation of Placement

Auscultatory confirmation of tube placement can be misleading, so confirm proper placement of the tube with a radiograph before feeding.³ However, radiographic confirmation of tube

Figure 40.12 **A**, In this scout view of a thoracic computed tomography scan, the tip of the nasogastric tube descends only to the level of the T7 vertebrae (*arrow*). The stomach is overinflated with air (*asterisk*). **B**, An axial image from the neck reveals that the nasogastric tube is coiled multiple times in the pharynx (*arrows*) and thus never reached the stomach. *ETT*, Endotracheal tube; *OPA*, oropharyngeal airway.

Figure 40.13 This axial computed tomography (CT) scan at the superior thoracic level demonstrates tracheal placement of a nasogastric tube (NGT). The NGT is seen twice in the esophagus (*small red arrows*), which suggests that it first descended and then coiled and ascended in the esophagus. It then coiled again, turned downward, and ultimately came to rest in the trachea (*large red arrow*) anterior to the endotracheal tube (*yellow arrow*). Luckily, no oral contrast media was injected through the NGT before the CT scan.

placement may also be misleading. In viewing the radiograph, it is particularly important to study the area around the carina. An esophageal tube shows at most a mild change in course, whereas a tracheally placed tube usually deviates significantly as it travels into the right or left main stem bronchus. The end of an NG tube may appear to be in the stomach, yet may actually be in the left lung behind and below the top of the diaphragm.⁴³ When a stylet has been used for passage, leave it in the feeding tube for the radiograph because the tube's course is not always visible without it. The stylets of most tubes are designed to allow insufflation and aspiration while in place. Even when stomach entry is certain, the intestinal location may be misleading on a radiograph. A nasogastric tube may lie completely to the left of midline and yet have its

tip in the duodenum, or it may occupy a position overlying the right side of the abdomen yet not have entered the duodenum. A contrast-enhanced study is necessary to ascertain duodenal position when pulmonary placement has been ruled out.^{44,45}

Examine the radiograph also for the presence of mediastinal air or pneumothorax, which may suggest pulmonary or esophageal puncture. An esophageal puncture should be evaluated with endoscopy and may require surgery, depending on the size of the rent.

The end-bulb of many nasoduodenal tubes will pass into the duodenum after positioning the patient in the right decubitus position for an hour. Some researchers recommend pretreatment with metoclopramide to enhance gastric emptying.⁴⁶⁻⁴⁸ One investigator found that metoclopramide enhances duodenal passage of nasogastrically placed feeding tubes in diabetic, but not nondiabetic, patients.⁴⁴ Gastric antral motility in diabetic patients is often impaired; metoclopramide helps restore normal synchronized activity in these patients but has little effect on emptying in those with normal antral function. The usual dose of metoclopramide is 10 mg, administered intravenously. In addition, 3 mg/kg of erythromycin lactobionate given intravenously over a 1-hour period works similarly and may be effective even if metoclopramide fails.⁴⁹ Endoscopy or fluoroscopy may be necessary if positioning and metoclopramide are not successful.

Complications

Pulmonary intubation is an uncommon but well-known and potentially fatal complication of insertion of nasal feeding tubes (see Fig. 40.10A). Coughing and respiratory distress are the most common symptoms of respiratory passage of an NG tube, but there may be relatively few apparent symptoms in a demented or comatose patient.⁵⁰ Decreased mentation and an absent cough reflex are predisposing factors for unrecognized

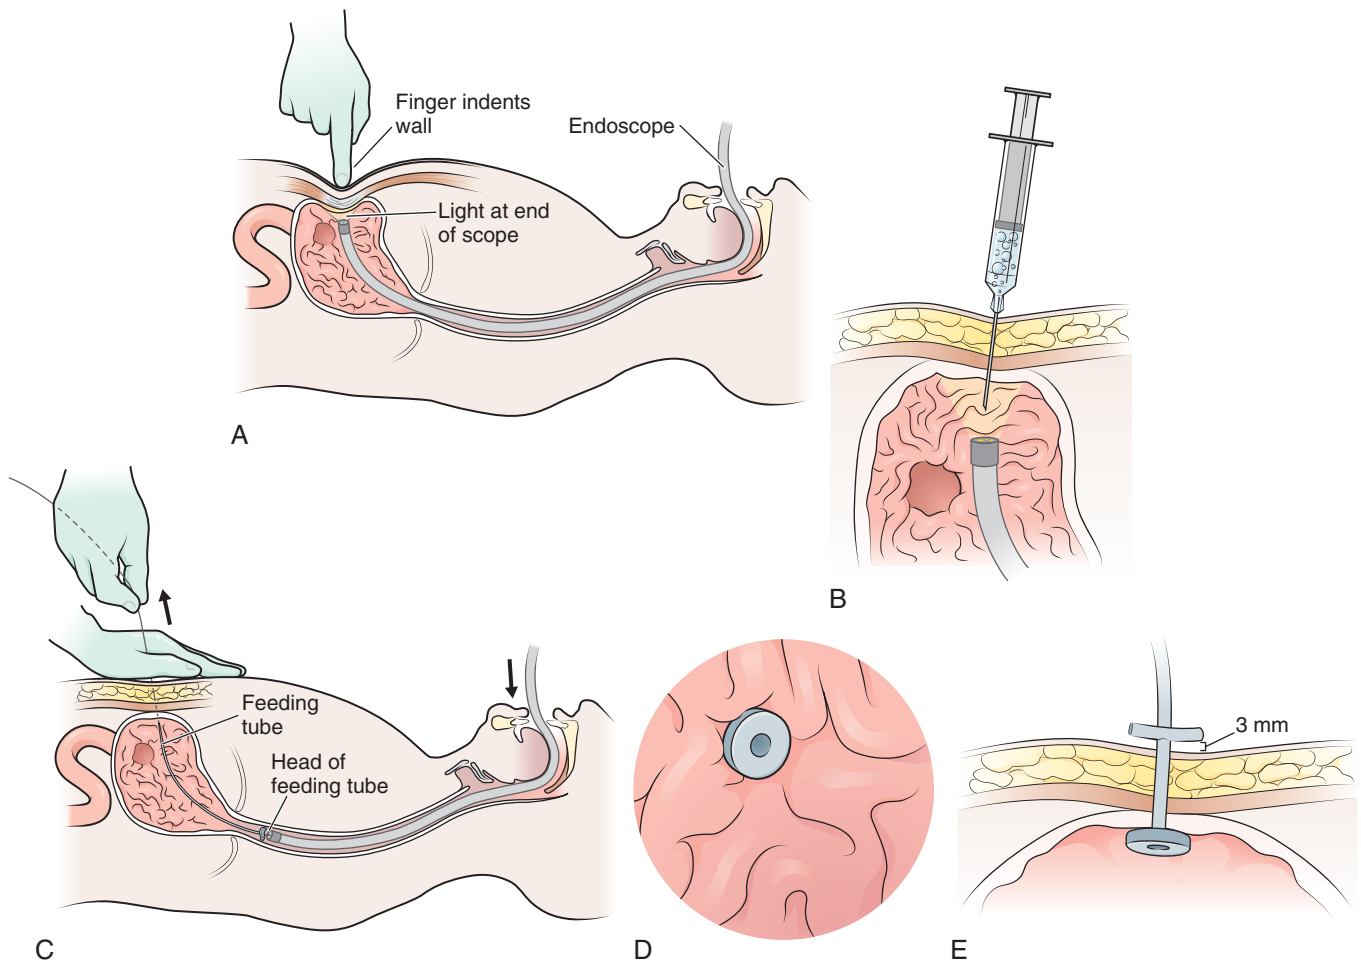

Figure 40.14 Placement of a percutaneous endoscopic gastrostomy tube. **A**, Under conscious sedation, pass a lighted endoscope into the stomach. Indent the skin with a finger to determine the optimal puncture site where the stomach and abdominal wall are closest, with no bowel between. **B**, Fill a syringe with saline and advance it percutaneously to the selected entry point until the tip of the needle is seen entering from the gastric lumen through the endoscope. If air is aspirated and no needle tip is seen, the needle is in the bowel, not the stomach. **C**, Push and pull the scope/snare/feeding tube combination into position (arrows show direction of travel). **D**, Pull the head of the feeding tube into contact with the gastric mucosa. **E**, Use an external bolster or crossbar to keep the tube snug against the skin and gastric wall, but not so tight that it causes ischemia of the intervening tissue.

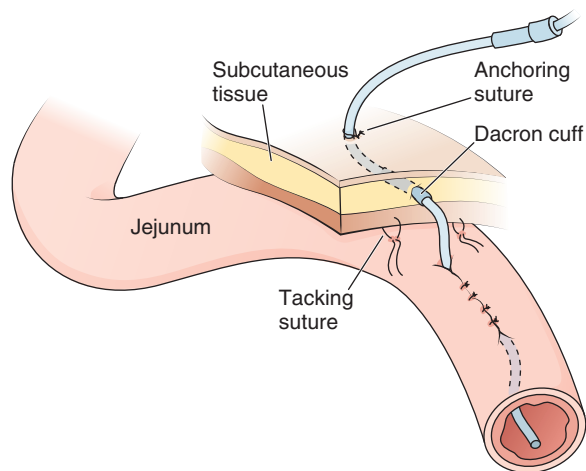

Figure 40.15 Formation of a Witzel tunnel and final permanent placement of a jejunal catheter. (From Wiedeman JE, Smith VC: Use of the Hickman catheter for jejunal feedings in children, *Surg Gynecol Obstet* 162:69, 1986.)

nasopulmonary intubation with NG tubes.³ Misplacement is far more likely in patients with ET or tracheostomy tubes, conscious or not, perhaps because tracheal stimulation by a misplaced tube is less likely to be appreciated or communicated. A small end-bulb (e.g., 2.7 mm in diameter) can slip past a tracheal high-volume, low-pressure cuff and easily pass to the periphery of the lung.^{3,50-54} Pneumothorax may result when an NG tube dissects into or is withdrawn from the pulmonary parenchyma.⁵⁵ Bloody aspirate from a tube should heighten awareness of possible tissue damage.

A clogged or nonfunctional NG tube may be difficult to remove. Fluoroscopy may allow careful insertion of a guidewire or stylet into an in situ tube to facilitate removal. Fluoroscopy may also identify the mechanical problem interfering with removal of the tube. Segments bent double are probably the most common cause. Knots, though uncommon, do occur. Do not use excessive force to remove an NG tube because serious injury to the patient may result.

Premature removal of an NG tube is the most frequent complication of the use of feeding tubes. For long-term use

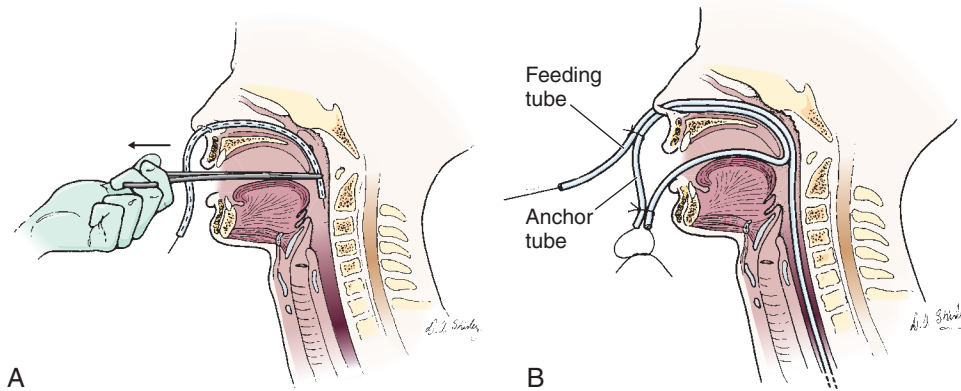

Figure 40.16 Placement of a nasogastric (NG) tube anchor to secure a companion NG or feeding tube in an uncooperative patient who repeatedly pulls out the feeding tube. **A**, Using forceps, grasp the tube in the pharynx and pull it out through the mouth (arrow shows direction of travel). This will serve as an anchor tube. **B**, Tie the ends of the short anchor tube together to form a loop, and tie the companion NG or feeding tube to the anchor loop.

or frequent removal of an NG tube by a patient, a gastric feeding tube will probably be inserted. To help prevent removal by an uncooperative patient, secure the NG tube to a loop anchor passed in the same naris. The anchor works by aversive stimulation of the soft palate and nose, with distraction from the NG tube rather than by mechanical stabilization of the tube.

Sax and Bower recommend a technique for creating a separate NG-tube anchor.⁵⁶ Cut a soft, weighted nasogastric tube approximately 12 inches from the top. Pass a heavy (2-0) silk suture through the tube to exit the side hole. Insert the guidewire with care because it must not protrude from the inserted end. Sedate the patient if uncooperative. Insert the tube through the anesthetized naris into the nasopharynx, grasp it with Magill forceps, and pull to remove it through the mouth (Fig. 40.16A). Trim excess tubing without cutting the silk suture. Make a closed loop by tying the silk suture in front of the nose. Leave the loop long enough so that it does not apply continuous pressure to the nose or palate while at rest. Pass the nasal feeding tube through the same nostril and secure it to the loop (see Fig. 40.16B). This anchor is simpler to construct and more comfortable than anchors that pass through the opposite nostril.⁵⁶

Complications of properly placed nasogastric tubes include nasopharyngeal erosion, esophageal reflux, tracheoesophageal fistula, gagging, rupture of esophageal varices, and otitis media.⁵⁷ One survey of nasogastrically fed patients found that the most distressing features of having an NG tube for feeding were deprivation of tasting, drinking, and chewing of food; soreness of the nose; rhinitis; esophagitis; mouth breathing; and the sight of other patients who were eating.⁵⁸

Checking feeding tolerance is difficult with small-gauge feeding tubes. Aspiration of tubes to check for residuals is not recommended with tubes 9 Fr in size or smaller. Aspiration is likely to clog the tubes because they collapse under pressure and relatively small particles can occlude the tube. For the same reasons, the residual is likely to be inaccurate.⁵⁹

Patient or Nursing Instructions

To maintain patency of the catheter, small tubes should be flushed with 20 to 30 mL of tap water at least two to three

times daily and after the administration of medication.^{45,59} Water is a more effective irrigant than cranberry juice.⁶⁰ Medications should be in liquid form or completely dissolved or they may clog the tube. Methods of dealing with a clogged tube are discussed subsequently. The tube should be anchored to the nose and face in such a way that it is not in contact with the skin at the nasal opening. This reduces tube discomfort and prevents necrosis of the alae, nares, and distal septum. Patients who exhibit a tendency to pull on their tubes need adequate restraints. Patients receiving tube feedings should have their head elevated to at least 30 degrees above the horizontal.⁵⁹

PHARYNGOSTOMY AND ESOPHAGOSTOMY FEEDING TUBES

Cervical pharyngostomy and cervical esophagostomy have both been developed relatively recently. Cervical esophagostomies are generally performed at the time of cervical or maxillofacial operations. Malignant growths in the proximal part of the esophagus, head, or neck are the primary indications for esophagostomy. Cervical esophagostomies may eventually evolve into a permanent sinus, thereby allowing the feeding tube to be removed between meals. Such tubes are unlikely to be replaced in the ED, but the concept of these feeding tubes is illustrated in Fig. 40.17. Complications of pharyngostomy and esophagostomy include local soft tissue irritation, accidental extubation because of excessive length of the external tube, pulmonary aspiration from vomiting, arterial erosion with exsanguination, and esophagitis or stricture of the esophagus from reflux.

GASTROENTEROSTOMY AND JEJUNOSTOMY TUBES

A nursing home patient with a nonfunctioning or displaced feeding tube represents a common ED scenario. The clinician cannot always determine the location of the original feeding tube by simply looking at a patient who arrives in the ED for replacement of the tube. Nevertheless, the emergency clinician should attempt to ensure that the terminal end of a replaced

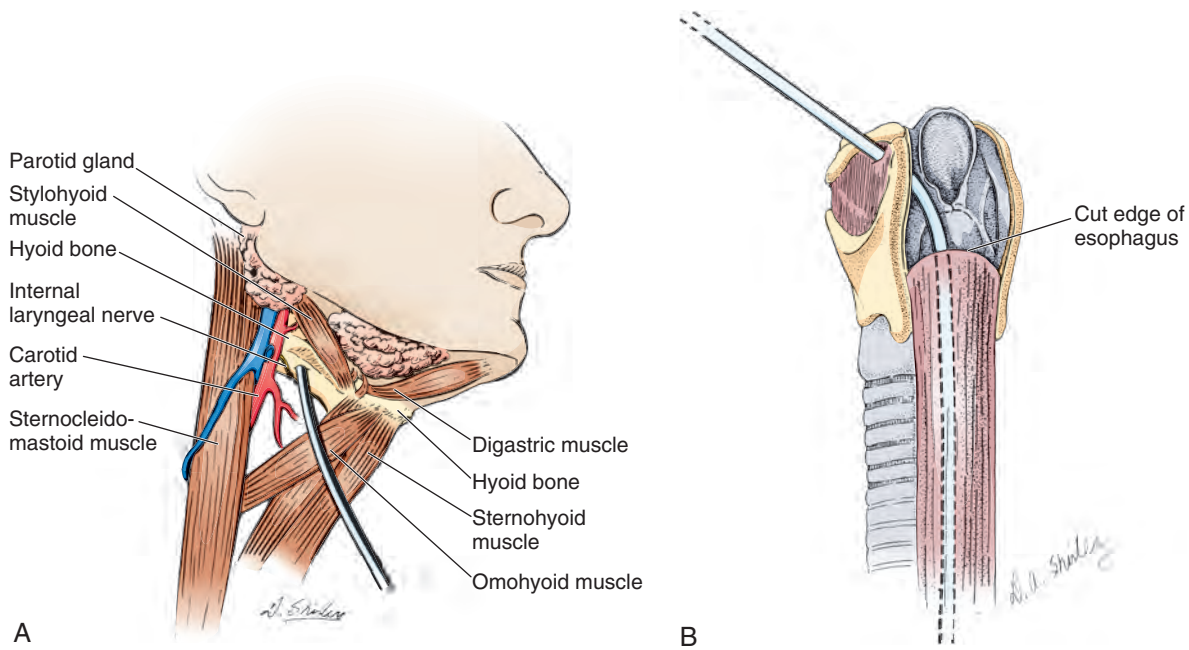

Figure 40.17 A, Pharyngostomy feeding tube. B, Pathway for an esophagostomy or pharyngostomy feeding tube.

tube is in the same viscus as the original was. External inspection may or may not reveal where a feeding tube should terminate. Contrast-enhanced studies and fluoroscopy usually provide such information (Fig. 40.18). G tubes are available in various types (Fig. 40.19). Tubes are kept in place by either a modified end (such as a mushroom tip) or an inflatable balloon. A de Pezzer (mushroom) tube, a Corflo tube (CORPAK MedSystems, Buffalo Grove, IL), or a Foley G tube is designed only for intragastric termination. Some tubes have two lumens, one terminating in the stomach for decompression and the other in the small bowel for feeding. These can be confused with tubes that have two entrances to one lumen (one for continuous feeding and the other for medications) and tubes that have a second lumen leading to an inflatable balloon. An original tube is not usually a Foley or balloon-tipped tube. An original PEG tube is pictured in Fig. 40.20. Note that on cross section this original long tube has no balloon or port to inflate a balloon but has a mushroom end that is removed by traction.

Foley catheters are not ideal as long-term feeding tubes. They clog easily and the balloon disintegrates in stomach acid. They may be used temporarily but should be replaced with specialized feeding tubes when feasible (Fig. 40.21). A call from a nursing home indicating that a tube has been pulled out should be answered with the advice that a Foley catheter be used immediately to keep the stoma open. Always inflate the balloon with saline and use a bolster to prevent migration of the tube. The clinician has a few options when faced with the task of replacing a feeding tube. Unfortunately, old records or nursing home personnel rarely give specific information that is helpful to the emergency clinician. If only a stoma exists, one may request that the nursing home describe or send the prior tube to the ED. If no surgical scar is seen at the stoma site, the tube is almost certainly a G tube or a G tube that terminated in the jejunum. When in doubt, pass a Foley catheter without balloon inflation, tape it to the skin, and refer the patient to a consultant or the original referring clinician.

Some type of tube must be placed to stent the stoma, or the stoma will quickly close (in a matter of hours) and the patient might require a more complicated procedure to regain access. The only real concern of placing a gastric tube into the jejunum is that the balloon will produce intestinal obstruction if it is fully inflated.

If the tube is nonfunctioning yet still in place, the clinician must make a judgment regarding the risk versus benefit of removal and replacement, versus an attempt at unclogging the tube (see the subsequent discussion on unclogging). The major concern is that a new tube may be misplaced (i.e., into the peritoneal cavity). If it appears that a skin incision was used to place the tube, it is unlikely that the patient has an easily removable tube. If the patient has signs of a complication (e.g., infection, ileus, intestinal obstruction), surgical consultation is warranted. Note that a migrated tube, with the balloon or tube obstructing the gastric outlet, is a common cause of gastric distention, persistent vomiting, or signs of intestinal obstruction. This is easily remedied (see procedural description in section on [Complications](#) and [Fig. 40.22](#)).

Most PEG tubes do not have sutures joining the stomach with the abdominal wall, so there is potential for a replaced tube to end up in the peritoneal cavity. Adhesions, however, usually keep the stomach appropriately positioned, but only after the tract has matured. Nonoperative tube replacement techniques are safe only through an established tract between the skin and the bowel. Catheter replacement should not be attempted in the immediate postoperative period. A simple gastrostomy takes approximately a week to form a tract.⁶¹ A stable tract may take 2 or 3 weeks longer to form if healing is compromised.

Poor nutrition is the most common element compromising wound healing in patients requiring a feeding tube. A Witzel tunnel may take up to 3 weeks after the operation to mature sufficiently for safe nonoperative tube replacement (see [Fig. 40.15](#)).

Figure 40.18 **A**, Without old records, the exact type and positioning of this nonfunctioning feeding tube are unknown. The operative scar on the abdominal wall suggests an implanted tube, not a simple gastric tube. **B**, Injection of contrast material before removal of the tube demonstrates the tip of the tube ending in the small bowel, not the stomach. **C**, If the tube has been removed and questions remain about the type of tube and circumstances of placement, a new tube is best placed under fluoroscopy with guidewire assistance.

Equipment for Replacing a Dislodged Tube

Equipment for replacing a feeding tube through a matured site includes gloves, a stethoscope, a feeding tube, an external bolster, lubricant, a basin, and a syringe that fits the tube. Tincture of benzoin, tape, and absorbent dressing material may be used to dress the wound, although many are better left undressed.⁶² Some feeding tubes require special plugs or connectors. Others need to be pinched with a clamp when not

in use to prevent leakage. Some tubes are placed with the aid of accompanying guidewires or stents.

The easiest tube to replace is one that has been removed in the ED or dislodged for only a few hours (Fig. 40.23). The stoma closes quite quickly, so replacement is best done as soon as possible. Gently probe the stoma site with a cotton-tipped applicator to determine patency and direction of the tract. In selected cases, a hemostat can gently dilate the opening to accept a replacement tube. Do all such attempts carefully to

Figure 40.19 A, Various types of gastrostomy tubes. 1, Silicone catheter (American Endoscopy, Bard Interventional Products, Billerica, MA). 2, Polyurethane catheter with a collapsible foam flange (to collapse, the tube should be cut) (VIASYS MedSystems, Wheeling, IL). 3, Latex catheter with a moveable external bolster and an internal mushroom or de Pezzer–type flange on the end (American Endoscopy, Bard Interventional Products). 4, Balloon (Foley) catheter (Wilson-Cook Co., Winston-Salem, NC). B, A user-friendly gastrostomy tube is supplied by VIASYS MedSystems. The CORFLO-dual GT gastrostomy tube is packaged with lubricant, a prefilled syringe for inflating the balloon, and an extension set. The color-coded inflation valve indicates tube size (12 to 24 Fr). The silicone tube uses a retention balloon and a movable bolster. Note that the retention bolster is designed to prevent inward migration of the tube and not to be an anchoring device sutured to the skin. C, A gastric balloon jejunal feeding tube enters the stomach and delivers feedings into the jejunum.

avoid creating a false tract. Use local anesthetic around the stoma if exploration causes pain. Bleeding is common. After the tube is passed, restrain the hands to avoid removal of the tube by uncooperative patients.

Removal of a Transabdominal Feeding Tube

A feeding tube may need to be removed because it is irreversibly clogged, leaking, or broken; persistently develops kinks; is too large or too small; causes a hypersensitivity reaction; is associated with an abscess; or is not the appropriate length for feeding into the desired viscus. Before a new transabdominal feeding tube is inserted, remove the old tube. Most, but not all tubes, can be removed without endoscopy. Before attempting to remove the tube in place, it is imperative to know whether it is safe to remove. Standard de Pezzer or mushroom catheters that have been modified with bolsters or rings at the time of endoscopic or surgical insertion may no longer be safe to remove with traction. Tubes are occasionally secured with sutures or rigid internal bumpers or stays. It is rare, however, to encounter a tube that cannot be removed with traction/countertraction. Modest force may be required. Use a hand for countertraction, and be prepared for a pop and splattering of gastric contents (Fig. 40.24). This causes the tube and end

mushroom to narrow, and the tube should come out easily. The inner crossbar, if present, may remain in the stomach when the rest of the feeding tube complex is removed by traction. The crossbar will pass in stool, and obstruction from it has yet to be reported in adults. In small children, obstruction is a possibility, and the crossbar should be removed by endoscopy.^{63,64}

Recently placed feeding tubes may need to be left in until a tract has formed (1 to 3 weeks, depending on the procedure), even if the tube is nonfunctional.

A simple Foley catheter G tube is the easiest to remove. Deflate the Foley balloon and the tube should slide right out. If the Foley balloon cannot be deflated, cut the tube to allow the balloon to deflate. Do not cut the catheter so close to the abdomen that it will be impossible to maintain a grip on it for removal by traction if the balloon still does not deflate. The balloon may also be punctured to cause it to deflate. To puncture a Foley balloon, apply traction on the catheter to draw the balloon up against the ostomy (Fig. 40.25). Using the taut feeding tube as a guide, pass a small-gauge needle along the tube to puncture the balloon. It may be necessary to try again on the other side of the catheter because the balloon may be inflated asymmetrically and contact with the needle may be established on one side and not the other. Be careful not to

Figure 40.20 **A**, This type of tube serves as the original percutaneous endoscopic gastrostomy (PEG) device. It has a mushroom head, not a balloon. **B**, When replaced, a balloon-type tube (*upper tube*) is used in place of the original mushroom tip tube (*lower tube*). **C**, This original tube is leaking because the mushroom tip has been pulled out of the stomach lumen and is lodged in the soft tissue of the abdominal wall. **D**, If the tube tract has matured (at least 2 weeks after placement), it may be removed by traction/countertraction. Significant force may be required; be prepared for a pop and splattering of gastric contents. **E**, It is easy to determine whether there is a balloon at the end of a PEG tube that cannot be removed. Simply cut the tube, and if there is no additional port or channel to inflate the balloon, then **F**, it must be the type of tube that can be removed by traction.

track away from the ostomy into the patient's abdominal wall or to cause separate punctures of the stomach. Allow a minute for the balloon to deflate before making another attempt at removal by traction. Large, nondeflating balloons should probably be punctured, whereas small balloons may be removed with traction.

If it is not possible to pull the inner bolster or mushroom out through the ostomy, cut the tube at the skin, push the remaining short stump into the stomach, and rely on later rectal passage. Although obstruction or impaction is infrequent, it can occur, and this alternative has the potential to be

problematic in children or patients who have had previous impaction, potential for bowel obstruction, or stool-passing problems. Rigid or large internal mushrooms and bolsters, the very kind that cause the most difficulty with percutaneous removal, are also more likely to cause difficulty with rectal passage. In no case should a device be released into the gut with a long length of tubing attached. Remember that double-part tubes may have an additional length of tubing for duodenal or jejunal feeding that extends far past the inner bolster. Korula and Harma reported successful intestinal elimination of 63 of 64 G tubes that were cut at the skin entrance and advanced

G-Tube Replacement (With Foley Catheter)

1 To make a bolster, cut a 3-cm segment of tubing from the proximal end of another Foley catheter. (A red rubber catheter is used in this case). A bolster will prevent migration of the tube, which can cause gastric obstruction.

2 Cut a small hole (on each side) in the middle of the 3-cm segment.

3 Insert a hemostat through the holes in the new bolster and grasp the feeding tube.

4 Pull the feeding tube through the bolster.

It should be placed 1 cm above the external abdominal skin.

5 Identify and inspect the stoma.

Surrounding scars may suggest that the tube is in fact an implanted jejunal tube, not a simple G tube.

6 Lubricate the tube and gently pass it into the stoma.

7 Inflate the balloon with saline once it is in proper position.

8 Advance the bolster so that it is 1 cm above the skin.

9 Confirm proper tube placement with auscultation and aspiration.

A contrast-enhanced radiograph may also be obtained.

10 Remember that Foley catheters are not ideal feeding tubes but are useful in temporarily maintaining stoma patency.

Disintegration of the catheter latex may occur in a few months.

Figure 40.21 G-tube replacement (with a Foley catheter). Foley catheters are not ideal feeding tubes but can be useful temporarily to maintain stoma patency.

Figure 40.22 **A**, Whenever possible, use a formal feeding tube instead of a Foley catheter. **B**, A common dilemma. This patient had gastric distention, and persistent vomiting after tube feedings. The tube had simply migrated distally (note the comparison of the new tube and positioning of the indwelling one) because the bolster was too far proximal. Withdrawing the tube and repositioning the bolster alleviated the problem.

into the stomach through the stoma.⁶⁵ These cases included tubes with internal bumpers, and success occurred regardless of the nature of the patient's underlying medical disorder, age, or method of original tube placement. However, no patient had suspected obstruction or potential for obstruction (e.g., no previous radiotherapy, inflammatory bowel disease). The one lodged tube required endoscopic removal from the pylorus. In most cases, passage of the tube was documented by sequential radiographs, with a mean interval of 24 days until passage (range, 4 to 181 days).

Some clinicians and surgeons strongly condemn cutting off the tube at the skin, even when the risks posed by the procedure are very low. It is always advisable to contact the patient's private clinician before cutting the tube. In some cases, endoscopic retrieval of the tube remnant is preferred over allowing rectal passage, and the tube should not be cut until just before or during endoscopy to ensure that migration does not occur before endoscopy.

Securing a Transabdominal Feeding Tube

If a bolster is used, no additional means of securing the tube is necessary if the patient is not prone to pulling it out. Some clinicians tape tubes to the skin rather than using a bolster, or use special adhesive devices designed to control the tube and prevent ingress, such as the Drain/Tube Attachment Device (Hollister, Inc.) or Flexi-Trak (ConvaTec, Skillman, NJ). Tape is particularly vulnerable to problems because the stress that

the tape places on the skin as the tube pulls on the tape can lead to skin damage. Strong adhesive tape can also damage the skin on removal. Tape that is not sufficiently adhesive can let go, particularly if it gets wet. Because tape is less durable, home or nursing home caregivers who are less skilled may retape the tube (Fig. 40.26). If the tape is replaced at home, it may be placed under too much tension and cause thinning of the abdominal wall at the stoma. If too much slack is allowed, the tube may be pulled in. Strong tape can also damage the tube during tape changes if it adheres too strongly to the tube. Special adhesive devices or bolsters are preferred.

Verification of Placement

There is no universally agreed standard with regard to performing a confirmatory contrast-enhanced study for all easily replaced feeding tubes. The editors of this text, and most clinicians, verify position routinely with a contrast-enhanced radiograph, whereas others use the clinical criteria outlined earlier. Radiographic verification is easily performed and interpreted in the ED. Routine use of postplacement contrast-enhanced radiography to confirm proper placement should be mandatory when the tube tract is immature (i.e., < 1-month duration),⁶⁶ when passage of the replacement catheter has been difficult, when the clinician is unable to aspirate intestinal contents, or when the patient is unable to communicate any symptoms that might occur with tube misplacement. Peritoneal infusion of feeding solution can be fatal.

The position of the G tube may be checked by air insufflation and aspiration of gastric fluid, as is done with nasogastric tubes. Air should enter the stomach without resistance and should produce immediate borborygmi. Gastric fluid should return with aspiration. It may be necessary to insert a small volume of water to obtain good return. Water pooling in soft tissue may be aspirated back through a misplaced catheter. Good tube placement is indicated when more fluid returns with aspiration than was originally placed into the catheter.

Correct tube placement is easy and readily verified radiographically with a small amount of contrast material passed into the tube (Fig. 40.27). Use a catheter-tipped syringe to introduce water-soluble contrast solution (e.g., diatrizoate meglumine–diatrizoate sodium [Gastrografin, Bracco Diagnostics Inc., Monroe Township, NJ]) into the tube. Barium is contraindicated because of the potential for peritoneal contamination. Inject 20 to 30 mL of water-soluble solution to document the intraluminal tube position. Take a supine abdominal film 1 to 2 minutes after instillation of dye to optimize visualization of the gut. Because the film must be obtained quickly, it is easiest to perform the injection in the radiology suite, followed by a radiograph in only a few minutes. If the contrast material does not flow freely into the tube, the procedure should be terminated immediately and the position of the tube questioned. With proper positioning, contrast material will outline the part of the gut containing the tube (e.g., stomach with a G tube). An irregular or rounded blotch with wispy edges or streamers suggests peritoneal leakage. In questionable cases, injection of dye can be performed under fluoroscopy.

Complications

Viscus puncture, viscus–abdominal wall separation, and creation of a false tract with subsequent misplacement of the tube are

Figure 40.23 **A**, The feeding tube was dislodged at 11 PM and by 9 AM the stoma was too tight for easy replacement of the tube. It was accomplished under fluoroscopic guidance, always the best option in questionable cases. **B**, The stoma opening and direction of the tract can be investigated by gently probing the site and tract with a Q-tip; in this case, it easily entered the stomach. **C**, This tight stoma was carefully dilated with a hemostat under local anesthesia. A false passage can easily be created, and this area usually bleeds readily. **D**, To give a Foley catheter sufficient rigidity to aid in passage, the end of a Q-tip was inserted in the side port of the distal end of the catheter, and traction was applied to the catheter. **E**, If a de Pezzer catheter is used, an endotracheal tube stylet distends the flange for passage, and the tip reforms once in the stomach. **F**, This patient removed her recently replaced feeding tube, with the balloon inflated, while still in the emergency department awaiting transfer. This could have been avoided if her hands were restrained.

risks associated with dilation procedures. Complications of gastrostomy include wound infection around the catheter, performance of an unnecessary laparotomy for suspected leakage, gastrocolic fistula, pneumatosis cystoides intestinalis, bowel obstruction, peritonitis, and hemorrhage.⁶⁴ Jejunostomies can cause most of these complications, as well as other types

Figure 40.24 Gentle, firm traction using the flat part of the opposite hand for countertraction will remove most percutaneous endoscopic gastrostomy tubes, even those with internal mushroom bumpers. Modest force may be required; be prepared for a sudden pop and splattering of gastric contents.

of fistulas and small bowel obstruction from adhesions or volvulus around the jejunostomy site.^{48,67} The most common complications of gastrostomy and gastroenterostomy are local skin erosion from leakage, wound infection, hemorrhage, and dislodgment of the tube.⁵⁹ Peritonitis and aspiration are the most critical complications of gastrostomy feedings.^{59,67} Jejunostomies are less prone to stomal leakage and cause less nausea, vomiting, bloating, and aspiration than do gastrostomies.^{68,69}

Dislodgment of G and J tubes is most common in the 2 weeks after creation of the ostomy.⁷⁰ Extrusion of the G tube is usually caused by excessive tension applied to the tube. Only gentle contact of the gastric and abdominal walls is desirable.

Figure 40.26 Tape is best avoided to minimize skin maceration. If needed, this is a simple but less secure technique for securing a gastrostomy tube to the skin.

Figure 40.25 **A**, If a Foley balloon will not deflate, use traction to bring the balloon against the abdominal wall. Gently pass a small needle along the course of the catheter while puncturing the balloon as many times as necessary. Wait a few minutes for the fluid to egress. **B**, Once the balloon is deflated, it can be withdrawn. Note the encrusted condition of this long-standing Foley catheter used as a percutaneous endoscopic gastrostomy tube. **C**, Occasionally, the wire from a central line kit can clear the inflation lumen and allow deflation. **D**, If the valve mechanism malfunctions, cut the catheter and attempt to drain the balloon by placing a needle in the inflation channel and flushing and withdrawing fluid.

Figure 40.27 **A**, Although this feeding tube seemed to be replaced easily in an uncommunicative nursing home patient, gastric contents could not be aspirated; therefore a contrast-enhanced study was performed. **B**, Note the free flow of contrast material throughout the abdomen, especially outlining the liver (*arrows*). This film indicates placement of the feeding tube into the peritoneum. Placing food through this tube could be disastrous. It is prudent to routinely obtain a contrast-enhanced study after replacement of a percutaneous endoscopic gastrostomy tube in the emergency department. Instill 20 mL Gastrografin (Bracco Diagnostics Inc., Monroe Township, NJ)/10 mL saline into the tube and take a radiograph in 3 to 5 minutes. **C**, Contrast-enhanced study demonstrating correct placement of a feeding tube. Note the outline of the gastric rugae and the characteristic mucosal folds of the small intestine.

Uncooperative patients should be restrained and mittens are often particularly helpful. Sutures and large mushrooms or balloons do not prevent purposeful removal of the G tube by an uncooperative patient.

A small amount of drainage is to be expected at the tube entry site. Local leakage of gastric juices may macerate and irritate the skin, which can predispose the site to local infections and abscesses and encourage the development of small granulomas.^{68,71} Granulomas are particularly common in children. They can be treated with silver nitrate at the time of dressing changes. Any dressing used around the entry site of an enteral nutrition tube should absorb fluid and not encourage persistent moisture.⁶² An unusually large stoma may promote a leak. Although insertion of a larger tube or firmer traction on the

tube might be transiently effective, these measures often result in further enlargement of the stoma. Rigid gastrostomies promote leakage by widening the stoma as they pivot. Insertion of a soft, pliant feeding tube through the widened stoma is often easy and allows later contraction of the stoma.¹ If these techniques are ineffective, temporary removal of the feeding tube may allow the stoma to shrink. Large amounts of drainage around the stoma site may occur with high residual volumes.⁷² The residual should be checked and feedings withheld until residuals are less than 100 mL. Feeding residuals should be checked every 4 hours when a patient is receiving continuous-drip feeding.⁷³

Pneumoperitoneum after percutaneous gastrostomy is neither unusual nor dangerous. Benign pneumoperitoneum may be

present as long as 5 weeks after PEG.^{64,72} Pneumatosis cystoides intestinalis can occur through the defect in the bowel wall created for the enterostomy tube. Though often clinically insignificant, its occurrence suggests air under pressure in the small bowel. NG suction and diet change generally permit resolution of the problem. Catheter or feeding tube removal is not usually required.⁷⁴

Clinically significant pulmonary aspiration can occur with G-tube feeding. Methods of checking for silent pulmonary aspiration include assessing tracheal aspirates with a glucose oxidant reagent strip or placing methylene blue in the formula and monitoring tracheal aspirates for pigmentation.^{57,75,76}

A Foley balloon accidentally inflated in the small bowel or esophagus can lead to perforation or obstruction.⁷⁷ Carefully inflate the balloon soon after it has entered the stomach to prevent perforation of the viscus. A G tube may migrate in the stomach and obstruct the gastric outlet. This complication is manifested clinically by vomiting and high residuals of feeding solution. Volvulus and jaundice may also occur as a result of balloon migration. To correct inward migration, first deflate the balloon. Pull the tube back just deep to the desired final position. Reinflate the balloon and pull it the rest of the way back into position.²⁹ The external bolster should be repositioned or one made and positioned, or inward migration will probably reoccur.^{63,72} If the balloon is not deflated before repositioning, the bowel in which it is wedged may be drawn back with it, thereby preventing relief of the obstruction and possibly precipitating intussusception.

A gastrocolic fistula is usually manifested as copious diarrhea. Once it is confirmed, treatment consists of removal of the G tube. Later creation of a gastrostomy in a different location may be possible. The patient may require hospital admission for nutritional support and monitoring of fluid and electrolyte status.

An external bolster that is snugged down too tightly might result in a short stoma and embedding of the internal bolster in the abdominal wall. An abscess may result. Overly tight external bolsters should be loosened. The correct position is 1 cm from the external surface of the abdomen.

CLOGGED FEEDING TUBES

Clogging, leaking, fracture, and kinking are problems common to all feeding tubes. Clearing a clogged tube may be a temporary benefit but is rarely a long-term solution. Hence, whenever feasible, replace nonfunctioning or leaking tubes with new ones. Although it may be only a temporary solution, if the tube has a complex placement or the clinician is unsure how the tube is secured internally, it is prudent to attempt to unclog the tube rather than replace it. Large G tubes are the least likely to clog. G tubes at least 28 Fr in size can tolerate home blenderized foods and viscous feeding solutions. Isosmotic feeding solutions are tolerated by fairly narrow tubes and cost one-sixth of what elemental feedings cost. Isosmotic feedings will clog needle catheters.⁴⁶ When tube lumens are 14 Fr or smaller, all pills and the contents of all capsules should be dissolved in water to prevent obstruction of the tube.⁶²

Kinking is a frequent cause of tube blockage during the immediate period after reinsertion. Withdrawing the tube a few centimeters usually relieves the kink and obstruction. A persistently recurring kink requires removal of the tube and insertion of a fresh tube.

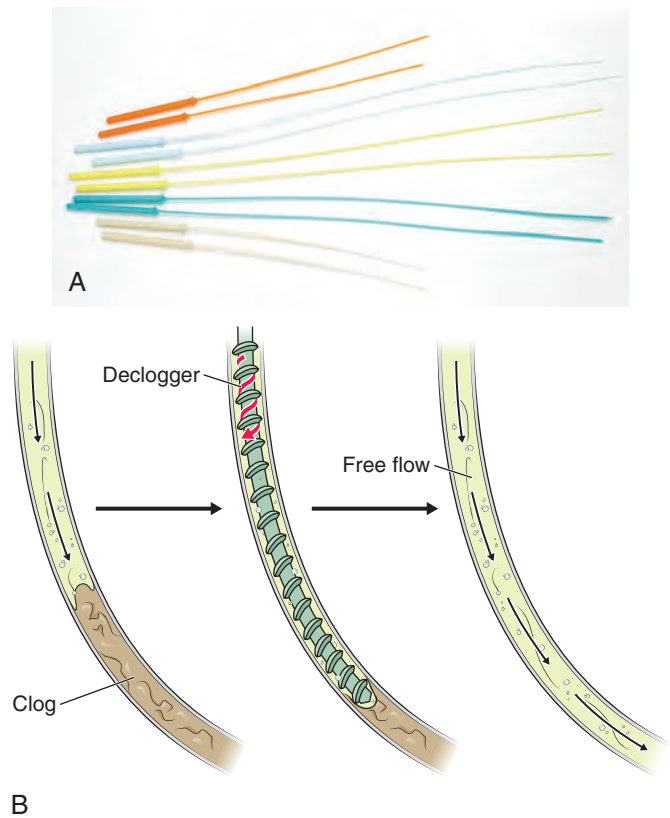

Figure 40.28 A and B, The Bionix tube declogger. Two lengths and several diameters are available. Caution must be observed any time that the screw end of the declogger passes from view because the potential exists to extend or puncture out of the tube and into the patient. (A and B, Redrawn courtesy Bionix Medical Technologies. Bionix Enteral Feeding DeCloggers are a registered trademark of Bionix Medical Technologies. <https://www.BionixMed.com>.)

Accumulated feeding solution or medication precipitates are very difficult to clean or remove. Milking a pliant tube backward may remove some of the cheesy precipitates. Guidewires or stylets may clear the proximal portion of a clogged tube lumen but are unsafe to use in subcutaneous areas of the lumen because they can puncture the tube and injure the patient or create a leak in the tube. Bionix Medical Technologies (Toledo, OH) supplies tube decloggers in two lengths and several diameters for clearing clogs in G and J tubes (Fig. 40.28). After selecting a declogger shorter than the feeding tube, insert it gently into the tube until the end of the screw hits the clog and then rotate it clockwise to bury the end in the clog. Next, slide the declogger up and down to break up and dislodge the clog. Insertion, rotation, and sliding might have to be repeated several times until the dislodged material can be flushed into the patient with saline or water. Gravity alone should be sufficient to allow fluid to pass through the feeding tube into the patient and is a better test of successful declogging than is passage of fluid with a syringe. Theoretically, the pointed screw end of the declogger can puncture the tube, or if a declogger that is too long is put in, it may puncture the bowel or stomach directly. According to the company, no cases have been reported.

Fogarty arterial embolectomy catheters can be used to unclog J and G tubes.⁷⁸ Insert the soft tip of the Fogarty catheter into the feeding tube and advance it while monitoring the insertion

distance to avoid penetrating farther than the length of the feeding tube. Premeasure the allowable length of insertion. A No. 4 embolectomy catheter is suitable for a 10- or 12-Fr feeding tube, and a No. 5 embolectomy catheter is suitable for a 14-Fr feeding tube. When the catheter meets an obstruction, inflate the balloon. This usually opens the obstruction sufficiently for passage of the catheter. Once the Fogarty has been manipulated to a point just proximal to the internal feeding opening, withdraw it while gently inflating and deflating the balloon intermittently. Do not withdraw the catheter when the balloon is inflated because the catheter and feeding tube tend to move as a unit. Repeat this procedure several times if necessary. Once declogging is successful, inject contrast material to confirm the position and integrity of the tube.⁷⁸

Irrigation with carbonated beverages and high-pressure irrigation with small-volume syringes have also been recommended as techniques for unclogging feeding tubes. Although irrigation seems like a straightforward and simple solution, these techniques are generally ineffective; furthermore, the possibility exists for dangerous tube rupture with internal leakage. Broviac catheters are especially prone to tube aneurysms, which can rupture under pressure.⁷¹ Tubes unclogged by forceful irrigation or by deep luminal probing should be radiographed after injection of contrast material to check the integrity of the tube.

Balloon Tamponade of Gastroesophageal Varices

Michael E. Winters

INTRODUCTION

Managing patients with acute gastrointestinal bleeding from gastroesophageal varices can be one of the most challenging scenarios in emergency medicine. These patients often have advanced liver disease and can arrive at the emergency department (ED) with massive hematemesis, airway compromise, hemodynamic instability, critical anemia, thrombocytopenia, and coagulopathy. Gastroesophageal varices are the fourth most common cause of upper gastrointestinal bleeding (UGIB) and account for almost 12% of cases (Fig. 41.1).¹ In patients with cirrhosis, varices account for up to 80% of cases of UGIB.^{2,3} In patients with established gastric or esophageal varices, the annual incidence of acute hemorrhage ranges from 4% to 15%.^{2,4}

Over the past 3 decades, advances in resuscitation, critical care, pharmacology, and endoscopy have significantly reduced the mortality rate associated with acute variceal bleeding. In fact, mortality rates in patients with acute variceal bleeding currently range from 15% to 20%.^{1,5-7} Despite advances in management, up to 20% of patients with acute variceal bleeding fail standard therapy.⁸ Rescue therapies for this group of patients

are limited and include surgery, placement of a transjugular intrahepatic portosystemic shunt or a covered esophageal metal stent, or balloon tamponade.⁸ This chapter details the indications and contraindications for balloon tamponade in patients with acute variceal bleeding, the techniques for placement of the various devices, and the potential complications of this intervention. Although this procedure is rarely needed and placement in the ED is not considered a standard intervention, emergency physicians with knowledge of the technique can attempt to place these critical and potentially lifesaving devices.

BACKGROUND

In 1950, Sengstaken and Blakemore developed and described the use of a double-balloon device to control variceal hemorrhage.^{9,10} Since that time, the Sengstaken-Blakemore tube (Video 41.1) has become the most widely known balloon tamponade device. The Sengstaken-Blakemore tube has an esophageal and a gastric balloon, along with a gastric aspiration port that allows continuous suction of stomach contents (Fig. 41.2). In 1968, Edlich and colleagues, from the University of Minnesota, modified the Sengstaken-Blakemore tube by adding an esophageal aspiration port and increasing the capacity of the gastric balloon.¹¹

Currently, three balloon tamponade devices are commercially available: the Linton-Nachlas, the Sengstaken-Blakemore, and the Minnesota tubes. In contrast to the Sengstaken-Blakemore and Minnesota tubes, the Linton-Nachlas tube is a single-balloon device that consists of a gastric balloon and two ports (esophageal and gastric) for aspiration and lavage. Because placement of these tubes remains a relatively rare procedure, most hospitals stock only one type of device. Regardless of the type of device, success rates for the control of hemorrhage with balloon tamponade tubes range from 60% to 90%.¹²

Balloon Tamponade of GE Varices

Indications

Unstable patients with massive variceal bleeding in the following scenarios:

- Endoscopy is not available
- Endoscopy is unsuccessful at controlling bleeding
- Consultant physicians are unavailable and vasoactive agents have failed to stop bleeding

Contraindications

- History of esophageal stricture
- Recent esophageal or gastric surgery

Complications

- Airway obstruction
- Esophageal rupture
- Aspiration pneumonia
- Pain
- Ulceration of lips, mouth, tongue, or nares
- Esophageal and gastric mucosal erosions
- Arrhythmia
- Dislodgment of previous variceal bands

Equipment

Review Box 41.1 Balloon tamponade of gastroesophageal varices: indications, contraindications, complications, and equipment.

Figure 41.1 Endoscopic appearance of esophageal varices. **A**, Upper gastrointestinal endoscopy demonstrating dilated and straight veins (small esophageal varices) in the distal end of the esophagus (arrows). **B**, Upper gastrointestinal endoscopy demonstrating large esophageal varices, greater than 5 mm in diameter, with a fibrin plug (arrow) representing the site of recent bleeding. (From Feldman M, Friedman LS, Brandt LJ, editors: *Sleisinger and Fordtran's gastrointestinal and liver disease*, ed 9, Philadelphia, 2010, Saunders.)

Figure 41.2 The Sengstaken-Blakemore (SB) tube. Note that this tube does not have esophageal aspiration ports; a nasogastric tube must be attached to the SB tube to allow esophageal suctioning (see text for details.)

INDICATIONS

The general management of unstable patients with acute variceal bleeding is described in detail elsewhere. In brief, initial resuscitation should focus on early endotracheal intubation; circulatory resuscitation, including blood transfusion and administration of vasoactive agents and antibiotics; and, most importantly, early endoscopy. Vasoactive agents should be given as soon as possible in cases of confirmed or suspected variceal hemorrhage. Vasoactive medications reduce portal pressure and have been shown to decrease or stop variceal bleeding.^{13–18} Somatostatin and its synthetic analogue octreotide decrease release of the vasodilator hormone glucagon, thereby indirectly resulting in splanchnic vasoconstriction and reduced portal blood flow. Vasopressin and its synthetic analogue terlipressin are direct vasoconstrictors and can be given systemically or locally during angiography. These two medications, however, can cause significant coronary, cerebral, and splanchnic ischemia and are typically used in patients who fail somatostatin or octreotide therapy.

Endoscopy by a gastroenterologist remains the “gold standard” for the diagnosis and treatment of acute variceal hemorrhage.² Sclerotherapy and band ligation are the two endoscopic techniques used to control bleeding esophageal or gastric varices. Endoscopic band ligation has been shown to be superior to sclerotherapy in initially controlling hemorrhage and improving survival.¹⁹ In fact, endoscopic band ligation is considered the treatment of choice for esophageal varices.^{2,19,20}

Balloon tamponade is indicated in unstable patients with massive hemorrhage in whom endoscopy either cannot be performed or is unsuccessful in controlling the bleeding. Balloon tamponade is also indicated when consultant physicians are unavailable and pharmacologic therapy with vasoactive agents has failed to stop the bleeding. In cases in which consultants are unavailable, balloon tamponade can be used to stabilize a patient for transfer to another institution with the resources to continue care.

It is important to recognize that balloon tamponade is only a temporizing measure. Even though success rates in controlling the initial hemorrhage are high, up to 50% of patients rebleed when the device is deflated.²¹ Although rebleeding rates can be reduced with the concomitant use of vasoactive agents, arrangements must be made for more definitive control of varices in patients with a balloon tamponade device in place.

CONTRAINDICATIONS

Because gastroesophageal balloon tamponade devices are typically placed as a final attempt to control hemorrhage and prevent imminent death, contraindications to the device are few. They are limited primarily to conditions that predispose patients to esophageal rupture with balloon inflation and include a history of esophageal stricture and recent esophageal or gastric surgery.

PROCEDURE

Patients with an acute variceal hemorrhage that requires a balloon tamponade device are critically ill. Because these patients are at high risk for vomiting, aspiration, and airway compromise, endotracheal intubation should be strongly considered in all patients before placement of a balloon tamponade tube.²² For the rare patient who is not intubated, use of soft restraints and administration of appropriate analgesia and sedation are critical for a successful procedure.

For placement of a balloon tamponade tube, begin by testing the esophageal and gastric balloons for air leaks (Fig. 41.3, step 1). If there is any concern about a leak, submerge the balloons in water during inflation. If time permits, inflate the gastric balloon in 100-mL increments to the maximal recommended volume while measuring the pressure. Importantly, do not exceed a pressure of 15 mm Hg within the gastric balloon with each successive instillation of 100 mL. Note the pressure at full inflation of the gastric balloon. If no air leaks are detected, fully deflate the esophageal and gastric balloons and clamp the inflation ports. If the kit comes with plastic plugs, they may be used in lieu of clamps to occlude the ports and maintain deflation of the balloon during insertion (see Fig. 41.3, step 2). Once fully deflated, coat the balloons with a thin layer of water-soluble lubricating jelly.

When using the Sengstaken-Blakemore tube, it is important to recall that the device does not have an esophageal aspiration port. To construct a makeshift aspiration port, secure a nasogastric (NG) tube to the tamponade tube with silk sutures such that the distal tip of the NG tube is placed approximately 3 cm proximal to the esophageal balloon (see Fig. 41.3, step 3).

Patients should be as heavily sedated as allowed by cardiovascular parameters. Patients are often hypotensive, limiting the use of many agents. Ketamine would be an excellent choice for sedation of most patients. Position the patient properly for insertion of the tube, with the head of the bed elevated to at least 45 degrees. For patients who are unable to tolerate this position, use the left lateral decubitus position. For nonintubated patients, anesthetize the nasopharynx and oropharynx adequately. Accomplish this by using a topical anesthetic spray or jelly combined with a nebulized lidocaine solution.

Orogastric passage of the tamponade tube is the preferred route of insertion, especially in intubated patients. Nasogastric insertion can be attempted in nonintubated patients. Pass the tube at least to the 50-cm mark and preferably to the maximum depth allowed by the length of the tube (see Fig. 41.3, step 4). A 2015 case series reported the successful use of indirect laryngoscopy to rapidly guide the tamponade tube into the esophagus.²³ After the tube is inserted, apply continuous suction to its gastric and esophageal aspiration ports (see Fig. 41.3, step 5). Inflate the gastric balloon with approximately 50 mL of air and obtain a chest radiograph to confirm that the gastric balloon is below the diaphragm (Fig. 41.4; also see Fig. 41.3, step 6). Confirm the location of the gastric balloon; this is essential to reduce the risk for esophageal rupture from inflation of a misplaced gastric balloon.

Case reports have described the use of an endoscope to guide placement of the tamponade tube.^{24,25} Essentially, a snare is placed through the endoscope and used to grasp the end of the tamponade tube. Use of the endoscope allows direct visualization of the tamponade tube and confirmation that the gastric balloon is in the stomach. Added benefits to this approach

include the avoidance of inadvertent tube placement in an esophageal diverticulum, dislodgment of previously placed variceal bands, and inflation of the gastric balloon in a hiatal hernia. This approach may be feasible if the emergency provider has experience with the endoscope device.

Once the location of the gastric balloon is confirmed, connect a manometer to the pressure-monitoring outlet of the gastric balloon (see Fig. 41.3, step 7). Inflate the gastric balloon to the recommended total volume of air in 100-mL increments. Compare the pressure at each 100-mL increment with the values obtained during testing of the gastric balloon. If the pressure during inflation is more than 15 mm Hg higher than the testing pressure at an equivalent volume, it is likely that the gastric balloon has migrated to the esophagus. At this point deflate the gastric balloon and advance it further into the stomach. Obtain another chest radiograph before reinflation.

When the gastric balloon is fully inflated, clamp the inflation and pressure-monitoring ports (see Fig. 41.3, step 8). Slowly pull the device back until resistance is encountered (see Fig. 41.3, step 9). Resistance indicates that the gastric balloon has engaged the cardia and fundus of the stomach (Fig. 41.5). To maintain proper position of the gastric balloon, apply continuous traction. To accomplish this, use an overhead frame and pulley system, a football helmet or catcher's mask, or the sponge rubber cuff (provided in most kits) for patients who underwent nasogastric insertion. Of these methods, the pulley system is preferred to deliver the recommended 0.5 to 1.0 kg of traction. If the emergency physician does not have the weights required for a pulley system, a 1-L bag of crystalloid solution can conveniently provide 1 kg of traction (Fig. 41.6).

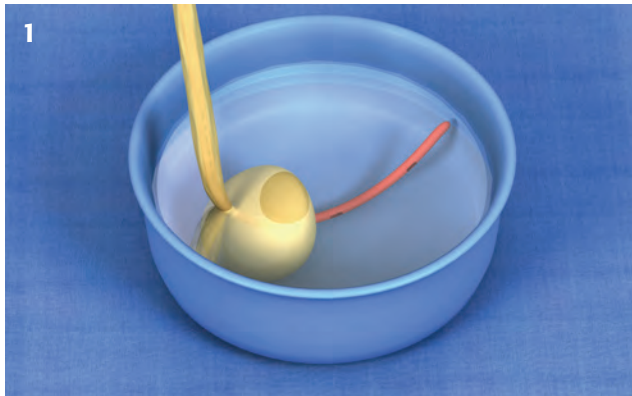

After traction is applied, connect the esophageal and gastric aspiration ports to continuous suction (see Fig. 41.3, step 10). If blood is obtained from either port, inflate the esophageal balloon to approximately 35 to 40 mm Hg. Similar to the gastric balloon, monitor inflation of the esophageal balloon with a manometer connected to the esophageal pressure-monitoring outlet (see Fig. 41.3, step 11). In general, do not inflate the esophageal balloon to more than 45 mm Hg. Keep the esophageal balloon pressure at the lowest inflation pressure that achieves hemostasis. Occasionally, esophageal pressure may transiently spike to values approaching 70 mm Hg. This can occur with respiratory variation or esophageal contraction and is not indicative of overinflation. Once hemostasis is achieved, clamp the esophageal inflation port to prevent air leaks (see Fig. 41.3, step 12).

If blood continues to be obtained from the gastric aspiration port despite maximal inflation of the esophageal balloon, it usually indicates an uncontrolled gastric varix. In this case, increase the traction gradually to a maximum of 1.2 kg.

AFTERCARE

Although the primary objective is to control variceal bleeding, the emergency physician must continue care of the patient with a balloon tamponade device until transfer to an intensive care unit, an operating room, a radiology suite, or another facility. Patients should be maintained in a position with the head of the bed elevated to approximately 45 degrees. In addition, it is critical to continue administering sedative and analgesic medications. Connect the esophageal and gastric aspiration ports to continuous suction for approximately the first 12 hours.

Balloon Tamponade of Gastroesophageal Varices

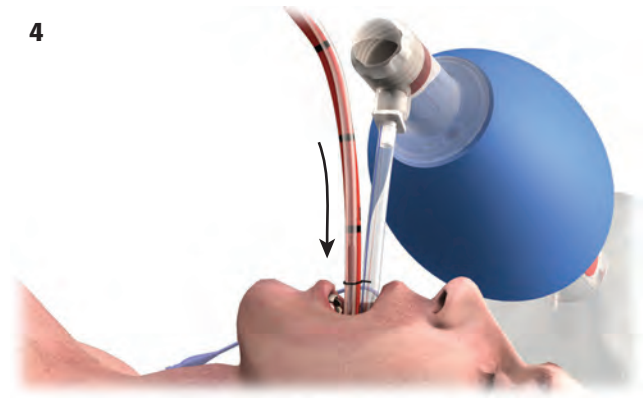

1 Test the esophageal and gastric balloons for air leaks, by submerging under water during inflation. If time permits, record pressures during gastric balloon inflation (see text for details).

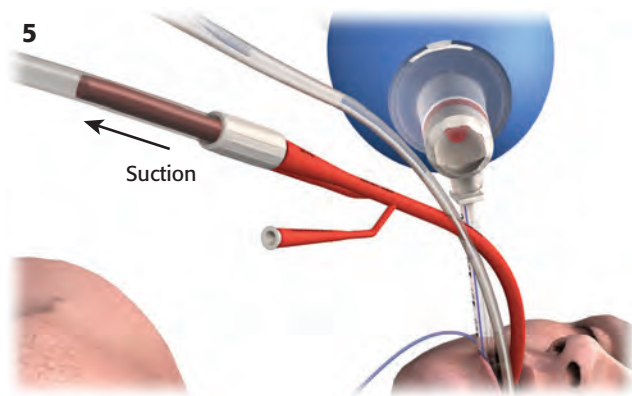

2 Fully deflate the esophageal and gastric balloons. Clamp the inflation ports with a tube clamp, or insert the plastic plugs supplied with the tube into the tube lumen. Lubricate the tube and balloons with water-soluble jelly.

3 Construct a makeshift esophageal aspiration port by securing a standard NG tube to the SB tube with silk sutures. The distal tip of the NG tube should be 3 cm proximal to the esophageal balloon.

4 Pass the tube orally (preferred) or nasally, to at least the 50-cm mark, or to the maximum depth allowed by the tube.

5 After the tube is fully inserted, apply continuous suction to the gastric and esophageal aspiration ports.

6 Inflate the gastric balloon with 50 mL of air and obtain a chest radiograph to confirm the position of the gastric balloon below the diaphragm.

Continued

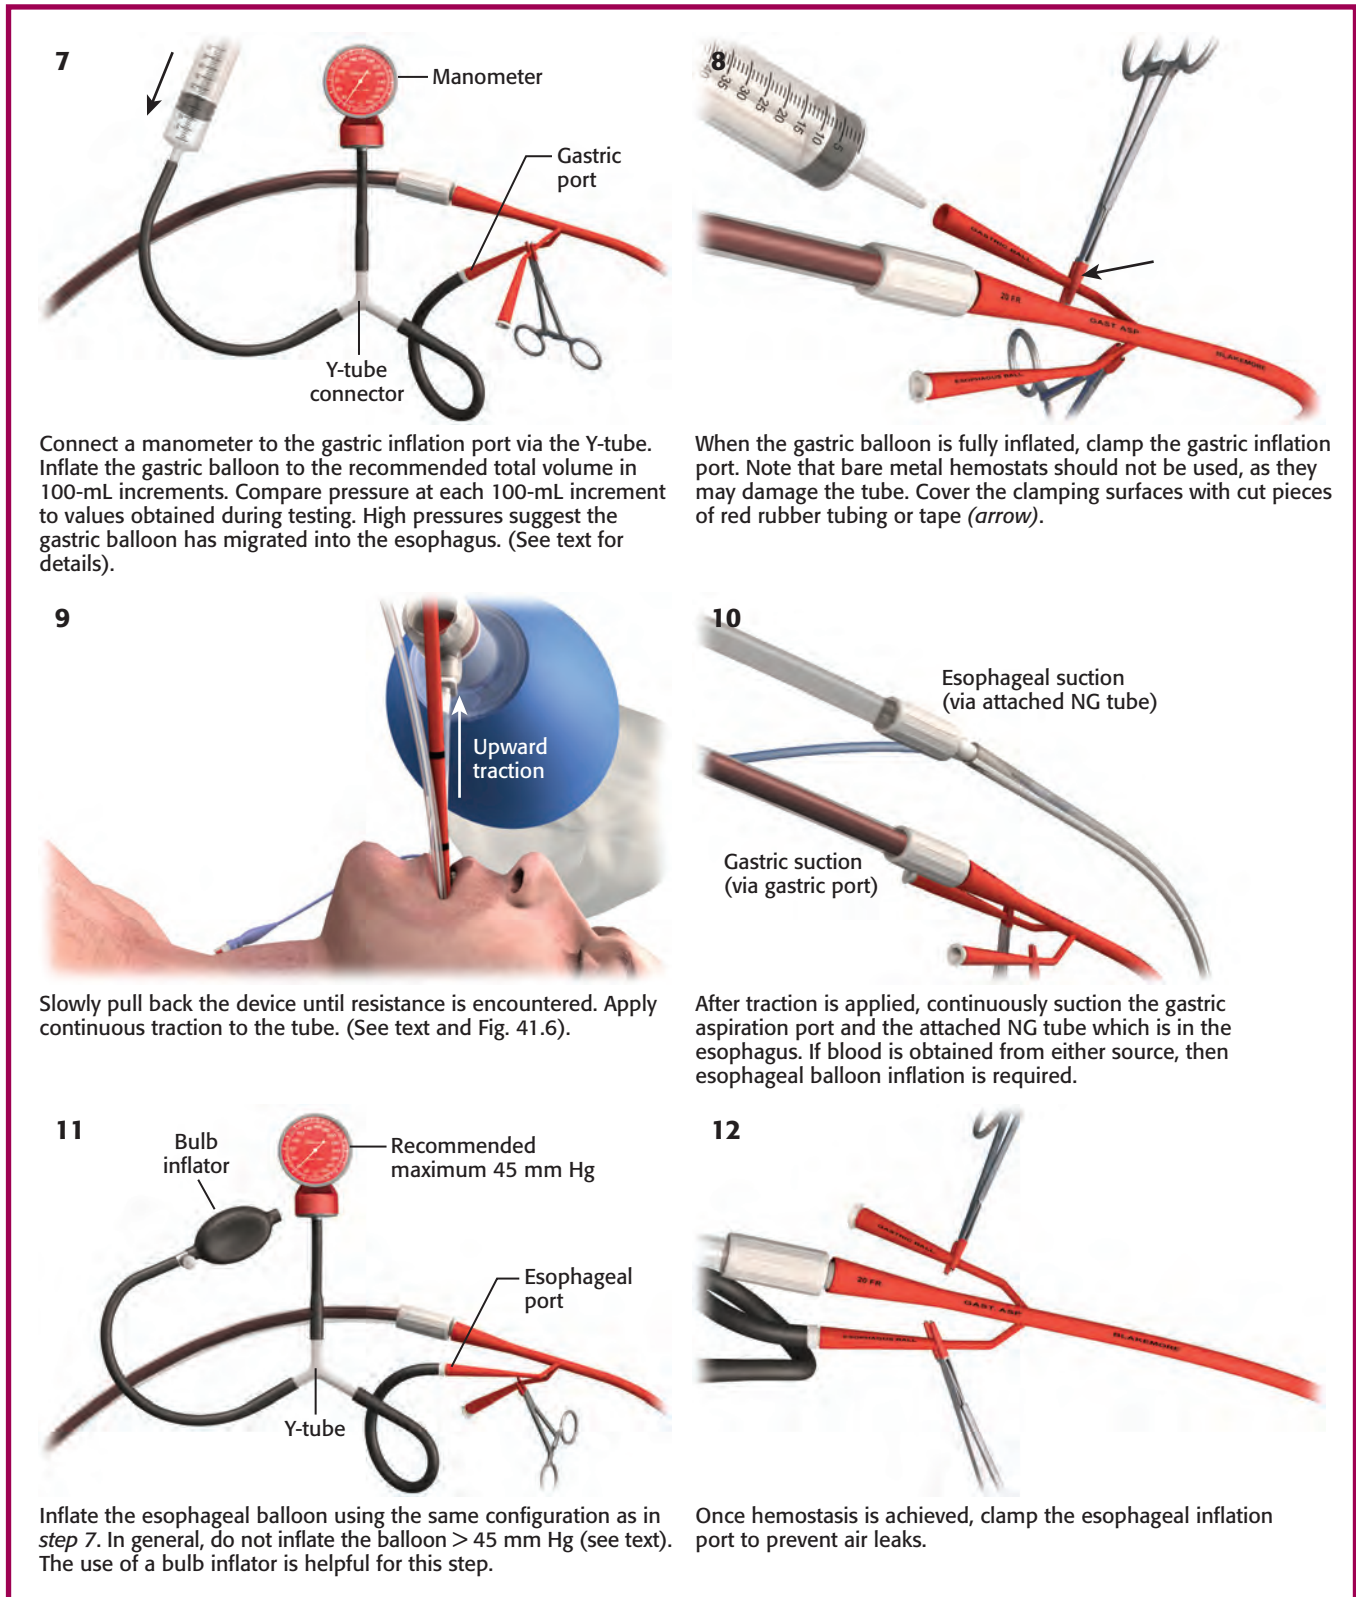

Figure 41.3, cont'd

Mucosal ulceration from direct pressure of the balloons can occur within just a few hours after tube placement. Accordingly, examine the tube, nares, mouth, tongue, and lips frequently, and monitor esophageal balloon pressure periodically. Once the bleeding has been controlled for several hours,

decrease the pressure in the esophageal balloon by approximately 5 mm Hg every 3 hours until a pressure of 25 mm Hg is reached. Regardless of the pressure, periodically deflate the esophageal balloon for several minutes every 5 to 6 hours to decrease the incidence of mucosal ischemia and necrosis. Once

Before inflation, obtain a radiograph to confirm that the gastric balloon is indeed in the stomach. Inflation of the gastric balloon in the esophagus can lead to esophageal rupture. (Courtesy Dr. Frank Gaillard, <http://www.radiopaedia.org>.)

Figure 41.5 The Sengstaken-Blakemore tube in position. **A**, With both balloons deflated. **B**, After partial inflation of the gastric tube to confirm proper position. **C**, After full inflation of the gastric balloon with appropriate traction applied to engage the cardia and fundus of the stomach. **D**, After full inflation of the gastric and esophageal balloons.

hemorrhage is controlled and the patient is stabilized, balloon tamponade devices are generally left in place for approximately 24 hours.

COMPLICATIONS

This is a difficult procedure that is rarely performed; hence, complications from balloon tamponade can be severe and occur in up to 20% of patients.^{21,25} Major complications include airway obstruction, esophageal rupture, and aspiration pneumonitis. Airway obstruction can be catastrophic and usually results from migration of a dislodged esophageal balloon into the oropharynx.^{11,26} Prevent proximal migration of the tube by maintaining adequate inflation of the gastric balloon, radiographic confirmation, and periodic monitoring of inflation pressure. In nonintubated patients with a balloon tamponade

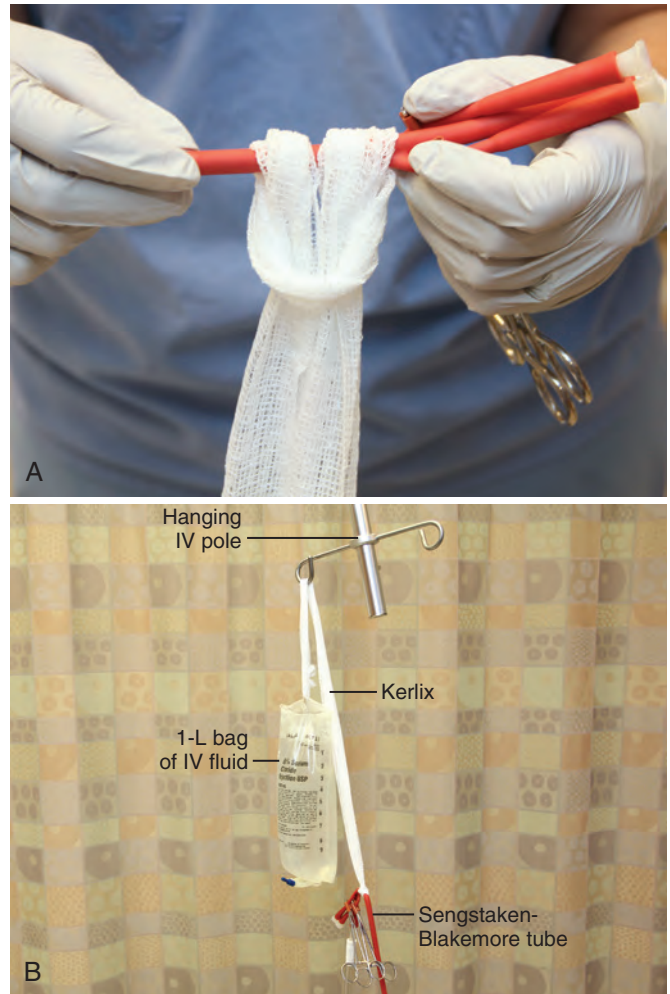

Figure 41.6 To maintain proper position of the gastric balloon and tamponade on the gastric fundus, apply continuous traction to the tube. Traditional methods of applying traction include the use of an overhead frame and pulley system, a football helmet, or a catcher's mask. A simpler solution uses a roll of Kerlix (Medtronic, Minneapolis, MN) and a bag of intravenous (IV) fluid. **A**, Make a lark's head knot around the proximal portion of the tube with the Kerlix. **B**, Tie the end of the Kerlix to a 1-L bag of IV fluid and suspend it from an overhead IV pole. The liter bag of fluid will provide the appropriate 1 kg of traction. Most patients require sedation to tolerate this procedure.

device, treat respiratory distress as airway obstruction until proved otherwise. In these patients, use surgical scissors to cut across the lumen of the tube just distal to the inflation and aspiration ports. This will result in deflation of both balloons and allow immediate extraction of the device. Given the risk for airway obstruction, always keep surgical scissors at the bedside of patients who have a balloon tamponade device in place.

Esophageal perforation is another catastrophic complication of balloon tamponade that is almost universally fatal. This dreaded complication can occur from a misplaced gastric balloon, an overinflated esophageal balloon, or prolonged inflation of the esophageal balloon and can result in decreased mucosal blood flow, ischemia, and necrosis. To minimize the risk for esophageal perforation, obtain radiographic confirmation

of gastric balloon placement before full inflation. In addition, keep the esophageal balloon at the minimum pressure necessary to control hemorrhage. If the device is required for longer than 24 hours, periodically deflate the esophageal balloon to limit mucosal damage and decrease the risk for necrosis.

Aspiration pneumonitis can result from the aspiration of blood, oral secretions, and gastric contents and is a frequent complication of balloon tamponade.²⁷ The incidence of pneumonitis can be decreased by evacuating the stomach and intubating the patient before placement of the tamponade device.²²

Additional complications of balloon tamponade include pain; ulceration of the lips, mouth, tongue, and nares; and esophageal and gastric mucosal erosions.²⁷ As discussed, patients with a tamponade device should receive adequate analgesia and sedation. Frequent monitoring of tube placement and pressure can decrease the incidence of esophageal or gastric mucosal erosions.

CONCLUSION

Balloon tamponade is a critical, lifesaving procedure that may be required in the ED management of unstable patients with bleeding gastroesophageal varices. Indications for placement of a balloon tamponade tube include unsuccessful control of hemorrhage with endoscopy and vasoactive medications, unavailability of consultant physicians when bleeding cannot be controlled with vasoactive therapy, and massive hemorrhage preventing endoscopy. Although complications of balloon tamponade can be fatal, their incidence can be markedly reduced through a stepwise approach to tube placement. Once bleeding is controlled, the emergency physician must continue to monitor tube position and measure balloon pressure until the patient is transferred out of the ED.

Decontamination of the Poisoned Patient

Christopher P. Holstege and Heather A. Borek

INTRODUCTION

In 2014, the National Poison Data System of the American Association of Poison Control Centers reported 2,165,142 human toxic exposures and 1408 resultant fatalities.¹ Of these total exposures, 28.3% were managed in a health care facility. Massive exposure to some toxic agents (e.g., calcium channel blockers, tricyclic and other antidepressants, antipsychotics, β -blockers, colchicine, chloroquine, cyanide, *Amanita phalloides* mushrooms, and paraquat) will probably result in severe morbidity or fatality regardless of even the most sophisticated and timely medical interventions. With general supportive care and the use of a few specific antidotes, however, the mortality rate in unselected overdose patients is less than 1% if the patient arrives at the hospital in time for the clinician to intervene.

Key management of poisoned patients seen in health care facilities initially focuses on confirming the diagnosis of possible exposure to a toxin, providing standard cardiovascular and respiratory supportive care, and using a small cadre of specific antidotes. In rare and yet undefined selected instances, prevention of further absorption of toxin by various decontamination procedures may theoretically ameliorate the morbidity or reduce mortality. Although a better final outcome after gastric decontamination may seem intuitively reasonable, there is no definitive evidence from prospective clinical trials that the use of various decontamination techniques positively alters the morbidity or mortality of a poisoned patient.²

Before the availability of objective or experimental evidence addressing gastric emptying procedures, most clinicians instituted previously performed unproven decontamination procedures in the emergency department (ED) as a reflex response for the majority of patients suspected of drug overdose, often without much forethought and certainly without confirming data. Mounting evidence relegates any benefit from any form of gastric decontamination to selected cases and specific individual scenarios. In fact, because of the lack of demonstrable benefit and the mounting evidence for potential harm, syrup of ipecac, once a mainstay in the management of poisonings, is no longer recommended,³ and parents have been instructed by the American Academy of Pediatrics to remove it from the home.⁴ Parents and health care providers appear to be heeding this recommendation because virtually no (less than 0.01%) poisoned patients received ipecac in 2014.¹

Nonetheless, a selective role for other methods of gastric decontamination exists, and there will always be a role for real-time clinical judgment. Because compelling circumstances may clinically support gastric decontamination, this chapter discusses specific clinical procedures. These techniques include gastric lavage, oral administration of activated charcoal, and

whole-bowel irrigation (WBI). In addition, dermal decontamination as a result of a toxic exposure is also addressed. Before performing these techniques, the clinician responsible for the care of a poisoned patient must clearly understand that these procedures are not without hazard and that any decision on their use must consider whether the benefit of decontamination outweighs any procedure-related harm.

GASTRIC DECONTAMINATION

Gastric Lavage

Background

The use of gastric lavage (Video 42.1) in poisoned patients has decreased significantly since the 1990s, and in the United States it is currently reported to be used in less than 1% of overdose cases.¹ Numerous animal and human volunteer studies have been conducted to examine the effectiveness of gastric lavage in removing toxins from the stomach, especially with respect to other gastrointestinal decontamination methods. The reported efficacy of gastric lavage in removing markers from the stomach varies significantly in these studies. The difference in these study results is due in part to the variability of the methods used (different fluid-instilled markers, animal models, positioning, amount of lavage, and lavage tube size) and the time that elapsed from instillation of the marker in the stomach until gastric lavage was performed. Even within individual studies, the range of effectiveness of gastric lavage in removing the marker varied considerably. For example, Tandberg and co-workers performed gastric lavage 10 minutes after ingestion of the marker and reported that its effectiveness in removing the marker varied from 18.9% to 67.7%.⁵

Many of these studies do not replicate the typical clinical scenario encountered in emergency medicine.^{2,6} The efficiency of gastric lavage in removing a marker significantly decreases with increasing time after ingestion. This is due to the fact that as time increases after ingestion, there is more time for the marker to be absorbed and passed out of the stomach. For example, Shrestha and colleagues reported that more than 70% of the marker used in their study passed out of the stomach in 60 minutes.⁷ It is rare that gastric lavage can be performed within the first hour after toxic ingestion. Not only does it take time for these patients to arrive at the ED, but it also takes time for evaluation, stabilization, and performance of gastric lavage. Watson and associates reported that the mean time required by experienced emergency medicine nurses to perform lavage was 1.3 hours.⁸ Gastric lavage may also propel the marker from the stomach into the small intestine, thereby decreasing the effectiveness of removing the toxin from the stomach and actually enhancing the rate of absorption.⁹

Three major studies have examined whether gastric lavage positively influences the outcome of poisoned patients.¹⁰⁻¹² In a study performed by Kulig and co-workers, there was no difference in outcome in patients who received gastric lavage followed by charcoal versus charcoal alone when these interventions were performed more than 1 hour after ingestion.¹⁰ In patients who were treated within 1 hour of ingestion, gastric lavage followed by charcoal provided a small but statistically significant advantage over activated charcoal alone. Merigian and colleagues demonstrated that in symptomatic patients, the rate of intensive care admission and need for intubation was significantly higher in patients who received gastric lavage

Gastric Lavage

Indications

Potentially life-threatening poisonous ingestions, but only if the procedure can be performed within 60 minutes

Contraindications

Compromised airway protective reflexes (unless patient is intubated)
 Ingestion of corrosive substances (acids or alkalis)
 Hydrocarbons (unless containing highly toxic substances such as pesticides)
 Known esophageal strictures
 History of gastric bypass surgery

Complications

Trauma due to tube insertion
 Instillation of lavage fluid into lungs/aspiration
 Cardiac dysrhythmias
 Hypoxia
 Laryngospasm
 Fluid and electrolyte disturbances
 Hypothermia

Equipment

Review Box 42.1 Gastric lavage: indications, contraindications, complications, and equipment

followed by charcoal than in those who received charcoal alone.¹¹ This increased admission and intubation rate was directly attributed to the aspiration of gastric contents as a result of gastric lavage. Pond and associates replicated the study by Kulig and colleagues.¹² They found no difference in outcome between patients who received gastric lavage followed by charcoal and those receiving charcoal alone, regardless of the time of performance of gastric lavage. They concluded that “gastric emptying procedures can be omitted from the treatment regimen for adults after acute overdose, including those who present within 1 hour of overdose and those that manifest severe toxicity.” Westergaard and colleagues recently demonstrated that despite current recommendations against routine use of gastric lavage, the vast majority of cases where it was actually performed did not meet specific criteria for the indications for gastric lavage.¹³

Indications

Based on the available literature, gastric lavage should not be routinely used in the management of poisoned patients (Fig. 42.1).^{14,15} There is no universally accepted standard of care that can be applied to the use of gastric lavage in unselected poisoned patients in the ED. Under certain circumstances, however, there may be a theoretical benefit from gastric emptying, and the local poison center should be contacted to assist in deciding whether gastric lavage may be of benefit. Whether specific subsets of overdose patients may benefit from gastric lavage has not been clearly defined.

Only patients who have ingested a potentially life-threatening amount of poison, and in whom the procedure can be performed within 60 minutes, are the primary candidates for gastric lavage. Oral charcoal alone is considered superior to gastric lavage if a drug is adsorbed by charcoal.

POSITION STATEMENT: GASTRIC LAVAGE

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Gastric lavage should not be employed routinely, if ever, in the management of poisoned patients. In experimental studies, the amount of marker removed by gastric lavage was highly variable and diminished with time. The results of clinical outcome studies in overdose patients are weighed heavily on the side of showing a lack of beneficial effect. Serious risks of the procedure include hypoxia, dysrhythmias, laryngospasm, perforation of the GI tract or pharynx, fluid and electrolyte abnormalities, and aspiration pneumonitis. Contraindications include loss of protective airway reflexes (unless the patient is first intubated tracheally), ingestion of a strong acid or alkali, ingestion of a hydrocarbon with a high aspiration potential, or risk of GI hemorrhage due to an underlying medical or surgical condition.

Figure 42.1 Position statement: gastric lavage. *GI*, Gastrointestinal. (From Vale JA, Kulig K, American Academy of Clinical Toxicology, et al: Position statement: gastric lavage, *J Toxicol Clin Toxicol* 42:933–943, 2004.)

Contraindications

Though generally safe, gastric lavage is not an innocuous procedure. Performance of gastric lavage is contraindicated in any person who demonstrates compromised airway-protective reflexes, unless that person is intubated.¹⁶ Many clinicians opt for lavage in a seriously ill patient who is intubated because airway protection is already accomplished. Tracheal intubation, however, does not ensure a totally protected airway. Paralyzing plus intubating a patient merely to initiate gastric lavage is generally eschewed.

Gastric lavage is contraindicated in persons who have ingested corrosive substances (acids or alkalis) or hydrocarbons (unless they contain highly toxic substances such as pesticides), have known esophageal strictures, or have a history of gastric bypass surgery.¹⁷ Caution should be exercised in performing gastric lavage in combative patients and in those who have medical conditions such as bleeding diatheses that could be compromised by performing this procedure.

Equipment and Preparation

If the decision is made to perform gastric lavage, careful attention to the details of the procedure results in increased safety for the patient and more effective removal of the ingested poison. Before lavage, intravenous access should be secured and continuous cardiac monitoring and pulse oximetry should be initiated (Fig. 42.2, step 1). A large, rigid suction catheter should be available immediately.

If the patient is highly anxious or agitated, give a small dose of an intravenous benzodiazepine (e.g., midazolam). If the patient's level of consciousness is significantly depressed, airway status is questionable, or the airway is likely to be compromised during the procedure, consider rapid-sequence induction and intubation with a cuffed endotracheal tube before initiating gastric lavage. If the patient is fully awake and alert, proceed to lavage without tracheal intubation. The procedure should proceed deliberately without significant patient resistance. It is intended to be therapeutic, not punitive. Antiquated arguments promulgating that a noxious lavage procedure will keep patients from overdosing again should be abandoned.

The position of the patient during gastric lavage is important. Place all patients in the left lateral decubitus, Trendelenburg position (≈ 20 -degree tilt on the table) (Fig. 42.3). This position diminishes the passage of gastric contents into the duodenum during lavage and decreases the risk for pulmonary aspiration of gastric contents should vomiting or retching occur. Restrain the hands of an uncooperative patient to prevent removal of the gastric or endotracheal tube. Intubated patients on a ventilator may be lavaged in the supine position because of logistic reasons (Fig. 42.4). Under no circumstances should a nonintubated patient undergo lavage in the restrained supine position. Such positioning invites aspiration and diminishes the patient's natural protective maneuvers, such as coughing and sitting up.

Most clinicians prefer the oral route for gastric lavage, but in selected circumstances a standard large-bore nasogastric (NG) tube (Salem sump pump) may be used. Large-diameter gastric hoses with extra holes cut near the tip have traditionally been recommended for gastric lavage. There are no convincing data on humans to refute or support this recommendation, and one study of a small number of dogs failed to show any difference in efficacy with lavage through a 32-Fr versus a 16-Fr lavage tube.¹⁸ It is generally held that large-diameter NG or orogastric tubes (>1 cm) are more likely to retrieve particulate matter successfully, but the tube size is such that whole pills are unlikely to pass (Fig. 42.5). Smaller, more flexible tubes may kink and are significantly more difficult to pass. An NG tube may be passed through the mouth or nose, but orogastric hoses should not be passed through the nose. Because most pills disintegrate in the stomach within minutes of ingestion, significant amounts of particulate matter may be retrieved with a large-bore NG tube such as an 18-Fr Salem sump tube. NG tubes are considerably easier to pass and less traumatic

for the patient. NG tubes are preferred for liquid ingestions and in children (Fig. 42.6).

In most cases, a 36- to 40-Fr or a 30-English gauge tube (external diameter, 12 to 13.3 mm) should be used in adults and a 24- to 28-Fr gauge (diameter, 7.8 to 9.3 mm) tube in children.¹⁴ Before passage, estimate the length of tube required to enter the stomach by approximating the distance from the corner of the mouth to the midpigastrium. Premeasurement avoids the curling and kinking of excess hose in the stomach (see Fig. 42.2, step 2). Passage of an excessive length of hose may cause gastric distention, bruising, and perforation, whereas passage of an insufficient length of hose may result in lavage of the esophagus and increased risk for emesis and aspiration. Commercial lavage systems are available and often use either a gravity fill-and-empty system with a Y-connector or a closed irrigation syringe system. Alternatively, an irrigation syringe can be used for intermittent input and withdrawal of lavage fluid.

Technique

Lubricate the gastric tube and pass it gently to avoid damage to the posterior pharynx (see Fig. 42.2, step 3). Use of a bite block or an oral airway may prevent the patient from chewing on the orogastric tube and biting the fingers of the inserter. If the patient is obtunded or paralyzed, extend the jaw to facilitate passage. Never use force to pass the tube. Once the pharynx has been entered, put the patient's chin on the chest to facilitate passage of the tube into the esophagus (see Fig. 42.2, step 4). Cough, stridor, or cyanosis indicates that the tube has entered the trachea; withdraw the tube immediately and reattempt passage. Once the tube is passed, confirm that it is in the stomach. Intra-gastric placement is usually evident on clinical grounds by the spontaneous egress of gastric contents but may be confirmed by auscultation of the stomach during injection of air with a 50-mL syringe followed by successful aspiration of gastric contents (see Fig. 42.2, step 5). However, due to the risk of lavage through a misplaced tube, confirm tube position radiographically before lavage is performed (Fig. 42.7A). A misplaced tube may irrigate the esophagus with a tube that has doubled back on itself during passage (see Fig. 42.7B). The most serious complication, other than esophageal perforation, is inadvertent passage of the tube into the lungs. Tracheal passage of a lavage tube should be readily obvious in an awake patient before lavage, and obtunded patients are intubated, thereby obviating this problem. If an awake patient begins to vomit during lavage, immediately remove the tube to allow the patient to protect the airway.

Before gastric irrigation, remove the gastric contents by careful gastric aspiration with repeated repositioning of the tip of the tube (see Fig. 42.2, step 6). With the Y-connector closed system, perform lavage by clamping the drainage arm of the Y-adapter and infusing aliquots of fluid into the stomach from a reservoir. Clamp the reservoir arm of the Y, and then open the drainage arm to permit drainage of the stomach contents by gravity. Repeat this procedure. Some resistance is produced by the Y-connector and tubing. Apply suction intermittently to the drainage tubing to enhance emptying of the stomach.

Lavage can be performed adequately with tap water in adults. Because electrolyte disturbances have occurred in children who underwent lavage with tap water, prewarmed (45°C) normal saline is generally recommended for children. Warmed lavage fluid increases the solubility of most substances, delays gastric

Gastric Lavage

1 Before lavage, obtain intravenous access and place the patient on a continuous cardiac monitor and pulse oximeter. Restrain the hands of uncooperative patients.

2 Measure and mark the appropriate depth of the gastric lavage tube before passage. This ensures that the tip is in the stomach and that there is no excess tubing that may kink or knot the tube.

3 Lubricate the gastric tube and pass it gently to avoid damage to the posterior pharynx. Use a bite block or an oral airway to prevent the patient from biting the tube or inserter.

4 Once the tube enters the pharynx, put the patient's chin on the chest to facilitate passage of the tube into the esophagus. Pass the tube into the stomach.

5 Once the tube is passed, confirm that it is in the stomach via auscultation and aspiration of gastric contents. A radiograph may be obtained if deemed clinically necessary.

6 Before gastric irrigation, remove the gastric contents by careful gastric aspiration with repeated repositioning of the tip of the tube.

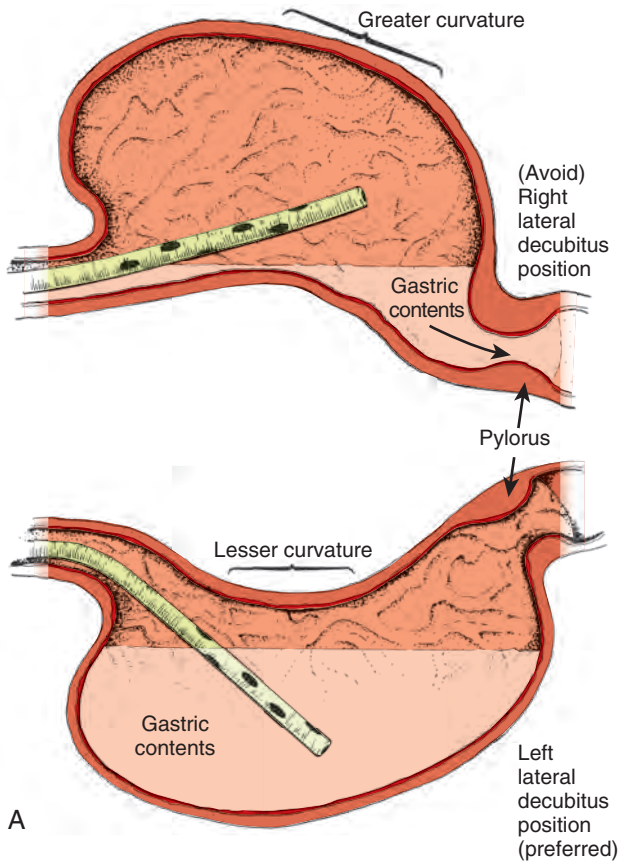

7 Repeatedly introduce small aliquots (200–300 mL in adults) into the stomach and then remove them. Perform this step with the patient in the left lateral decubitus position.

8 After gastric aspiration and lavage are completed, administer a slurry of activated charcoal through the gastric tube. When no longer needed, clamp off the gastric tube before removal.

Figure 42.2 Gastric lavage. In an awake patient the orogastric tube can be passed with the patient in the sitting position, but the lavage procedure is best performed with the patient in the left lateral decubitus position.

A

B

Figure 42.3 A, Effect of patient positioning on lavage. B, The left lateral decubitus position is preferred for lavage to isolate the gastric contents and avoid reflux. Avoid the right lateral decubitus position.

emptying, and should theoretically increase the effectiveness of the procedure.^{10,19} Repeatedly introduce small aliquots of lavage solution (200 to 300 mL in adults and 10 mL/kg body weight in children up to a maximum of 300 mL) into the stomach and then remove them (see Fig. 42.2, step 7). Larger amounts of fluid create the potential for an increased risk of washing the gastric contents into the duodenum or lungs. Much smaller amounts are not clinically practical because of the dead space in the tubing (≈ 50 mL in a 36-Fr hose) and the increased time required. The amount of fluid that is returned

Figure 42.4 Patients on a ventilator or intubated with airway protection may undergo lavage while supine for logistic reasons, but an awake nonintubated patient should never undergo lavage in the supine position. Instead, use the left lateral decubitus position.

Figure 42.5 This large-diameter gastric lavage tube demonstrates the size of the holes and the size of some typical pills. Extra holes can be cut in the side of the tube to facilitate the removal of large fragments.

should approximate the amount introduced. Manual agitation of the patient's stomach by gently "kneading" it with a hand placed on the abdomen may increase recovery.²⁰ Continue lavage until the fluid becomes clear.

After gastric aspiration and lavage have been completed, administer a slurry of activated charcoal through the gastric tube (see Fig. 42.2, step 8). When no longer needed, clamp off the gastric tube before removal to avoid "dribbling" fluid into the airway. With the increasing use of repetitive doses of activated charcoal, an NG tube may be left in place, or passed,

Figure 42.6 Gastric lavage in a child is always problematic. Obviously, an adult-sized large-bore oral gastric tube cannot be used, but a nasogastric (NG) tube may suffice. Some pediatric textbooks recommend a 24-Fr oral gastric tube for toddlers and a 36-Fr tube for adolescents. In this case, a child was found with an open bottle of digoxin, and it could not be determined whether ingestion had occurred. She would not drink charcoal. An 18-Fr NG tube was used in an attempt to aspirate digoxin from the stomach (none was recovered) and to instill charcoal. Some would suggest an oral route for this tube, but it was passed rather easily through the nose. An NG tube is not ideal for some ingestants (iron, sustained-release products), but most pills quickly dissolve in the stomach and the small particles can easily be removed with an NG tube. Although lavage may have been reasonable in this scenario, a potent and safe antidote for digoxin does exist. The common routine practice of passing an NG tube in a child who is unwilling to drink charcoal is controversial, and though intuitively reasonable, it is of unproven value and probably done far too often for benign ingestions.

after the lavage procedure is completed. A patient who remains obtunded may receive additional doses via a standard NG tube. Because the large gastric tube is irritating and may predispose the patient to gagging, drooling, or aspiration, it should be removed. Alert patients should take subsequent doses of charcoal orally as necessary.

Complications

A correctly performed procedure in the appropriate environment is generally safe, but numerous complications have been associated with gastric lavage.¹⁶ The complications can be divided into those caused by mechanical trauma and those resulting from the lavage fluid.

Depending on the route selected for insertion of the tube, damage to the nasal mucosa, turbinates, pharynx, esophagus, and stomach has been reported.^{21–23} After insertion of the tube, it is imperative to confirm correct placement. Scalzo and associates found radiographically that 7 of 14 children had improper tube placement (too high or too low) despite positive gastric auscultation in all cases. The clinical effects of such misplacement were not evaluated, however. Radiographic confirmation of tube placement should be considered in all patients prior to administering lavage fluid (see Fig. 42.7).²⁴ Instillation of lavage fluid and charcoal into the lungs through

tubes inadvertently misplaced within the airways has been reported.²⁵

During lavage, changes in cardiorespiratory function have been noted. Thompson and co-workers reported that during lavage 36% of patients had atrial or ventricular ectopy, 4.8% had transient ST elevation, and 29% had a fall in oxygen tension to 60 mm Hg or lower.²⁶ Laryngospasm may also occur during gastric lavage.¹⁴

The lavage fluid itself is a potential source of complications. The large amount of fluid administered during lavage has been reported to cause fluid and electrolyte disturbances. These disturbances have been seen with the use of both hypertonic and hypotonic lavage fluid in the pediatric population.^{27–29} Hypothermia is a possible complication if the lavage fluid is not prewarmed.

Pulmonary aspiration of gastric contents or lavage fluid is the primary potential risk during gastric lavage, especially in patients with compromised protective airway reflexes.^{30–32} Merigan and colleagues reported a 10% incidence of aspiration pneumonia in patients who underwent gastric lavage.¹¹ This risk is reduced by using small aliquots of lavage fluid, adequately positioning the patient, and intubating patients with compromised airway-protective reflexes.

If the lavage tube cannot be removed easily, do not force it. Kinking or knotting of the tube can occur, but occasionally a tube may become stuck because of lower esophageal spasm. If neither fluoroscopy nor radiography demonstrates deformation of the lavage tube, 1 to 2 mg of intravenous glucagon can be infused in an attempt to relieve lower esophageal spasm.³³ Surgical removal may be necessary if the gastric tube is deformed by kinking or knotting.

Use of Endoscopy to Perform Gastric Lavage

The technique of gastric lavage can also be accomplished using an endoscopic approach.³⁴ Whereas this is not routinely recommended or performed, there is literature that shows favorable outcomes using endoscopy in specific cases, especially when a pharmacobezoar develops. Bezoar formation may occur with overdoses of a large number of pills or certain types of agents (e.g., salicylates, anticholinergics). There are numerous case reports of bezoar formation following acute overdose, with subsequent endoscopic removal and clinical improvement.^{35–41}

Activated Charcoal

Background

Activated charcoal is a carbon product that is subjected to heat and oxidized to increase its surface area (Fig. 42.8). It has the capacity to adsorb substances onto the porous surface of the charcoal. The use of activated charcoal for poisoning has been recognized for almost two centuries. To demonstrate the effectiveness of charcoal, in 1930, French pharmacist Touery ingested several times the lethal dose of strychnine mixed with 15 g of activated charcoal. He performed this act in front of a class of colleagues and exhibited no ill effects.

Activated charcoal acts both by adsorbing a wide range of toxins present in the gastrointestinal tract and by enhancing elimination of toxins if systemic absorption has already occurred. It enhances elimination by creating a concentration gradient between the contents of the bowel and the circulation, but it also has the potential to interrupt enterohepatic circulation if the particular toxin is secreted in bile and enters the gastrointestinal tract before reabsorption.⁴² Oral activated charcoal

Figure 42.7 Radiographic confirmation of gastric lavage tube placement. **A**, This radiograph confirms proper placement of the lavage tube. It can be seen descending below the diaphragm (1), and the interruption in the radiopaque line (which signifies the most proximal hole) is in the stomach (2). The tip of the tube (3) is also visible. **B**, The lavage tube in this patient is misplaced. The tube can be seen descending beneath the diaphragm (1) but is kinked in the stomach (2) and has doubled back on itself. The gap in the radiopaque line (3) is at the level of the gastroesophageal junction, and the distal tip of the tube is in the midesophagus (4). Proper measurement of the tube before insertion would probably have prevented this misplacement. If there is any doubt about proper positioning of the tube, a radiograph should be obtained before lavage.

Figure 42.8 Activated charcoal. Because the contents may settle with time, shake the bottle vigorously before administration. Rinse the container with a small amount of tap water as well to ensure that the patient receives the full dose. Plain charcoal, without sorbitol, is preferred.

is given as a single dose or in multiple doses. The adsorptive capacity of charcoal depends on the inherent properties of the toxin and the local milieu, such as pH. Adsorption begins within minutes of contact with a toxin but may not reach equilibrium for 20 to 30 minutes. Desorption of toxins from

charcoal occurs over time, although this has little clinical significance for most patients and can be overcome by administering additional charcoal.

Indications

For years, administration of a single oral dose of activated charcoal for essentially all overdoses was routine. However, with the emergence of new guidelines in overdose management⁴³ the use of charcoal declined to less than 1% of poisoned patients in 2014.¹ Clearly, charcoal binds many toxins in the gut, thereby decreasing some systemic absorption. It has been shown to decrease the total amount of drug absorbed by the body and also the drug's half-life. Despite a lack of scientific data demonstrating a decrease in morbidity and mortality and firm evidence to support its widespread use, charcoal is a reasonable intervention for most poisoned patients encountered in the ED if it can be administered easily and safely (Fig. 42.9). The exact indications are not established, and no universally accepted standard of care has been promulgated.^{44,45} A single dose of activated charcoal is indicated if the clinician estimates that a clinically significant fraction of the ingested substance remains in the gastrointestinal tract, the toxin is adsorbed by charcoal, further absorption may result in clinical deterioration, and it can be administered safely. This will usually be a clinical decision because adequate historical data may often be lacking. It may also be administered by multiple dosing if the clinician anticipates that the charcoal will result in increased clearance of an already absorbed drug. It is most effective within the first 60 minutes after an oral overdose, however this time frame may

POSITION STATEMENT: SINGLE-DOSE
ACTIVATED CHARCOAL

*American Academy of Clinical Toxicology; European
Association of Poisons Centres and Clinical Toxicologists*

Single-dose activated charcoal should not be administered routinely in the management of poisoned patients. Based on volunteer studies, the effectiveness of activated charcoal decreases with time; the greatest benefit is within 1 hour of ingestion. The administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hour previously; there are insufficient data to support or exclude its use after 1 hour of ingestion. There is no evidence that the administration of activated charcoal improves clinical outcome. Unless a patient has an intact or protected airway, the administration of charcoal is contraindicated.

Figure 42.9 Position statement: single-dose activated charcoal. (From Chyka PA, Seger D: Position statement: single-dose activated charcoal. American Academy of Clinical Toxicology; European Association of Poisons Centers and Clinical Toxicologists, *J Toxicol Clin Toxicol* 35(7):721–741, 1997.)

be longer for substances that are likely to form bezoars, such as aspirin. Charcoal is generally considered to provide superior gut decontamination over gastric lavage. There is no definitive evidence, however, that administration of activated charcoal improves outcome.

Contraindications

Administration of charcoal is contraindicated in any person who demonstrates compromised airway-protective reflexes unless already intubated.⁴⁵ It is absolutely contraindicated in persons who have ingested corrosive substances (acids or alkalis). Not only does charcoal provide no benefit in a corrosive ingestion, but its administration could also precipitate vomiting, obscure endoscopic visualization, and lead to complications if a perforation developed and charcoal entered the mediastinum, peritoneum, or pleural space. Charcoal should be avoided with ingestion of a pure aliphatic petroleum distillate. Hydrocarbons are not well adsorbed by activated charcoal and its administration could lead to further risk for aspiration. Many hydrocarbons are potential systemic toxins (e.g., carbon tetrachloride and benzene) or are mixed with other potentially significant toxins such as pesticides. In these cases, data are lacking, but charcoal administration can be considered. Caution should be exercised in using charcoal in patients with medical conditions that could be further compromised by charcoal ingestion, such as gastrointestinal perforation or bleeding and in those patients with gastric bypass. Charcoal is not indicated for isolated ingestion of ethanol or metals (e.g., iron, lithium) because these substances are not adsorbed. If the airway is not secure, charcoal should be given with caution to minimally symptomatic patients who have ingested a toxin that may suddenly induce seizures. Because it is often impossible to determine the exact nature of an ingestion, a liberal-use policy is advocated for potentially mixed overdoses.

Charcoal administration by paramedics and other emergency response personnel should be performed with caution.⁴⁶ There is insufficient evidence to recommend for or against administration of activated charcoal in the prehospital setting. The same indications and contraindications apply as for patients who are

in the hospital. The motion of the ambulance during transport may make the patient more prone to emesis. Either spilling of charcoal or vomiting of charcoal may result in significant contamination of the transport vehicle and subsequently place that vehicle out of commission until it can be cleaned.

Technique

There is no universally accurate dose for charcoal. A 10:1 ratio (charcoal to toxin) is recommended if the amount of ingestion is known. Dosing of charcoal should be considered in light of the specific ingestion, but the following empirical doses of single-dose activated charcoal (standard aqueous products such as Liqui-Char [King Pharmaceuticals, Bristol, TN]) are recommended⁴⁴:

- Up to 1 year: 1 g/kg of body weight
- 1 to 12 years: 25 to 50 g
- Older than 12 years: 25 to 100 g

If the ingestion were, for example, clonidine (0.1-mg tablets) or digoxin (0.25-mg tablets), this regimen would be more than adequate for even a massive overdose to achieve the desired 10:1 ratio. If the ingestion consisted of a large number of 325-mg aspirin tablets or 240-mg verapamil tablets, the dosing regimen could be insufficient. If toxic medications with a high-milligram dosage are ingested, it would be prudent to administer more charcoal than indicated by these guidelines. There is no known benefit of mixing charcoal with a cathartic (i.e., sorbitol), and the combination is not suggested. Sorbitol may increase the incidence of vomiting.

Because in many charcoal formulations the contents settle with time, shake the preparation vigorously before administering it to the patient. Follow this by rinsing the container with a small amount of tap water before administering it to the patient to allow ingestion of the full dose.⁴⁷ Aqueous activated charcoal has a gritty texture that most patients find unpleasant, but attempts have been made to improve its taste and texture. Mixing activated charcoal with chocolate milk, chocolate- or cherry-flavored syrup, or ice cream may increase palatability, but mixing with these additives has been suggested, though not proved, to cause a decrease in the adsorptive capacity of activated charcoal.⁴⁸ Rangan and colleagues reported no decrease in adsorption after mixing superactivated charcoal with a noncaffeinated cola.⁴⁹ Scharman and associates demonstrated that a regular, sugared cola was favored by children over a diet cola, but only 20% of the time were they able to cajole even nonpoisoned children younger than 3 years to drink a therapeutic amount of flavored charcoal.⁵⁰

Give activated charcoal orally if the patient is awake and cooperative and by NG tube if the patient is unconscious. If an NG tube is inserted, it is imperative that correct placement be verified radiographically before administering charcoal, especially in obtunded or intubated patients (see Fig. 42.7). Instillation of charcoal into the lungs has been reported after inadvertent misplacement within the airways, and massive aspiration can be fatal (Fig. 42.10).^{25,51} Intubation is protective, but it is not uncommon to see some charcoal in the airway even if the patient has been intubated.

A clinical conundrum exists when a patient refuses to drink charcoal and an NG tube must be passed without consent if charcoal is deemed advisable. The common tactic of passing an NG tube in an awake but uncooperative patient merely to administer charcoal is controversial, and no standards exist. Such a scenario is more likely to result in trauma from placement of the tube, a misplaced tube, or subsequent emesis from the

Figure 42.10 **A**, Vomiting can be expected following charcoal administration, especially if sorbitol is added (not recommended). This patient rapidly became drowsy after administration of charcoal, vomited, but fortunately did not aspirate. **B**, In another patient who aspirated, the charcoal can be seen at the carina with a fiberoptic scope. Massive aspiration can be fatal. Intubation does not totally protect against minimal charcoal aspiration.

rapid administration of charcoal. Given the unproven efficacy of charcoal, the authors advise against routine insertion of an NG tube simply to administer charcoal in an awake and minimally symptomatic patient. Such a decision is, however, a clinical one that must be made by the health care provider and be based on the entire clinical milieu (Fig. 42.11).

Complications

Administration of activated charcoal is not without risks and complications. Published reports have demonstrated adverse effects associated with activated charcoal therapy, including childhood deaths.⁵² The most common complications of charcoal administration include constipation, diarrhea, and vomiting.^{53,54} Bowel perforation has been described in a patient with diverticular disease.⁵⁵ Pulmonary aspiration of activated charcoal is a dreaded complication that can result in pneumonitis, obstruction of the respiratory tree, bronchiolitis obliterans, acute lung injury, and barotrauma.⁵⁶ Risk factors for serious aspiration

Figure 42.11 **A**, If an overdose patient will voluntarily drink charcoal, there are few reasons to withhold it, even though a definite clinical benefit in routine cases cannot be proved. If a patient will not drink charcoal, patient management becomes controversial. Passing a nasogastric (NG) tube in a struggling patient or in a recalcitrant child merely to instill the unproven, but theoretically useful antidote is not supported by scientific data. Nonetheless, it remains a common procedure. Though not always easy or pleasant, such an intervention is usually safe. Pulmonary aspiration, even in an awake patient, is the major downside. Restrained supine patients are at greatest risk for aspiration, and that position should be avoided, even in an initially awake patient. **B**, Charcoal that is voluntarily swallowed or instilled via an oral-gastric lavage tube or an NG tube can induce emesis. This occurs in both obtunded and awake patients. In this instance the patient was unconscious from the overdose and the airway was protected with prior tracheal intubation. Although the intubation procedure does not totally exclude pulmonary aspiration and it carries some morbidity in its own right, it is recommended before use of charcoal in patients who are not able to fully protect their airway. Patients who are initially asymptomatic or minimally affected but have ingested drugs that have the potential to produce rapid deterioration, seizures, or loss of airway protection make decisions on the use of charcoal difficult for the clinician. In borderline cases, some experienced clinicians avoid the use of charcoal altogether.

are large amounts of charcoal instilled over a short period, multiple-dose charcoal in the setting of ileus, charcoal administration in a patient who becomes obtunded, charcoal that is inappropriately diluted, or forced administration of charcoal via an NG tube, especially in a restrained supine patient. These complications can be prevented by prudent dosing of charcoal, close monitoring of the airway, performing abdominal examinations with attention to bowel sounds, and focusing on the mechanism of the substance ingested (i.e., is the substance likely to cause profound sedation or seizures that would increase aspiration risk). Trivial aspiration of charcoal is common and usually innocuous, even if the patient is intubated. Studies show a 4% to 39% incidence of aspiration pneumonia in intubated patients who received activated charcoal.⁵⁷ It has been shown that even in patients with a protected airway and a cuffed endotracheal tube, vomiting can lead to pulmonary aspiration of the charcoal.⁵² This can result in a significant increase in lung microvascular permeability and lead to pulmonary edema and respiratory compromise.⁵⁸

Multiple Doses of Activated Charcoal

Indications

The use of multiple-dose activated charcoal (MDAC) may be indicated in selected cases (Fig. 42.12).⁵⁹ Its use has been advocated for two purposes: first, to prevent continued absorption of a drug that may still be present in the gastrointestinal tract, and second, to increase serum clearance of a drug that has already been absorbed.

MDAC prevents continued absorption by either binding a drug that may be present throughout the gastrointestinal tract or binding a drug that exists as an extended-release or enteric-coated preparation. MDAC enhances elimination of a drug by interrupting enterobiliary recirculation or augmenting enterocapillary exsorption.⁵³ With interruption of enterobiliary recirculation, charcoal binds to an active drug that is secreted by the biliary system, thus subsequently preventing reabsorption. With augmentation of enterocapillary exsorption, charcoal produces sink conditions that drive diffusion of the drug from capillaries into the intraluminal space, where it is subsequently eliminated. This process is called *intestinal dialysis*.⁶⁰ Drug characteristics associated with enhanced systemic clearance via MDAC include a low intrinsic clearance, a prolonged distributive phase, low protein binding, and a small volume of distribution.⁶¹

MDAC has been shown to increase total-body clearance of multiple drugs, including carbamazepine,⁶² dapsone,⁶³ phenobarbital,⁶⁴ quinine,⁶⁵ and theophylline.⁶¹ Despite the reported increase in drug clearance associated with the use of MDAC, improved clinical outcomes have not been definitively demonstrated. For example, Pond and co-workers described 10 comatose patients following phenobarbital overdose who were randomized to receive either single-dose activated charcoal or MDAC.⁶⁶ Despite the fact that the MDAC group had a significantly shorter phenobarbital serum half-life, no difference was found between the groups with regard to the duration of intubation or hospitalization. A retrospective study of hospitalized patients with phenytoin toxicity showed that those who received single-dose activated charcoal or MDAC did not benefit in the time to clinical improvement or duration of hospitalization compared to those who did not receive charcoal.⁶⁷ In a rural, developing-world setting, routine use of MDAC was not found to alter mortality rates.⁶⁸

POSITION STATEMENT: POSITION STATEMENT AND PRACTICE GUIDELINES ON THE USE OF MULTI-DOSE ACTIVATED CHARCOAL IN THE TREATMENT OF ACUTE POISONING

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Although many studies in animals and volunteers have demonstrated that multiple-dose activated charcoal increases drug elimination significantly, this therapy has not yet been shown in a controlled study in poisoned patients to reduce morbidity and mortality. Further studies are required to establish its role and the optimal dosage regimen of charcoal to be administered.

Based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, Phenobarbital, quinine, or theophylline. With all of these drugs there are data to confirm enhanced elimination, though no controlled studies have demonstrated clinical benefit.

Although volunteer studies have demonstrated that multiple-dose activated charcoal increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, there are insufficient clinical data to support or exclude the use of this therapy.

The use of multiple-dose charcoal in salicylate poisoning is controversial. One animal study and 2 of 4 volunteer studies did not demonstrate increased salicylate clearance with multiple-dose charcoal therapy. Data in poisoned patients are insufficient presently to recommend the use of multiple-dose charcoal therapy for salicylate poisoning. Multiple-dose activated charcoal did not increase the elimination of astemizole, chlorpropamide, doxepin, imipramine, meprobamate, methotrexate, phenytoin, sodium valproate, tobramycin, and vancomycin in experimental and/or clinical studies.

Unless a patient has an intact or protected airway, the administration of multiple-dose activated charcoal is contraindicated. It should not be used in the presence of an intestinal obstruction. The need for concurrent administration of cathartics remains unproven and is not recommended. In particular, cathartics should not be administered to young children because of the propensity of laxatives to cause fluid and electrolyte imbalance. In conclusion, based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, Phenobarbital, quinine, or theophylline.

Figure 42.12 Position statement and practice guidelines on the use of multidose activated charcoal in the treatment of acute poisoning. (From Position statement and practice guidelines on the use of multi-dose activated charcoal in the treatment of acute poisoning. American Academy of Clinical Toxicology; European Association of Poisons Centers and Clinical Toxicologists, *J Toxicol Clin Toxicol* 37:731–751, 1999.)

Contraindications

MDAC is contraindicated in patients with evidence of bowel obstruction. Ileus is a relative contraindication.⁶⁹ Many ill patients in whom ileus develops may be candidates for MDAC if the airway is protected. Administration of MDAC is contraindicated in any patient who does not have an intact or protected airway. MDAC should be avoided in patients with repetitive emesis, especially when associated with decreased mental status or a decreased gag reflex. Concurrent use of cathartics with MDAC remains unproven and is not

recommended.⁷⁰ MDAC with cathartics should not be administered to young children because of the propensity for laxatives to cause fluid and electrolyte imbalance. For example, MDAC with sorbitol has been associated with hypernatremia and dehydration⁷¹ and MDAC with magnesium cathartics has been associated with hypermagnesemia, neuromuscular weakness, and coma.^{72,73}

Technique

Give 1 g/kg (≤ 100 g) for the first dose of charcoal. If a cathartic is used, administer it only with the first dose of charcoal to decrease the potential risk for cathartic-induced electrolyte abnormalities, especially in children. Follow the initial dose of charcoal with 0.5 g/kg (≤ 50 g) every 4 hours. Stop giving MDAC if repeated examination reveals an absence of bowel sounds or a distended abdomen. In this case, consider placing an NG tube and put it on low intermittent suction. Patients receiving MDAC may be at increased risk for emesis because of the larger total dose of activated charcoal received. The use of antiemetics may help decrease the incidence of vomiting associated with MDAC.⁷⁴ Charcoal therapy should be continued until clinical improvement is evident and plasma drug levels have fallen to acceptable levels.

Complications

The complications encountered with single-dose activated charcoal are also encountered with MDAC. In addition, there have been reports of gastrointestinal obstruction and perforation with MDAC therapy, especially in conjunction with the ingestion of drugs that have anticholinergic properties.^{75–79}

Cathartics

Background

The use of cathartics is theoretically intended to decrease the absorption of substances by accelerating expulsion of the poison from the gastrointestinal tract. Cathartics are often used in conjunction with activated charcoal because of charcoal's side effect of constipation. The mechanism of action of cathartics is such that, theoretically, it would minimize the possibility of desorption of the drug bound to activated charcoal. There is little evidence that a single dose of aqueous activated charcoal is significantly constipating; however, cathartics are often given for this potential problem. The majority of data suggest negligible clinical benefit from the use of cathartics, and the use of cathartics is not supported by the editors.^{80,81}

Indications

Routine administration of a cathartic in combination with activated charcoal is not endorsed by the American Academy of Clinical Toxicology or the European Association of Poison Centers and Clinical Toxicologists.⁸² Administration of a cathartic alone has no role in the management of a poisoned patient.

Contraindications

Cathartics are contraindicated in patients with volume depletion, hypotension, significant electrolyte imbalance, ingestion of a corrosive, ileus, recent bowel surgery, and intestinal obstruction or perforation. Administration of cathartics is also contraindicated in patients who do not have an intact or protected airway. They should be avoided in those with repetitive emesis, especially when associated with decreased mental status or a

decreased gag reflex. Cathartics should be used cautiously in young children and the elderly because of the propensity for laxatives to cause fluid and electrolyte imbalance.

Technique

There are two types of osmotic cathartics: saccharide cathartics (sorbitol) and saline cathartics (magnesium citrate, magnesium sulfate, and sodium sulfate). The optimal dose of sorbitol or magnesium citrate remains to be determined. The recommended dose of sorbitol is approximately 1 to 2 g/kg of body weight or 1 to 2 mL/kg of 70% sorbitol in adults and 4.3 mL/kg of 35% sorbitol in children (single administration only).⁸² Charcoal formulations may come premixed with sorbitol, but the sorbitol content varies considerably. The recommended dose of magnesium citrate is 250 mL of a 10% solution in an adult and 4 mL/kg body weight of a 10% solution in a child. Multiple doses of cathartics should be avoided.

Complications

Administration of sorbitol has been associated with vomiting, abdominal cramps, nausea, diaphoresis, and transient hypotension.^{83–85} Because the sorbitol content varies between different charcoal-sorbitol combination products, pay attention to the sorbitol content in each brand to avoid excessive sorbitol administration. Be aware that multiple doses of sorbitol have been associated with volume depletion.⁷¹ Multiple doses of magnesium-containing cathartics have been linked to severe hypermagnesemia.^{72,73} Children are particularly susceptible to the adverse effects of cathartics, so use caution or totally avoid using cathartics in children.

Whole Bowel Irrigation

Background

WBI involves the enteral administration of an osmotically balanced polyethylene glycol electrolyte solution (PEG-ES) in a sufficient amount and rate to physically flush ingested substances through the gastrointestinal tract, thereby purging the toxin before absorption can occur.⁸⁶ PEG-ES (CoLyte [Pendopharm, Montreal, Quebec, Canada], GoLYTELY [Braintree Laboratories Inc., Braintree, MA]) is isosmotic, is not systemically absorbed, and will not cause electrolyte or fluid shifts. The data available suggest that the large volumes of this solution needed to mechanically propel pills, drug packets (such as in body packers or stuffers), or other substances through the gastrointestinal tract are safe, including use in pregnant women and young children.^{87–89}

Clinical data on the efficacy of WBI remain limited. Ly and colleagues found that the effect of WBI on reduction of acetaminophen concentration versus time was not statistically significant.⁹⁰ However, WBI did have a mechanical effect on radiopaque markers in the gastrointestinal tract, with 8 of 10 patients' markers congregating in the right hemicolon after WBI. A retrospective study by Bretaudeau Deguigne and colleagues suggested a reduction in the severity of acute-on-chronic lithium poisoning at a given ingested dose and serum lithium level with those undergoing early decontamination (by sodium polystyrene sulfonate and/or WBI) versus those in whom decontamination was delayed.⁹¹ WBI was shown to mobilize lead BB pellets to the large bowel in a child, where less absorption occurs and the foreign bodies could be removed by colonoscopic intervention.⁹² In addition, PEG-ES may play a role in the pharmacologic conversion of some toxins. For

example, it has been shown that the relatively high pH of PEG-ES increases the rate of spontaneous conversion of cocaine to its inactive metabolite benzoylecgonine.⁹³

Indications

WBI may be considered for the ingestion of exceedingly large quantities of potentially toxic substances, toxins that are poorly adsorbed by activated charcoal (e.g., iron, lithium), delayed-release formulations, late arrival at the ED after ingestion of a toxin, pharmacobezoars, and body stuffers or packers (Fig. 42.13).⁸⁶ WBI remains a theoretical option for these ingestions and is often performed on body packers who have ingested many times the lethal amount of such drugs as heroin or cocaine (Fig. 42.14). No definitive evidence exists to show that WBI improves the outcome of poisoned patients.⁸⁶ Though not a

proven procedure, WBI is often suggested by toxicologists, and its use in selected cases is intuitively reasonable and supported by the authors. The most common indication for WBI in the ED is for the treatment of toxic sustained-release medications (such as iron, calcium channel blockers, β -blockers, and lithium) and iron tablets (Fig. 42.15).⁹⁴

Contraindications

WBI is contraindicated in patients with gastrointestinal obstruction, perforation, ileus, or ingestion of a corrosive agent. It should also be avoided in patients with hemodynamic instability or an unprotected airway.⁹⁴ WBI should likewise be avoided

POSITION STATEMENT: WHOLE BOWEL IRRIGATION

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Based mainly on volunteer studies, whole bowel irrigation (WBI) can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs particularly for those patients presenting later than 2 h after drug ingestion when activated charcoal is less effective. WBI can be considered for patients who have ingested substantial amounts of iron, lithium, or potassium as the morbidity is high and there is a lack of other potentially effective options for gastrointestinal decontamination. WBI can be considered for removal of ingested packets of illicit drugs in "body packers." However, controlled data documenting improvement in clinical outcome after WBI are lacking. WBI is contraindicated in patients with bowel obstruction, perforation, or ileus, and in patients with hemodynamic instability or compromised unprotected airways. WBI should be used cautiously in debilitated patients and in patients with medical conditions that might be further compromised by its use. The concurrent administration of activated charcoal and WBI might decrease the effectiveness of the charcoal.

Figure 42.13 Position statement: whole-bowel irrigation. (From Thanacoody R, Caravati EM, Troutman B, et al: Position paper update: whole-bowel irrigation for gastrointestinal decontamination of overdose patients, *Clin Toxicol (Phila)* 53:5–12, 2015.)

Figure 42.15 Whole-bowel irrigation (WBI) is commonly recommended for the treatment of iron ingestion. These radiographs depict the effect of 5 hours of WBI. Note the marked decrease in radiopaque pills (arrows) in the gastrointestinal tract. Intact pills were recovered in the rectal effluent.

Figure 42.14 A, This body packer attempted to smuggle more than 50 packets of heroin. All packets were passed intact after 12 hours of whole-bowel irrigation. B, Note the integrity of the carefully wrapped packets that were passed.

with patients who have repetitive emesis, especially when associated with decreased mental status or a decreased gag reflex. WBI should be used cautiously in debilitated patients. WBI should be avoided in gastric bypass patients, due to the large volume of fluid that must be administered and risk of perforation.

Technique

PEG-ES is marketed in a powder form. Add tap water to make a total volume of 4 L. The recommended rate of administration is as follows⁹⁴:

- 9 months to 6 years: 500 mL/hr
- 6 to 12 years: 1000 mL/hr
- Older than 12 years: 1500 to 2000 mL/hr

Cooperative patients with intact airway-protective reflexes may drink the solution. The large volume and taste often limit even the most motivated patient's ability to comply. If the patient is unable or unwilling to drink this solution, administer it through a small-bore NG tube after placement is confirmed. Because it is common for WBI to be delayed while the patient and medical personnel attempt to administer the large volumes of oral WBI solution required to be effective, it is suggested that NG instillation be instituted early in the ED course (Fig. 42.16). Unconscious patients with protected airways may receive WBI via an NG tube. In one study, patients vomited shortly after beginning WBI infusion at a rate of 1.5 to 2 L/hr. Antiemetics such as ondansetron, as well as gradually advancing the infusion rate over a 60-minute period, can help ease this side effect. Prewarming the irrigant to a temperature of approximately 37°C avoids the potential complication of hypothermia. To collect the waste products, ask an awake patient to sit on a commode. In an obtunded patient, insert a rectal tube to collect the waste. Toxicologists have recommended adding two to three bottles of activated charcoal to each liter of WBI solution. The benefit is unproved, but there is little theoretical downside to this technique and it is supported by the authors. The binding capacity of charcoal is decreased when combined with PEG-ES, but the clinical consequences of this observation are unknown and probably minimal. Empirically, metoclopramide (10 to 20 mg intravenously) may be coadministered to decrease nausea and facilitate gastrointestinal passage.

The end point of WBI is the arrival of clear rectal effluent or resolution of the toxic effect (or both).⁹⁴ There are rare case reports of late purging of drug packets, plant parts, and tablets after the arrival of clear effluent.⁹⁵ Radiographic studies may also be beneficial to determine the end point in body packers or in patients who have ingested radiopaque medications.

Complications

Few complications from WBI therapy, especially pertaining to acute poisonings, have been reported. Nausea, vomiting, abdominal cramps, bloating, and aspiration have been described.^{69,96} Nausea and vomiting may make administration of WBI difficult. Antiemetics and a 15- to 30-minute break followed by a slower rate may allow readministration. As discussed with the other methods of decontamination, attention should be directed to the airway and the potential for aspiration. Administration of a large amount of chilled or room-temperature WBI fluid to pediatric patients could potentially cause hypothermia. Consider warmed fluids in these patients. If activated charcoal is administered concurrently with WBI, desorption of toxin from charcoal might occur.⁹⁷⁻⁹⁹

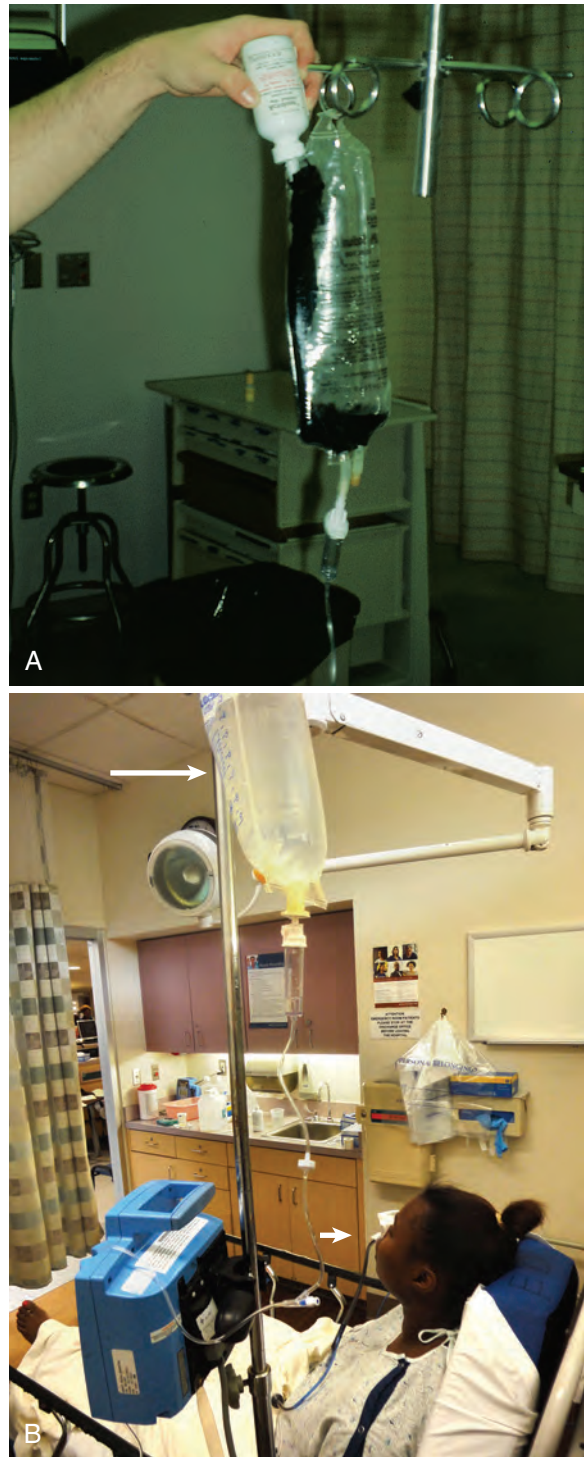

Figure 42.16 A and B, It is very difficult for even the most motivated patient to drink an effective volume of whole-bowel irrigation (WBI) solution. To enhance compliance and to decrease vomiting, polyethylene glycol electrolyte solution (PEG-ES) may be slowly and continuously administered via a nasogastric (NG) tube. An empty bag of saline is hung on an intravenous pole, the corner of the bag is removed, and the PEG-ES is poured into the bag. Standard intravenous tubing is connected to the proximal end of an NG tube (arrow) and the solution is infused continuously via a pump (1 L/hr). In this picture (A), charcoal has been added to the WBI solution. Metoclopramide (intravenous) was coadministered to reduce nausea, a common side effect of WBI.

DERMAL DECONTAMINATION

Background

Numerous hazardous material (HAZMAT) incidents occur each year in the United States. Although many of these events involve little morbidity or mortality, hospitals must prepare for the inevitability of caring for the chemically contaminated patient. Recent conflicts and terrorist attacks in the Middle East highlight the availability and use of chemical weapons, despite international chemical weapons treaties. The Joint Commission (TJC) requires that each US facility perform a hazard vulnerability analysis specific for the community in which that facility is located. Due to this variability in resource need for HAZMAT response, TJC gives limited guidance regarding the specifics of HAZMAT response. Guidelines from TJC involve developing an emergency operations plan (EOP) that describes how that hospital will handle chemical decontamination, as well as handle hazardous materials and waste (Standard EM.02.02.05). This leads to wide variability in HAZMAT response and decontamination practices.

Both the US Occupational Safety and Health Administration and TJC advocate that hospitals work with local emergency planning committees to best utilize community resources. In addition, TJC mandates that each hospital practice their emergency operations plan at least twice yearly, with one of these drills being a community-wide event. However, even in those communities with excellent integration of resources, resource utilization and communication during a HAZMAT incident is expected to be limited.^{100,101} Information regarding the event is often delayed or inaccurate, necessitating care of patients with limited knowledge of the extent or type of exposure.¹⁰⁰⁻¹⁰² Whereas recommendations of specific personal protective equipment (PPE) or decontamination techniques may vary depending on the specific chemical exposure, this information is unlikely to be known in the initial stages of decontamination. Deployment of community decontamination resources to the scene may be deficient.¹⁰² In addition, despite the best communication, patients are expected to present to health care facilities with little or no warning following a HAZMAT incident.^{100,103} Those requiring more hospital resources will be interspersed with those patients with little or no chemical exposure but present for precautionary evaluation nonetheless.¹⁰⁴ The end result is that in spite of preparation, in mass-casualty incidents the influx of patients will quickly overcome the health care system. Whereas some facilities may develop an EOP that utilizes local fire departments as a facility decontamination strategy, this is an unrealistic expectation in a HAZMAT incident; health care facilities must be prepared to be self-sufficient.

HAZMAT events frequently result in injuries to medical personnel. After the Tokyo attack, 13 of 15 clinicians (87%) reported symptoms while treating patients in the ED, and 23% of involved hospital staff complained of acute poisoning symptoms.¹⁰⁵ Burgess and associates reported that 13% of Washington state emergency care facilities had evacuated their ED or another part of the hospital because of contamination during a 5-year period.¹⁰⁶ Ghilarducci and co-workers surveyed level 1 US trauma centers and reported that only 6% had the necessary equipment required for safe decontamination.¹⁰⁷ Less than 36% of emergency medicine staff had received appropriate training in handling contaminated patients, and 5.6% had experienced injuries to their staff from contact with contami-

nated patients during a 1-year period. It is imperative that EDs have plans in place to handle patients who have been exposed to potential toxins, provide adequate decontamination facilities, and ensure the safety of the treating medical staff.¹⁰⁸

Technique

There are a number of key components in the management of HAZMAT incidents and the care of contaminated patients seen in the ED.¹⁰⁹ These components should include early recognition of a HAZMAT event, rapid activation of a plan to manage contaminated patients, initiation of primary triage, appropriate patient registration, patient decontamination, secondary triage, and final treatment.

First, the ED must be able to recognize that an event has occurred before contaminated patients gain entrance into the health care facility (Fig. 42.17, *step 1*). Communication with the local fire, police, and paramedic systems provides early detection of such events and allows preparation before patients arrive. Security should be arranged to prevent contaminated patients from entering the hospital, and “lockdown” of the facility should be considered.

Second, the ED should have the authority to activate a plan expeditiously to prepare the decontamination facility and allow appropriate preselected personnel to don PPE (see Fig. 42.17, *step 2*). If necessary, the hospital disaster plan should be activated quickly at the discretion of the ED clinician who is in contact with scene operations and incoming patients. Specific data to determine the appropriate level of PPE to maintain protection of hospital workers remain limited. The minimum PPE for hospital-based decontamination (level C) consists of a splash-proof, chemical-resistant suit with tape, double-layer protective gloves, and a powered air-purifying respirator per the National Institute of Occupational Safety and Health. Higher levels of protection, such as a level A self-contained breathing apparatus (SCBA), fully encapsulated chemical-resistant suit, or level B SCBA chemical-resistant suit, are recommended with unknown chemical and biologic exposures and for entering “hot” zones, but these levels of protection are not readily available in EDs.^{110,111} Fortunately, most chemical exposures are known. For those that occur in the workplace, Material Safety Data Sheets can be obtained and either the local poison center or the Agency for Toxic Substances and Disease Registry (ATSDR) can be contacted for advice on what level of protection is appropriate.

Third, appropriate primary triage should take place (see Fig. 42.17, *step 3*). Contaminated patients should not enter the ED until proper decontamination has occurred to ensure that the hospital staff will not be subjected to secondary contamination. Appropriate triage should then take place, with experienced personnel performing an initial brief assessment of each patient. The triage and decontamination areas should be organized into several “zones” to prevent further contamination. The hot zone is the location with the highest level of contaminant or where the incident occurred. In most cases of hospital-based decontamination there is no hot zone because patients have been removed from the initial chemical insult. On average, patients arrive at the ED 20 minutes after the event and have had significant off-gassing by this time; however, the majority of patients will have transported themselves and will not have received any prehospital decontamination by emergency medical services/HAZMAT personnel. Basic lifesaving treatments, airway and hemorrhage control, antidote administration (e.g., for cyanide or nerve agents), and

Management of Hazardous Materials Incidents

1 The ED recognizes that an incident has occurred before patients gain entry into the facility, via communication with police and EMS officials. Security prevents contaminated patients from entering the hospital.

2 The ED activates its disaster plan. The decontamination facility is prepared and trained individuals don personal protective equipment. Shown here are providers in level C splash-proof, chemical-resistant suits.

3 The ED staff, with the assistance of EMS providers, performs primary triage. A brief initial assessment of each patient is performed, and the patient's name and date of birth are recorded. Contaminated clothing is placed in an impervious bag.

4 Decontamination is performed. A portable decontamination facility as shown here is ideal, although may not be available at many institutions. Simpler solutions, such as a warm shower nozzle and a wading pool outside the ED, may be used.

Figure 42.17 During a hazardous materials (HAZMAT) incident, a decontamination tent with personnel in protective gear is assembled outside the emergency department entrance. *ED*, Emergency department; *EMS*, emergency medical service.

decontamination occur in the “warm” zone. The “cold” zone is safe from contaminant.¹¹¹

Fourth, a brief sign-in process in the warm zone should capture the patient's name and date of birth, with full registration to occur after decontamination. Contaminated clothing and valuables should be placed in an impervious bag to avoid potential off-gassing.

Fifth, decontamination should be performed (see [Fig. 42.17, step 4](#)). The hospital ED should have preexisting HAZMAT incident protocols that designate the decontamination area and the triage and decontamination team. Ideally, a hospital should have a permanent decontamination facility capable of handling a small number of chemically exposed patients and, in addition, a large portable unit for mass casualties. The decontamination area should meet several qualifications: (1) it should be secured to prevent spread to other areas of the

hospital, (2) the ventilation system should be separate from the rest of the hospital or it should be shut off to prevent airborne spread of contaminants, and (3) provisions must be made to collect the rinse water from contaminated patients to prevent contamination of the facility and water supply. At most facilities, the best place to begin initial treatment and evaluation is outdoors. Portable decontamination facilities are available, but their cost may be prohibitive for many institutions. A practical alternative is to have a warm shower nozzle, soap, and a wading pool available outside the entrance to the ED. A tent or screen can provide privacy.

The first priority in decontaminating patients is to remove their clothing while both maintaining privacy and preventing hypothermia. This step is the most important in the decontamination process and can reduce a significant level of contaminant. Clothes should be cut off rather than pulling them

off if possible. All clothing and valuables should be placed in labeled bags. Solids should be brushed off with a soft brush or towel.

Water irrigation has been shown to be efficacious in numerous clinical trials, it is widely available, and it is inexpensive.¹¹² Skin should be irrigated with copious amounts of warm water and cleansed with soap. Although some agents (e.g., metallic sodium, potassium, cesium, and rubidium) may react with water, it is still more beneficial to immediately irrigate and decontaminate the skin than to delay treatment. Starting from head to toe, exposed skin and hair should be irrigated for 10 to 15 minutes. Scrubbing with a soft surgical sponge is advocated, while being careful to not abrade the skin. Wounds should be irrigated for an additional 5 to 10 minutes with water or saline. Remove contact lenses and irrigate the eyes for 10 to 15 minutes with saline. Direct irrigation away from the medial canthus to avoid forcing contaminants into the lacrimal duct. With strongly alkaline substances, irrigate for longer times. Irrigate the nares and ear canals, with frequent suctioning if contamination is suspected. Clean underneath the fingernails with a brush. Avoid using stiff brushes and abrasives because they may enhance dermal absorption of the toxin and can produce skin lesions that may be mistaken for chemical injuries. Sponges and disposable towels are effective alternatives.

Products that do not require rinsing constitute a new approach in cases of emergency situations with limited access to water. There are neutralizing products already deployed in various militaries for this exact purpose. For example, the Canadian and the US militaries use Reactive Skin Decontamination Lotion (Emergent BioSolutions, Inc., Rockville, MD), a solution of potassium 2,3-butanedione monoximate and diacetylmonoxime (2,3-butanedione monoxime) dissolved in a solvent of polyethylene glycol monomethyl ether and water and absorbed on a synthetic pad. It is a water miscible lotion,

distributed as a sealed pack containing a single-use pad. This product has been shown to neutralize many chemical warfare agents and toxic industrial chemicals.¹¹³ As chemicals are rendered inactive, used pads can be directly disposed of in traditional trash, avoiding the problem of large volumes of contaminated irrigation water. Neutralizing products have been shown to be superior to traditional decontamination methods in head-to-head trials.¹¹³⁻¹¹⁵

Secondary triage should occur after decontamination. Transfer patients with major or moderate injuries to areas designated for such cases. Send patients with minor or no injuries to appropriate holding areas for further evaluation. Medical care at this stage depends on the toxin to which the patient has been exposed and the potential toxicity of that agent. Wounds, after copious irrigation, may need thorough exploration and possibly surgical removal of the contaminant.

For the ED to care for contaminated patients, protocols should be in place and be regularly rehearsed by the facility. Train staff in the procedures and protocols, establish communication between community agencies and hospitals, regularly inspect equipment, and rehearse setups. Obtain template protocols from both the peer-reviewed medical literature and the government literature if needed.¹¹⁶ For example, guidelines for managing HAZMAT incidents are available from ATSDR. In addition, prompted by the 2001 terrorist attacks, the US Department of Veterans Affairs and several policy experts have developed a “comprehensive hospital-wide emergency mass casualty decontamination program.” This program has been applied at most Veterans Affairs medical centers and has been demonstrated to be a cost-effective protocol, suitable for implementation at other US hospitals.¹¹⁰

Peritoneal Procedures

Alex Koefman and Brit Long

Paracentesis and diagnostic peritoneal lavage (DPL) constitute the two primary intraperitoneal procedures. They are fundamentally similar in purpose and design; however, the former is generally reserved for medical concerns and the latter for evaluation of traumatic pathology.

DPL

Root and colleagues introduced DPL in 1964.¹ It has withstood the passage of several decades and remains a useful diagnostic adjunct for the management of penetrating torso trauma. Following a blunt mechanism of injury, its greatest utility is as a triage tool in the assessment of hemodynamically unstable, multiply injured patients. The intent is to rapidly discover or exclude the presence of intraperitoneal hemorrhage (IPH). The advent and availability of ultrasound (US) in the emergency department (ED) have rendered this purpose complementary to that of US in the diagnostic armamentarium of emergency clinicians evaluating blunt trauma patients.²

Though commonly referred to as diagnostic peritoneal lavage, this procedure has two distinct components: peritoneal aspiration and peritoneal lavage. Peritoneal aspiration, in which an attempt is made to retrieve free intraperitoneal blood, precedes lavage. A finding of intraperitoneal blood is a marker for intraperitoneal organ injury and obviates the need for subsequent lavage. In the lavage portion, normal saline is introduced by catheter into the peritoneal cavity, recovered by gravity, and analyzed for evidence of significant intraperitoneal injury.

Peritoneal lavage can be used as a therapeutic tool in patients with hypothermia and as a means of removing toxins.³ It has also been used as a diagnostic instrument for suspected intraabdominal infection and nontraumatic sources of hemorrhage.^{4,5} Although the steps of the procedure are the same regardless of the indication, the primary use of DPL is to determine the need for laparotomy after trauma, and this chapter focuses on that indication.

Indications

Blunt Trauma

Before the advent of computed tomography (CT) and US, DPL was the sole diagnostic option to supplement physical examination for predicting the need for operative intervention (Table 43.1). It was integral to both reduction of unnecessary laparotomies and discovery of unsuspected and life-threatening intraabdominal hemorrhage in patients with significant closed-head injury.^{6,7}

This procedure may be undertaken by the emergency physician, but its use is not mandated nor considered standard of care, and is often relegated to the trauma service or consulting

surgeon. In a number of respected centers in the United States, DPL continues to be a focal diagnostic instrument.^{2,8} It serves two primary functions.⁹ First, it can be used to rapidly determine or exclude the presence of IPH. Thus, a patient with a critical closed-head injury, an unstable motor vehicle crash victim with multiple potential sources of blood loss, or a patient with pelvic

Diagnostic Peritoneal Lavage

Indications

- Rapidly determine presence of intraperitoneal hemorrhage
- Determine the presence of hollow viscus injury
- Determine diaphragmatic violation

Contraindications

- When clinical mandates for urgent laparotomy already exist

Complications

- Infection, hematoma, and dehiscence
- Solid organ or hollow viscus injury
- Vascular injury

Equipment

Review Box 43.1 Diagnostic peritoneal lavage (semi-open and closed techniques): indications, contraindications, complications, and equipment.

TABLE 43.1 Clinical Indications for Laparotomy After Blunt Trauma

MANIFESTATION	PITFALL
Unstable vital signs with strongly suspected abdominal injury	Alternative sources of shock
Unequivocal peritoneal irritation	Unreliable
Pneumoperitoneum	Insensitive; may be due to a cardiopulmonary source or invasive procedures (diagnostic peritoneal lavage, laparoscopy)
Evidence of diaphragmatic injury	Nonspecific
Significant gastrointestinal bleeding	Uncommon, unknown accuracy

From Marx J, Isenbour J: *Abdominal trauma*. In Marx JA, Hockberger RS, Walls RM, et al, editors: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St. Louis, 2006, Mosby, p 509.

fractures and retroperitoneal hemorrhage can be appropriately routed to lifesaving laparotomy.^{10,11} Furthermore, given its exquisite sensitivity, a negative peritoneal aspiration allows the clinician to proceed to alternative management steps and the patient to forego unnecessary laparotomy. Second, DPL has been used in less exigent circumstances as a means of predicting solid or hollow visceral injury requiring laparotomy.^{12,13} However, in this venue its sensitivity to the presence of hemorrhage may prompt unnecessary laparotomy in patients with self-limited lacerations of the liver, spleen,¹⁴⁻¹⁷ or mesentery.¹⁷ CT specifically evaluates all intraperitoneal structures, as well as the retroperitoneum, a region inaccessible to DPL. Because the resolution and the speed with which it can be undertaken have vastly improved, CT has become an invaluable adjunct in the management of blunt trauma and has largely replaced DPL in stable patients. It is most useful in identifying injury to solid organs with accompanying IPH and greatly assists nonoperative management of these injuries. The ability of CT to discern hollow viscus and pancreatic pathology has continued to improve as the modality has evolved.¹¹ With regard to hollow viscus injury, it is when serial clinical evaluations cannot be performed that gut perforation leads to preventable mortality. This is especially true in patients with severe closed-head injury or high spinal cord injury, in whom physical assessment of the abdomen is quite compromised. It is for these express scenarios that some authorities recommend the performance of DPL. The clinician's concern for hollow viscus injury should be heightened if US or CT demonstrates minimal amounts of free intraperitoneal fluid without evidence of solid organ damage.¹⁸

Two paradigms have brought US to the forefront. First, this modality has been adopted as the primary triage instrument, in lieu of DPL, for the detection of IPH on the basis of identifying which pouches and gutters are filled with fluid.¹⁹⁻²¹ Clinical success in this role has been mixed, with reported sensitivity for IPH of 65% to 95%.²²⁻²⁸ In addition, to be useful in this role, a competent technician and interpreter and the

appropriate equipment must be present in real time. It has been demonstrated that emergency clinicians and surgeons can be trained in this technique to a level of competence sufficient for this need.²⁹ In centers that rely on US, DPL should serve as a reliable study when US equipment is unavailable, performance of US is technically difficult, or the results of US are indeterminate, especially when the patient demonstrates hemodynamic compromise.

DPL is a readily available procedure that can be conducted rapidly in the safe confines of the ED. The ability to undertake CT in particular or, to a lesser extent, US in a similar manner requires careful consideration of the clinical circumstances, location of equipment, and capabilities of the personnel available (Fig. 43.1).^{2,11}

Penetrating Trauma

The advent of DPL was seminal in the promotion of selective management for penetrating abdominal injury. Here its role is more dominant than for blunt trauma because of the far greater likelihood of occult injury to hollow viscera and the diaphragm after a penetrating mechanism.^{30,31}

Instruments and missiles may penetrate the abdominal cavity via the anterior abdominal wall, flank, back, or low chest region.³² The intraperitoneal space is vulnerable if penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh space laterally and posteriorly because the diaphragm may rise to these levels in the expiratory phase of respiration.³³ Coincident thoracic penetration occurs in up to 46% of patients with abdominal injuries.³⁴⁻³⁶ The likelihood of retroperitoneal injury increases when the entry site is over the flank or back, but the prospect of intraperitoneal pathology remains considerable, with cited incidences of up to 43% for the flank and 14% for the back.³⁷⁻³⁹

Stab Wounds

Because only one fourth to one third of patients who sustain stab wounds to the anterior aspect of the abdomen require laparotomy, diagnostic algorithms are used to decrease the rate of unnecessary surgery.^{30,35,40} An optimal approach would not sacrifice sensitivity for morbid intraperitoneal injury. A pathway using a combination of clinical mandates, local wound exploration, and DPL is well established (Fig. 43.2).⁴¹ These clinical mandates are reasonably accurate predictors of significant intraperitoneal injury (Table 43.2). Thus, the presence of one or more mandates the need for urgent laparotomy and precludes the undertaking of other diagnostic studies.

DPL fills three roles in the evaluation of patients with abdominal stab wounds: (1) rapid determination of the presence of hemoperitoneum, (2) discovery of intraperitoneal injury requiring surgery in stable patients, and (3) establishment of diaphragmatic violation. As is the case in blunt trauma patients, DPL can be invaluable as a rapid triage tool when the source of hemodynamic instability is not known. Pericardial tamponade, intrathoracic hemorrhage, and IPH may be contributory to hemodynamic instability or wholly causal. Again, as for blunt trauma evaluation, US is the only bedside diagnostic modality for IPH that is competitive in this role, and it carries the added advantage of scanning for intrapericardial and intrathoracic hemorrhage.³⁵ In determining injury after stab wounds, DPL has 90% accuracy.⁴²⁻⁴⁴ Serial examinations,⁴⁵⁻⁴⁷ CT, and laparoscopy⁴⁸⁻⁵¹ are alternative modalities in specific circumstances and centers.⁵² The diaphragmatic rents created by stab wounds are generally small; thus, at the outset they do not

BLUNT ABDOMINAL TRAUMA ALGORITHM

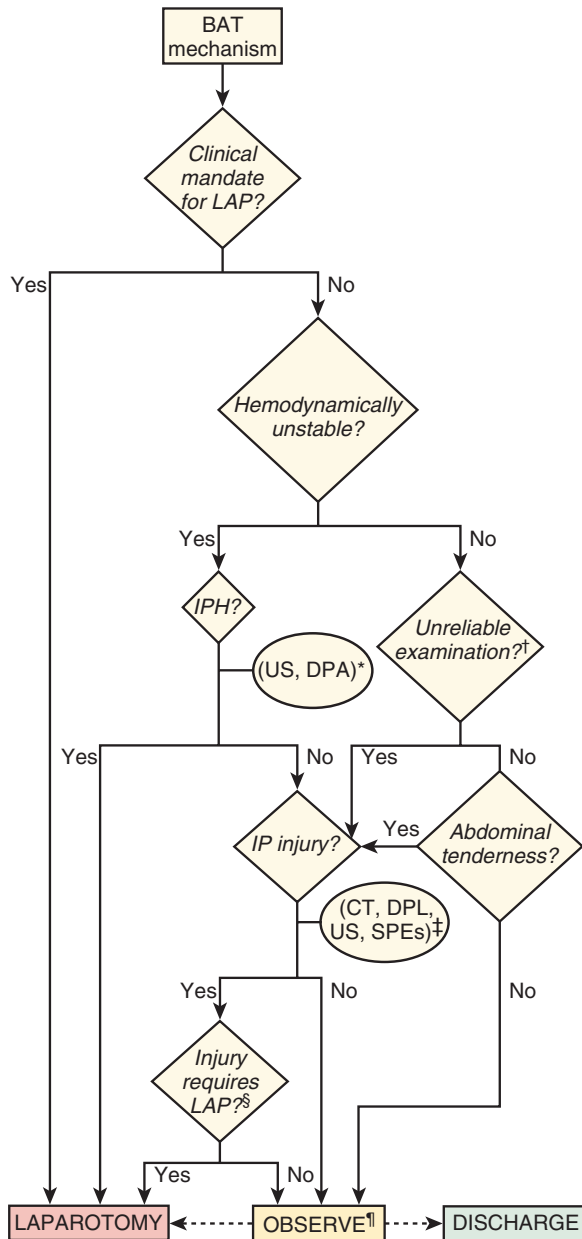

Figure 43.1 Algorithm for blunt abdominal trauma (BAT). *Determined by unequivocal free IP fluid on US or positive peritoneal aspiration on DPA. †May be unreliable because of closed-head injury, intoxicants, distracting injury, or spinal cord injury. ‡One or more studies may be indicated. §The need for LAP is based on the clinical scenario, diagnostic studies, and institutional resources. The duration of observation should be 6 to 24 hours, depending on whether diagnostic tests have been performed, the results of the tests, and clinical circumstances, including the absence of factors rendering the examination unreliable. CT, Computed tomography; DPA, diagnostic peritoneal aspiration; DPL, diagnostic peritoneal lavage; IP, intraperitoneal; IPH, intraperitoneal hemorrhage; LAP, laparotomy; SPE, serial physical examination; US, ultrasound. (From Marx J, Isenhour J: Abdominal trauma. In Marx JA, Hockberger RS, Walls RM, et al, editors: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St. Louis, 2006, Mosby, p 508.)

ANTERIOR ABDOMEN STAB WOUND ALGORITHM

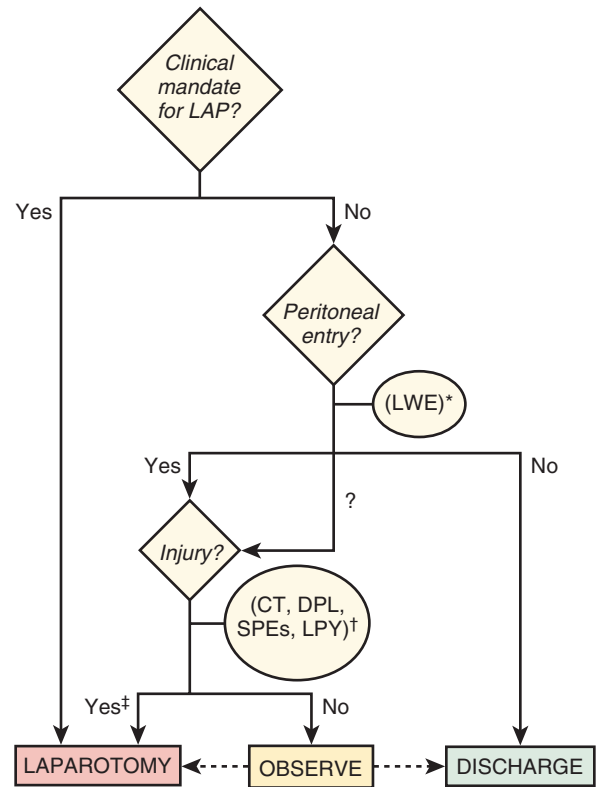

Figure 43.2 Algorithm for anterior abdominal stab wounds. *Plain films, ultrasonography, LPY, and CT can also assess peritoneal entry. †CT, DPL, SPEs, or LPY can be used in singular or complementary fashion depending on the clinical scenario. ‡Expectant management of injuries is infrequently attempted. CT, Computed tomography; DPL, diagnostic peritoneal lavage; LAP, laparotomy; LPY, laparoscopy; LWE, local wound exploration; SPE, serial physical examination. (From Marx J, Isenhour J: Abdominal trauma. In Marx JA, Hockberger RS, Walls RM, et al, editors: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St. Louis, 2006, Mosby p 503.)

create apparent clinical or radiologic abnormalities.^{53,54} However, morbidity from delayed herniation of bowel is common and substantive.⁵⁵ Physical examination is notoriously insensitive, and DPL is currently the most sensitive means of discerning this injury in the immediate posttrauma phase.⁴² There is some evidence that coronal reconstruction of CT images provides greater sensitivity for detecting small diaphragmatic tears, and as CT technology continues to evolve, it may surpass DPL for evaluation of these subtle injuries.⁵⁶ For these small wounds, magnetic resonance imaging may be diagnostic, but because of safety and accessibility concerns, it should be reserved for the nonacute phase of management. Laparoscopy has demonstrated promise in experienced hands.^{48,49}

Gunshot Wounds

Injury to multiple organs is the rule after gunshot wounds, and mortality is significantly greater than after stab wounds.⁵² The diagnostic approach is more conservative for gunshot wounds because in some studies the likelihood of intraperitoneal injury requiring operative intervention has exceeded 90% when the projectile has entered the intraperitoneal cavity (Fig. 43.3).⁵⁷ If clinical mandates are met (see Table 43.2) or if peritoneal

TABLE 43.2 Clinical Indications for Laparotomy After Penetrating Trauma

MANIFESTATION	PREMISE	PITFALL
Hemodynamic instability	Major solid visceral or vascular injury	Thorax, mediastinum
Peritoneal signs	Intraperitoneal injury	Unreliable, especially immediately after injury
Evisceration	Additional bowel, other injury	No injury in one fourth to one third of stab wound cases
Diaphragmatic injury	Diaphragmatic herniation	Rare clinical, radiographic findings
Gastrointestinal and vaginal hemorrhage	Proximal gut or uterine injury	Uncommon, unknown accuracy
Impalement in situ	Vascular impalement	High operative risk, pregnancy
Intraperitoneal air	Perforation of a hollow viscus	Insensitive; may be caused by intraperitoneal entry only or be due to a cardiopulmonary source

Modified from Marx JA: *Diagnostic peritoneal lavage*. In Ivatury RR, Cayten CG, editors: *The textbook of penetrating trauma*, Baltimore, 1996, Williams & Wilkins.

ABDOMINAL GUNSHOT WOUND ALGORITHM

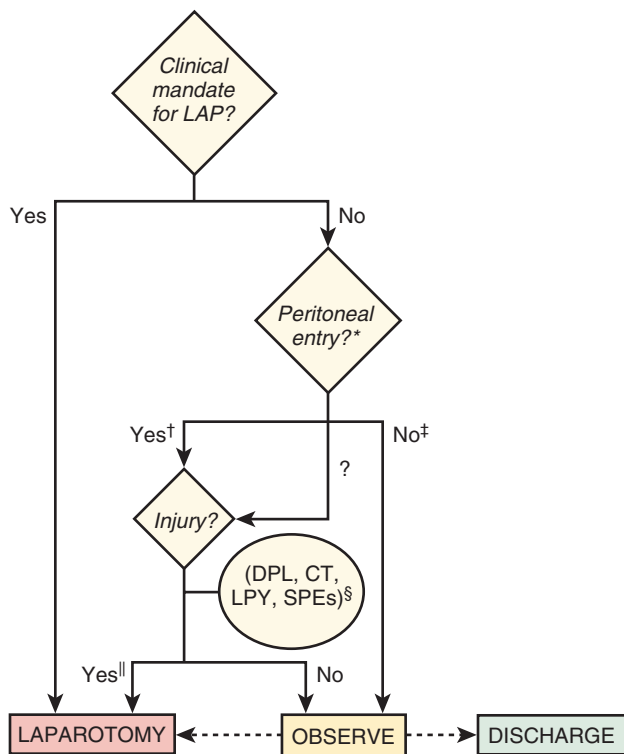

Figure 43.3 Algorithm for abdominal gunshot wounds. *Can be assessed by the path of the missile, plain films, local wound exploration, ultrasonography, and LAP. †Most centers proceed to LAP if peritoneal entry is suspected. ‡Patients with documented superficial and low-velocity injuries can be discharged; high-velocity injuries or those of unknown depth require further tests or observation. §DPL, CT, LPY, or SPEs can be used in singular or complementary fashion depending on the clinical scenario. Expectant management of injuries caused by gunshot wounds is rarely attempted. CT, Computed tomography; DPL, diagnostic peritoneal lavage; LAP, laparotomy; LPY, laparoscopy; SPE, serial physical examination. (From Marx J, Isenhour J: *Abdominal trauma*. In Marx JA, Hockberger RS, Walls RM, et al, editors: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St. Louis, 2006, Mosby p 506.)

violation has occurred, most centers proceed to laparotomy.⁴¹ One series, however, cited intraabdominal injury in 70% to 80% of cases, thus supporting the contention that nonoperative management could be applied to a substantial percentage of patients.⁵⁸ In a separate cohort of 152 patients sustaining solid organ injury from penetrating abdominal trauma (70% gunshot wounds and 30% stab wounds), 27% were successfully managed without laparotomy after selection by a protocol combining clinical examination and CT scanning.⁵⁹ DPL is reserved for two circumstances: (1) the wound tract is neither obviously superficial nor intraperitoneal, and (2) penetration occurred in the low chest region, where diaphragmatic injury is more likely, yet the possibility of intraperitoneal injury also exists.

Contraindications

DPL can be undertaken in virtually any patient irrespective of age or comorbid illness. Adjustment of the technique and site of performance allows relative contraindications to be overcome. Relative contraindications include previous abdominal surgery or infections, obesity, coagulopathy, and second- or third-trimester pregnancy. The sole absolute contraindication is when clinical mandates for urgent laparotomy already exist.

Procedure

Prior to DPL, decompress the stomach and bladder to prevent inadvertent injury. Place the patient in the supine position and administer sedatives and analgesics as appropriate. Perform DPL according to compliance with standards for body fluid precautions. Observe sterile technique throughout the procedure. Before making the skin incisions described later, prepare the site with standard skin antiseptics and drape appropriately. Prophylactic antibiotics are not indicated for routine DPL because local and systemic infections are rare.⁶⁰

Infiltrate the area for incision and dissection with a local anesthetic such as 1% lidocaine *with* epinephrine (Fig. 43.4, step 1). Delay the incision for more than 30 seconds after infiltration of local anesthetic to permit local vasospasm, which minimizes bleeding of the wound during the procedure.

Diagnostic Peritoneal Lavage: Semi-Open Technique

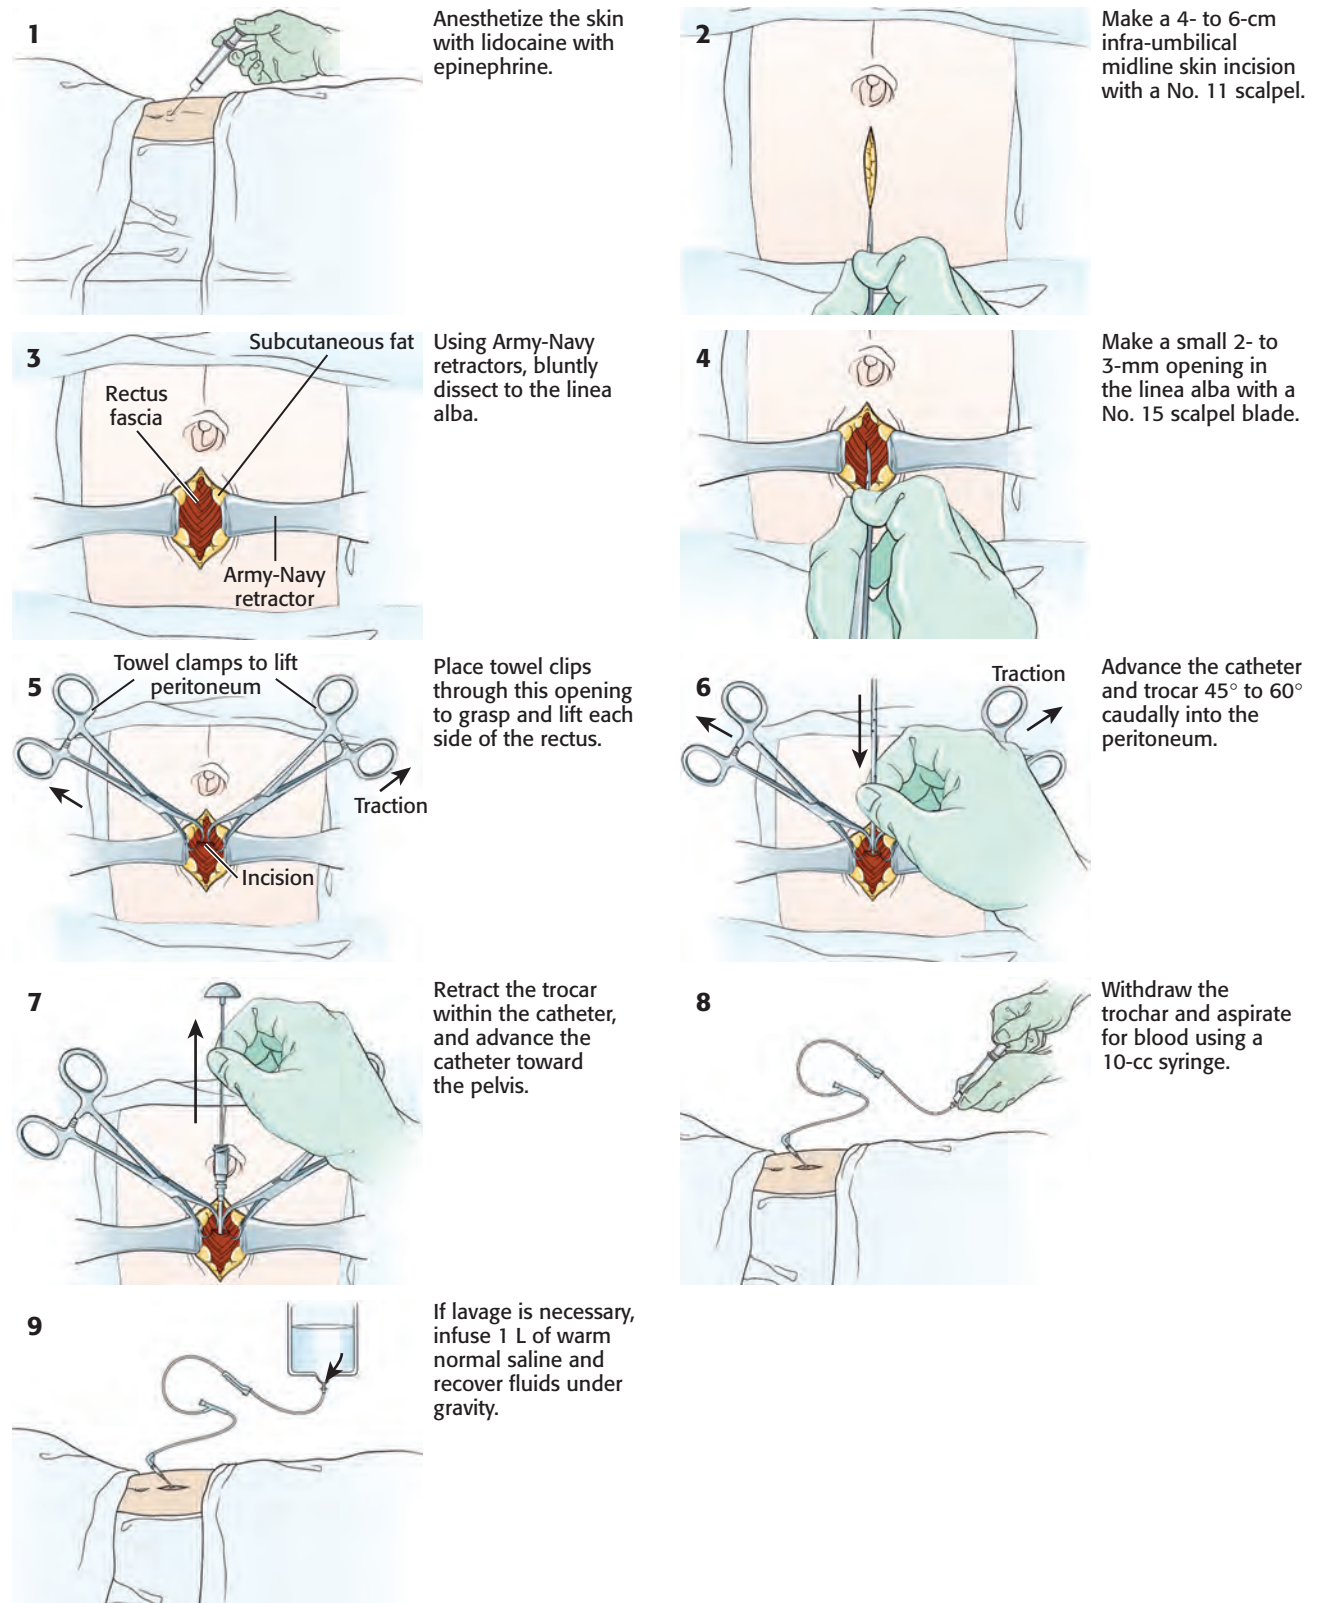

Figure 43.4 Semi-open technique of diagnostic peritoneal lavage. Note that the stomach and bladder have been decompressed under most circumstances.

Placement of the Catheter

There are two basic methods for DPL: open and closed. The two open techniques are *semi-open* and *fully open*, and both typically require an assistant. DPL is clearly within the diagnostic armamentarium of the emergency clinician and surgeon. Either may undertake it in keeping with clinical policies established at the particular trauma center.

Semi-open Technique

Make a skin incision 4 to 6 cm in length with a No. 11 scalpel blade. Using Army-Navy retractors, proceed with blunt dissection to expose the rectus fascia (see Fig. 43.4, steps 2 and 3). With the infraumbilical incision in the midline, continue blunt dissection until the linea alba is seen. Its crossing bands of crural fibers may be apparent.⁶¹ Make a small 2- to 3-mm opening in the linea alba with a No. 15 scalpel blade (see Fig. 43.4, step 4). You may notice a tough, gritty sensation when cutting the linea alba with the scalpel. Place towel clips through this opening to grasp each side of the rectus fascia (see Fig. 43.4, step 5). Ask an assistant to lift the two towel clips and carefully advance the catheter and trocar in a 45- to 60-degree caudad orientation. Proceed through the peritoneum into the peritoneal cavity (see Fig. 43.4, steps 6 and 7).⁶²

One method to decrease the likelihood of penetrating any underlying viscera is to hold the fingers low on the catheter/trocar instrument such that on entering the abdominal peritoneum, the fingers prevent deep penetration. Excessive pressure during penetration with the trocar is a common error. Apply steady one-finger pressure to the handle sufficient to “pop” through the peritoneum. After controlled peritoneal penetration of 0.5 to 1.0 cm in the midline, retract the trocar 1.0 to 2.0 cm within the catheter, and advance the catheter carefully toward the pelvis. Some operators advance the catheter toward the right or left side of the pelvis. Use a slight twisting motion during advancement to minimize visceral or omental injury.

The fully open technique extends the semi-open technique by one step. Lengthen the opening in the linea alba to open the peritoneum, and use direct visualization to advance the catheter into the peritoneal cavity. The trocar is unnecessary with the open technique.

A single technician can accomplish the two open techniques, but it is useful to have an assistant help with retraction and handling of the instruments. The fully open method is the more technically demanding and time-consuming. Reserve this method for clinical circumstances in which neither the closed nor the semi-open technique is deemed safe, or they have been attempted and failed. Examples of such circumstances include pelvic fracture, pregnancy, previous abdominal surgery, adhesions, infections, and obesity.

Closed Technique

For the closed technique, introduce the catheter into the peritoneal space in a blind percutaneous fashion.⁶³ Use the simple Seldinger (guidewire) method, in which a small-gauge guide needle is inserted into the peritoneal cavity in the midline just inferior to the umbilicus (Fig. 43.5, step 2). Pass a flexible wire through the needle (see Fig. 43.5, step 3), and remove the needle but not the wire. Make a small stab with a No. 11 scalpel blade at the entry site of the wire to allow easier passage of the catheter through the abdominal wall (see Fig. 43.5, step 4), and then advance a soft catheter over the wire and into the peritoneal cavity. Rotate the catheter while pushing it over the guidewire to facilitate entry into the peritoneal cavity

if the catheter does not advance easily. Place the catheter into the right or left pelvic gutter.

Always control the guidewire to avert intraabdominal migration of the wire. Withdraw the wire and aspirate for blood with a 10-mL syringe. Follow this with peritoneal lavage when necessary. Proponents of the guidewire technique promote its ease and rapidity.⁶⁴⁻⁶⁸ Those who prefer the semi-open method argue that the time until peritoneal aspiration, the more critical interval, is minimally different and that this method may have fewer complications and thus be more accurate than the guidewire technique.⁶⁹⁻⁷³ Note that for both the semi-open and closed approaches, the time until aspiration is performed should be no more than 2 to 5 minutes.

Site

The optimum location for DPL is at the infraumbilical ring at the inferior border of the umbilicus (Table 43.3). Here, between the rectus abdominis muscles there is adherence of the peritoneum and relative lack of vascularity and preperitoneal fat.⁶¹ Closed DPL should always be conducted here. In the event of second- or third-trimester pregnancy, a suprauterine approach is used. If midline scarring is present, a fully open technique at the lateral border of the rectus abdominis in the left lower quadrant may be necessary. The left side is preferred to avoid later confusion about whether an appendectomy has been performed. It is interesting to note that Moore and associates found no increase in complications or misclassified lavage when the closed technique was used in a small series of patients with previous abdominal surgery.⁷⁴ In the presence of a pelvic fracture, use a fully open supraumbilical approach. This greatly decreases the likelihood of passing the catheter through a retroperitoneal hematoma that has dissected from the fracture anteriorly and across the abdominal wall.⁷⁵ In patients with penetrating trauma, do not perform DPL through the stab or missile entry site. This approach can contaminate the intraperitoneal cavity, potentially exacerbate the abdominal wall bleeding, and lead to a false-positive result.

Aspiration and Lavage

Once the catheter has been placed successfully into the peritoneal cavity, attach the right-angle adapter, extension tubing, and a non-Luer-Lok syringe and attempt aspiration (see Fig. 43.4, step 8). If 10 mL of blood is aspirated, the test is positive and the procedure is terminated. With penetrating

TABLE 43.3 Preferred Site for DPL

CLINICAL CIRCUMSTANCE	SITE	METHOD

Diagnostic Peritoneal Lavage: Closed Technique

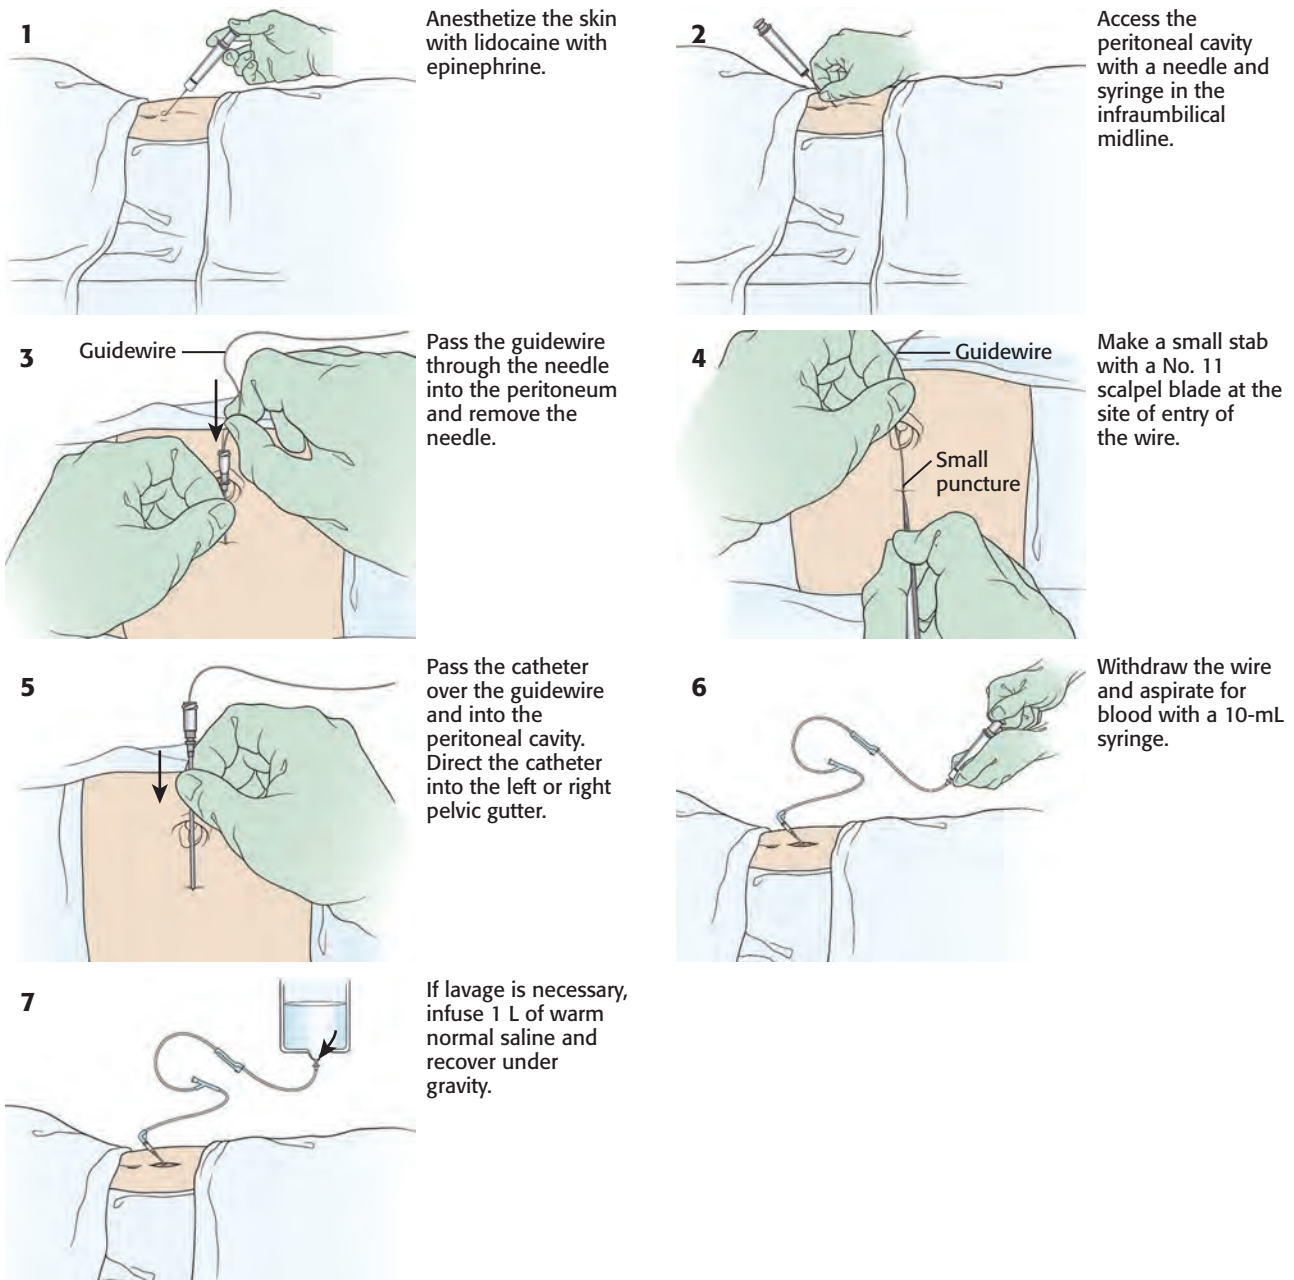

Figure 43.5 Closed technique of diagnostic peritoneal lavage. Note that the stomach and bladder are decompressed under most circumstances.

trauma, acquisition of lesser amounts may be meaningful because of the tendency for the diaphragm and bowel to hemorrhage minimally when injured. However, no rules have been established in this regard.

If little to no blood is aspirated, lavage the peritoneal cavity with either normal saline or lactated Ringer's solution (see Fig. 43.4, step 9). Apply a blood pressure cuff or blood infusion pump around the plastic intravenous (IV) bag to speed the influx (i.e., decrease lavage time) if necessary. Large-bore

infusion tubing (e.g., urologic irrigation tubing sets, such as the Abbott No. 6543 cystoscopy/irrigation set [Allergiance, Michigan]) also shortens fluid influx time. Infuse 1 L of fluid in adults or 15 mL/kg in children. When possible, roll or shift the patient from side to side after the infusion to increase mixing. Place the IV bag or bottle on the floor (or below abdominal level), and allow the fluid to return by gravity.

If the fluid does not return, there may be several reasons. Some IV tubing contains a one-way valve. If tubing with a

valve was used in error, replace it with valveless tubing and reattach it to the IV bag. Another reason for poor return is inadequate suction. To correct this problem, insert a needle into the second opening at the bottom of the IV bag or into the head of the IV bottle for aspiration of 10 mL of air. Alternatively, the catheter may be adherent to the peritoneum. If so, try to relieve some of the pressure in the IV bottle by gently wiggling and twisting the catheter or applying abdominal pressure to aid in the return of flow.

Return of 700 mL or more in an adult is generally accepted as adequate for interpretation of the findings. However, as little as 10% to 20% of the infusate may give a representative sample for both gross and microscopic determination. Send 10 mL of fluid from the return to the laboratory for cell count analysis, and send another 10 mL for enzyme analysis (see the section on [Interpretation](#) later in this chapter). Some operators prefer to leave the catheter in place until the returned fluid is analyzed so that lavage may be repeated if the initial results are borderline or an occult bowel perforation is suspected.

Complications

Local and Systemic

Local wound complications, including infection, hematoma, and dehiscence, occurred in only 0.3% of patients in two large series.^{42,76} Dehiscence with evisceration is an even rarer condition.⁷⁷ Systemic infection has been described rarely ([Table 43.4](#)).

Intraperitoneal

The trocar, wire, and rarely, the catheter can inflict iatrogenic intraperitoneal injury. Virtually any structure in the peritoneal cavity can be breached, including the small and large bowel, the bladder, and major vessels. Typically, if the needle is the culprit and even if the trocar is responsible, injury to these structures is minimal and self-limited, and observation of the patient is sufficient.

Technical Failure

Inability to recover peritoneal aspirate or lavage fluid can result in a false-negative interpretation. This can occur in several circumstances. It follows unwitting placement of the catheter into the preperitoneal space, which is less likely to occur with either open technique. Compartmentalization of fluid by adhesions or obstructing omentum can impede the egress of fluid. When a fully open supraumbilical or suprauterine technique is used, the catheter may be too short to access the depths of the intraperitoneal cavity. Finally, the large diaphragmatic tears typical of blunt pathophysiology allow flow of lavage fluid from the intraperitoneal to the thoracic cavity. Saunders and coworkers compared percutaneous DPL and the open technique in a prospective, randomized trial.⁷⁸ Fluid obtained by the two techniques had similar test performance for intraabdominal pathology. The open technique took, on average, more than 4 minutes longer, but the percutaneous approach had an 11.2% technical failure rate (versus 3.8% with the open approach).

False-positive findings can occur in two ways. First, iatrogenic misadventure may be responsible. Second, in penetrating trauma, particularly stab wounds, bleeding from the abdominal wall injury site into the peritoneal cavity can lead to positive findings when no injury to intraperitoneal structures has occurred.⁴⁴

TABLE 43.4 Complications of DPL

CATEGORY	COMMENTS
Local and Systemic	
Hematoma incision site	Local wound care
Dehiscence incision site	Local wound care
Local wound infection	As indicated
Systemic infection	As indicated
Intraperitoneal Injury	
Bowel	Observe, usually self-limited
Bladder	Observe, usually self-limited
Vascular	Observe, usually self-limited
Technical Failure	
<i>Inability to Recover Fluid^a</i>	
Preperitoneal catheter placement	Repeat DPL
Compartmentalization of fluid	US, CT
Obstructed catheter	Gentle catheter manipulation
Diaphragm injury	Reverse Trendelenburg; consider US, CT
“Short” catheter (supraumbilical or suprauterine approach)	Trendelenburg
<i>Intraperitoneal Hemorrhage^b</i>	
Iatrogenic injury	As indicated by clinical markers
Stab wound, abdominal wall bleeding	As indicated by clinical markers
Pelvic fracture (RBC count)	Complementary CT

^aMay lead to false-negative DPL results.

^bMay lead to false-positive DPL results.

CT, Computed tomography; DPL, diagnostic peritoneal lavage; RBC, red blood cell; US, ultrasound.

Interpretation

Gross Blood

Recovery of 10 mL or more of blood via aspiration is considered a positive finding. Aspirates with lesser volume are generally discarded and are not factored into analysis of the lavage fluid. Grossly bloody aspirates are typically indicative of solid visceral or vascular injury, with a positive predictive value of greater than 90%.^{79,80} Aspiration of blood is responsible for approximately 80% of true-positive DPL findings with blunt trauma and for 50% with stab wounds.⁴³

A positive aspiration in a blunt trauma patient who is hemodynamically stable or has been resuscitated to apparent

TABLE 43.5 Diagnostic Peritoneal Lavage

	POSITIVE	INDETERMINATE
Blunt trauma (RBC/mm ³)	100,000 ^a	20,000–100,000
Stab wound (RBC/mm ³)		
Anterior abdomen	100,000	20,000–100,000
Flank	100,000	20,000–100,000
Back	100,000	20,000–100,000
Low chest	5000–10,000	1000–5000
Gunshot wound (RBC/mm ³)	5000–10,000	1000–5000
LAM (IU/L)	>20	10–19
LAP (IU/L)	≥3	NA
WBCs (per mm ³)	>500	250–500

^aIn a hemodynamically stable patient with a pelvic fracture and a positive or equivocal red blood cell count, computed tomography should be obtained to corroborate or refute intraperitoneal injury.

stability need not mandate urgent surgery. Unnecessary laparotomy will occur if there has been minimal and self-limited damage to the liver, spleen, bowel serosa, or mesentery.⁸¹ In this situation, CT and clinical indicators should be used in concert with the findings on DPL.

RBC Count

The recommended red blood cell (RBC) threshold varies according to the mechanism and, in the case of stab wounds, the external site of injury (Table 43.5). The optimum criterion will deliver excellent sensitivity, a high positive predictive value, and a minimal incidence of unnecessary laparotomy. Negative laparotomy incurs a prolongation of hospitalization and increases the cost of care, in addition to creating the potential for procedural complications.^{82,83} RBC counts greater than 10⁵/mm³ (10⁵/μL) are generally considered positive with a blunt mechanism or after stab wounds in the anterior part of the abdomen, flank, or back. Counts of 20,000 to 100,000/mm³ should be considered indeterminate.^{43,45,84,85} For stab wounds in the low chest region, where the diaphragm is at increased risk for injury, the RBC criterion should be lowered to 5000/mm³ to maximize sensitivity for isolated injury to this structure.^{36,43,86,87} With gunshot wounds involving the abdomen or low chest region, the same RBC criterion of 5000/mm³ is applied. This is intended to increase the sensitivity of the test because intraperitoneal entry by a missile carries a 90% or greater likelihood of intraperitoneal injury.^{36,60,88} An uncomplicated DPL should not result in more than several hundred to several thousand RBCs in the peritoneal lavage fluid.

The incidence of false-positive RBC interpretation in the setting of pelvic fracture is considerable. However, aspiration of free blood in patients with critical pelvic fractures predicts active IPH in more than 80% of cases. A positive RBC count should generally prompt corroboration or refutation of intraperitoneal injury by CT. In this fashion, needed pelvic

angiography and embolization will not be delayed unnecessarily should active intraperitoneal bleeding not be found (Fig. 43.6).

WBC Count

An inflammatory peritoneal response to a multitude of stimuli can occur, including stool, blood, and enzymes.⁸⁹ The white

blood cell (WBC) count in lavage effluent was formerly touted to predict small bowel injury but has since been proved unreliable.⁹⁰ It is insensitive in the immediate postinjury period because 3 to 5 hours is necessary before the test becomes positive (see [Table 43.5](#)).^{91,92} Moreover, a positive finding is likely to be falsely so.^{91,93} Therefore, the WBC level in and of itself should not determine the need for laparotomy.

Enzymes

Alkaline phosphatase is contained intramurally in the small bowel, as well as in hepatobiliary secretions released into the proximal part of the intestine. Amylase is contained in the latter only. Perforation of the small bowel allows access of these two markers to the peritoneal cavity, where they can be recovered by peritoneal lavage.⁹⁴⁻⁹⁶ Although levels of the two markers usually rise in tandem, lavage amylase has been shown to be a more accurate marker than lavage alkaline phosphatase (see [Table 43.5](#)). In contradistinction to the WBC count, these tests will be positive in the immediate postinjury period. However, they may not be economical if used on a mandatory rather than a selective basis. Neither is helpful in discerning the presence of pancreatic pathology.

Miscellaneous

Routine bile staining, Gram staining, and microscopy to identify vegetable fibers are rarely productive and are of untested accuracy. Deck and Porter reported that finding urine in the lavage fluid, as evidenced by a straw color, and creatinine in the peritoneal fluid should suggest an intraperitoneal bladder or collecting system injury.⁹⁷

Conclusion

In the current era of readily available advanced imaging techniques such as CT and US, DPL maintains a diminished, but important role in the evaluation of injured patients. It can identify life-threatening IPH in unstable patients when US is unavailable, indeterminate, or negative for free fluid. In addition, DPL can identify hollow viscus injury when CT is nondiagnostic in patients in whom serial clinical evaluations are impractical or unreliable, as in those with severe traumatic brain and spinal cord injuries. Finally, DPL remains more accurate than CT in identifying occult diaphragmatic injuries and is useful in high-risk patients without other indications for surgical abdominal exploration. It should be used in commonsense fashion. The noted laboratory parameters are guidelines and should not be embraced to the exclusion of pertinent clinical features. Optimal strategies depend largely on the capability of an institution's resources and personnel in each clinical scenario.

PARACENTESIS

Therapeutic abdominal paracentesis, the removal of intraperitoneal fluid, is one of the oldest medical procedures and dates to approximately 20 BC. Paracentesis was first described in the modern medical literature by Saloman at the beginning of the 20th century, and it became a valued decompressive therapy.⁹⁸ With the advent of diuretics in the early 1950s, paracentesis fell out of favor as a treatment option. Controlled clinical trials in the late 1980s up to the present have restored its reputation by demonstrating the safety and efficacy of large-volume

paracentesis (LVP) in adults and children.⁹⁹⁻¹⁰⁵ Because this mode is invasive and consumes clinician hours, it is generally reserved for the treatment of patients with chronic ascites who have tense ascites or whose condition is refractory to diuretic therapy.¹⁰² However, paracentesis ([Videos 43.1 and 43.2](#)) remains an important diagnostic agent for patients with new-onset ascites or to determine the presence of worrisome conditions, notably infection, in those with preexistent ascites.¹⁰⁶

Clinical Features

Determination of Ascites

Small amounts of ascites may be asymptomatic. Larger collections typically cause a sense of abdominal fullness, anorexia, early satiety, and perhaps nausea and abdominal pain. Substantial accumulations create symptoms of respiratory distress by restricting lung capacity.¹⁰⁷

The most predictive history and physical examination findings for excluding the diagnosis of ascites are the absence of ankle swelling and increased abdominal girth and an inability to demonstrate bulging flanks, flank dullness, or shifting dullness.¹⁰⁸ Positive predictors for the diagnosis are a positive fluid wave, shifting dullness, or peripheral edema, with flank dullness having the greatest sensitivity at 94% and positive fluid wave having the greatest specificity.^{108,109}

Patients who lack obvious clinical markers may benefit from the performance of US, which can discern the presence of as little as 100 mL of fluid.¹¹⁰ Endoscopically guided US may detect as little as 10 mL. It is more sensitive than CT in this respect and can assist in the identification of malignancy.¹¹¹ In addition, it is a useful adjunct for determining the location of fluid that may be compartmentalized by preexistent infection or surgical adhesions.

Differential Diagnosis

Causes of ascites can be categorized in several ways. On a structural basis, the causes are divided into diseases of the peritoneum and diseases not involving the peritoneum. The former group includes infection, neoplasm, collagen vascular disease, and idiopathic causes. The latter includes cirrhosis, congestive heart failure, nephrotic syndrome, protein-losing enteropathy, malnutrition, myxedema, pancreatic disease, ovarian disease, chylous effusion, Budd-Chiari syndrome, and hepatic venous occlusive disease. Pathophysiologic categories are listed in [Box 43.1](#). In the United States, parenchymal liver pathology is overwhelmingly the most likely cause. Within this group, alcoholic liver disease is responsible for approximately 80% of cases ([Table 43.6](#)).¹¹² Finally, ascites can be classified on the basis of a serum-ascites albumin gradient, that is, the difference between albumin values obtained simultaneously from serum and ascites samples ([Box 43.2](#)).¹¹³

Indications and Contraindications

Therapeutic paracentesis is often undertaken in the ED setting to relieve the cardiorespiratory and gastrointestinal manifestations of tense ascites.¹¹⁴⁻¹¹⁶ LVP, or removal of more than 5 L, ameliorates the shortness of breath and early satiety that these patients experience. It may also be associated with collateral advantages, such as a reduction in hepatic venous pressure gradients, intravariceal pressure, and variceal wall tension. These parameters are considered important predictors of variceal bleeding, and the improvement after LVP may decrease

Abdominal Paracentesis

Indications

New onset ascites
 Suspected spontaneous bacterial peritonitis
 To relieve the cardiorespiratory and gastrointestinal manifestations of tense ascites

Contraindications

Uncorrected coagulopathy AND clinically evident fibrinolysis or disseminated intravascular coagulation
 Bowel dilation or obstruction
 Pregnancy (technique should be altered as noted below)
 Abdominal hematoma, engorged veins, or superficial infection at puncture site

Complications

Systemic

Hyponatremia
 Renal dysfunction
 Hepatic encephalopathy
 Hemodynamic compromise
 Significant bleeding
 Death

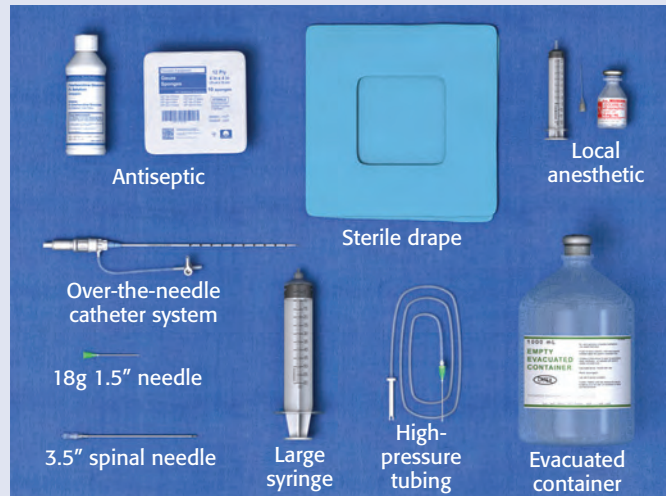

Local

Persistent ascitic fluid leak at the wound site
 Abdominal wall hematoma
 Localized infection

Intraperitoneal

Perforation of vessels and viscera
 Generalized peritonitis
 Abdominal wall abscess

Equipment

the risk for bleeding. Diagnostic paracentesis, often relegated to inpatient services, is indicated in any patient whose ascites is of new onset or to disclose the presence of infection in patients with known or suspected ascites, particularly in the context of alcohol-related cirrhotic liver disease.^{117,118} Diagnostic paracentesis is also useful in the management of patients with acquired immunodeficiency syndrome (AIDS), in whom the etiology of ascites will be non-AIDS related in three-quarters of cases.¹¹⁹ There are few relative contraindications to abdominal paracentesis. Certain systemic and anatomic risks should be considered, however.

Systemic

Given the predominance of alcohol-related cirrhotic liver disease as the cause of ascites, as many as two thirds to three quarters of patients who undergo paracentesis will have a coagulopathy. However, the only prospective study that evaluated the complications of paracentesis determined that transfusion-requiring abdominal hematomas occurred in less than 1% of cases despite the fact that 71% of the patients had an abnormal prothrombin time (PT).¹²⁰ Because transfusion-requiring hematoma is so unlikely, even in this population, prophylactic administration of fresh frozen plasma or platelets is not standard, nor mandated, and imposes considerable cost, in addition to the risk for posttransfusion hepatitis, with little net gain.¹²¹ Therefore, for patients undergoing repeated therapeutic paracentesis, in the absence of previous problems or obvious clotting issues, obtaining a platelet count and international normalized ratio (INR) before the procedure is not routine. In an investigation of 628 patients undergoing outpatient LVP, the procedure was safely performed when the INR was as high as 8.7 (mean value, 1.7) and the platelet count as low as 19,000/mm³ (mean value,

50,000/mm³).¹²² These data countermand older and more conservative recommendations to administer platelets to patients with levels of less than 50,000/mm³ or to give fresh frozen plasma to those with a PT exceeding 20 seconds (1.5 times the therapeutic level).¹²³ These blood products should be reserved for clinically evident fibrinolysis and disseminated intravascular coagulation.

Anatomic

Structural impediments to the safe introduction of a paracentesis needle can include the bladder, bowel, and pregnant uterus. The bladder is normally tucked into the recess of the pelvis. However, bladders that are neuropathologically distended as a result of pharmacologic agents or medical conditions should preferably be emptied by voiding or by catheterization to avoid puncture. The intestines typically float in ascitic fluid and will move safely away from a slowly advancing paracentesis needle.¹²³ Therefore, US guidance may be indicated in cases of suspected adhesions or bowel obstruction. Even if penetrated by an 18- to 22-gauge needle, leakage of intestinal contents will not occur unless intraluminal pressure is five- to tenfold greater than normal conditions.¹²⁴ In second- and third-term pregnancy, an open supraumbilical or US-assisted approach is preferred. The abdomen should be inspected carefully for evidence of abdominal hematoma, engorged veins, or superficial infection, and these sites should be strictly avoided.

Technique

Preliminary Actions

Paracentesis should be performed after the patient has voided. It is not standard to decompress the stomach with a nasogastric tube or the bladder with a catheter before paracentesis. Place the patient in the supine position. Some clinicians prefer the supine lateral decubitus position. Perform paracentesis according to compliance with standards for body fluid precautions. Observe sterile technique throughout the procedure to prevent the iatrogenic introduction of bacteria into the abdominal wall tract or peritoneal cavity. Before making the skin incisions described later, prepare the site with standard skin antiseptics and drape appropriately.

Site of Entry

The best site of entrance for repeated paracentesis is determined by the patient's previous experience, so this question should be asked of the patient. Theoretically, most sites on the abdominal wall can be used, but in absence of previous experience with the individual patient, two sites are preferred. One site is approximately 2 cm below the umbilicus in the midline (Fig. 43.7), where the fasciae of the rectus abdominis muscle join to form the fibrous, thin, avascular linea alba. Large collateral veins may occasionally be present and should be avoided (Fig. 43.8), as should suspected areas of skin infection. If the patient has midline scarring or if previous experience has been positive, the preferred alternative site is in either the right or left lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine (see Fig. 43.7). The importance of remaining lateral to the rectus sheath is to avoid the inferior epigastric artery. Patients with a large quantity of ascites can readily undergo the procedure in the supine position with the head of the bed slightly elevated. Those with lesser amounts of fluid may benefit from a lateral decubitus position with introduction of the needle into the

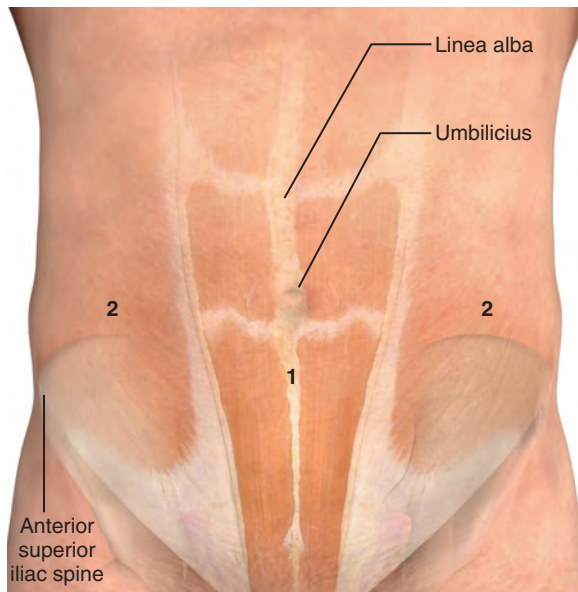

Figure 43.7 The best site for drainage of recurrent ascites is based on success in previous similar procedures on the patient or ultrasound evaluation. The following are the preferred sites for paracentesis. 1, The primary site is infraumbilical in the midline through the linea alba. 2, The preferred alternative (lateral rectus) site is in either lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine.

Figure 43.8 Avoid sites on the abdominal wall with engorged veins.

midline or dependent lower quadrant (Fig. 43.9). Some clinicians prefer to use the lateral decubitus position routinely because the bowel tends to float upward and away from the path of the needle. Hence, the site of needle entrance is in the midline or on the side closest to the bed. Rarely, patients may need to be placed in a facedown, hands-on-knees position.¹²⁰ In patients with multiple abdominal scars or suspicion of compartmentalized abdominal fluid for any reason, US guidance is prudent.¹²⁵

Procedure

A prepackaged kit, such as the Safe-T-Centesis system (CareFusion, Vernon Hills, IL), is a convenient way to perform the

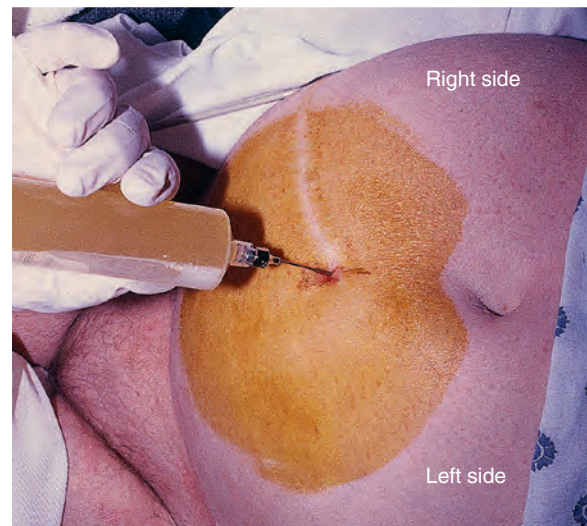

Figure 43.9 An alternative to the sitting or supine position for diagnostic or therapeutic needle paracentesis is to place the patient in the lateral decubitus position. In this example the midline is aspirated, although lateral rectus sites may also be used. Some prefer the lateral decubitus position routinely because the bowel tends to float upward and out of the path of the needle. Note the cloudy fluid seen with spontaneous bacterial peritonitis. The patient had vague abdominal pain only, a subtle manifestation of a serious problem.

Figure 43.10 Paracentesis can be performed with a prepackaged kit. The Safe-T-Centesis (CareFusion, Vernon Hills, IL) system depicted here includes safety features such as a blunt-tipped obturator needle, a color-changing indicator, and a pigtail catheter. The blunt-tipped obturator retracts with pressure to expose the sharp needle tip. This causes the color in the device to change from white to red. Once the abdominal cavity is entered and there is no longer pressure on the tip, the spring-loaded obturator covers the sharp tip of the needle to prevent damage to the underlying organs. This will cause the color to revert to white.

procedure (Fig. 43.10). Following sterile preparation of the skin, inject local anesthetic at the paracentesis site (Fig. 43.11, step 4). Use a standard 3.8-cm (1.5-inch) metal needle in most cases. If necessary, use a longer 8.9-cm (3.5-inch) spinal needle in obese patients. Plastic sheath cannulas tend to kink and run the risk of being sheared off into the peritoneal cavity, but a

Abdominal Paracentesis

1 Localize the fluid collection by percussion or by ultrasound. Mark the entry site.

2 With ultrasound, identify free pockets of ascitic fluid, as well as organs such as the liver, spleen, kidney, or bowel.

See details of ultrasound techniques at the end of this chapter.

3 Cleanse the overlying skin with antiseptic and apply a sterile drape.

4 Anesthetize the skin and the proposed tract of the paracentesis needle with local anesthetic.

5 Insert the needle perpendicular to the skin and slowly advance.

See text and Fig. 43.12 for details on the Z-tract method of paracentesis.

6 Advance the needle in 5-mm increments until fluid is returned in the syringe.

Advance the catheter over the needle and into the peritoneal cavity (if a catheter-over-the-needle system is being used).

7 Aspirate peritoneal fluid into a 20- to 60-mL syringe for a diagnostic sample.

8 If large-volume (therapeutic) paracentesis is desired, attach the high-pressure tubing to the catheter hub.

9 Insert the high-pressure tubing needle into the evacuated container to withdraw the fluid.

10 After fluid collection is completed, remove the catheter and apply an adhesive bandage (or a pressure dressing if there is persistent fluid leakage).

Figure 43.11 Abdominal paracentesis.

steel needle can be left in the abdomen during a therapeutic tap for intervals of an hour or longer without injury. The 15-gauge, 3.25-inch Caldwell needle/cannula is an alternative for LVP that has been shown to perform similar to a steel needle in terms of procedural complications and the volume of fluid removed.¹²⁶ Use a smaller-gauge (20- to 22-gauge) needle for diagnostic taps because such needles lessen the likelihood of leakage of ascitic fluid through the wound site after the procedure. However, for therapeutic LVP, use an 18-gauge needle because it permits expeditious outflow.^{104,127}

Insert the needle directly perpendicular to the skin at the preferred site (see Fig. 43.11, step 5). Alternatively, use the “Z-track” method. For this method, pull the skin approximately 2 cm caudad to the deep abdominal wall with the non-needle-bearing hand while slowly inserting the paracentesis needle (Fig. 43.12). Release the skin when the needle has penetrated the peritoneum and fluid flows. This technique also holds the draining needle in place without suture or tape. Remove the needle after the procedure, and the skin will slide to its original position, helping seal the tract. In any case, insert the needle slowly in 5-mm increments to detect undesired entry of a vessel and to help prevent unnecessary puncture of the small bowel. Avoid continuous suction because it may attract bowel or omentum to the end of the paracentesis needle with resultant occlusion. Once fluid is flowing, stabilize the needle to ensure

a steady flow. If flow ceases, gently rotate the needle and advance it inward in 1- to 2-mm increments. When fluid removal is complete, remove the needle and place an adhesive bandage over the puncture site. If there is persistent leakage of fluid, a pressure bandage may be required. Cyanoacrylate adhesive can also be utilized for persistent leakage. First place the patient so the site is in a non-dependent position and apply pressure to the site with gauze for ten minutes. Then withdraw the gauze and apply the adhesive over the puncture site. Dry air applied to the adhesive using nasal cannula can improve drying of the adhesive.

Ultrasound Guidance

US-guided paracentesis may be performed by a radiologist or an experienced emergency clinician ultrasonographer (see [Ultrasound Box 43.1](#)). This technique clearly delineates the pocket of ascitic fluid and allows visualization of loculated collections and avoidance of bowel adherent to the anterior abdominal peritoneum. The ultrasonographer scans the abdomen and marks the skin at the point overlying the optimal puncture site (see Fig. 43.11, step 2). Once the entry site is marked, keep the patient immobile and perform the procedure (as detailed previously) as soon as practical to avoid shifting of the fluid, which may decrease the utility of US guidance.

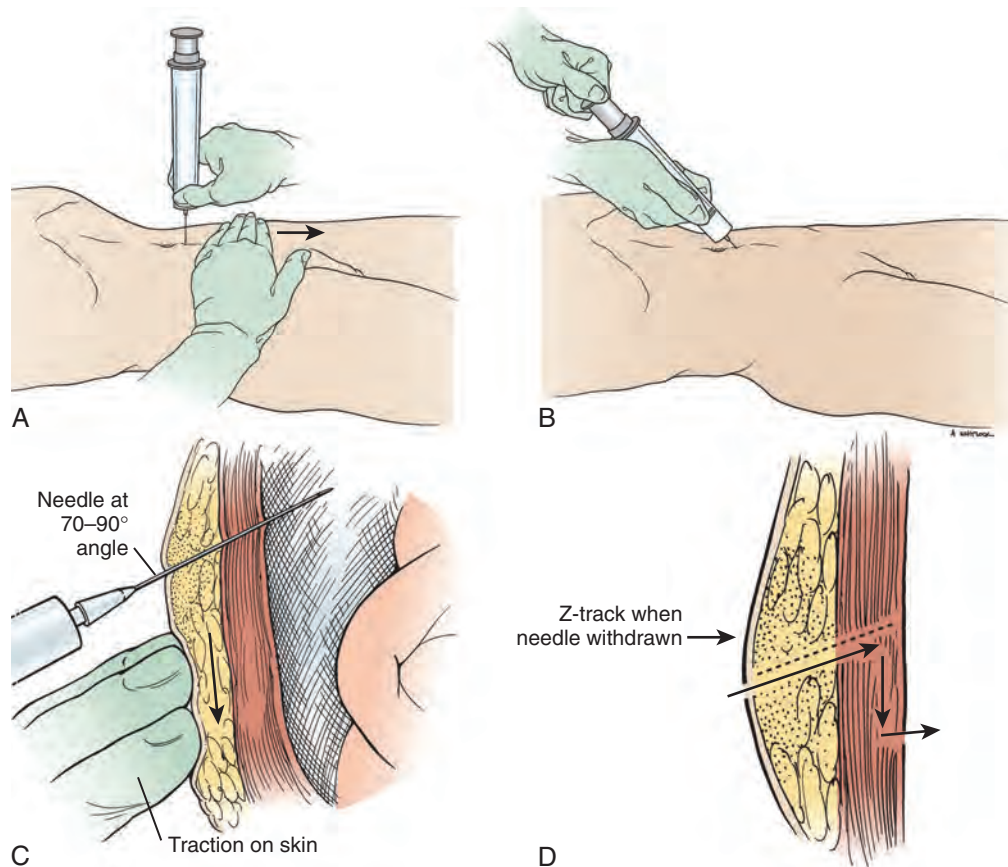

Figure 43.12 A, Z-track method of needle paracentesis. Pull the skin approximately 2 cm caudad in relation to the deep abdominal wall with the non-needle-bearing hand while slowly inserting the paracentesis needle perpendicular to the skin. B, After penetrating the peritoneum and obtaining return of fluid, release the skin. Note that the needle is now angled caudally. C and D, Use of the Z-track method helps seal the tract and prevent persistent fluid leaks.

Volume of Fluid Removed

Many patients with chronic ascites are well versed on the procedure and have experienced it many times. Some undergo paracentesis on a regular basis in the outpatient setting. Therefore, the best guide to the volume of fluid to be removed for recurrent ascites is based on the patient's previous experience, and this question should be asked. Removal of 5 or 6 L is routine and well tolerated, and for therapeutic purposes, at least this volume should be removed. Patients seen in the ED are probably less compliant with outpatient regimens and seek care only when in extremis. Hence, their ascites is likely to be much more voluminous than in those treated regularly. In general, the paracentesis volume consists of as much fluid as can be removed without excessive manipulation of the patient. Volumes greater than 5 L are termed LVP. Up to 10 to 12 L may be removed safely in most patients with chronic ascites (Fig. 43.13). For first-time paracentesis and for diagnostic purposes (ruling out bacterial peritonitis, screening for cancer), 200 to 500 mL is usually sufficient, but more can be drained if it flows easily.

Removal of large amounts of ascitic fluid during paracentesis can be accomplished with the assistance of continuous wall

suction. This technique should be used for patients with large amount of ascites (chronic liver failure patients) and who regularly have large volumes removed during paracentesis. Materials required include continuous wall suction, three-way stopcock, tubing elbow, syringes (3 mL, 5 mL, and 10 mL), suction tubing, three or more suction canisters, and usual paracentesis supplies (Fig. 43.14A). The patient is prepped for paracentesis. Standard tubing is attached to the wall suction, with the other end connected to the first suction canister. Tubing is then utilized to attach the first and second canister. Each canister must have one port with self-sealing filter, which is needed to close the system (see Fig. 43.14B). Seal and cap all ports. This process can be repeated creating a suction train (see Fig. 43.14C). Once the suction canisters are connected, take the final suction tubing end and place into a syringe, with plunger removed. After the paracentesis catheter has been placed and flow obtained, attach the suction syringe to the catheter or first to a 3-way stopcock (see Fig. 43.14D). Turn the paracentesis catheter to the open position and turn on wall suction. Fluid should begin to drain into the first canister, and once full, fluid will continue into the other canisters in order. If flow stops, a stopcock can be helpful to flush the catheter with sterile saline or the patient's ascitic fluid. The final setup is shown in Fig. 43.14E.¹²⁸

Figure 43.13 Large-volume paracentesis in a patient with a history of recurrent ascites. See text for guidelines on the volume to remove and potential complications of removing large volumes. Note the use of blood pressure monitoring.

ULTRASOUND BOX 43.1: Abdominal Paracentesis

by Christine Butts, MD

Although paracentesis has traditionally been performed “blindly,” use of ultrasound allows the physician to confirm the presence of ascites. In addition, it allows the clinician to evaluate the most optimal location to attempt the procedure, which can be less straightforward in patients with smaller fluid collections or in whom physical examination alone is insufficient to make the diagnosis.

Equipment

Use a low-frequency transducer (2 to 5 MHz) to obtain a sufficient depth of penetration to visualize the area of interest. It is frequently

helpful to set the initial depth to 20 to 25 cm to ensure that the entire abdomen is visualized.

Image Interpretation

The location of ascites is variable and depends on the amount of fluid present, as well as the position of the patient. The dependent areas of the abdomen, those evaluated with the focused abdominal sonography for trauma (FAST) examination, are ideal initial areas of evaluation. Evaluate the right upper quadrant by placing the transducer in either the transverse or the longitudinal orientation in the 8th to

Continued

ULTRASOUND BOX 43.1: Abdominal Paracentesis—cont'd

11th intercostal space at the anterior axillary line (Fig. 43.US1). The transducer will probably need to be adjusted slightly to allow an optimal view of this area, either by moving up or down a rib space or by adjusting the angle of the transducer. Ascitic fluid will appear anechoic (black) and may be seen in Morison's pouch (in the hepatorenal space), near the inferior aspect of the liver, or at the superior aspect of the liver (Fig. 43.US2). Once this area has been evaluated in detail, evaluate the left upper quadrant in much the same fashion. Because the spleen is typically slightly more superior and posterior than the liver, place the transducer in the 8th to 11th intercostal space in the posterior axillary line (Fig. 43.US3). Again, make slight adjustments as needed to fully evaluate the area in

question. Ascitic fluid will appear as anechoic (black) areas in the splenorenal space, as well as the potential space between the diaphragm and the spleen (Fig. 43.US4). Once these areas have been evaluated, look at the pelvis and lower part of the abdomen by placing the transducer just superior to the pubic symphysis (Fig. 43.US5). First identify the bladder to avoid any confusion. The bladder is typically seen as a well-demarcated area that is rectangular in shape in the transverse orientation and slightly triangular in shape in the longitudinal orientation (Fig. 43.US6). In contrast, free fluid will appear to have irregular borders and may seem to "seep" into the crevices of the lower part of the abdomen and pelvis. Additionally, bowel may be seen to float freely within free fluid (Fig. 43.US7). If

Figure 43.US1 Placement of the ultrasound transducer in the right upper quadrant to evaluate for the presence of free fluid.

Figure 43.US2 Free fluid in the right upper quadrant. The liver can be seen as the hypoechoic (*dark gray*) object *on the left* of the image, with anechoic (*black*) fluid seen between the liver and kidney (*on the right* of the image).

Figure 43.US4 Free fluid in the left upper quadrant. Anechoic (*black*) free fluid can be seen surrounding the spleen at the right of the image. The diaphragm is seen as the bright white arcing structure on the far right of the image.

ULTRASOUND BOX 43.1: Abdominal Paracentesis—cont'd

Figure 43.US5 Placement of the ultrasound transducer to evaluate the pelvis for free fluid.

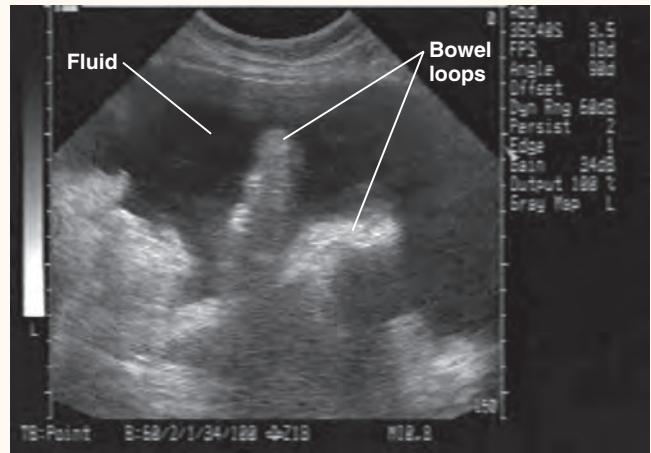

Figure 43.US7 Large area of free fluid seen with ultrasound. Bowel loops are seen to “float” within the fluid.

Figure 43.US6 In this ultrasound image of the pelvis, the bladder can be seen as the rectangular object filled with anechoic (*black*) urine. An area of free fluid can be seen posterior to the bladder.

free fluid is not appreciated in this area, evaluate the right and left aspects of the lower part of the abdomen as well. To do this, place the transducer in either the transverse or longitudinal orientation over the right and left lower quadrants, or near the areas where the traditional “blind” approach to paracentesis would be performed.

Figure 43.US8 Place the paracentesis needle at the site that ultrasound had previously identified as being free of bowel loops and containing a large amount of fluid.

Procedure and Technique

Once free fluid has been seen, identify the area with the largest collection of fluid. Use ultrasound to identify the areas that contain the least number of loops of bowel. If the fluid collection appears to be large, use ultrasound to “mark the spot” and then put it aside. Proceed with the procedure in the typical sterile fashion in the area that has been identified and marked (Fig. 43.US8).

In cases in which the fluid collection is smaller, cover the transducer with a sterile cover to guide direct placement of the catheter.

Complications

Complications of paracentesis can be divided into systemic, local, and intraperitoneal categories.

Systemic

Retrospective studies have suggested a risk for deterioration in hospitalized patients following LVP. However, the risk

attributable to paracentesis is unclear given the difficulty in adjusting for the underlying severity of illness and comorbid conditions in these patients. The risk in ambulatory ED patients has not been investigated but is clearly less because paracentesis is often an outpatient procedure. Most systemic complications of paracentesis are merely temporally related or seen in seriously ill patients with end-stage liver failure who have a plethora of comorbidities.

Oft-cited but poorly documented concerns include hemodynamic compromise and other physiologic conditions caused by the overzealous removal of large volumes of ascitic fluid (greater than 5 L). This has been termed postparacentesis circulatory dysfunction (PCD), which may occur in 15% to 20% of patients undergoing LVP. It may not occur for several hours or days after paracentesis and is characterized primarily by hypovolemia (often asymptomatic), hyponatremia, and impaired renal function. The actual clinical significance of the associated disorders is unclear. Hypotension, for example, is common after paracentesis and is often asymptomatic.

Because upward of 6 L has been reportedly removed in less than 15 minutes without complication, certain authorities decry this issue as folklore.¹²⁹ Others believe that rapid total paracentesis is accompanied by marked cardiovascular and humoral changes, some of which are explained by mechanical factors directly or indirectly related to relief of abdominal pressure.^{130,131} Other changes, including systemic vasodilation and humoral deactivation, are of a nonmechanical nature. Hepatic encephalopathy, hyponatremia, hepatorenal syndrome, and rapid reaccumulation of ascitic fluid have also been ascribed to LVP. In the editor's clinical experience, PCD of varying degrees is a real syndrome, and it may occur more often than suspected because many patients are discharged after the procedure. The consequences of LVP in ED patients have not been well studied, and the implications are somewhat obscure in this subset of patients. Because many patients require therapeutic paracentesis on a regular basis, ask the patient about previous experience and the usual volume of fluid removed to help guide treatment.

Because fluid and electrolyte shifts tend to be minimal after the removal of large amounts of fluid,¹³² colloid infusion is considered strictly optional by some for patients with paracentesis of more than 5 L and is universally *not recommended* for paracentesis of lesser volume.^{106,133,134} Others support the routine administration of albumin if more than 5 L is removed. When colloid is indicated, albumin has been the de facto choice. Being a blood product, albumin has been associated with rare complications, including anaphylaxis. The recommended infusion is 6 to 8 g of IV albumin per liter of ascitic fluid removed, or 50 g.^{133,135} However, colloid dextran 70 is favored by some authorities because of cost and concern for infection.¹³⁶⁻¹³⁸

The necessity of routine plasma expansion after LVP remains controversial. No study has shown a direct survival advantage of one expander over another or in comparison to no expander. Postparacentesis plasma volume expansion does not prevent asymptomatic laboratory abnormalities. The mere fact that controversy still exists suggests that no clear indications can be promulgated to the emergency physician. The authors suggest *not* using IV albumin after taps of less than 5 L. We suggest that it may be used (6 to 8 g of albumin per liter of fluid removed, or 50 g) when more than 6 to 8 L is removed. Twenty-five percent albumin can be given if the patient is hypervolemic, whereas 5% albumin can be given if dehydration is suspected. If used, albumin is generally given immediately after the procedure, although administering it immediately before the procedure also seems reasonable.

Local

Local complications include persistent leakage of ascitic fluid at the wound site, abdominal wall hematoma, and localized infection. Persistent fluid leaks can be corrected with a single

suture at the site of puncture.¹²⁷ Just as in DPL site persistent leakage, cyanoacrylate glue can be utilized to stop leakage. The patient is positioned so the site is non-dependent and then pressure applied to the site with gauze for ten minutes. The gauze is then withdrawn and adhesive applied over the puncture site. To assist with drying, supplemental air can be applied to the site using nasal cannula or tubing connected to wall air or oxygen supply. An abdominal wall hematoma requiring transfusion is very uncommon, but careful observation in such cases is necessary.

Intraperitoneal

Intraperitoneal complications include perforation of vessels and viscera.¹³⁹ In experienced hands these complications are uncommon, and in most circumstances, they are self-sealing and clinically inconsequential. However, generalized peritonitis and abdominal wall abscess have been reported after paracentesis in rare cases. The most common cause of postparacentesis IPH is bleeding as a result of a coagulopathy rather than large-vessel injury per se.¹⁴⁰

Interpretation

Ascitic fluid should undergo gross inspection. Routine laboratory testing includes a differential cell count, albumin assay, and cultures (Box 43.3). The prevalence of occult infection of ascitic fluid in asymptomatic outpatients undergoing therapeutic LVP for resistant ascites is low. As a result, in the absence of concerning symptoms or cloudy fluid, routine laboratory tests and culture of fluid during outpatient or ED paracentesis are not warranted.

Inspection

Ascitic fluid is typically translucent and yellow. A dark greenish brown hue may reflect biliary perforation. Cloudy fluid generally indicates particulate matter, including neutrophils; fluid with WBC counts greater than 5000/ μL (i.e., $> 5000/\text{mm}^3$) are cloudy, and those greater than 50,000/ μL are purulent. An opaque, milky appearance may indicate elevated triglyceride levels.¹⁴¹ A blood-tinged appearance requires at least 10,000 RBCs/ μL . This may reflect an iatrogenic complication,

malignancy, hemorrhagic pancreatitis, or tuberculous peritonitis, although the last diagnosis creates hemorrhagic-appearing fluid in less than 5% of cases.¹²⁰

Cell Count

Several milliliters of ascitic fluid are sufficient to obtain a differential cell count. Cirrhotic ascites should generally contain less than 250 WBCs/ μ L (Table 43.7). However, because cells may exit through the peritoneal cavity more slowly than fluid does, the WBC count can rise in the ascitic fluid during the procedure.¹⁴² Thus, an upper limit for uncomplicated cirrhotic ascites is reported as 500 cells/ μ L.^{143–145} Lymphocytes should predominate, and clinical signs or symptoms of peritoneal infection should be absent.¹⁴⁶ In cases in which spontaneous bacterial peritonitis (SBP) is a clinical consideration, the WBC criterion is 250/ μ L with greater than 50% polymorphonuclear leukocytes.^{115,117,146,147}

Albumin

A serum-ascites albumin gradient can be obtained by simultaneously measuring albumin in ascites and serum and calculating the gradient. A serum-ascites albumin gradient greater than 1.1 g/dL indicates portal hypertension with greater than 95% accuracy (see Box 43.2).^{148–150}

Culture and Gram Stain

The most valuable method for determining the presence of infection is culture. The sensitivity of this test is markedly increased by direct inoculation of blood culture bottles at the bedside as opposed to simply delivering the ascitic fluid to the laboratory.^{151,152} Gram staining of peritoneal fluid is rarely helpful in the evaluation of ascites.¹¹⁸ Approximately 10 bacteria/ μ L of fluid is required for a positive Gram stain. Thus, the Gram stain is notoriously insensitive in patients with SBP, in whom the medium concentration of bacteria is 10^{-3} organisms/ μ L of fluid.¹⁵³ Gram stain can be expected to be helpful only in cases of free gut perforation.

Miscellaneous

Optional tests include measurement of total protein, glucose, lactate dehydrogenase, and amylase. These tests will be beneficial in selected circumstances and need not be obtained on a routine basis. Immunosuppressed patients, including those with HIV/AIDS, should undergo microbiologic testing for opportunistic infections, including tuberculosis.¹¹⁹ Cytologic analysis is recommended in patients with suspicious constitutional symptoms and signs.^{153,154} Triglyceride and bilirubin studies are indicated if the gross appearance of the fluid is suggestive of increased levels.¹⁵⁵

TABLE 43.7 Ascitic Fluid Characteristics in Various Disease States

CONDITION	GROSS APPEARANCE	SPECIFIC GRAVITY	PROTEIN (g/dL)	Cell Count		OTHER TESTS
				RBCs (>10,000/ μ L)	WBCs/ μ L (WBCs/mm ³)	
Cirrhosis	Straw colored or bile stained	<1.016 (95%) ^a	<25 (95%)	1%	< 250 (90%), ^a predominantly mesothelial	
Neoplasm	Straw colored, hemorrhagic, mucinous, or chylous	Variable, >1.016 (45%)	>25 (75%)	20%	> 1000 (50%); variable cell types	Cytology, cell block, peritoneal biopsy
Tuberculous peritonitis	Clear, turbid, hemorrhagic, or chylous	Variable, >1.016 (50%)	>25 (50%)	7%	> 1000 (70%); usually > 70% lymphocytes	Peritoneal biopsy, stain and culture for acid-fast bacilli
Pyogenic peritonitis	Turbid or purulent	If purulent, >1.016	If purulent, >2.5	Unusual	> 250; mainly polymorphonuclear leukocytes	Positive Gram stain, culture
Congestive heart failure	Straw colored	Variable, <1.016 (60%)	Variable, 15–53	10%	< 1000 (90%); usually mesothelial, mononuclear	
Nephrosis	Straw colored or chylous	<1.016	<25 (100%)	Unusual	< 250; mesothelial, mononuclear	If chylous, ether extraction, Sudan staining
Pancreatic ascites (pancreatitis, pseudocyst)	Turbid, hemorrhagic, or chylous	Variable, often >1.016	Variable, often >25	Variable, may be blood stained	Variable	Increased amylase in ascitic fluid and serum

^aBecause the conditions of examining fluid and selecting patients were not identical in each series, the percentages (in parentheses) should be taken as an indication of the order of magnitude rather than as the precise incidence of any abnormal finding.

RBC, Red blood cell; WBC, white blood cell.

Medical Therapy and Disposition

Total paracentesis may be performed safely in the ED, even in cirrhotic patients with large volumes of ascitic fluid (> 5 L). However, the immediate relief provided by the procedure is temporary, and medical therapy is indicated to prevent or slow the reaccumulation of fluid. Measures include reduction of dietary sodium intake (< 2000 mg/day) and the use of diuretics (spironolactone and furosemide) to promote natriuresis. It is prudent to observe patients undergoing LVP in the ED for 2 to 4 hours for hemodynamic compromise. In the absence of other indications for hospital admission, these patients may then be managed in the outpatient setting with close follow-up to ensure adequacy of their medical regimen. Overall, the clinician should base the decision to admit or discharge on the initial scenario, individual patient characteristics, and response to paracentesis.

Spontaneous Bacterial Peritonitis

SBP is an ascitic fluid infection, occurring almost always in patients with cirrhosis and ascites. It is often associated with fever, abdominal pain, altered mental status, abdominal tenderness, diarrhea, paralytic ileus, hypotension, or hypothermia. It may be clinically quite subtle in some patients. Patients suspected of SBP, and after paracentesis, should be treated with empiric antibiotic therapy to improve patient morbidity and mortality. The majority of cases are due to *E. coli* and *Klebsiella*. Unfortunately, studies comparing antibiotics in patients with SBP are limited. Cefotaxime 2 g intravenously every 8 hours provides optimal blood and ascitic fluid levels.¹⁵⁶ Other options include cephalosporins and fluoroquinolones, such as ceftriaxone 2 g intravenous.¹⁵⁷ For patients with secondary bacterial peritonitis or polymicrobial infections, broader coverage is warranted with the addition of metronidazole.¹⁵⁸

Renal failure develops in up to 40% of patients with SBP, which is a significant cause of mortality.¹⁵⁹ This risk of death may be decreased with albumin infused at 1.5 g/kg body

weight within six hours of diagnosis,¹⁶⁰ and albumin should be provided with creatinine greater than 1 mg/dL (88 mmol/L), blood urea nitrogen greater than 30 mg/dL (10.7 mmol/L), or total bilirubin greater than 4 mg/dL.¹⁶¹ Albumin infusion is associated with decrease in incidence of renal impairment and mortality.¹⁶²

Chronic Ambulatory Peritoneal Dialysis

Patients undergoing chronic ambulatory peritoneal dialysis are at an increased risk for peritonitis because of the presence of a chronic indwelling peritoneal catheter. Culture yield is maximized by obtaining a sample of greater than 10 mL of the peritoneal effluent under sterile conditions after a dwell time of at least 2 to 4 hours.^{163,164} Peritonitis is defined by cloudy fluid with more than 100 WBCs/mm³ and greater than 50% polymorphonuclear cells.¹⁶⁴ Although Gram stain is often negative in patients with bacterial peritonitis, it may reveal the presence of yeast and prompt timely initiation of antifungal therapy. Intraperitoneal antibiotics are superior to IV dosing, and removal of the catheter may be required for refractory or recurrent infections. Initial empirical intraperitoneal therapy usually includes a first-generation cephalosporin along with an aminoglycoside, ceftazidime, cefepime, or carbapenem.¹⁶⁴ Vancomycin should be considered in patients with a previous history of methicillin-resistant *Staphylococcus aureus* colonization or infection, in those who are seriously ill, or in areas with an increased local rate of methicillin resistance. The optimal treatment strategy should be discussed with the consulting nephrologist.

Abdominal Hernia Reduction

Michael T. Fitch and David E. Manthey

When a patient is seen in the emergency department (ED) with a suspected abdominal hernia, the emergency clinician should consider three issues: (1) Is a palpable mass truly a hernia? (2) Is the hernia easily reducible or incarcerated? (3) Is the vascular supply to the bowel strangulated? A patient with an easily reducible hernia can be discharged safely for outpatient follow-up and elective repair, whereas an acutely incarcerated and strangulated hernia is a surgical emergency. Some seemingly incarcerated hernias can be reduced by careful manipulation in the ED. A patient seen in the ED with a chronically incarcerated hernia without obstruction or significant changes in symptoms is not necessarily a surgical emergency. Any patient with symptoms of bowel obstruction should also be evaluated for the possible presence of an abdominal hernia (Fig. 44.1).¹

Hernias in the groin area have been the subject of medical diagnosis and treatment as long ago as 1550 BC. Throughout history, treatment of this condition has been the focus of ongoing discussion and debate.²⁻⁷ This chapter addresses abdominal and groin hernias, both of which are amenable to diagnosis and potential manual reduction in the ED.

BACKGROUND

A *hernia* is defined as: a protrusion of any viscus from its normal cavity through an abnormal opening. Abdominal hernias are characterized by protrusion of intraabdominal contents (usually bowel or omentum) through an abnormal defect in the abdominal wall musculature. Hernias can develop along a congenital tract that fails to close (e.g., indirect inguinal or umbilical hernias), or along an area of weakness in the muscular and fascial layers (e.g., direct inguinal, ventral, or incisional hernias). This weakness may be the result of aging and the accompanying loss of tissue elasticity, increased intraabdominal pressure, failure of proper healing, or trauma involving the abdominal wall. It is estimated that hernias develop in 5% of men and 2% of women,^{8,9} and that 75% of them occur in the groin.¹⁰ In children and young adults the majority of hernias are indirect inguinal hernias of congenital origin,¹¹ whereas most direct hernias are acquired and become more common as a patient ages.¹² In patients with abdominal surgery, incisional hernias can occur in up to 20% of cases.

CLASSIFICATION

One of the first priorities for an emergency clinician is to determine whether a suspected hernia is reducible, incarcerated, or strangulated. A *reducible hernia* is one whose contents can

be returned through the fascial defect back into the abdominal cavity without surgical intervention. Patients often have large reducible hernias for years and are able to reduce them easily, but such hernias can also become strangulated or incarcerated. An *incarcerated hernia* is one whose contents are not reducible without surgical intervention. These hernias often have associated swelling of the hernia sac contents. A *strangulated hernia* is an incarcerated hernia whose blood supply to the herniated structures is compromised. Hernias with a small neck are more likely to become incarcerated or strangulated. A strangulated hernia is a surgical emergency because tissue ischemia and necrosis will result if adequate blood flow is not restored.

A primary *ventral hernia* of the abdominal wall may be umbilical, epigastric, or spigelian, depending on its location. An *incisional hernia* is found along or near a previous surgical scar. An *inguinal hernia* is found within the inguinal triangle, which is formed by the inguinal ligament on the inferior side, the inferior epigastric artery on the superior lateral side, and the lateral edge of the rectus abdominis muscle on the medial side. Direct and indirect inguinal hernias occur superior to the inguinal ligament, whereas a femoral hernia is located inferior to the inguinal ligament. A spigelian hernia (lateral ventral hernia) is located in the abdominal wall just lateral to the rectus abdominis muscle.

Indirect Inguinal Hernia

An indirect inguinal hernia passes through the internal (deep) inguinal ring and into the inguinal canal (Fig. 44.2). It is located lateral to the inferior epigastric vessels. During fetal development, the processus vaginalis allows descent of the testes into the scrotum. Failure of this to close before birth can lead to a hernia or hydrocele.

An indirect inguinal hernia is the most common type of hernia. These occur more frequently in males and are commonly diagnosed in children and young adults. Approximately 5% of full-term infants and 30% of preterm infants will have an inguinal hernia.^{13,14} Incarceration occurs more commonly in patients younger than 1 year, and 30% of hernias in children younger than 3 months become incarcerated.^{15,16} When an incarcerated inguinal hernia is successfully reduced in a child, surgical repair within 24 to 48 hours should be considered because of the risk for recurrent incarceration.¹⁷ When an inguinal hernia is diagnosed, even without incarceration or strangulation, it is important to make a referral for elective repair. Asymptomatic and painless inguinal hernias can progress to cause symptoms over time if they are not surgically repaired,⁴ although watchful waiting may also be appropriate in some patients.¹⁸ Clinical studies demonstrate increased morbidity with emergency versus elective repair of inguinal hernias.¹⁹

Direct Inguinal Hernia

A direct inguinal hernia comes directly through the muscular and fascial wall of the abdomen. It is located medial to the inferior epigastric vessels within the inguinal triangle (Fig. 44.3). These can be differentiated from indirect inguinal hernias as direct hernias do not travel along the inguinal canal.

A direct inguinal hernia is the second most common groin hernia. It is an acquired weakening of the myofascial wall caused by aging and the repetitive stress of increased abdominal pressure. This hernia carries a lower risk for incarceration because the hernia orifice is typically wide.

Figure 44.1 **A**, This patient was admitted with the diagnosis of bowel obstruction. **B**, It was not until the physician carefully examined the groin area that an incarcerated inguinal hernia was found. Symptoms of the obstruction, the impressive radiographic findings, and an incomplete physical examination led to initial failure to diagnose the obvious hernia.

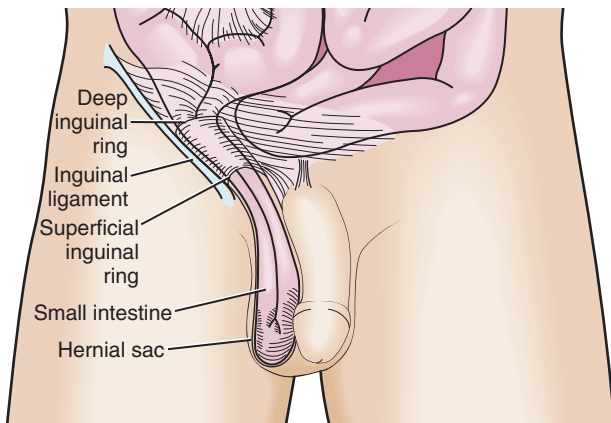

Figure 44.2 Indirect inguinal hernia.

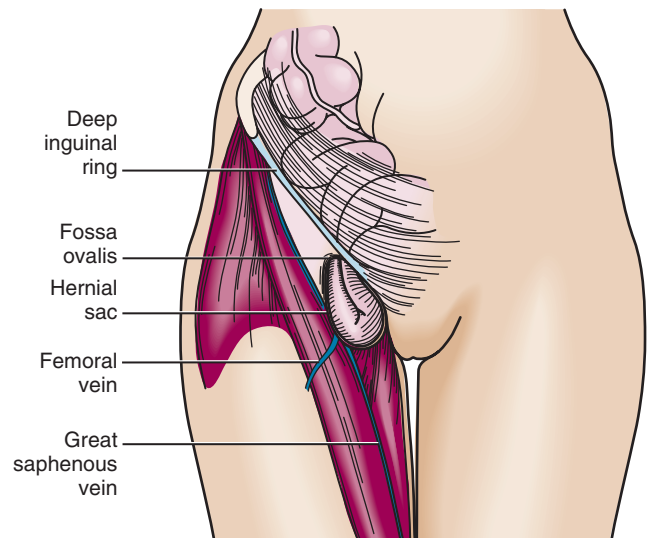

Figure 44.4 Femoral hernia.

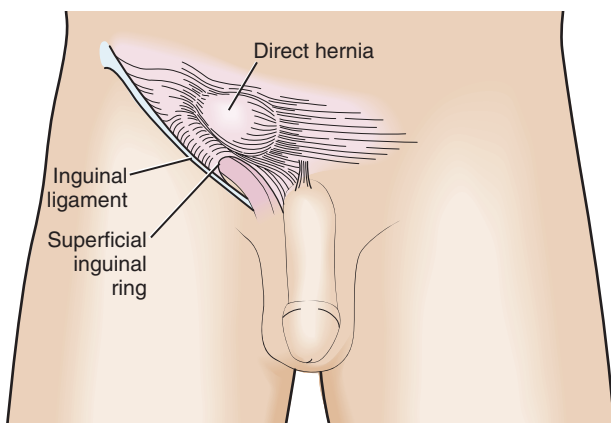

Figure 44.3 Direct inguinal hernia.

Pantaloön Hernia

A pantaloön hernia is a combination of direct and indirect hernias. This variation of an inguinal hernia is difficult to diagnose in the ED, is difficult to achieve sustained reduction using standard manual techniques, and is often discovered during surgical exploration.

Femoral Hernia

A femoral hernia occurs inferior to the inguinal ligament through a defect in the transversalis fascia. Abdominal contents protrude into the potential space medial to the femoral vein and lateral to the lacunar ligament in the femoral canal, and appear as a medial thigh mass below the area where direct and indirect hernias are typically identified (Fig. 44.4). A small fascial defect leading to constriction by the inguinal ligament means that this hernia becomes incarcerated in up to 45% of cases.²⁰ A femoral hernia is relatively uncommon, occurs more frequently in women, and is an uncommon condition in children.²¹

Incisional Hernia

An incisional hernia may occur in as many as one out of every five patients following abdominal surgery (Fig. 44.5A). Poor wound healing (e.g., because of infection) increases the likelihood of developing an incisional hernia.^{22,23} After repair,

Figure 44.5 Ventral hernias. **A**, Incisional hernia. **B**, Umbilical hernia. **C**, Epigastric hernia. **D**, Spigelian hernia.

incisional hernias carry a recurrence rate of 20% to 50%.²⁴ Incarceration risk depends upon the size of the hernia, with larger defects having a lower risk.

Umbilical Hernia

An umbilical hernia traverses the fibromuscular ring of the umbilicus (see Fig. 44.5B). This hernia is most commonly found in infants and children, is congenital in origin, and often resolves without treatment by the age of 5.²⁵ If the hernia persists beyond this age, is larger than 2 cm, or becomes incarcerated or strangulated, it may be repaired surgically.^{19,26} An acquired umbilical hernia may also be seen in an adult, particularly with increased abdominal pressure (such as with obesity, ascites, or pregnancy). An umbilical hernia is more prone to incarceration and strangulation in an adult than in a child.

Epigastric Hernia

This hernia occurs in the midline through the linea alba of the rectus sheath. (see Fig. 44.5C). It is usually located in the epigastric region between the xiphoid and the umbilicus. Though previously considered rare in infants, one study found epigastric hernias in 4% of all pediatric patients evaluated for hernias.²⁷ In adults, these hernias are usually small and contain preperitoneal fat.

Spigelian Hernia

A spigelian hernia is rare and occurs through a defect in the lateral edge of the rectus muscle at the level of the semilunar line and near the arcuate line (see Fig. 44.5D). It is caused by a partial abdominal wall defect in the transverse abdominal

aponeurosis, the spigelian fascia. Patients are typically 40 to 70 years of age, but the hernia has also been reported in younger patients.¹ Incarceration rates (often with omentum) have been reported to be as high as 20% with these uncommon hernias.^{25,28} Some reports suggest that ultrasound may be a valuable adjunct for the diagnosis of these hernias and may be helpful during attempted reduction procedures.^{29,30}

DIAGNOSIS

History and Physical Examination

A patient with a symptomatic hernia may seek treatment in the ED because of swelling or pain in the region of the hernia or abdomen. Ask whether the patient has a history of heavy lifting. Inquire about signs of infection and systemic illness, such as fever, chills, and malaise. Seek symptoms associated with sustained increases in intraabdominal pressure such as chronic cough, chronic constipation, or straining to urinate. Determine whether the patient has signs or symptoms of bowel obstruction, including nausea and vomiting. Document a record of previous surgeries and hernia repairs, including the presence of synthetic mesh.

On physical examination, palpate the inguinal canal in males by inverting the scrotal skin and passing a finger into the external ring. Ask the patient to cough or perform a Valsalva maneuver, which increases intraabdominal pressure and facilitates detection of a hernia. Examining the patient in both standing and supine positions can be helpful. Palpation of the external ring is more difficult in females because it is narrower. An indirect inguinal hernia is manifested as a swelling in the area of the inguinal ligament or as scrotal swelling in male patients. It is often painless and may be noted as an incidental finding. On examination, an indirect hernia can be differentiated from a direct hernia in several distinct ways: (1) an indirect hernia begins lateral to the inferior epigastric arteries; (2) the contents of an indirect hernia will strike the top of the finger instead of the volar pad during examination, as the hernia protrudes down the canal instead of directly across a fascial defect; (3) applying pressure over the internal ring after hernia reduction will block recurrence of the hernia during Valsalva, without impacting the bulge of a direct hernia during straining; and (4) a hernia that fills the scrotum is most likely an indirect hernia.

An asymptomatic hernia may be manifested as a mass that is found incidentally on physical examination of the abdomen or groin. If a hernia is easily reducible, no specific intervention is required in the ED, but instructions should be given for appropriate outpatient surgical follow-up for potential elective repair. This is particularly important for inguinal hernias because elective repair is associated with much less morbidity than emergency repair for strangulation.^{4,19,20}

A child with a groin hernia may have a reducible inguinal or scrotal mass that occurs with straining or crying. Consider the possibility of an incarcerated or strangulated hernia in young children with nonspecific complaints such as vomiting, poor eating, lethargy, or irritability.

Radiologic Imaging

When findings on physical examination are equivocal and the emergency clinician suspects an occult hernia, several options are available for diagnostic imaging.³¹ Computed tomography

Figure 44.6 Incarcerated spigelian hernia identified on abdominal computed tomography (CT). **A**, Dilated loops of small bowel with air-fluid levels (AFL) are noted in the abdomen. Loops of both small bowel (SB) and large bowel (LB) are seen outside the peritoneal cavity in a lateral position, which is diagnostic of a spigelian hernia. **B**, A CT slice lower in the abdomen shows the site of the hernia. The efferent loop of small bowel is of normal caliber; however, the afferent loop is decompressed, thus suggesting a transition point within the hernia. Operative repair was required.

Figure 44.7 Strangulated hernia in a 56-year-old man. An axial, contrast-enhanced, computed tomography image of the abdomen shows a strangulated left inguinal hernia with a C-shaped configuration (arrows). Note the bowel wall thickening, severe fat stranding, mesenteric engorgement, and extraluminal fluid confined to the hernia sac, findings that suggest strangulation. (Reprinted with permission from Aguirre DA, Santosa AC, Casola G, et al: Abdominal wall hernias: imaging features, complications, and diagnostic pitfalls at multidetector row CT, *Radiographics* 25:1501–1520, 2005.)

scanning is the diagnostic modality used to confirm the presence of hernias and associated complications such as bowel obstruction or perforation.³² Magnetic resonance imaging has a high positive predictive value for patients with clinically uncertain herniations,³³ but its utility in the urgent setting is limited. (Figs. 44.6 and 44.7). Ultrasound examination has been shown to have good sensitivity and specificity for the diagnosis of groin hernias,³⁴ and may decrease the rate of emergency surgery by improving the ability to reduce hernias.³⁵ Ultrasound may also have good specificity and a high positive predictive value for diagnosing postoperative incisional hernias.³¹ However, ultrasound results can be operator dependent and a difficult modality to interpret.

Diagnosis of Incarcerated Versus Strangulated Hernias

When the patient or emergency care provider cannot manually reduce the contents of the hernia back into the abdominal cavity, the hernia is described as *incarcerated*. Although hernias are a leading cause of bowel obstruction, patients with incarcerated hernias do not necessarily have associated bowel obstruction. Incarceration is more common with femoral hernias, small indirect inguinal hernias, and ventral or incisional hernias. Incarceration can be caused by the presence of a small fascial defect, by constriction of the defect by surrounding musculature, adhesions, or by swelling of the hernia contents.

A strangulated hernia is one in which the vascular supply to the herniated bowel is compromised, thus leading to ischemia. Strangulated hernias will most commonly also be incarcerated, but this is not a universal finding. Ischemic injury of the bowel is suggested by a red, purple, or bluish discoloration of the skin over the hernia, significant abdominal tenderness with peritoneal signs, and radiographic findings of extraluminal air, or poor perfusion of herniated bowel on a CT scan with IV contrast.²⁵ Patients with strangulated hernias may exhibit bowel obstruction, peritonitis, viscus perforation, intraabdominal abscess, or septic shock. Associated symptoms may include nausea, vomiting, fever, or abdominal distention.

In rare instances a strangulated or incarcerated hernia may inadvertently be reduced en masse to a preperitoneal location (Fig. 44.8), thus making the contents no longer palpable.^{36–38} In this case, the hernia has not been reduced fully into the peritoneal cavity, and the incarceration and ischemia therefore have not been relieved. Because the clinician believes that the hernia has been appropriately reduced, this can result in delay in the diagnosis of ischemic bowel. Fortunately, this occurs in less than 1% of hernias.³⁹ Persistent pain after reduction of a hernia, especially more than at the orifice of the fascial defect, should alert the physician to the possibility of either preperitoneal reduction or reduction of ischemic bowel.

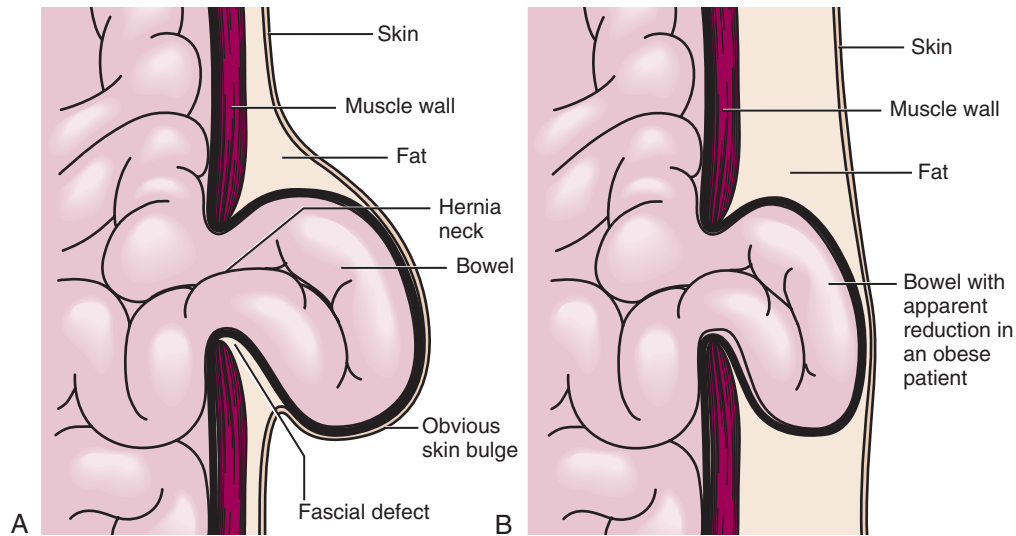

Figure 44.8 En masse reduction. **A**, When a hernia forms, it projects from the fascia into subcutaneous fat. The object of reduction is to replace the hernia into the peritoneal cavity. **B**, If the hernia sac is partially reduced into the subcutaneous fat of an obese patient, it may appear reduced and not be palpable because of the patient's body habitus. However, the hernia is still susceptible to incarceration or ischemia because it has not been returned to the peritoneal cavity.

BOX 44.1 Differential Diagnosis of Groin Masses

Hernia	Epididymitis
Testicular torsion	Hidradenitis suppurativa
Retracted or undescended testicle	Groin abscess
Hydrocele	Hematoma
Spermatocele	Lipoma
Venous varix	Epidermal inclusion cyst
Pseudoaneurysm	Tumor
Lymphadenopathy	Tracking of intraperitoneal blood
Lymphogranuloma venereum	

Differential Diagnosis

The differential diagnosis for a groin mass is large. [Box 44.1](#) lists a number of disease processes that may masquerade as hernias. For example, testicular torsion can be mistaken for a hernia, especially if there is an associated reactive hydrocele. Examine the testicle for tenderness, swelling, lie, and cremasteric reflex. If there is concern for testicular torsion, urology should be notified immediately, while diagnostic studies are undertaken. A hydrocele can also be confused with a hernia because both can occupy the same anatomic space ([Fig. 44.9](#)). A hydrocele may transilluminate, whereas a hernia generally does not. Differentiation can be difficult and may require ultrasound to define the contents of the scrotum.

REDUCTION

Indications and Contraindications

The indications for reducing a hernia are the presence of a hernia and the absence of strangulation. If manual reduction proves to be difficult, limit repetitive attempts as this may

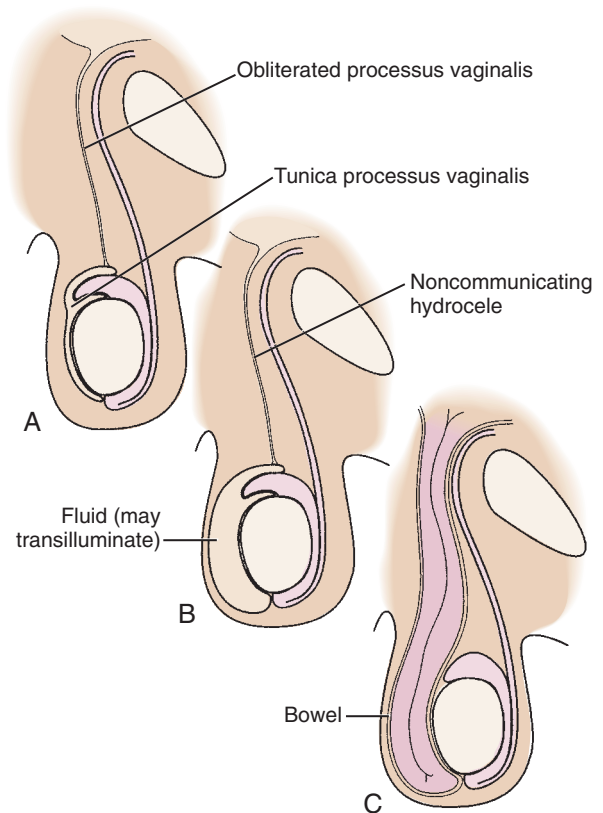

Figure 44.9 Hydrocele versus hernia. **A**, Normal anatomy. **B**, Noncommunicating hydrocele (which may transilluminate) that may be confused with a hernia. **C**, Indirect hernia that can be palpated from the inguinal ring to the testicle.

increase the swelling and limit the chance of nonoperative reduction by a surgical consultant. Some patients may require sedation to facilitate a successful manual reduction, and thus it may be helpful to have a surgeon available while reduction is attempted and the patient is under sedation in the ED.

In addition to persistent incarceration despite attempted reduction, several other clinical situations may benefit from surgical consultation. Reduction of a strangulated hernia in the ED is contraindicated and operative management will be required. Surgical consultation in the ED is indicated for bowel obstruction associated with a hernia, undescended testicles or ovaries within the hernia contents, or traumatic hernias.

Procedure

The first step in successful hernia reduction is to position the patient properly to reduce intraabdominal pressure. Place the patient in a position so that gravity can facilitate hernia sac reduction back into the peritoneal cavity. Ensure patient comfort to decrease voluntary or involuntary muscle contraction and guarding, as this can increase intraabdominal pressure and make reduction more difficult. For ventral abdominal hernias, place the patient in the supine position. The Trendelenburg position (supine with the head 20 degrees downward) may facilitate reduction of inguinal hernias. Many hernias can reduce spontaneously if the patient is left comfortably in this position for 10 to 20 minutes. In children, spontaneous reduction has been reported in up to 80% of inguinal hernias over a 2-hour period using appropriate patient positioning and relaxation without manipulation.

A cool compress or ice pack may help to reduce swelling and facilitate reduction of the hernia. Before attempting reduction, strongly consider sedation and/or analgesia to facilitate patient relaxation and minimize pain associated with the procedure. Options for procedural sedation include etomidate, propofol, midazolam, and fentanyl. If manual reduction is necessary, approach slowly with soft, ongoing dialogue, and warm hands. This method encourages patient relaxation and minimizes muscular contractions resulting from pain, cold, or other physical discomfort.

Before beginning hernia reduction, identify the components of the hernia that will be manipulated during the procedure. A hernia consists of a defect in the existing wall of tissue (muscle and fascia) that makes up the neck of the hernia sac. If the neck is small, the hernia will be more difficult to reduce, and a higher incidence of incarceration and strangulation will result. When attempting to reduce the hernia, take care to not allow the contents of the hernia sac to override the edge of the hernia orifice because this will cause “ballooning” of the contents of the hernia sack around the hernia neck. Attempt to find the edge of the hernia defect and position your hand or fingers along that edge to help reduce ballooning and stabilize the edge of the fascial defect.

When available, bedside ultrasound may facilitate specifically locating the fascial defect and the hernia sac to be reduced. A high frequency linear probe can be used to identify the extent of the fascial defect, thus allowing the clinician to guide the hernia sac back through in the plane of maximal opening in the fascial defect under direct visualization. This real-time imaging allows guidance of the proximal end of the hernia contents through the defect and limiting the “ballooning” that may occur without the benefit of visualization.⁴⁰

Begin the reduction procedure by gently guiding the proximal contents of the hernia sac back through the neck of the hernia first. In other words, reduce the hernia in the opposite order from which the contents protruded. Guiding the distal end of the contents of the hernia through the fascial defect

Figure 44.10 A, This very large hernia is challenging to reduce. B, Merely pushing on the distal end of the mass, as shown here, will not be successful. C, Instead, try to first reduce the contents that are more proximal by stabilizing the neck and first replacing the portion of bowel closest to the fascial defect.

first may cause the proximal contents to be displaced around the opening (ballooning) and prevent reduction. Apply gentle, steady pressure on the tissue at the neck of the hernia to overcome this problem and then gradually reduce the hernia (Figs. 44.10 and 44.11). Failure to perform this important procedure is a common error that precludes reduction.

When attempting to reduce inguinal hernias in children, place the patient supine in an approximate 20-degree Trendelenburg position, which may allow spontaneous reduction. Another option is to place the patient in the “unilateral frog-leg” position⁴¹ (Fig. 44.12). Stabilize the patient by grasping the anterior superior iliac spines to prevent lateral movement of the pelvis. Abduct the ipsilateral leg, externally rotate and flex the hip, and flex the knee to obtain the classic frog-leg position. The purpose of this position is to allow the greatest reapproximation of both the internal and external rings. After achieving this position, use the fingers of one hand to prevent the hernia contents from overriding the external ring, while using the other hand to provide steady but gentle pressure on the contents of the hernia sac. Repeated forceful attempts are not recommended.

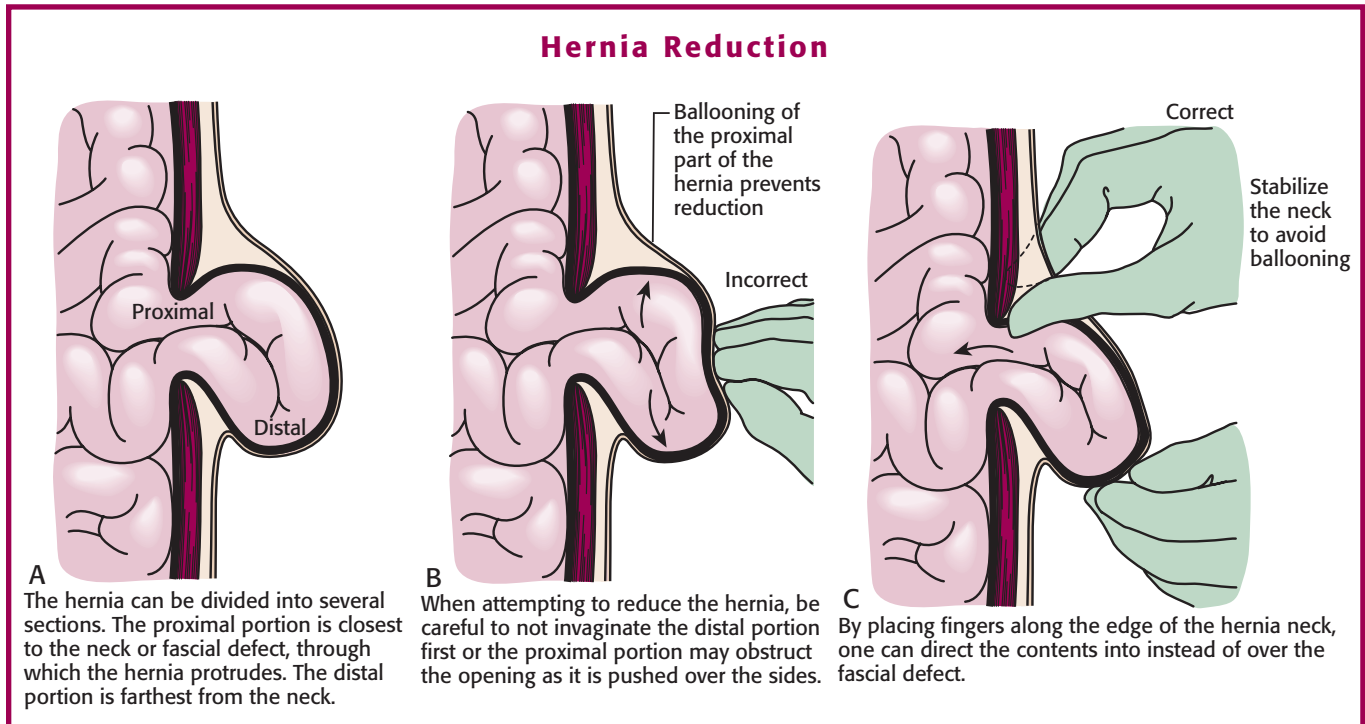

Figure 44.11 Hernia reduction (see Fig. 44.10).

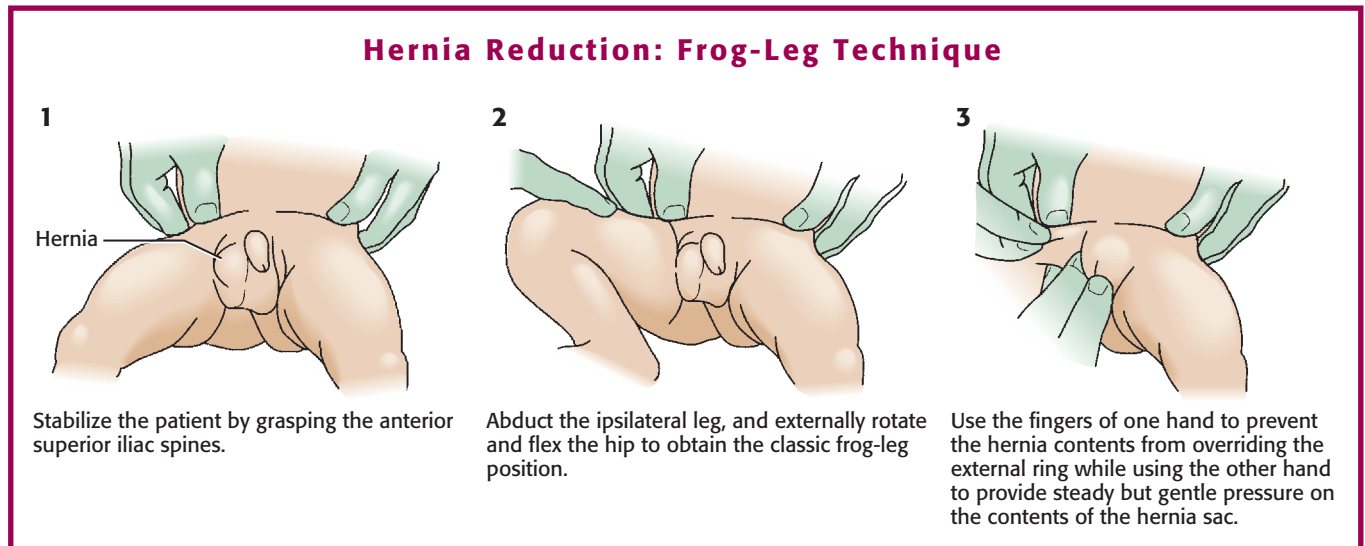

Figure 44.12 Frog-leg technique of hernia reduction.

POTENTIAL COMPLICATIONS

Major complications may occur during the reduction of hernias. Underlying bowel may be injured from overzealous attempts at reduction. Repetitive and overaggressive attempts may aggravate the swelling and make the hernia irreducible. This complication can be avoided with appropriate patient preparation, positioning, sedation, and reduction techniques. Reduction of ischemic bowel in the setting of an undiagnosed strangulated hernia is a potential complication that may occur when the clinician inadvertently reduces ischemic bowel back into the peritoneal cavity or en masse into the preperitoneal space.

INTERPRETATION

In general, successful reduction can be identified by the absence of a mass, palpation of the hernia ring, and relief of pain. Continued significant pain suggests the possibility that strangulated bowel has been reduced back into the peritoneal cavity. Inability to palpate the hernia ring after reduction suggests that the hernia is in the preperitoneal position, is not completely reduced, or is not palpable because of body habitus.

Anorectal Procedures

Wendy C. Coates

Patients with anorectal disorders frequently seek care in the emergency department (ED). The condition may be isolated or the anorectal complaint may be an outward manifestation of a serious underlying illness. A thorough history and physical examination must precede any procedure. Because of the nature of these conditions, extreme sensitivity and professionalism must be applied.

Patients may be anxious about anorectal examination or associated procedures, including the simple digital rectal examination (DRE). The results of DRE may lead to performing diagnostic or therapeutic procedures such as anoscopy, excision of thrombosed external hemorrhoids, drainage of anorectal abscesses or pilonidal cysts, reduction of rectal prolapse, or removal of rectal foreign bodies (FBs). For these procedures, analgesia, sedation, or both may be useful adjuncts.

ANATOMY

The rectum and anus compose the most distal portion of the gastrointestinal tract. The rectum begins at the level of the third sacral vertebra and extends distally 12 to 15 cm. Blood supply to the anorectum is derived from the superior, middle, and inferior hemorrhoidal arteries. Venous drainage from the rectum and anus returns to both the portal and systemic systems (Fig. 45.1). The dentate (pectinate) line marks the transition from the rectum to the anus and contains submucosal glands in anal crypts. Occlusion with subsequent infection of these glands is the cause of anorectal abscesses. Sensory innervation to the rectum is primarily visceral, whereas the anus is innervated by cutaneous fibers. Therefore patients are often unaware of rectal pathology because the pain associated with it may be vague or absent. By contrast, anal lesions are usually very painful and well localized.¹

DIGITAL RECTAL EXAM (DRE)

Indications and Contraindications

The physical examination should be performed in a private location and the patient should be completely draped and relaxed. Generally, a calm atmosphere and caring examiner preclude the need for analgesic or anxiolytic agents, although they may be needed to facilitate a thorough examination. In some extremely painful conditions, such as thrombosed or gangrenous hemorrhoids, DRE may be postponed until the patient is anesthetized. If a sharp-edged FB (e.g., metal blade or broken glass) is suspected, performing a DRE may cause injury to the clinician, as well as the patient. In these cases,

radiologic evaluation with subsequent operative management may be indicated.

Procedure

Place the patient in the lateral decubitus position and wear protective gloves. Begin the examination with a preliminary visual inspection of the perianal area for important information regarding patient hygiene, trauma, or sexually transmitted diseases. Next, ask the patient to perform a Valsalva maneuver and look for prolapsing rectal mucosa or hemorrhoids. When the patient relaxes, prolapsed structures may retreat or remain external to the anus. By placing a gloved finger firmly against the anal sphincter, it will relax and allow entry of the examiner's gloved, lubricated finger (Fig. 45.2A). Once inserted into the anus, make a 360-degree sweep to identify any irregularities in the anorectum and prostate. After withdrawing the finger, examine stool remaining on the glove for the presence of visible or occult blood (see Fig. 45.2B and C).² Testing for blood in stool is discussed in detail in Chapter 67.

Complications

Although DRE causes some vasovagal depression, it is safe to perform in patients with acute myocardial infarction.³ Although it is not a firm contraindication in patients whose absolute neutrophil count is dangerously low, many would defer routine DRE, especially avoiding vigorous prostate manipulation, to minimize the likelihood of bacteremia.

ANOSCOPY

Indications and Contraindications

When evaluating a patient for anal pathology, some practitioners use anoscopy as an adjunct to DRE. Internal hemorrhoids, tears in the distal rectal mucosa, FBs, and distal anorectal masses may be visualized. An imperforate anus is the only absolute contraindication to anoscopy; however, severe rectal pain, a common complaint in the ED, may preclude awake anoscopic examination in anxious patients or those suffering from thrombosed hemorrhoids or other painful conditions. Internal visual inspection in these patients is better performed with sedation. In many cases a more definitive study such as sigmoidoscopy or colonoscopy is being planned by the treating physician, and thus anoscopy can be deferred in the acute care setting.

Equipment and Setup

The anoscope is a plastic or stainless steel tube with a removable obturator (Fig. 45.3). It may have an integrated light source or require an external light or head lamp. An appropriate examination table, topical anesthetics, lubricant, gauze, and forceps may also be required.

Positioning

Ideally, place the patient in a prone position on a proctoscopic examination table. The lateral decubitus position with the knees and hips flexed may also be adequate and is sometimes tolerated better. In the lateral decubitus position, place the patient on the left side if the examiner is right-handed (Fig. 45.4, step 1).

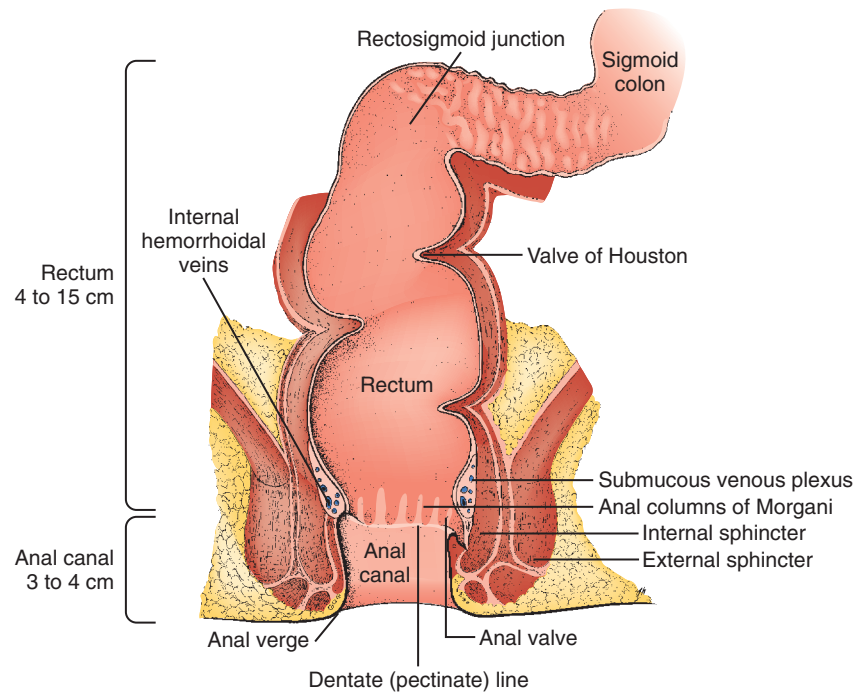

Figure 45.1 Anatomy of the terminal gastrointestinal tract. (Redrawn from Abrahams PH, Webb PJ: *Clinical anatomy of practical procedures*, London, 1975, Pitman.)

Digital Rectal Examination

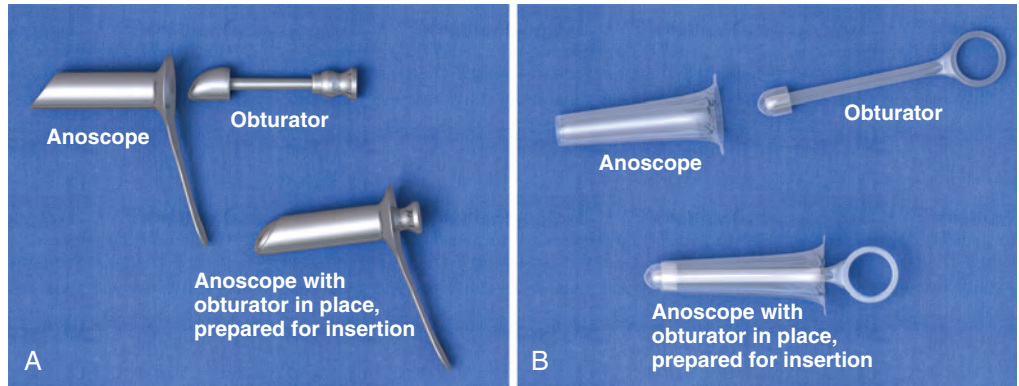

Figure 45.2 Digital rectal examination. **A**, Insert a gloved, lubricated finger into the anus and perform a 360-degree sweep to check for any irregularities in the anorectum and prostate. **B**, Examine the stool for visible and occult blood. This patient had melena, which is dark and tarry in consistency and indicative of upper gastrointestinal hemorrhage. **C**, This sample is positive for blood. The *large arrow* points to the blue coloration on the test area of the card, whereas the *small arrow* points to the control. The control should turn blue. See also a discussion of testing stool for blood in [Chapter 67](#).

Procedure

Although most patients do not require intravenous sedation and analgesia, administer these agents as needed to keep the patient relaxed and comfortable. Before anoscopy, perform a routine DRE to identify sources of bleeding or pain and to locate any palpable masses. Next, lubricate the anoscope. After DRE and with the obturator inserted completely into

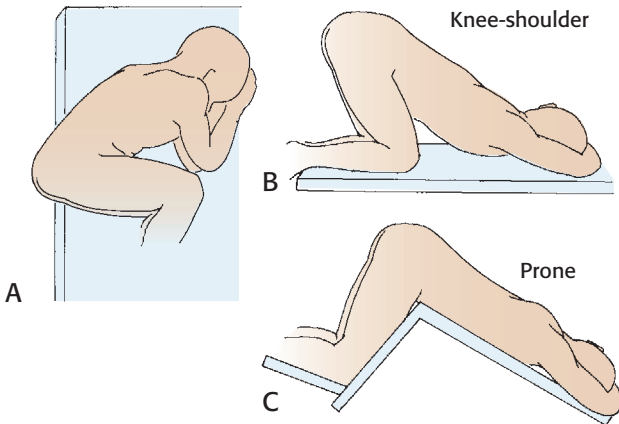

the anoscope, carefully introduce the scope into the anus. Use gentle, constant pressure to overcome resistance from involuntary contraction of the external anal sphincter. Gently advance the anoscope while asking the patient to bear down slightly. Pass the anoscope gently into the anorectum (see [Fig. 45.4, step 2](#)). The examiner should keep a thumb pressing on the obturator to prevent it from being dislodged. If the obturator falls back during insertion, remove the anoscope completely

Figure 45.3 **A**, Reusable stainless steel and **B**, disposable plastic anoscopes are available. Regardless of the type of anoscope used, the obturator must be fully inserted and held in place with the thumb during advancement of the device into the anorectum.

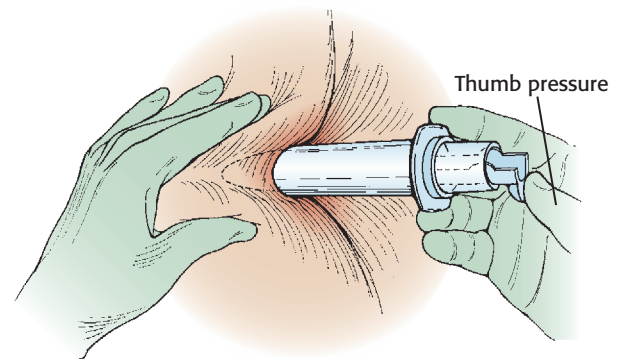

Anoscopy

1 Left lateral or Sims' position

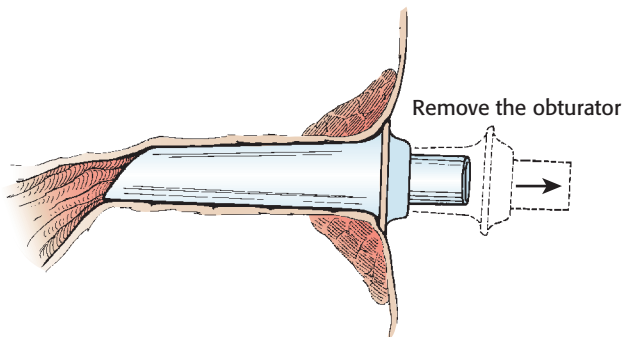

Place the patient in the left lateral position (**A**), prone position (**B**), or ideally prone on a proctoscopic examination table (**C**).

2

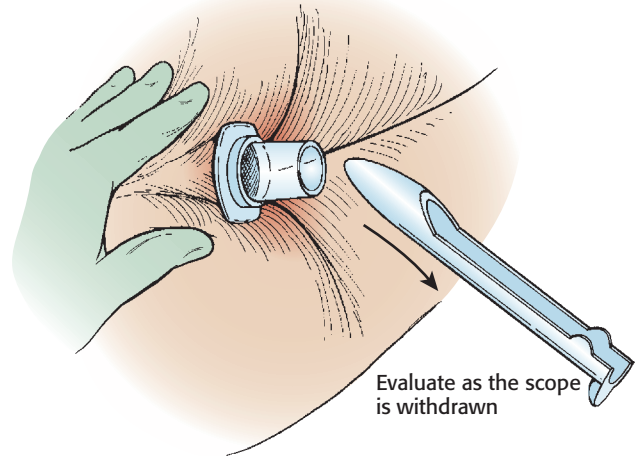

With the obturator fully inserted into the anoscope, carefully introduce the scope into the anus. Hold the obturator in place with your thumb. Use gentle, constant pressure to pass the anoscope into the anorectum. Advance until the outer flange impinges on the anal verge.

3

Remove the obturator when the anoscope is fully inserted.

4

Gradually withdraw the anoscope and visualize the anal canal. Swab away blood or debris to aid in visualization, culture any discharge, and inspect for hemorrhoids, anal fissures, ulcerations, abscesses, or tears.

Figure 45.4 Anoscopy. Remember to keep your thumb on the obturator during passage of the instrument until it is fully inserted (Fig. 45.2). (Step 1, From Hill GJ II: *Outpatient surgery*, ed 3, Philadelphia, 1988, Saunders.)

and replace the obturator to avoid pinching the anal mucosa. Advance the anoscope until the outer flange impinges on the anal verge. Unless the anoscope has an internal light, use an external light source such as a penlight, otoscope, headlamp, or pelvic examination light.

When the anoscope is fully inserted, remove the obturator (see Fig. 45.4, step 3). The area is visualized as the anoscope is withdrawn. While gradually withdrawing the anoscope, visualize all areas of the anal canal (see Fig. 45.4, step 4). Swab away blood or debris to aid in visualization, and culture any abnormal discharge that is found. Note whether there is rectal bleeding or an FB beyond the reach of the anoscope. Withdraw the anoscope slowly and inspect the entire circumference of mucosa for hemorrhoids, anal fissures, ulcerations, abscesses, or tears. Near the last stage of withdrawal, be aware of reflex spasm of the anal sphincter, which may cause the anoscope to be expelled quickly. Use firm counterpressure to prevent such rapid expulsion.

Complications

Although complications are rare, patients often complain of increased pain after the examination. Local mucosal irritation with subsequent bleeding is the most common complication. To prevent transmission of infectious diseases, dispose of or sterilize instruments after each use.

MANAGEMENT OF HEMORRHOIDS

Hemorrhoids are a common affliction and have been described and treated for more than 4000 years. The refined, low-fiber diet of Western nations makes hemorrhoids extremely common in the United States, where 1 in 25 to 30 individuals is afflicted. One million patients annually seek medical attention for this condition.⁴

Hemorrhoids are normal vascular structures in the submucosal layer of the anal canal, arising from a channel of arteriovenous connective tissues that drains into the superior and inferior hemorrhoidal veins. Hemorrhoidal tissue is composed of vascular, mucosal, and muscular tissue (Fig. 45.5). There are two types of hemorrhoids: internal and external. *Internal hemorrhoids* originate above the dentate line, are covered with mucosa, and lack sensory innervation. They can be identified by noting that their covering differs in appearance from the surrounding perianal skin. Internal hemorrhoids may prolapse and bleed, which usually produces bright red blood on toilet paper or in the toilet bowl. This bleeding is arterial from presinusoidal arterioles and is mostly associated with brown stool and bleeding only with a bowel movement. Atypical bleeding requires further investigation. Internal hemorrhoids are rarely felt by digital palpation unless they are very large or thrombosed. Internal hemorrhoids are usually painless unless gangrenous, strangulated, extruded, or thrombosed, and then

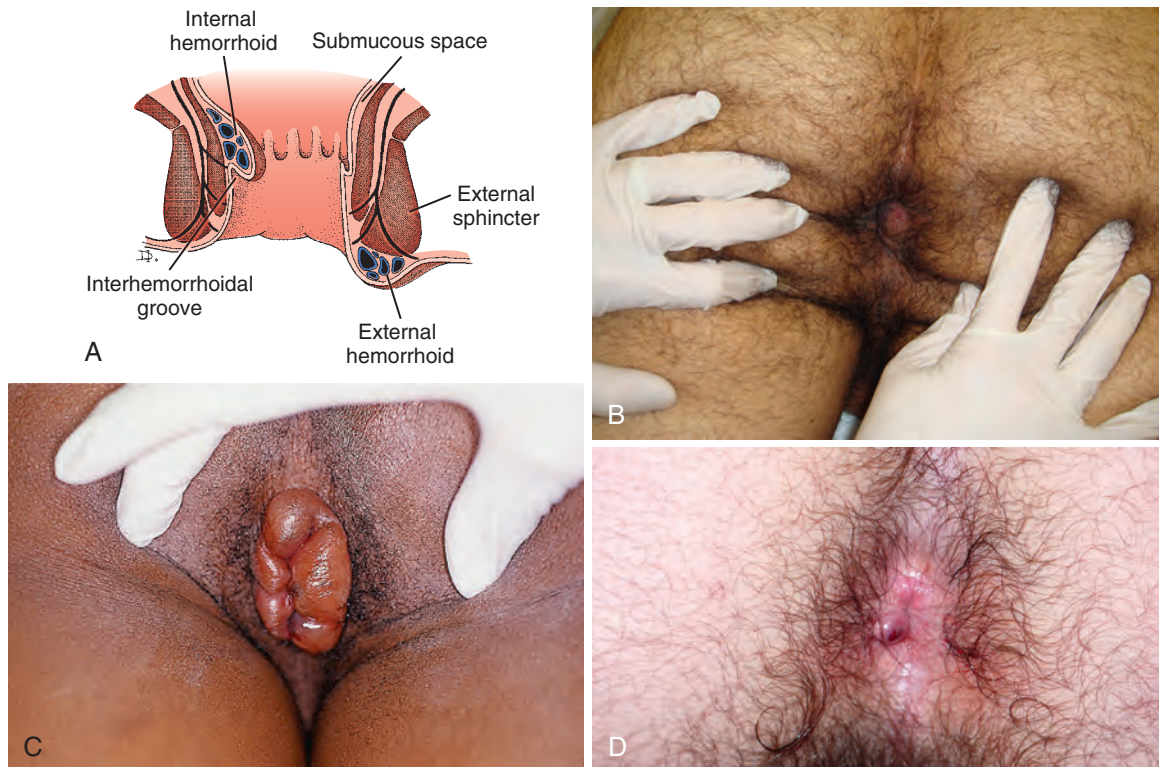

Figure 45.5 A, Anatomic location of internal and external hemorrhoids. B, Thrombosed external hemorrhoid. C, Thrombosed prolapsed internal hemorrhoids. These hemorrhoids cannot be permanently reduced and are quite painful; occasionally, partial relief can be obtained by manual reduction if they are not gangrenous. They should not be incised in the emergency department; formal hemorrhoidectomy is required if conservative measures are not successful. They are often mistaken for a partial “rectal prolapse.” Sitz baths and stool softeners are frequently futile in such severe cases. D, This small external hemorrhoid ruptured and produced minor but persistent bleeding and pain. Conservative treatment consisting of topical corticosteroids or Preparation H (Pfizer Inc., New York, NY) and frequent sitz baths will be curative in 5 to 7 days. (A, From Hill GJ II: *Outpatient surgery*, ed 2, Philadelphia, 1980, Saunders.)

they may be extremely painful. Anal pain in the absence of such pathology suggests a problem other than simple internal hemorrhoids.^{4,5}

Internal hemorrhoids can be further classified as first through fourth degree. First-degree hemorrhoids do not prolapse but may be identified on anoscopic examination. Second-degree hemorrhoids prolapse on straining but reduce spontaneously. Third-degree hemorrhoids prolapse on straining and can be reduced manually, whereas fourth-degree hemorrhoids prolapse and are irreducible. Fourth-degree hemorrhoids are prone to thrombosis, strangulation, and eventually gangrene (see Fig. 45.5C).

External hemorrhoids originate below the dentate line and are covered with squamous epithelium. This makes them easily recognizable because their covering matches the surrounding skin. A thrombosed external hemorrhoid appears as a bluish mass covered by epidermis. Acute thrombosis occurs suddenly and is generally very painful because external hemorrhoids are innervated by the inferior rectal nerve. Many patients feel a tender mass and are unable to sit comfortably. Significant bleeding is uncommon but may occur with spontaneous rupture. Increased pressure from straining, or trauma from constipation or diarrhea, may exacerbate external hemorrhoids. Distention and trauma predispose the hemorrhoidal venous plexus to stasis with ensuing clot formation and edema.^{2,4-6}

Conservative Treatment

ED management of minor *internal hemorrhoids* is conservative. Prolapsing internal hemorrhoids will not benefit long-term from conservative intervention and should receive surgical consultation. A useful mnemonic for managing hemorrhoids is WASH: water (increase fluid intake, warm water contacting the hemorrhoid via bath or directed shower), analgesics, stool softeners, and a high-fiber diet.² Psyllium (e.g., Metamucil [The Procter & Gamble Company, Cincinnati, OH]) is often prescribed as a dietary supplement to increase fiber. Hemorrhoids that fail to respond to medical management may be treated on an outpatient basis with rubber band ligation, sclerosis, and thermotherapy consisting of an infrared beam, electric current, CO₂ laser, or ultrasonic energy. Patients who must push hemorrhoids back in after a bowel movement have symptomatic third-degree internal hemorrhoids and would benefit from elective surgical referral. This condition can easily be demonstrated by having the patient strain before DRE. *Nonreducible prolapsed internal hemorrhoids* should receive prompt surgical consultation and, frequently, admission to the hospital.⁴

Without treatment, thrombosed *external hemorrhoids* and those that have spontaneously ruptured will generally resolve over a period of 1 to 3 weeks. Residual skin tags may persist. During the interim, however, they are quite painful and may bleed. Small ruptured or nonruptured hemorrhoids that are seen acutely with minimal discomfort may be managed conservatively with warm water baths or a directed stream of water, topical corticosteroids (Anusol HC [Salix Pharmaceuticals, Raleigh, NC]), or Preparation H (Pfizer Inc., New York, NY). These topical agents may promote skin breakdown from the corticosteroid or local anesthetic if used for more than a couple of days. Because the pain is most severe within the first 48 hours, patients evaluated within this time window benefit from excision (not incision and drainage) of the contents of the thrombosed external hemorrhoid and its overlying skin. Patients

seen after this time are usually best managed with conservative treatment because the thrombosis begins the reabsorption process and the clot may have liquefied (see Fig. 45.5D).^{2,4,7}

Surgical Excision of Thrombosed External Hemorrhoids

Indications and Contraindications

Indications for surgical excision of acutely (<48 hours) thrombosed external hemorrhoids in the ED include relief of symptoms and prevention of the formation of permanent perianal skin tags. These appendages remain as loose skin after the body reabsorbs the thrombosis and serve as a nidus for poor perianal hygiene and local irritation. Surgical consultation should be obtained in the ED for multiple painful external hemorrhoids and for profuse bleeding that is hemodynamically significant. Bleeding disorders, serious systemic illness, and hemodynamic instability are all relative contraindications to excision in the ED.

Procedure

Place the patient in the prone or lateral decubitus position. Tape the buttocks apart to aid in visualization (Fig. 45.6, step 1). An assistant is often needed. Administer parenteral analgesics and sedatives as an adjunct to local anesthesia if necessary. Infiltrate with a local anesthetic (such as 0.5% bupivacaine or buffered 1% lidocaine with epinephrine at 1:100,000) just under the skin and over the dome of the hemorrhoid (Fig. 45.7; also see Fig. 45.6, step 2). The overlying skin should blanch, which indicates that anesthesia has been introduced at the appropriate depth. Inject additional anesthetic through the incised tissue into the base of the hemorrhoid, if needed, rather than through the intact skin (see Fig. 45.7C).

Grasp the skin overlying the thrombosis with forceps. Make an elliptical incision around the clot and direct it radially from the anal orifice (Fig. 45.8; also see Fig. 45.6, step 3). Elevate the edges of the skin with forceps and excise from the edges to expose the underlying thrombosis. Remove the clot with forceps or by applying digital pressure (see Fig. 45.6, steps 4 and 5). Frequently, multiple individual clots will be present. If any skin ulceration is noted over the hemorrhoid, include it in the excised portion. Pack the wound loosely with standard cotton gauze to prevent the skin edges from reapproximating prematurely.

For the trip home, place a gauze pad between the buttocks and tape the buttocks together to hold the gauze in place (see Fig. 45.6, step 6). Advise the patient to avoid prolonged standing or straining for the next few days. Minor bleeding may occur. Hygiene with a directed stream of warm water or sitz baths can be started a few hours after the procedure. The gauze may fall out or can be removed at the first sitz bath. After the packing has been removed, the patient may apply a soothing cream to the area for a couple of days (such as Preparation H, Anusol HC, or witch hazel pads). Instruct the patient to avoid using toilet paper after a bowel movement for a few days but to wash the area with mild soap and water in the shower. Most patients are relatively asymptomatic in 48 hours and do not need a routine wound check unless the pain or bleeding persists. Once the clot has been removed recurrent thrombosis is unlikely, but these patients are predisposed to future episodes. Long-term therapy should be directed toward avoiding constipation by increasing dietary fiber and fluid intake. Antibiotics are not routinely indicated.^{2,4,5,7}

Excision of Thrombosed External Hemorrhoids

1 Place the patient in the prone or lateral decubitus position. Tape the buttocks apart to aid in visualization.

2 Infiltrate with a local anesthetic just under the skin and over the dome of the hemorrhoid (see Fig. 45.7).

3 Make an elliptical incision around the clot and direct it radially from the anal orifice (see Fig. 45.8).

4 Remove the clot with digital pressure. Often, multiple individual clots will be present.

5 Use forceps to remove residual clots.

6 Pack the wound loosely with standard cotton gauze. Place a gauze pad between the buttocks and tape the buttocks together to hold the gauze in place.

Figure 45.6 Excision of thrombosed external hemorrhoids.

If an invasive procedure would not be well tolerated by the patient, alternative nonoperative treatments include topical nitrates or topical nifedipine. Applied to the thrombosed hemorrhoid, these creams relax the anal sphincter, relieve pain, and promote healing. Systemic absorption is minimal, and the application is usually well tolerated.^{4,5}

Complications

Although complications are rare, bleeding and infection do occur. The bleeding usually stops with direct pressure. When simple incision plus drainage is performed instead of an elliptical excision, or when the ellipse of skin is not removed completely, the edges of the skin can close prematurely and result in

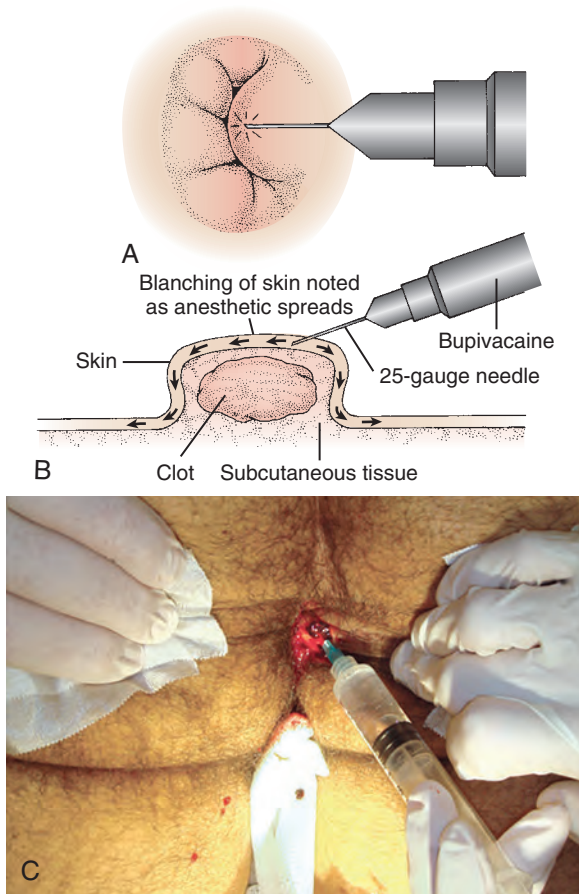

Figure 45.7 **A**, For surgical treatment of a thrombosed external hemorrhoid in the emergency department, anesthesia can usually be obtained with a *single injection* of buffered long-acting bupivacaine with epinephrine. In elective cases, apply a eutectic mixture of local anesthetics (EMLA [Actavis Pharma, Inc., Parsippany, NJ]) cream for 1 hour before the procedure. Parenteral sedation is optional. Using a 25-gauge needle, inject an anesthetic solution into the middle of the swollen hemorrhoid just below the surface of the skin. **B**, Do not move the tip of the needle. With slow injection, the anesthetic will spread over the surface of the dome and into the surrounding tissue. Avoid deep field blocks at the base of the hemorrhoid because they are unnecessary and very painful. **C**, If pain persists, inject additional anesthetic into deeper tissues *through the cut edges, not through the intact skin*.

infection and a permanent perianal skin tag. Premature closure can also result in incomplete evacuation of the clot.

MANAGEMENT OF ANORECTAL ABSCESS AND PILONIDAL CYST AND ABSCESS

These topics are covered in detail in [Chapter 37](#).

MANAGEMENT OF RECTAL FBS

Causes of rectal FBS include autoeroticism (most common), iatrogenic or self-administered placement (thermometer, enema tip), assault, accidental ingestion, and concealment (body packing). The myriad of objects that have been removed include

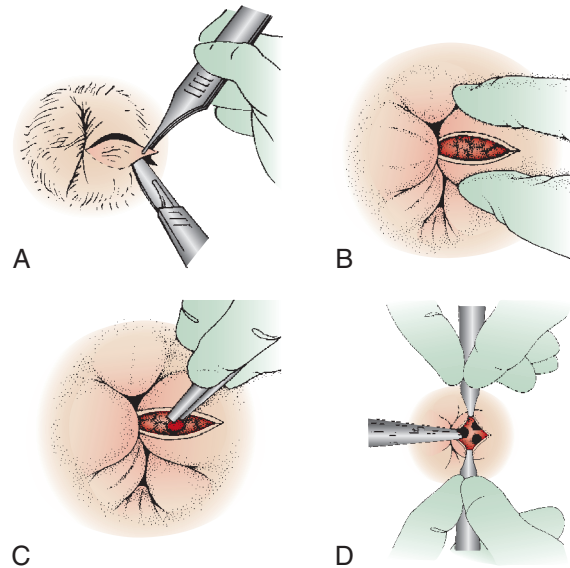

Figure 45.8 Schematic technique as described in [Fig. 45.6](#). **A**, For the unroofing technique, make an elliptical incision to remove a piece of the overlying skin. To prevent skin tags, do not use a simple linear incision. **B**, Blood clots may extrude spontaneously, but **C**, remove the remaining ones with forceps or express them with the fingers. **D**, Frequently, multiple clots are present, and they should all be removed. Ask an assistant to provide exposure with forceps if necessary.

vibrators, sex toy phalluses, aerosol cans, lightbulbs, glass bottles, billiard balls, fruits, vegetables, and small animals ([Fig. 45.9](#)). Many of these objects can be removed successfully in the ED. By following some simple guidelines, outpatient treatment can be practical and cost-effective.

Diagnosis of a rectal FB is usually made from the history. The physical examination should therefore concentrate on excluding anorectal or intestinal perforation and determining which objects will be accessible in the ED. DRE will identify objects that are low lying or palpable. Such objects are most likely to be removed successfully in the outpatient setting. Plain radiographs can supplement the examination by delineating the shape, position, and number of objects. If an FB with a sharp edge is suspected from the history or radiograph, omit the DRE to prevent injury to the provider.^{8,9}

Indications and Contraindications

Although some objects may pass spontaneously, delayed removal may lead to obstipation, pain, infection, and perforation. For these reasons FB removal is indicated according to the algorithm included in this chapter ([Fig. 45.10](#)). Rectal FB removal can lead to rectal perforation. Although many FBs can be removed safely in the ED, complicated or prolonged attempts may be better performed under general anesthesia.

Removal of FBs in the ED is contraindicated in patients who have severe abdominal pain or signs of perforation, a nonpalpable FB, or sharp objects or broken glass in the rectum. Other situations precluding ED removal include a rectal FB that is unusually difficult to remove (a set time limit has elapsed, or the patient cannot tolerate removal), or when there is insufficient experience or equipment to perform the procedure. Patients who arrive at the ED under these conditions require surgical consultation.^{8,9}

Figure 45.9 Rectal foreign bodies. **A**, Two large tungsten spheres, one on top of the other, gave a snowman-like appearance on the radiograph. They were removed manually in the emergency department (ED) with the aid of a Foley catheter and large-volume balloon. **B**, A vibrator that migrated into the sigmoid colon. It required removal in the operating room under general anesthesia. **C**, A small glass jar that the patient had tried to remove multiple times over a period of hours at home. On arrival at the ED, he had signs of peritonitis and was taken to the operating room, where perforation of the distal colon was discovered. Diverting colostomy was required. **D**, A toothbrush that was removed manually in the ED.

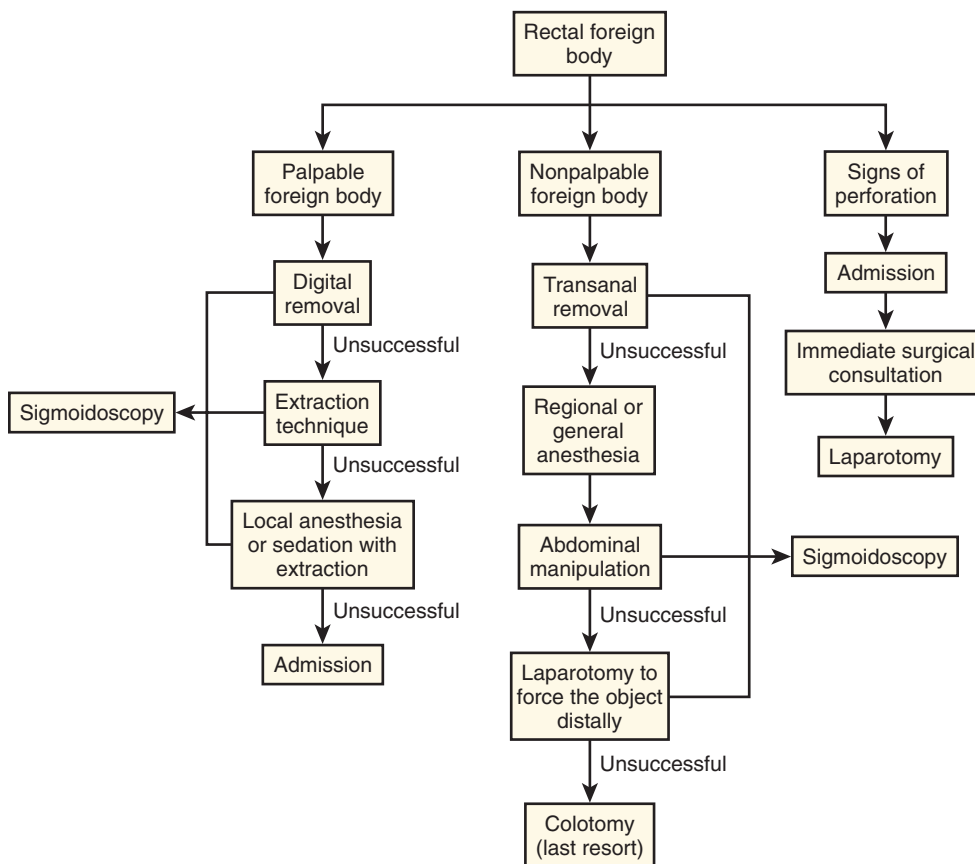

Figure 45.10 Emergency approach to the removal of rectal foreign bodies. Foreign bodies that are fragile or associated with rectal spasm are generally managed with regional or general anesthesia. The use of supplemental analgesic, anxiolytic, and local anesthetic medications is recommended.

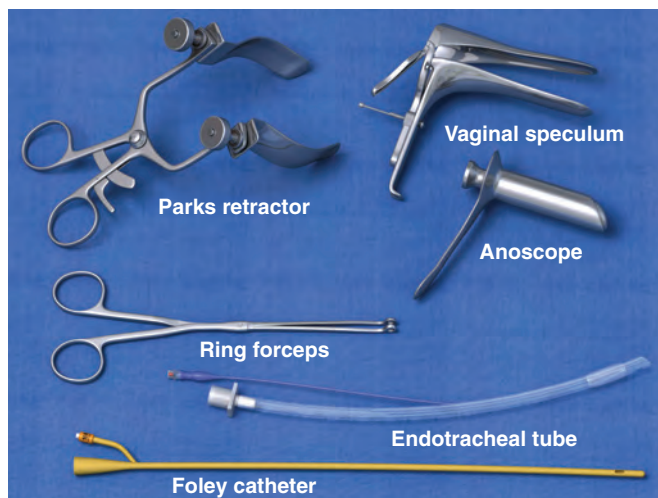

Figure 45.11 A variety of equipment may be required to remove a rectal foreign body, and the choice of specific equipment will depend on the clinical scenario. Individual situations may lead to creative use of standard medical equipment, but one must ensure safety before using a device to remove a rectal foreign body.

Equipment

The specific equipment required will often depend on the nature of the FB (Fig. 45.11). In general, the clinician will need a speculum with a light source and an instrument to grasp the FB. The speculum can be an anoscope, a rigid sigmoidoscope, a vaginal speculum, or a retractor. Instruments useful for grasping the FB include ring forceps, tenaculum forceps, and obstetric forceps. In some instances, a Foley catheter or endotracheal tube will be helpful. A suction dart, vacuum extractor, and plaster of Paris have also been used to aid in FB retrieval. Individual situations may lead to creative use of standard medical equipment, but one must ensure safety of the patient and health care personnel before using a device to remove a rectal FB.

Procedure

The technique for removal depends on the size, location, orientation, and composition of the FB. Place the patient either prone in the knee-chest position or in a lateral decubitus position. Alternatively, if the patient is in the lithotomy position, pressure can be placed on the abdomen to help maneuver the FB toward the distal end of the rectum. Parenteral analgesia is often required to relieve the pain from anal stretching and manipulation. Intravenous sedation is almost always required to calm the patient and facilitate relaxation of the anal sphincter. A perianal block allows greater dilation of the sphincter. Local infiltration with 0.5% bupivacaine or 1% lidocaine with epinephrine at 1:100,000 may be administered circumferentially around the anus in the submucosal tissue.

After analgesia and sedation of the patient, perform a DRE to gauge the position and orientation of the FB. Suprapubic pressure from above, the examiner's finger from below, and the patient performing a Valsalva maneuver may successfully deliver the object without instrumentation. If the FB is lodged against the sacrum posteriorly, redirect it by cradling its posterior aspect between two fingers and directing it slightly proximally and anteriorly while the patient gently bears down.

If DRE reveals that the object has an accessible edge or lip, use an instrument to extract it under direct visualization (Fig. 45.12). First, insert an anoscope, rigid sigmoidoscope, vaginal speculum, or retractor into the anus as described previously in the section on **Anoscopy**. If an intact object is visualized clearly, use a blunt instrument to secure it. Apply gentle traction to remove the object, the instrument, and the anoscope or speculum as a single unit. Grasp the object under direct visualization to avoid pinching or tearing the mucosa.

Rigid sigmoidoscopes offer a unique advantage in that air can be insufflated into the rectum around the FB. This technique can be particularly helpful when retrieving glass objects. Glass rectal FBs often create a vacuum in the segment of bowel just proximal to where they lie. This makes removal with simple traction almost impossible. The vacuum can be released by distending the rectal wall around the object with air. If a sigmoidoscope cannot be used to retrieve a glass object, pass one or two Foley catheters or an endotracheal tube beyond the FB and inflate the balloon or cuff. Then remove the object with the inflated balloons and gentle traction. Specific equipment is often not available to remove all FBs, and the clinician must improvise depending on the circumstances. Something as simple as two large spoons or an endotracheal tube may be used in lieu of complicated forceps and clamps.

Besides creating a vacuum, glass objects are especially difficult to remove because they can break and cause a tear or perforation in the rectal wall. If forceps are used for retrieval of a glass object, coat the grasping edge with rubber or plastic or pad it with gauze. Plaster of Paris has been used to remove a hollow glass object if the object has an open end facing distally. Insert a hollow tube (e.g., an endotracheal tube, or small chest tube) into the open end. Fill the FB with plaster by injecting it through the hollow tube with a large irrigation syringe. Once the plaster cools and hardens around the tube, it can be used as a handle to remove the object with gentle traction. Be careful to not leak plaster onto the mucosa. In addition, heat is released as the plaster hardens and may cause the glass to crack or shatter. After removal, perform sigmoidoscopy to evaluate for edema and possible perforation of the mucosa. Patients with normal findings on postextraction examination and no evidence of perforation may be released home safely after a period of observation.^{8,9}

FBs that are positioned proximal to the rectum warrant surgical consultation. Management options include observation to enable passage to the rectum or surgical removal. Enemas or cathartics should not be used because they may increase the impaction of a rectal FB or cause it to move higher into the colon.

Complications

The most common complication is an inability to remove the rectal FB, which should prompt surgical consultation. The most serious complication of rectal FB retrieval is perforation or a deep mucosal tear, which may necessitate surgery. Cracking or shattering of glass may also require surgical exploration and retrieval. Mild mucosal edema and rectal bleeding are common sequelae of prolonged rectal FB presence and retrieval. These complications may not require any specific treatment. However, the presence of postprocedural abdominal pain, fever, sustained or profuse rectal bleeding, or discharge warrants surgical consultation.

Rectal Foreign Body Removal Techniques

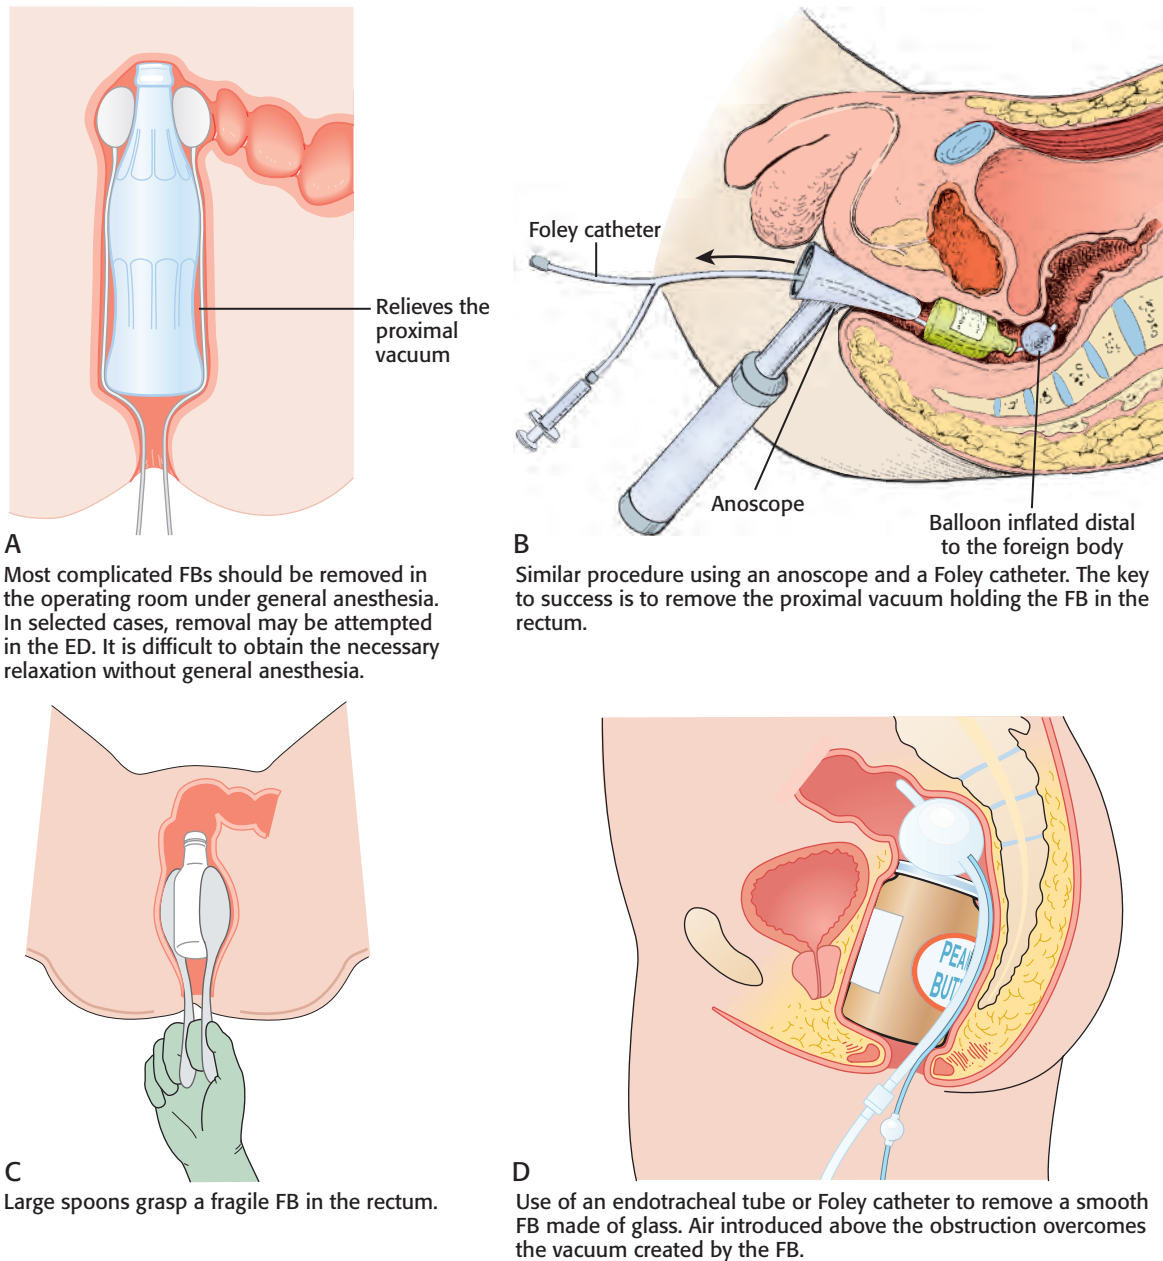

Figure 45.12 Rectal foreign body (FB) removal techniques. *ED*, Emergency department. Difficult-to-remove FBs require operating room techniques.

MANAGEMENT OF RECTAL PROLAPSE

Rectal prolapse is protrusion of some or all the layers of the rectal wall through the anal orifice. Prolapse is not usually an emergency, and manual reduction is often easily accomplished in the ED. The most common complaint is protrusion of a rectal “mass” or tissue. Patients may complain of pain on defecation, itching, incomplete evacuation, incontinence, or bloody mucosal discharge and mistake the condition for “hemorrhoids.” Rectal prolapse is diagnosed by visual inspection of the anus. DRE may diagnose occult prolapse that is situated

inside the anal canal. The differential diagnosis includes hemorrhoids, polyps, cystocele, and carcinoma.

There are three types of prolapse. (1) Complete prolapse, or procidentia, involves all layers of the rectum protruding through the anal orifice (Figs. 45.13 and 45.14). (2) Incomplete, or occult, prolapse describes internal prolapse that does not reach the orifice. This type is difficult to diagnose in the ED and requires no emergency intervention. (3) Mucosal prolapse is limited to protrusion of mucosa through the anal opening.

Complete and partial prolapse can be distinguished from each other by digital palpation. A thick muscular layer of tissue

Figure 45.13 A, Type I procidentia (rectal prolapse). B, Intussusception of the sigmoid colon beyond the anus. (A and B, From Kratzer GL, Demarest RJ: *Office management of colon and rectal disease*, Philadelphia, 1985 Saunders.)

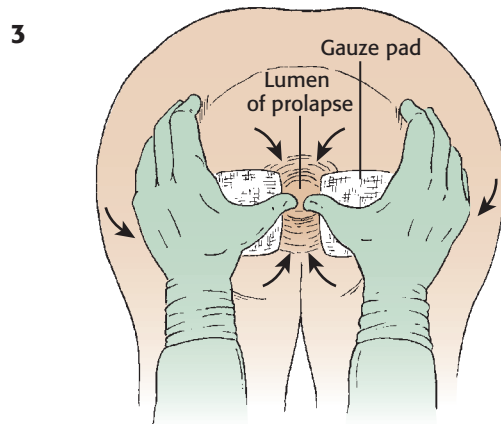

Rectal Prolapse Reduction

1 Complete (recurrent) rectal prolapse in a nursing home patient. To reduce the prolapse, place the patient in the prone or lateral decubitus position. Parenteral sedation may be required.

2 Tape the buttocks apart (or enlist the help of an assistant to spread the buttocks) to aid in reduction.

3 Apply constant, gentle circumferential pressure to the prolapsed area, beginning with the portion closest to the lumen (the most distal segment). Apply pressure with the thumbs while rolling the walls inward to force the prolapse back through the anus.

4 Successful reduction of the rectal prolapse.

Figure 45.14 Reduction of rectal prolapse.

between the examiner's thumb and forefinger suggests complete prolapse. With partial or mucosal prolapse, radial rectal folds may be seen protruding through the rectum. This type of prolapse rarely extends more than 3 to 4 cm from the anus. Complete prolapse can extend 10 to 15 cm outside the anal verge.

Rectal prolapse is most common in children and older adults. Prolapse in children is typically incomplete, or mucosal. It usually affects children younger than 3 years and is often associated with cystic fibrosis, parasitic infection, chronic diarrhea, malnutrition, or as a sequela of chronic neurologic disease. Prolapse is usually self-limited; outpatient management (after manual reduction) includes correcting constipation, avoiding straining, and referring for testing to exclude cystic fibrosis. Rectal prolapse in adults occurs most often in older women and may be recurrent. The cause is poorly understood, but it is associated with chronic constipation, chronic neurologic conditions, or pudendal neuropathies that weaken the anal sphincter.^{10,11}

Indications for Reduction

Rectal prolapse may be reduced in the ED. If unsuccessful, surgical referral is appropriate. Definitive surgery may be attempted, but occasional prolapses in debilitated patients are usually treated conservatively. Patients should be referred for outpatient proctoscopy to search for a polyp or malignancy that may have acted as a lead point. If the prolapse is incarcerated, surgical consultation should be obtained.

Procedure

Reduce a mucosal prolapse by applying gentle, constant pressure on the mass for a few minutes. In children, intravenous sedation may be necessary to allow reduction. Children are often more relaxed if they are allowed to remain on the parent's lap during the procedure. After reduction, send the child home with a pressure dressing and stool softeners. Counsel the parents on the use of dietary fiber and increased fluid intake to prevent constipation and straining. Refer the child for outpatient follow-up.¹²

For reduction of a complete prolapse, place the patient in the prone or lateral decubitus position (see Fig. 45.14, step 1). Parenteral sedation should be provided if the patient is anxious or has difficulty relaxing the sphincteric muscles. Tape the buttocks apart or have an assistant aid in reduction (see Fig. 45.14, step 2). Apply constant, gentle circumferential pressure to the prolapsed area, beginning with the portion closest to the lumen (the most distal segment). Place the thumbs on either side of the lumen while grasping the exterior walls with the fingers. Apply pressure with the thumbs while rolling the walls inward to force the prolapse back through the anus (see Fig. 45.14, step 3). Care should be taken to avoid poking at the tissue with the fingertips. If substantial tissue edema has developed, application of gauze soaked in sugar water may promote shrinkage and subsequent manual reduction.¹⁰

Complications

Complications after successful reduction are uncommon but may include bleeding and ulceration. Failure to reduce a prolapse requires surgical consultation. Apply saline-moistened gauze over the rectal tissue while awaiting consultation. A

persistently prolapsed rectum can result in ulceration, strangulation, and perforation of the bowel wall. Moreover, the possibility of loss of anal sphincter tone and incontinence increases with delays in reduction of rectal prolapse.

ANAL FISSURE

An anal fissure is a small laceration or ulcer at the anal verge.⁵ Anal fissures are the most common cause of sudden, searing anorectal pain. Though appearing trivial on examination, fissures can be extremely painful, even hours after a bowel movement, because of persistent spasm (Fig. 45.15). The condition is quite difficult to eradicate, is debilitating, and can last for months. It is occasionally associated with bright red rectal bleeding. An anal fissure is most commonly found in young adults, men, and women equally. In children, it can be a sign of child abuse. Anal fissures are usually associated with constipation, a hard or strained stool, or chronic diarrhea, but the exact cause is unknown. The diagnosis is relatively easy to make, and the fissure is readily seen by spreading the buttocks. The vast majority of anal fissures occur in the posterior midline, 10% to 15% occur in the anterior midline, and less than 1% occur in lateral positions. Fissures occurring in atypical locations should prompt consideration of other diseases. Multiple or recurrent fissures are associated with Crohn's disease, tuberculosis, syphilis, human immunodeficiency virus infection, and malignancy. Conservative therapy with the WASH regimen (see the section on hemorrhoids) may promote gradual healing in 4 to 6 weeks.

Most patients with acute anal fissures and almost half of patients with chronic fissures will experience healing with medical therapy. Therapy is aimed at breaking the cycle of pain, spasm, and ischemia, factors thought to be responsible for the development of the fissure. Therapies include relaxation of the internal sphincter, institution and maintenance of atraumatic passage of stool, and relief of pain. Simple measures include bulk agents, stool softeners, and probably most helpful,

Figure 45.15 A posterior midline anal fissure (arrow) is the most common type. Although some topical preparations may be helpful (see text), these lesions are painful and difficult to heal. In a child, an anal fissure may arouse suspicion of child abuse. (By permission of Mayo Foundation.)

warm sitz baths following bowel movements to relax the sphincter. Based on the theory that anal fissures are caused by ischemia through a spasmodic internal sphincter, pharmacological agents, including glyceryl trinitrate (GTN), diltiazem, and botulinum toxin, may be useful as alternatives to surgical sphincterotomy for chronic fissures. GTN ointment applied two to four times per day to the anus results in various healing rates, but a major side effect is dose-related headaches. Nitroglycerin 0.2% ointment applied twice daily may heal chronic ulcers via a reduction in resting anal pressure and an increase in anodermal blood flow. Diltiazem ointment (2%) appears to

have efficacy similar to that of GTN but may cause fewer side effects. Diltiazem may be associated with the development of pruritus. Both diltiazem and GTN are first-line therapies. Botulinum toxin causes temporary muscle paralysis by preventing the release of acetylcholine from presynaptic nerve terminals, thereby decreasing pressure in the internal sphincter. Surgical treatment is generally reserved for fissures that have failed medical therapy and is usually curative.

Musculoskeletal Procedures

CHAPTER 46

Prehospital Immobilization

Anne Klimke, Molly Furin, and Ryan Overberger

Modern emergency medical service (EMS) was created in 1966 as a result of the National Highway Safety Act. Since then, provision of medical care in the prehospital setting has undergone considerable change. Today's EMS providers perform many advanced lifesaving procedures. Nonetheless, the task of immobilizing potential injuries to the spine, pelvis, and extremities has remained a primary EMS function. This chapter reviews basic prehospital immobilization techniques and equipment, including spinal motion restriction, pelvic stabilization, extremity splinting, and removal of protective equipment.

SPINAL MOTION RESTRICTION

Background

The first widely accepted recommendations for “spinal immobilization” following blunt trauma came from the American Academy of Orthopaedic Surgeons in 1971.¹ These guidelines called for spinal immobilization of patients with symptoms or physical findings suggestive of spinal injuries.^{1,2} Since then, recommendations for spinal immobilization have evolved considerably.

During the 1980s and 1990s, indications for spinal immobilization were based primarily on the mechanism of injury, regardless of the presence or absence of symptoms or physical findings suggestive of a spinal injury.²⁻⁵ This resulted in routine and often unnecessary prehospital spinal immobilization for all but the most trivial injuries.⁶

In 1998, Hauswald and colleagues⁷ published the results of a 5-year retrospective review comparing patients from Malaysia, where cervical spine immobilization was nonexistent, to patients from New Mexico, where cervical spine immobilization based on the mechanism of injury was standard practice. The authors concluded that out-of-hospital immobilization has little or no effect on neurologic outcome in patients with blunt spinal injuries.⁷ This study, and others demonstrating increased complications⁸⁻¹³ and significant spinal movement, despite the

use of cervical collars (c-collars) and long spine boards,^{14,15} prompted the development and evaluation of prehospital clinical decision rules to selectively immobilize patients after blunt trauma.¹⁶⁻¹⁹

A 4-year prospective study in two Michigan counties found that the use of a selective immobilization protocol resulted in spine immobilization for most patients with spinal injury without causing harm to patients in which spine immobilization was withheld.¹⁸ A larger study in Maine demonstrated that selective immobilization based on a statewide protocol resulted in only one nonimmobilized unstable cervical spine fracture in more than 32,000 patient encounters.¹⁹

Data demonstrating the safe application of selective spinal immobilization protocols by prehospital providers, a lack of scientific evidence demonstrating improved outcomes with the use of long spine boards, and a keen awareness of the complications associated with spinal immobilization has resulted in new recommendations from the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma²⁰ and the American College of Emergency Physicians.²¹ These recommendations include the selective use of long spine boards following blunt trauma and elimination of their use following penetrating trauma in patients with no evidence of spinal injury (Box 46.1).²⁰

At the present time, the effects of spinal immobilization on mortality, neurologic injury, spinal stability, and adverse effects in trauma patients remains uncertain. Due to the low incidence of actual spinal cord injury (SCI) and associated neurologic sequelae, prospective trials are difficult to safely design and perform. Nevertheless, available data suggests that we should reduce or eliminate routine prehospital spinal immobilization in favor of using validated clinical rules to determine which patients may have sustained a spinal column injury and applying spinal motion restriction strategies only to these patients. However, these new approaches will take time to promulgate through the EMS community. Until then, emergency physicians must be knowledgeable about prehospital spinal immobilization. Therefore the remainder of this section provides a detailed review of immobilization devices and techniques.

Epidemiology

According to the National Spinal Cord Injury Statistical Center, an estimated 12,500 new, survivable SCIs occur in the United States annually,²² and 276,000 people were living with SCIs in the United States in 2014.²² Since 2010 the most common cause of SCI is motor vehicle collision, which accounts for almost 40% of cases, followed by falls and acts of violence, primarily gunshot wounds.²² Sports such as American football, rugby, swimming and diving, gymnastics, ice hockey, track and

BOX 46.1 EMS Spinal Precautions and the Use of the Long Backboard: Position Statement of the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma

The National Association of EMS Physicians and the American College of Surgeons Committee on Trauma believe that:

- Long backboards are commonly used to attempt to provide rigid spinal immobilization among EMS trauma patients. However, the benefit of long backboards is largely unproven.
- The long backboard can induce pain, patient agitation, and respiratory compromise. Furthermore, the backboard can decrease tissue perfusion at pressure points, leading to the development of pressure ulcers.
- Utilization of backboards for spinal immobilization during transport should be judicious, so that potential benefits outweigh risks.
- Appropriate patients to be immobilized with a backboard may include those with:
 - Blunt trauma and altered level of consciousness;
 - Spinal pain or tenderness;
 - Neurologic complaint (e.g., numbness or motor weakness)
 - Anatomic deformity of the spine;
 - High-energy mechanism of injury and:
 - Drug or alcohol intoxication;
 - Inability to communicate; and/or
 - Distracting injury.
- Patients for whom immobilization on a backboard is not necessary include those with all of the following:
 - Normal level of consciousness (Glasgow Coma Scale 15);
 - No spine tenderness or anatomic abnormality;
 - No neurologic findings or complaints;
 - No distracting injury;
 - No intoxication.

- Patients with penetrating trauma to the head, neck, or torso and no evidence of spinal injury should not be immobilized on a backboard.
- Spinal precautions can be maintained by applying a rigid cervical collar and securing the patient firmly to the EMS stretcher. They may be most appropriate for:
 - Patients who are found to be ambulatory at the scene;
 - Patients who must be transported for a protracted time, particularly prior to interfacility transfer; or
 - Patients for whom a backboard is not otherwise indicated.
- Whether or not a backboard is used, attention to spinal precautions among at-risk patients is paramount. These include application of a cervical collar, adequate security to a stretcher, minimal movement/transfers, and maintenance of in-line stabilization during any necessary movement/transfers.
- Education of field EMS personnel should include evaluation of risk of spinal injury in the context of options to provide spinal precautions.
- Protocols or plans to promote judicious use of long backboards during prehospital care should engage as many stakeholders in the trauma/EMS system as possible.
- Patients should be removed from backboards as soon as practical in an emergency department.

EMS, *Emergency medical service.*

White CC, Domeier RM, Millin MG: EMS spinal precautions and the use of the long backboard – resource document to the position statement of the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma, *Prehosp Emerg Care* 18:306, 2014.

field (specifically pole vaulting), cheerleading, and baseball all place participants at increased risk for spinal injuries.²² The cost of care in both the immediate and extended care setting can be exorbitant, especially among the young. The average lifetime cost of medical care for patients with SCI varies depending on the level of injury and age at time of injury, and ranges from \$1 million to more than \$4.7 million, with annual costs from \$42,000 to \$1 million.²²

Pathophysiology

The direction and strength of the injurious force may help predict the type of injury sustained. Generally speaking, the basic forces that can be exerted on the spine are flexion, extension, rotation, lateral bending, distraction (stretching), and compression (axial loading).^{23,24} Of course, complex mechanisms may exert multiple forces. For example, high-speed rollover motor vehicle collisions could easily exert all the aforementioned forces.

Injuries to the upper cervical spine (C1 and C2) (Fig. 46.1) occur more often in older, osteoporotic patients than in younger patients. The spectrum of injuries in the cervicocranium includes occipital condyle fractures, occipitoatlantal dislocations, dislocations and subluxations of the atlantoaxial joint, fractures of the ring of the atlas, odontoid fractures, fractures of the arch of the axis, and fractures of the lateral mass of the axis

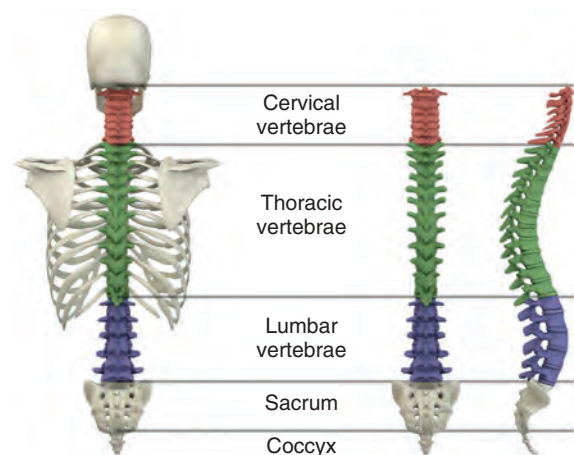

Figure 46.1 The human spinal column.

(Fig. 46.2). Involvement of the spinal cord at this high level can cause devastating neurologic injury, and it is reasonable to believe that many of these injuries are not reported because they result in death.²⁵ Subaxial cervical spinal injuries involving C3–C7 have broad clinical implications. Approximately two-thirds of cervical injuries causing quadriplegia occur within

Figure 46.2 Type III odontoid (C2) fracture (*arrow*). A common scenario for this type of injury is an elderly woman who falls from a standing height.

the lower cervical spine, with fractures occurring most often in C6 and C7 and dislocations most commonly occurring between C5–C6 and C6–C7.²⁶

The orientation of the facets in the thoracic spine allows significantly less flexion and extension than in the cervical or lumbar spine. In addition, the free space between the thoracic spinal cord and the borders of the spinal canal is relatively small, and the blood supply is less robust. These factors increase the susceptibility of the spinal cord to injuries at this level. At the thoracolumbar junction there is an acute transition in stability because of the loss of rib restraint, which increases the risk for flexion-extension and rotational injuries. Disk size and shape also change, thus making this section of the spine particularly susceptible to injury. Approximately half of all vertebral body fractures and 40% of all SCIs occur between T11 and L2.²⁷

The lumbar spine is protected only by the abdominal and paraspinous musculature, making it subject to distracting and shearing forces, such as those seen with lap belt injuries. There is also a higher prevalence of compression and burst fractures in the lumbar spine. These fractures commonly occur when axial loading forces straighten the natural lordosis at the moment of impact.²⁸

The sacrum forms both the terminal portion of the spine and the central portion of the pelvis, which gives it added stability and makes isolated sacral fractures uncommon. Such fractures are usually caused by direct trauma or falls from a height, or occur as a result of sacral insufficiency secondary to osteopenia, chronic steroid use, or previous pelvic irradiation. More often, sacral fractures occur as a result of high-energy mechanisms and are associated with major pelvic disruption.²⁹

Indications

Spinal motion restriction should be considered for victims of blunt trauma who sustain an injury with a mechanism that has the potential for causing spinal injury and who have at least one of the following criteria: altered mental status, intoxication,

Figure 46.3 This seizure patient was initially postictal and combative and did not allow prehospital cervical spine immobilization. Although this is a dilemma for all involved, it is best to avoid forcing such immobilization. Sedation may be an alternative if injury is strongly suspected and immobilization is deemed clinically necessary. After recovering from his postictal state with a clear mental status and no neck pain (and National Emergency X-radiology Utilization Study rules negative), an unneeded collar was subsequently unnecessarily applied in the emergency department, to the annoyance of the patient, who then became very agitated and tried to leave. Note that the patient is now physically restrained and is sitting upright.

a distracting painful injury (e.g., long-bone fracture), a neurologic deficit, and spinal pain or tenderness (see [Box 46.1](#)).²⁰

Extremes of age and the presence of communication barriers (e.g., language, hearing impairment) may affect the ability to accurately assess the patient's perception and communication of pain and should lower one's threshold for spinal precautions.²⁵ It is also important to remember that serious cervical cord injuries can occur in the absence of demonstrable fractures. SCI is common in elderly patients with cervical spondylosis, in whom an arthritic osteophyte may sever a portion of the cord as permanently as a fracture or dislocation. In such cases there may be little subjective pain, and the mechanism of injury may appear seemingly minor.³⁰

Although data is sparse, patients who have had a seizure in the field are at low risk for spinal injury.³¹ Nevertheless, immobilization of postictal patients due to a presumed risk for spinal injury and inability to adequately assess the patient is commonplace. Unfortunately, attempts at immobilization often prompt further patient confusion and agitation, and struggling may exacerbate injuries that do exist ([Fig. 46.3](#)). In these situations, when there is concern for a spinal injury based on the mechanism of injury, physical findings (e.g., focal neurologic deficit, facial injuries), or patient complaints, administer sedation rather than, or in addition to, spinal immobilization.

In summary, there is no good evidence that cervical immobilization restricts harmful movement, and the use of c-collars may cause harm. There is evidence that c-collars reduce venous return and hence may cause an increase in intracranial pressure (ICP). Taking a patient out of a comfortable position and placing them in a collar that extends the neck does not make them safer.

Contraindications

Spinal immobilization with a c-collar or a backboard following blunt trauma is not necessary in patients with a normal mental status (Glasgow Coma Scale 15), no spinal tenderness or anatomic abnormality, no neurologic findings or complaints, no distracting injuries, and no intoxication (see [Box 46.1](#)).²⁰

In general, spinal immobilization with a c-collar and a backboard is contraindicated (or may require modification) when its use could harm the patient, when it is logistically impossible, or when the scene is unsafe ([Box 46.2](#)). Good clinical judgment, not blind application of protocols, is essential. For example, if application of a c-collar will cause or mask airway compromise secondary to swelling, an expanding hematoma, or other process, it should not be used. Obviously, if a patient requires a surgical airway, the EMS provider will need immediate, unencumbered access to the anterior aspect of the neck. Sometimes preexisting airways (e.g., tracheotomy tube) and associated equipment prohibit proper application of a c-collar. These situations can often be managed with an improvised cervical immobilizer, such as a collar fashioned from a towel roll or prolonged manual stabilization without traction.

Other conditions that may prevent spinal immobilization or require modification of standard techniques and equipment (e.g., towel roll and manual in-line stabilization) include obesity, impaled objects, underlying respiratory problems or acute respiratory distress, altered mental status (e.g., combative patients due to intoxication or psychiatric illness), and cervical dislocation with fixed angulation or anatomic limitations from preexisting conditions such as ankylosing spondylitis and kyphosis.³²

BOX 46.2 Contraindications to Prehospital Spine Immobilization

- May be potentially harmful (e.g., prevents identification of airway compromise)
- Need for a surgical airway
- Presence of a preexisting airway (e.g., tracheostomy tube)
- Obesity
- Impaled objects
- Chronic respiratory diseases (e.g., congestive heart failure) or acute respiratory distress from any cause (e.g., ascites)
- Altered mental status or agitation (e.g., intoxicated patients)
- Cervical dislocation or anatomic limitation because of preexisting conditions (e.g., ankylosing spondylitis)
- Logistically impractical (e.g., mass-casualty incident, hazmat incident)
- Unsafe scene:
 - Exposure to hazardous material, fire, or smoke
 - Building explosion or collapse
 - Deep or fast moving water that poses a risk for drowning
 - Risk for injury from assault (e.g., gunshot, stabbing, blunt trauma)
 - Any other circumstance that the emergency medical service provider deems an immediate danger to the life or health of the patient, provider, or both

**Situations listed in this table can often be managed with modified spinal precautions (see text for details).*

There are also scenarios when spinal motion restriction is logistically difficult or impossible. In a mass-casualty incident or wilderness accident, maintaining spinal motion restriction may be impractical or impossible ([Fig. 46.4](#)). Moreover, spinal motion restriction may need to be delayed or modified when the scene poses a significant threat to the patient or providers (see [Box 46.2](#)).²³ In these situations, the prehospital provider may opt for rapid extrication of the patient from the scene without immobilization of the spine ([Fig. 46.5](#)).

In general, victims of penetrating trauma to the head, neck, or torso, such as gunshot wounds, with no evidence of spinal injury should not be immobilized.²⁰ No study has demonstrated worsening neurologic outcomes related to a lack of prehospital spinal immobilization,³³ whereas delays

Figure 46.4 During a mass-casualty incident such as a train accident, spinal motion restriction of multiple victims with a low probability of spinal injury may not be practical and may delay other more pressing interventions if resources are limited.

Figure 46.5 Spinal motion restriction may need to be delayed, modified, or omitted when the scene poses a significant threat to the patient or providers, such as evacuating a wounded soldier during a sniper attack. Rescue from a toxic or poisonous environment, such as hydrogen sulfide or carbon monoxide, is a similar situation.

Figure 46.6 A gunshot wound to the head is not an indication for routine cervical spine immobilization. No study has demonstrated worsening neurologic outcomes related to a lack of prehospital spinal immobilization. Immobilizing the cervical spine in these patients may lead to missed injury under the collar, airway compromise, increased intracranial pressure, and delay in resuscitation.

to definitive care for life-threatening hemorrhage or airway obstruction can lead to increased morbidity and mortality in these patients (Fig. 46.6).³⁴⁻³⁷ In hemodynamically stable patients with focal neurologic deficits following a penetrating injury, it may be reasonable to restrict spinal motion; however it is prudent to err on the side of expediting care at the expense of immobilization.

Equipment

C-Collars

Traditionally, c-collars have used a four-point support structure at the bottom of the collar: at the two trapezius muscles posteriorly and at the two clavicles anteriorly. Most modern collars are modified rigid head-cervical-thoracic devices that use the sternum as a fifth support structure. Current collar designs support the head with winglike flaps on the collar's upper posterior edges. Anteriorly, the collar supports the mandible. The collar's flaring design generally prevents compression of the thyroid cartilage and cervical vessels, even when applied firmly. Some collars come as single units that conform to the neck once a chin support has been assembled, whereas others come in two parts, with a front and a back that are secured with Velcro (Fig. 46.7). Some manufacturers have developed collars that have adjustable heights to account for different neck lengths. Soft collars, though comfortable, have no role in spinal immobilization because they provide minimal support and do not reduce cervical motion to any significant degree.^{38,39}

Investigators have attempted to evaluate c-collars in an objective fashion. The accepted “gold standard” for comparison is the halo brace, which restricts motion to 4% flexion-extension, 1% rotation, and 4% lateral bending.⁴⁰ Unfortunately, even

Figure 46.7 Cervical collars. **A**, Philadelphia collar. This two-piece, high-type collar comes in four sizes. The collar supports the head in a dish-shaped contour that is formed when the front and rear halves are joined by Velcro fasteners. When properly sized for a patient, this collar provides excellent support. When applied too tightly, it tends to force the mandible backward and can cause compression of the thyroid in some patients. **B**, Stifneck collar. This collar is made of high-density polyethylene (a hard material) and padded with semiflexible foam margins. Note the low-reaching anterior panel, which contacts the sternum for additional support.

Figure 46.8 Cervical extrication splints. **A**, Rigid short boards. **B**, Kendrick Extrication Device. (Courtesy Ferno-Washington, Inc., Wilmington, OH.)

the best c-collars (when used independently) restrict flexion and extension by only 70% to 75% and overall neck movement by 50% or less.⁴¹ A number of studies have evaluated neck motion in volunteers immobilized supine on a backboard with various collars in place.^{38,39,42-45} Although these studies demonstrated small differences among some of the collars, overall they merely confirm the fact that c-collars do not completely prevent motion of the cervical spine. Interestingly, some cadaver studies have shown the potential for c-collars to actually increase motion and force in the unstable cervical spine.⁴⁶ Despite these limitations, c-collars remain a widely used component of most spinal motion restriction strategies (Video 46.1).

Cervical Extrication Splints

A large variety of short spine boards and intermediate-stage extrication devices are available for prehospital use (Fig. 46.8). Generally, these devices are manufactured from rigid lightweight material. They have a narrow board design that permits easy application in automobiles or confined spaces and are constructed with multiple openings along the edges to allow for a variety of strapping options. Ideally, these devices should also be translucent so that radiographs can be readily obtained

in the emergency department (ED), and they should allow repeated use and easy cleanup.

▶ Application of a cervical extrication splint (Video 46.2) should not produce unnecessary movement or change the position of the head, neck, shoulders, or torso. In conjunction with a good c-collar, a properly applied cervical extrication splint should effectively limit flexion, extension, lateral motion, and rotational motion of the head, neck, and torso.

One commonly used device that meets all these criteria is the Kendrick Extrication Device (KED) (see Fig. 46.8B). This device consists of two layers of nylon mesh impregnated with plastic and sewn over plywood slats to provide rigidity. It has a nylon loop behind the patient's head that is continuous with the pelvic support straps for additional strength. Part of its anterior thoracic panels can be folded backward to fit obese, pregnant, or pediatric patients.⁴⁷ When properly applied, the KED is a snug-fitting, highly adaptable immobilizer that can be used in even the most adverse circumstances.

When patients require immobilization or extrication (or both) in more difficult or treacherous environments, many EMS providers prefer the LSP half-back (Allied Healthcare Products, Inc., St. Louis, MO), which resembles a KED, but is more rugged and durable. In addition to providing spinal motion restriction, it also acts as a harness and can be used for hauling patients over flat surfaces and for vertical lifts (Fig. 46.9).⁴⁸

Mosesso and coworkers⁴⁹ compared six prehospital cervical immobilization devices and concluded that the devices were similar in their ability to limit motion of the cervical spine.

Figure 46.9 The LSP half-back (Allied Healthcare Products, Inc., St. Louis, MO). This cervical extrication splint resembles a Kendrick Extrication Device but is more rugged and durable. In addition to providing spinal immobilization, it also acts as a harness that can be used for hauling patients over flat surfaces and for vertical lifts.

Full-Body Spinal Restriction Long Spine Boards (Backboards)

Backboards are made of wood or plastic composites and can be either rectangular or tapered in shape (Fig. 46.10A). Most rescuers prefer the tapered type because it takes up less horizontal room when angled into a narrow opening or doorway. In addition, the slight narrowing of these boards on either end enhances the effectiveness of strapping.

▶ Most backboards (Video 46.3) have strategically placed openings along the edges that can be used to secure head-stabilizing devices, strap the patient to the board, or lift the patient. Many also feature runners, usually approximately 2.5 cm thick, on their undersides that serve both as stiffeners and as spacers. They raise the board slightly off the ground so that rescuers can get their fingers under the board during lifting. The runners, however, may make it more difficult to slide a patient onto the board.

Advantages of backboards over full-body splints include their ease of storage, low cost, and extreme versatility. The backboard can be used to slide a victim out of an automobile or to protect a victim during removal of a windshield.

Board splints, as a class, are the least comfortable of all immobilizers. Studies have demonstrated that spinal immobilization on a hard backboard causes head, back, and jaw pain.^{8,13} Pain in these areas may become severe if patients are left immobilized on these boards for extended periods.⁹⁻¹¹ In addition, the pain caused by application of a backboard may be difficult to separate from other sources of pain in a trauma patient and might lead to costly radiographs and unnecessary radiation exposure to the patient.^{2,50} Discomfort may be minimized by using padding at points of contact between a bony prominence and the board. This concept was reaffirmed by Hauswald and colleagues,⁵¹ who found that increasing the amount of padding on a backboard decreases the amount of ischemic pain caused by immobilization. In some cases, tissue ischemia can lead to frank pressure ulcers, particularly in the elderly or nutritional deficient populations.⁵² Other concerning, well-described risks of long spine board immobilization include respiratory compromise,⁵³ aspiration in the event of vomiting, delay to care for management of emergency injuries, and restraint-related “combativeness.”

Scoop Stretchers

In many cases, a litter that separates longitudinally into two halves, commonly called a scoop stretcher, is an ideal field immobilizer (see Fig. 46.10B). In fact, one study found that using the scoop stretcher caused less spinal motion than did a traditional long backboard and logroll technique.⁵⁴

The scoop stretcher is designed to split into two or four pieces. It is comfortable, rigid, and adaptable to patients of various lengths and provides unobstructed radiographic transparency of the entire spine. If necessary, it can be applied almost instantly or removed without disturbing the position of the victim. The scoop stretcher also provides good lateral stability because of the troughlike shape of its top surface, and it is stable enough to be used for carrying. When cervical motion restriction is desired, a c-collar can be used with the scoop stretcher. In keeping with current recommendations regarding rigid long boards (see Box 46.1), the scoop should be removed once the patient is transferred to the ambulance cot and the practice of placing a long spine board under the scoop or transferring a patient to a spine board for transport should be abandoned. If the patient must be transported to

Figure 46.10 Full-body spine boards (backboards.)

the hospital on a scoop stretcher, removal is achieved by unfastening the latches at the top and the bottom of the device (see the section on [Procedure](#) later in this chapter).

One limitation of the scoop stretcher is the potential for trapping clothes, skin, or other objects between interlocking parts. It also interferes slightly with the ischial section of a half-ring traction splint, but works well with Sager-type devices. The Ferno-Washington model 65 scoop (Ferno-Washington, Inc., Wilmington, OH) is the most widely used stretcher of this type. Other devices such as the CombiCarrier (Hartwell Medical, Carlsbad, CA) and the Scoop EXL (Ferno-Washington, Inc.) offer lightweight polymer construction and additional spinal support (see [Fig. 46.10C and D](#)).

Full-Body Splints

A variety of full-body splints are available and may be used by some prehospital providers. One popular device is the Miller

body splint, which consists of a polyethylene shell injected with closed-cell foam that is radiographically translucent and provides buoyancy in water (see [Fig. 46.10E](#)). This full-body splint has a removable head harness and a thoracic harness, as well as pelvic and lower extremity belts. The space between the lower extremities facilitates wrapping with bandage material in the event of fractures. In addition, it is shaped so that it can easily fit into a basket-type rescue stretcher. Similar spine immobilization systems are available for pediatric patients (e.g., Pedi-Pac, Ferno-Washington, Inc.).

Another full-body splint designed to reduce the pain associated with many of the immobilization devices described previously is the vacuum mattress splint (e.g., EVAC-U-SPLINT, Hartwell Medical, and Immoblie-Vac, MDI, Gurnee, IL) (see [Fig. 46.10F](#)). It consists of a vinyl-coated polyester envelope filled with thousands of 1.1-mm-diameter polyester foam spheres. A manual or electric vacuum pump is used to evacuate

Figure 46.11 Lateral neck stabilizers. **A**, The HeadBed, a cervical immobilization device made of a water-resistant corrugated board. **B**, Universal Head Immobilizer. (A, Courtesy Laerdal Medical Corporation, Wappingers Falls, NY; B, courtesy Ferno-Washington, Inc., Wilmington, OH.)

the interior to a pressure of approximately 0.25 atm. The reduction in internal pressure causes the mattress to conform to the contours of the patient's body. Vacuum splints have been shown to produce lower sacral interface pressure and lower mean pain scores than traditional hard backboards^{13,55} and may provide better immobilization in patients with known SCI.^{56,57} It should also be pointed out, however, that vacuum splints are larger and more cumbersome than backboards, thus making ambulance storage more difficult.

Lateral Neck Stabilizers

Lightweight objects such as blocks (10 × 10 × 15 cm) made of medium-density foam rubber are commonly used to provide additional lateral stabilization of the head and neck. Foam blocks are inexpensive and disposable and do not slip on the backboard. Disposable cardboard devices that have the same advantages as foam blocks are also available (Fig. 46.11A).

Another commercial device is the Universal Head Immobilizer (Ferno-Washington, Inc.). It is a lateral neck stabilizer designed to quickly and easily fasten the patient's head to a scoop stretcher or spine board (see Fig. 46.11B). The Universal Head Immobilizer is made of a Herculite nylon and a polyethylene foam platform that fastens to the stretcher with Velcro straps. The lateral pillows are then attached to the nylon platform by means of large Velcro interfaces.

It should be noted that, although sandbags are effective devices for lateral immobilization, they may cause significant

Figure 46.12 Padding increases comfort and theoretically may prevent further injury. It can also help support an injured extremity or impaled object or allow an obese or kyphotic patient to lie supine on a long backboard.

movement of the neck if the board is suddenly tilted (e.g., to decrease the risk for aspiration in a vomiting patient). Therefore their use is no longer recommended. Additionally, tightly securing the head to any device without similarly securing the body has the potential to increase forces on the cervical spine during transportation and transfer. Because any manner of strapping is unlikely to completely prevent movement of the torso, the head should always be able to shift axially as a unit with the body.

Foam Padding

Padding increases comfort and can help prevent further injury. It can also help support an injured extremity or impaled object or allow an obese or kyphotic patient to lie supine on a long backboard or stretcher (Fig. 46.12).⁴² Pregnant women may benefit from padding under the right hip to help shift the gravid uterus off the inferior vena cava and increase venous return.⁵⁸ Padding applied under the neck and shoulders prevents hyperflexion in children with large occiputs (Fig. 46.13) or in individuals wearing certain types of helmets (e.g., bicycle, motorcycle, rock climbing) that cannot be removed in the field.

Procedure

Cervical Spinal Motion Restriction

The first priority in cervical spinal motion restriction is maintaining the head and spine in the neutral position. If patients are able to cooperate, instruct them to keep their head and neck in the neutral position and remain still. Next, place both hands on the sides of the patient's head to manually stabilize the cervical spine and minimize flexion, rotation, or bending. Be sure to avoid cervical traction as it can theoretically increase the risk for SCI. Once the cervical spine has been manually stabilized, examine the neck for swelling, ecchymosis, deformity, bony tenderness, or penetrating wounds. Application of a c-collar follows and is generally a straightforward procedure (Fig. 46.14). The rescuer's intentions should be thoroughly explained to the patient throughout the procedure.

Once the collar is in place, caution conscious patients against movement of the head. Investigate any persistent complaints

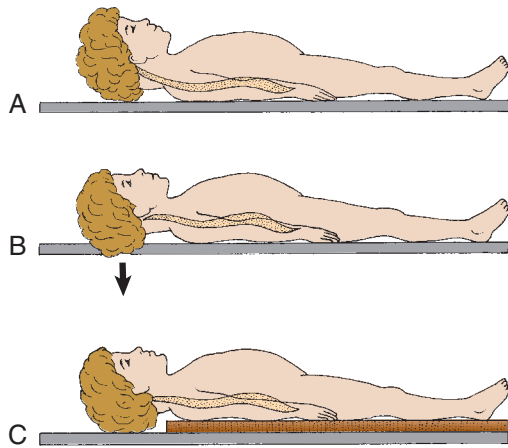

Figure 46.13 A, Young child immobilized on a standard backboard. Note how the large head forces the neck into flexion. Backboards can be modified by an occiput cutout (B) or a double mattress pad (C) to raise the chest, the actual clinical consequences of which are unknown. (A–C, Adapted from Herzenberg JE, Hensinger RN, Dedrick DK, et al: Emergency transport and positioning of young children who have an injury of the cervical spine, *J Bone Joint Surg Am* 71:15, 1989.)

of pain or dyspnea by removal and possible replacement of the collar while manual stabilization is maintained. The size of collar should be determined from the manufacturer's suggested guidelines. For example, the Stifneck collar (Laerdal Medical Corporation, Wappingers Falls, NY) is available in various sizes and uses the distance from the top of the shoulder to the chin to determine the appropriate size. Use the tallest collar that does not cause hyperextension. For extremely short necks, a special c-collar such as the No-Neck (Laerdal Medical Corporation) is recommended. In cases in which a c-collar of the proper size is not available, construct an improvised device from available materials (Fig. 46.15).

It should also be remembered that application of a c-collar should not be attempted until the patient's head has been brought into a neutral position and manual in-line stabilization has been applied.⁴¹ If the patient experiences cervical muscle spasm, increased pain, neurologic complaints (e.g., paresthesias, weakness), or airway compromise, immediately halt any further movement of the head and neck. In these situations, immobilize the head and neck in the position they are found or in the position of comfort by using an alternative technique (e.g., blanket, towel roll, manual in-line stabilization).

Cervical Collar Application

A Posterior-First Method

1 While one provider applies in-line stabilization (*not* traction!), slide the posterior portion of the collar behind the patient's neck. Maintain in-line stabilization in the neutral position until the patient is fully immobilized.

2 Bring the front portion of the collar around, under the patient's chin. Ensure that the chin is well supported by the chin piece. Difficulty positioning the chin piece may indicate the need for a shorter collar.

3 Attach the loop Velcro from the posterior portion of the collar to the hook Velcro on the anterior portion. Recheck the position of the patient's head for proper alignment. Tighten the collar as needed until proper support is obtained.

B Anterior-First Method

1 While in-line stabilization is provided, position the chin piece under the patient's chin.

2 Slide the posterior portion of the collar behind the patient's neck.

3 Secure the collar and assess proper placement as described above.

Figure 46.14 Cervical collar application.

Figure 46.15 Horse collar. Most extrication collars are available in three to five factory sizes. If a collar is not sized properly to fit a particular patient, it performs no function. Patients with extremely long necks or especially short ones can be immobilized by means of a horse collar fashioned from a blanket or towel. The blanket (or towel) is rolled to the thickness desired and slid under the patient's neck while a bystander applies manual stabilization; the ends of the blanket (or towel) are then brought across the anterior aspect of the patient's chest. (Courtesy AtlantiCare Regional Medical Center, Emergency Medical Services, Atlantic City, NJ.)

Thoracolumbar Spinal Motion Restriction

Studies have shown that healthy individuals are able to self-extricate from a vehicle with less spinal motion than when extricated by emergency medical technicians.^{59,60} Consequently, ambulatory patients or those who are able to self-extricate without undue pain should have a c-collar applied and be allowed to move themselves to an EMS cot. If used, backboards should be removed as soon as possible and patients should not be unnecessarily placed on rigid boards during interfacility transfer (see [Box 46.1](#)).

Sitting Position

To immobilize patients who require extrication and are found in a sitting position, providers can use a short backboard or commercially available cervical extrication device (e.g., KED) or perform rapid extrication using manual in-line stabilization, a c-collar, and a long spine board.

At least two rescuers should be present to apply an extrication splint to a sitting patient.

Open the device butterfly style and gently slide it behind the victim via a rocking motion ([Fig. 46.16, step 1](#)). If necessary, carefully rock the patient forward a few degrees to facilitate placement of the splint. Once behind the victim, free the splint's pelvic support straps from their retainers and allow them to dangle at the patient's sides. Next, bring the lateral thoracic panels around the chest just beneath the patient's shoulders. Grasp these panels and slide the splint upward until the top edges of the panels firmly engage the patient's axillae. Now use the thoracic straps to secure the splint, beginning with the middle strap, then the bottom strap, and finally the top strap (see [Fig. 46.16, step 2](#)). The straps should be snug, but not so tight that they interfere with respiration.

Fasten the pelvic support straps next. They can be slipped one at a time beneath the patient's lower extremities and brought directly beneath the pelvis with a back-and-forth motion. If the pelvic straps are not applied properly, considerable slippage

may occur when the patient is lifted. Connect the free end of each pelvic strap to buckles located at the patient's hip on the outside of the splint. Once a strap is ready to be buckled, it can be either attached to the buckle on its own side or moved across the patient's lap and engaged with the opposite buckle. Many prehospital care providers prefer the latter method because it allows the patient's knees to remain together without discomfort. It is also a good idea to pad the groin area when placing the pelvic support straps because these straps may cause the patient considerable discomfort.

This procedure may need to be modified for certain injuries and preexisting conditions. For example, patients with pelvic fractures may not tolerate placement of the pelvic support and bottom straps, and the gravid abdomen of a pregnant patient may prevent placement of the middle strap.

Next, secure the head to the device (see [Fig. 46.16, step 3](#)). When using the KED, wrap the head panels snugly around the head and neck while another rescuer applies the diagonal head straps. It may be necessary to place padding behind the head to maintain a neutral position. Use the forehead as a point of engagement for one strap and the c-collar for the other.

As a final step, tighten all buckles until the entire splint is firmly in place. The patient can now be moved. If the patient is to be lifted from a vehicle, bring the ambulance cot (with a spine board if needed to facilitate extrication) as close to the patient as possible (see [Fig. 46.16, step 4](#)). While one rescuer supports the patient's knees, the other rescuer uses the handholds on the splint to lift the patient. The patient should be rotated and laid in a supine position onto a backboard or cot as needed. Loosen the pelvic straps to allow the legs to be lowered onto the backboard. The legs can then be extended and secured or left in the flexed position with a pillow placed under the knees for support.

If needed, apply a lateral immobilizer to help prevent movement of the head and neck and secure the body with straps. Once the patient is on the stretcher, the thoracic straps may need to be readjusted. The device should be removed as soon as possible, with care to avoid unnecessary movement of the spine until significant injuries are ruled out.

Recumbent Position

A patient who is found in a recumbent position should be placed in a supine position, if not already in one. If repositioning is necessary, examine the back during the process. Physical examination, spinal immobilization, airway management, and transport are easier to accomplish with the patient in the supine position.

Patients who are found supine do not require the use of a cervical extrication splint. They should, however, receive initial manual in-line cervical stabilization and a c-collar. The patient can then be secured to a full-body spinal immobilizer, such as a scoop stretcher, backboard, or full-body splint if indicated (see [Box 46.1](#)).

Scoop Stretcher. A patient who is in a supine position can be moved by means of a scoop stretcher. In a conscious patient, rescuers should explain that they are about to apply a scoop-type stretcher beneath the patient's body. Prior to beginning, apply a c-collar and maintain manual in-line cervical stabilization until the patient is completely secured to the stretcher.

Place the scoop on the ground next to the patient and open the latches that regulate its length. Adjust the length to fit the full length of the patient's body and reengage (lock) the latches.

Kendrick Extrication Device (KED)

1 Apply a cervical collar and maintain in-line stabilization throughout the procedure. Gently slide the KED behind the patient; it may be necessary to rock the patient forward a few degrees to facilitate placement of the device.

2 Bring the lateral panels around the chest beneath the patient's shoulders. First secure the thoracic straps (*short arrows*), and then fasten the pelvic support straps (*long arrow*). See text for details.

3 Next, secure the patient's head to the device. Wrap the head panels snugly around the head and neck while another rescuer applies the diagonal head straps (*arrows*).

4 Bring the ambulance stretcher (with a backboard on it) as close to the patient as possible. Rotate the patient out of the vehicle and onto the backboard. Loosen the pelvic straps, and secure the patient to the board.

Figure 46.16 Kendrick Extrication Device. Use of other short boards follows the same principles as depicted here.

Next, release the latches at each end and separate the stretcher into two halves. Place each half next to the patient. One rescuer then gently pushes half the stretcher under one side of the patient. In some cases it may be necessary to have another rescuer rock the patient to allow proper positioning. Repeat the procedure with the opposite half of the scoop until both halves are aligned beneath the patient. Engage the latch at the head of the device first. Then bring the lower ends together and engage the foot latch to complete the integrity of the stretcher. Strap the patient's torso into place and immobilize the head with a suitable lateral neck stabilizer. The patient can then be lifted onto another device for transport, such as a stokes basket or ambulance litter. After placement on another device (e.g., ambulance cot), the scoop stretcher can be removed without disturbing the patient's position.

Full-Body Spine Boards (Backboards). There are several ways of placing a patient onto a spine board. The precise

technique used will depend on the space available and the position of the patient within that space. Apply a c-collar or maintain manual cervical in-line stabilization throughout the procedure and avoid spinal compression or traction. For lengthwise extrication, as from an automobile seat, the patient can be slid, either feet first or head first, onto the backboard. It is important that the patient be moved as a unit during this process. Place one end of the backboard on the seat or doorsill of the automobile. One rescuer stabilizes the opposite end of the board while at least two other rescuers lift and slide the patient's body onto the board. Once the patient is secured to the board, slide the board out of the vehicle and onto a waiting stretcher. The patient should be removed from the long board as soon as possible using the *logroll maneuver* or a lift-and-slide technique described hereafter.

If the patient is in the recumbent position, logroll or slide the patient onto the board. The logroll maneuver requires the presence of at least three rescuers. Position one rescuer at the

Full-Body Spine Board (Backboard): Logroll Maneuver

1 Position one rescuer at the patient's head to apply manual in-line stabilization. This rescuer oversees and directs all body movement throughout the procedure.

2 Position the backboard next to the patient's body. Note that a lateral neck stabilizer has been preapplied to the board.

3 When the rescuer at the patient's head gives the command, roll the patient onto his side, examine the patient's back, and slide the backboard under the patient.

4 Roll the patient back onto the board when the head rescuer gives the command. Center the patient on the board before applying the straps.

5 Strap the patient to the board. Proper strap placement (chest, pelvis, and legs) and firm contact between the straps and the patient are important in limiting lateral motion.

6 Apply a lateral neck stabilizer, like the Ferno Universal Head Immobilizer shown above. Secure it in place using the supplied straps or tape.

Figure 46.17 Full-body spine board (backboard): the logroll maneuver.

patient's head to apply manual in-line cervical stabilization (Fig. 46.17, step 1). It is this person's responsibility to oversee and direct body movement throughout the procedure. Next, position the backboard alongside the patient's body (see Fig. 46.17, step 2). To minimize thoracolumbar movement, extend

the patient's arms at the sides with the palms resting on the lateral aspect of the thighs.⁶¹ To keep the patient from reaching for a rescuer or object during transfer, some rescuers prefer to have patients cross their arms across the thorax. Place the backboard against the injured (more painful) side of the body

so that the patient can be rolled onto the uninjured (less painful) side. Position the other rescuers on the side that the patient will be rolled toward, with one rescuer at the midchest and the other at the legs. The rescuer at the chest should reach across the victim and take hold of the shoulder and hips while the other rescuer grasps the hips and lower part of the legs. When everyone is ready, the rescuer at the head gives the command to roll the patient onto the side (see Fig. 46.17, step 3). If possible, examine the patient's back at this point. Slide the backboard under the patient, and when everyone is ready, the rescuer at the head gives the command to roll the patient back onto the board (see Fig. 46.17, step 4). Before applying straps, it is often necessary to center the patient on the board.

To center the patient on the long spine board, support the cervical spine, shoulders, and hips and slide the patient first caudally, then cephalad, in a zigzag pattern to avoid applying uneven lateral or rotational force onto the spine. Alternatively, during lateral extraction, a recumbent patient can be slid sideways onto the spine board. This improvised technique also requires the presence of three or four rescuers, one of whom can maintain control of the patient's head and neck.

The lift-and-slide technique, sometimes referred to as a six-person lift or bridge lift, is a technique which may reduce the amount of motion at an unstable vertebral segment when compared with the logroll. Del Rossi and coworkers demonstrated this in cadaver studies,⁶² but the difference has never been shown to be clinically relevant and the logroll remains nearly ubiquitous. One disadvantage of this technique is the inability to visually assess the spine during the lift.

To perform the lift-and-slide, rescuers line up opposite each other on both sides of the patient, ideally with at least two rescuers per side. An additional rescuer is located at the patient's head and provides in-line stabilization and coordinates the lift. When all are ready, they place hands underneath the patient in an alternating fashion and lift the patient directly upward a few inches. At this point, another rescuer inserts the carrying device (e.g., backboard, stokes basket, vacuum mattress) and the patient is lowered and secured. For heavier patients, additional rescuers may be needed. Rescuers may place their head on the shoulder of the person across from them to form an arch and reduce the strain on the lower back. In some cases, such as in environments with limited space, standing over the patient and lifting straight upward may be required.

When necessary, various techniques can be used to secure a patient to the backboard. In addition to the standard thoracic, pelvic, and lower extremity straps, use of an abdominal strap may reduce lateral motion without compromising respiration.⁶³ Proper strap placement and firm contact between the straps and the patient are also important in limiting lateral motion (see Fig. 46.17, step 5).⁶⁴ Commercial products such as Spider-Straps are also available or webbing may be used in a zigzag alternating fashion.

After the body has been strapped to the board, the head can be secured. If necessary, padding should be placed under the occiput to maintain the head in the neutral position. Apply a lateral neck stabilizer (e.g., foam blocks, HeadBed device [Laerdal Medical Corp.]) and secure the head in place with tape or straps (see Fig. 46.17, step 6). Most taping techniques involve the use of one piece across the forehead and one piece across the c-collar. Remember, taping across the neck may make airway management difficult. Placing straps across the head and neck may cause hyperextension or axial stretching of the neck. For this reason, omitting the lower strap is recom-

mended. The head should only be secured as tightly as necessary to minimize motion; it should be able to easily slide axially if the torso shifts during transportation. Thus, if the body is not secured to the board, the head should similarly not be fastened to the board.

Standing Position

Traditionally, standing patients were placed on a backboard by positioning the board behind the patient, stabilizing the head, and lowering the patient and the backboard backward until the patient was lying on it. However, there is no evidence that this protects the spine from further injury. Current recommendations are to apply a c-collar and allow ambulatory patients to walk to the stretcher and assist them into supine position on the mattress.²⁰ Nevertheless, there may still be a role for using a backboard or other rigid device placed behind the patient when a stretcher is not available (as in a wilderness or technical rescue environment) and the patient is unable to comfortably lower themselves to a ground-level extrication device, such as a long board or scoop stretcher. In this case the device should be placed behind the patient while at least one rescuer on each side (more may be needed for large patients) grasps the handles underneath the patient's arms and slowly tips the patient and board backward until the board is completely on the ground. There is no need to provide manual head stabilization during this maneuver, but the patient should be reminded to keep his head still.

Pediatric Patients

Little information is available on the proper selection and application of spinal immobilization devices for children. Most of the data available were derived from studies of adults and might not be applicable to children, especially those under 8 years of age. Half the total growth in head circumference is achieved by the age of 18 months, giving children a disproportionately large head in comparison to the rest of the body. Before 8 years of age, these anatomic and developmental differences result in a higher incidence of upper cervical spine injuries (C1–C2). Because injuries in this area are frequently unstable, proper cervical immobilization in the neutral position is critically important.

In the neutral position, the pediatric cervical spine is normally lordotic or extended.⁶⁵ However, because the occiput is large, positioning the child's body on a standard backboard may force the neck into flexion or a relative kyphosis. The clinical significance of this is currently unclear, but theoretically it may be hazardous for young children. Therefore the standard backboard should be modified to adapt to the child's larger head size. As a rough guide, the external auditory meatus should be on the same level as the midpoint of the shoulder. Suggested modifications include a cutout in the backboard that accommodates the occiput or a pad under the back at the level of the chest (see Fig. 46.13). If not modified, the standard backboard in conjunction with the disproportionately large head of a child may force the neck into hyperflexion and potentially aggravate an underlying cervical spine injury. Nypaver and Treloar⁶⁶ showed that all children required elevation of the back (mean height, 25.4 ± 6.7 mm) for correct neutral position on a spine board. Children younger than 4 years required greater elevation than did those 4 years or older. It must be pointed out, however, that there have been no published reports of an SCI resulting from the use of standard

immobilization techniques and equipment in children.⁶⁵ Current guidelines recommend spinal precautions in children under 8 years who have suffered a sufficient mechanism of injury.²⁰

Complication

Cervical Immobilization

Improper application of a c-collar can occur if the wrong size is used or too little care is exercised during placement. The best means of preventing either error is strong clinician involvement in training and continuing education of EMS crews together with vigorous feedback regarding correct and incorrect application. In addition, adherence to the manufacturer's collar-specific recommendations for size and application should be emphasized.

A collar that is too small for a patient may be either too tight for the girth of the neck or too short to provide adequate immobilization. Too large a collar commonly results in hyperextension, which can exacerbate a preexisting spinal injury. Underlying spinal abnormalities from conditions such as ankylosing spondylitis, rheumatoid arthritis, or kyphosis can also contribute to exacerbation of injuries with c-collar application.³²

Improper or prolonged application of an extrication collar may impede venous return and raise ICP.⁶⁷ Although the clinical significance of increased ICP produced by cervical immobilization is still unknown, two studies have confirmed that application of a rigid c-collar causes a statistically significant and sustained rise in ICP.^{68,69} Kolb and colleagues⁶⁸ reported a 24.8-cm H₂O increase in cerebrospinal fluid pressure in 20 adult patients undergoing lumbar puncture. Hunt and associates⁶⁹ reported a 4.6-mm Hg mean rise in ICP in 30 patients with severe traumatic brain injury. The largest rise in ICP was noted in patients with a baseline ICP higher than 15 mm Hg. The authors of these studies concluded that the elevation in ICP produced by cervical immobilization might have deleterious effects in patients with acute or sustained intracranial hypertension.^{68,69}

Long-term use of the Philadelphia extrication collar (Philadelphia Cervical Collar Co., Westville, NJ) as part of the treatment plan for an underlying cervical spine injury has been associated with pressure ulcers of the scalp.⁷⁰ Because some collars (e.g., Philadelphia and Stifneck [Laerdal Medical Corporation]) have been shown to exert higher capillary closing pressure at contact points, it is suggested that only collars with favorable skin pressure patterns and superior patient comfort (e.g., Nec-Loc, Jerome Medical, Moorestown, NJ) be used for long-term application.

One final complication should be mentioned. A patient who, for whatever reason, actively resists placement of a c-collar or other splint should not be forced to wear it (see Fig. 46.3). Postictal and intoxicated patients may present such a dilemma. Immobilization of a combative patient cannot be accomplished without considerable muscular exertion, not only by rescuers, but also by the patient. If fractures do exist, it is possible that struggling and using muscles attached to these fractured fragments may actually cause further injury. If the patient permits manual stabilization, this should be used as an alternative. Sedation should be used judiciously to enhance compliance.

Thoracolumbar Immobilization

In general, complications are more likely to occur from failure to immobilize spinal injuries rather than from the process of

immobilization itself. When complications do arise, they may be related to improper choice or use of equipment or prolonged immobilization.

Victims are generally strapped in place on a spine board to prevent sliding during transport. If too few straps are used or if the straps are loosely applied, motion during transport can occur. Even when applied correctly, spinal immobilization on a hard board may be extremely uncomfortable for patients and may induce pressure-related tissue damage. In one study, 100% of healthy volunteers reported significant pain after only 30 minutes on a long spine board.⁸ Occipital headaches, as well as mandibular, lumbar, and sacral pain, developed in these individuals. Other studies have demonstrated elevated tissue interface pressure in patients on spine boards without air mattress padding.^{9,71,72} These studies underscore the need to use adequate padding when patients require immobilization on a long board, as well as removal from the board as soon as possible.

Excessive strapping can interfere with respiratory function in both children⁷³ and adults.^{53,74,75} In healthy children 6 to 15 years old, forced vital capacity (FVC) has been shown to decrease from 4% to 59% during spinal immobilization.⁷³ Totten and Sugarman⁵³ evaluated the effect of two spinal immobilization methods (wooden backboard and vacuum mattress) on eight respiratory function measurements in healthy volunteers. In comparing baselines for each method, six of the eight measures (FVC, FVC%, forced expiratory volume in 1 second [FEV₁], FEV₁%, peak expiratory flow [PEF], and forced expiratory flow [FEF₂₅₋₇₅%]) were reduced an average of 15%. Although this may not be a problem in healthy volunteers, the effects on patients with chest trauma or preexisting respiratory disease may be significant.⁵³

Patients immobilized on a backboard are also at risk for aspiration if they vomit. If vomiting does occur, logroll the patient and board as a unit and suction the airway as needed. Although this procedure may be associated with some spinal movement, airway protection takes priority.

Conclusion

Although spinal immobilization has not been shown to decrease the likelihood of spinal injury and is associated with a variety of complications, prehospital spinal immobilization remains commonplace. Nevertheless, recent evidence supports a widespread shift to selective spinal immobilization by prehospital providers. Until these new recommendations become universal, emergency medicine practitioners should know when spinal immobilization is indicated, recognize properly and improperly applied devices, minimize unnecessary immobilization time, and work with prehospital providers to ensure appropriate indications and proper use.

EXTREMITY IMMOBILIZATION

Upper Extremity

Background

The earliest evidence of upper extremity splinting comes from the Egyptians circa 300 BC. In 1903 archaeologists from the Hearst expedition discovered two specimens whose open fractures had been treated with wooden splints and bandages. Their bones showed no signs of healing, so the individuals probably died soon after their injuries; however, numerous

other ancient Egyptian specimens have demonstrated evidence of well-healed forearm fractures.⁷⁶

The purpose of splinting is to prevent motion of broken or dislocated bone ends. Carefully applied splints decrease pain while minimizing further damage to muscles, nerves, and blood vessels. Splinting also reduces the risk of converting a closed injury to an open one.⁷⁷ Nevertheless, injuries to adjacent structures may still occur, so circulation, motor function, and sensation distal to the injury must be assessed early and monitored closely during transport.

Over the last 3 decades, prehospital splinting materials, equipment, and techniques have evolved considerably. Today's prehospital providers can choose from a wide assortment of ready-to-use splints made from a variety of sturdy lightweight materials.

Indications and Contraindications

Indications for splinting an extremity are usually clear. Pain after trauma, with or without deformity, should arouse suspicion of underlying bone or joint injury. Other signs include swelling, discoloration, deformity, crepitus, and loss of neurovascular function. However, absence of these findings does not rule out an underlying fracture or dislocation. Thus, in most cases where a musculoskeletal injury is suspected, a splint should be applied and maintained.

There are no absolute contraindications to splinting suspected extremity fractures or dislocations. However, in the setting of multisystem trauma with life-threatening injuries, rapid transport may be more important than extremity splinting. Averting loss of life takes precedence over loss of limb.

Equipment

Various types of splints are currently available for immobilizing upper extremity injuries. Emergency care providers should be well trained and familiar with their equipment. The type of splint used is less important than the expertise of the provider. Upper extremity splints can be divided into two basic types: rigid and soft.⁷⁸

Rigid Splints

Rigid and semirigid splints are the mainstays of EMS fracture care (Fig. 46.18 A–C). These splints are made of many different materials, including cardboard, plastic, aluminum, wire, and wood. They are fastened to the injured extremity with tape, gauze, cravats, or Velcro straps. Rigid splints are generally nonflexible (some commercially available splints may have some flexibility in their design) and, when applied properly, immobilize the limb in a rigid fashion to maintain stability. Although most commercial rigid splints are prepadded, many will still benefit from additional soft padding to cushion the splint and increase comfort. This is particularly true over bony prominences. When applying rigid splints, leave the fingertips exposed so that the distal circulation can be continuously monitored.

Cardboard splints are excellent for long-bone fractures in the upper part of the arm. They can be formed into many shapes and are easy to apply, inexpensive, lightweight, radiolucent, and compatible with magnetic resonance imaging. Splints made from wax-impregnated cardboard are also water resistant. Plastic, aluminum, wire, and wood splints, though less malleable, are also good choices. An inexpensive aluminum splint that is popular with emergency care providers and is found in many wilderness medical kits is the SAM Splint (Sam Medical Products, Portland, OR) (see Fig. 46.18D). The SAM Splint

is built from a thin core of soft aluminum alloy sandwiched between two layers of closed-cell foam. The SAM Splint is extremely pliable. Bent into any of three simple curves, it is extremely strong and provides support for any fractured or injured extremity. In addition, it is water resistant, lightweight, radiolucent, reusable, and not affected by extreme temperatures or altitudes. These characteristics make it an ideal tool for emergency care providers and outdoor enthusiasts.

Vacuum splints (see Fig. 46.18E) are a special type of rigid splint in which the air is evacuated from a closed bag containing tiny foam beads. Flexibility of the splint before removal of the air allows molding of the splint to conform to the patient's position. Removal of the air compresses the contents into a solid mass and results in a rigid splint that encases the extremity, immobilizing it in the position it was found. As a result, vacuum splints in general are more comfortable than other rigid splints. Vacuum splints are radiolucent and do not apply external pressure, thus ensuring maximum circulation to the injured extremity.

Soft Splints

Soft splints include air splints, pillows, slings, and swaths. Depending on the type of injury being treated, immobilization with pillows, slings, or swaths alone may be inadequate because they allow significant motion. Therefore, when treating fractures and dislocations, these splints are most effective when used in conjunction with some form of a rigid device. However, even when used alone, pillows, slings, or swaths provide cushioning and some limitation of motion that may be adequate for less severe injuries such as sprains and contusions. Table 46.1 provides splint recommendations for a variety of upper extremity injuries.

Air splints are soft splints that become rigid when inflated. Besides providing immobilization, they help compress the underlying soft tissue, reducing local hemorrhage. These devices are sensitive to differences in atmospheric pressure and temperature. Therefore their inflation must be closely

TABLE 46.1 Management of Specific Upper Extremity Orthopedic Injuries

SITE	SUGGESTED IMMOBILIZATION TECHNIQUES
Clavicle	Sling and swath
Shoulder	Sling and swath as it lies
Humerus	Cardboard or vacuum splint with a sling and swath
Elbow	Cardboard or vacuum splint as it lies, realign if circulation deficit exists
Forearm	Cardboard, malleable metal, air, or vacuum splint with a sling and swath
Wrist	Pillow, cardboard, malleable metal, or vacuum splint applied in the position found
Hand	Pillow, cardboard, or malleable metal splint in the position of function
Finger	Tongue depressor or small malleable metal splint

GENERAL SPLINTING GUIDELINES:

- Remove unnecessary clothing and visualize the extremity.
- Check neurovascular status before and after splinting.
- Cover open wounds with a dry sterile dressing.
- Immobilize the joint above and below the fracture site.
- Cool and elevate the injured area if possible.
- Frequently reassess neurovascular status and pain.

Figure 46.18 Upper extremity splints. **A–C**, Padded rigid splints. **D**, SAM Splint. **E**, EVAC-U-SPLINT vacuum splint. **F**, Soft towel splint (a pillow can be used in a similar manner). **G**, Sling and swath. (D, Courtesy SAM Medical Products, Portland, OR; E, courtesy Hartwell Medical, Carlsbad, CA.)

monitored to ensure that the underlying tissue is not being subjected to pressure-induced ischemia and the development of a compartment syndrome. One study suggested a maximum splint pressure of 15 mm Hg to reduce the risk for ischemia.⁷⁹ With long ambulance transport times, deflate the splint for 5 minutes every 1.5 hours.

Disadvantages of most air splints include an inability to continuously monitor pulses and susceptibility to puncture. Air splints are designed to conform to a specific shape when inflated and should not be used on angulated fractures. In addition to being radiolucent, some types can be inflated with a refrigerant to provide concurrent cooling.

Pillow splints (see Fig. 46.18F) can be fashioned from any soft bulky material and are excellent choices for hand or wrist injuries. These splints are extremely comfortable and are easily applied.

Slings and swaths are generally used in combination with a rigid or a soft splint. When used alone they can effectively immobilize injuries to the shoulder, clavicle, and humerus (see Fig. 46.18G).

Procedures

To properly apply a splint to an injured extremity, employ the following general guidelines. Communicate with patients to ensure that they understand what is being done at all times. When possible, administer an appropriate analgesic to make splint application less painful. Remove any unnecessary clothing to adequately visualize the injured extremity. Stabilize the fracture site manually to help limit unnecessary movement and prevent further injury. Check the patient's neurovascular status (i.e., pulse, motor function, and sensation) before and after the application of a splint. For a severely angulated extremity with neurovascular compromise, reduce the deformity with gentle longitudinal traction (not exceeding 10 lbs of pressure) before splinting. Make only one attempt at fracture reduction. If resistance or pain is encountered, splint the extremity in the position found. Cover open wounds with a dry sterile dressing before applying the splint. When possible, immobilize the joint above and below a suspected fracture site. Once the splint has been applied, cool and elevate the injured area to help reduce swelling and pain. Assess distal neurovascular status frequently. Any deterioration requires immediate evaluation of the splint to determine whether excessive pressure is being applied. In addition, frequently assess and treat pain.

Rigid Splints

To apply a rigid splint, have an assistant provide support and gentle traction above and below the injury. Apply the splint on the side of the extremity away from any open wounds. The splint should be large enough to immobilize the joint above and below a suspected fracture or the bone above and below a dislocation and should be well padded to reduce the risk for pressure necrosis. Secure the splint to the extremity with gauze, tape, cravats, or Velcro straps (see Fig. 46.18A–C).

Apply vacuum splints in much the same manner as other rigid splints. While an assistant stabilizes the injured site and applies traction, wrap the splint around the extremity and secure it in place with the attached straps. Evacuate the air from the splint with a hand pump until the splint becomes rigid.

Soft Splints

The application procedure for an air splint depends on whether the splint is equipped with a zipper. If the splint does not have

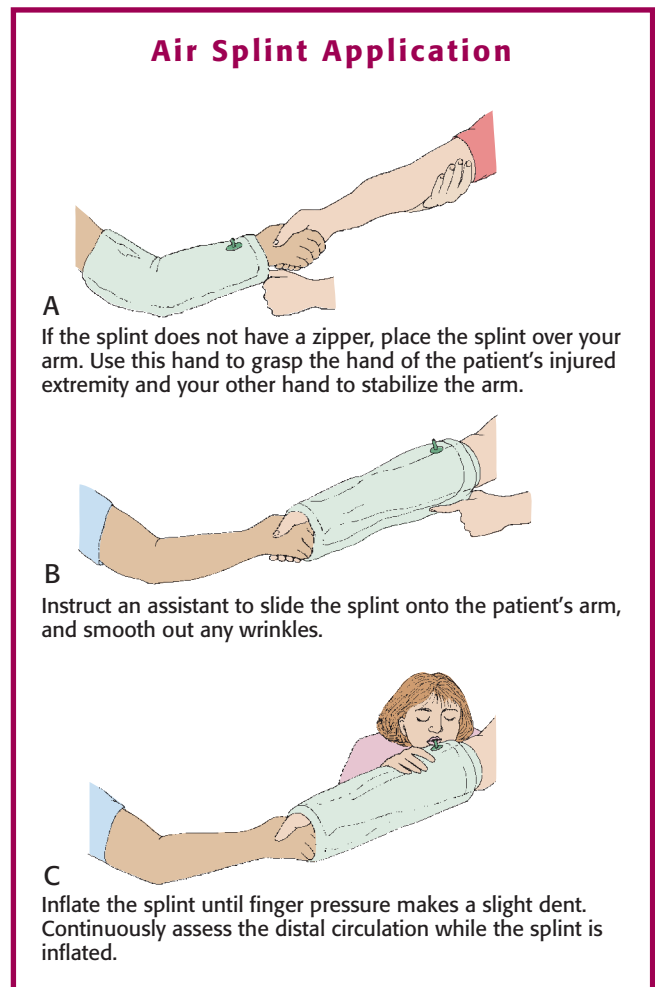

Figure 46.19 Air splint application.

a zipper, first place the splint over the rescuer's arm until the bottom edge lies above the wrist. Use this hand to grasp the hand of the patient's injured extremity and use the free hand to provide support and gentle traction above the injury (Fig. 46.19A). An assistant then slides the splint onto the patient's arm (see Fig. 46.19B). Smooth out any wrinkles and inflate the splint until finger pressure makes a slight indentation (see Fig. 46.19C). Open a zippered air splint and place it around the injured area. Close the zipper and inflate the splint as described previously. With air splints that completely enclose the hand, continuously assess the distal circulation by checking fingertip color, temperature, and capillary refill.

Apply pillow splints by encasing the injury in the pillow and securing it with tape, cravats, or gauze (see Fig. 46.18F). If possible, keep the nail beds exposed to allow frequent neurovascular checks.

To apply a sling, have an assistant support the injured arm in a flexed position across the patient's chest (Fig. 46.20). Place the long edge of the triangular bandage lengthwise along the patient's side opposite the injury with its tip over the uninjured shoulder. Bring the other tip over the injured shoulder to enclose the arm in the sling. Adjust the sling so that the arm rests comfortably with the hand higher than the elbow. Tie the ends of the sling together at the side of the neck and pad the knot for comfort. Finally, wrap the point of the sling

Sling Application

First, place tip *A* over the uninjured shoulder. Next, bring tip *B* over the injured shoulder to enclose the arm. Then, draw tip *C* around the front and secure with a pin.

The completed sling. A swath may be added to provide further immobilization (see Fig. 46.18G).

Figure 46.20 Sling application. Note that the wrist is supported by the sling (*arrow*) as the tendency is to flex the wrist with any upper extremity injury.

at the elbow around the front of the forearm and pin. With the sling properly applied, rest the patient's arm comfortably against the chest with the fingertips exposed.

To apply a swath, place a cravat of sufficient length under the uninjured arm and over the injured arm at the level of the midhumerus. Tie the ends circumferentially around the thorax so that the injured extremity is secured snugly to the chest (see Fig. 46.18G). In adults, two cravats may have to be tied together in an end-to-end fashion to produce a swath of sufficient length.

Complications

Potential complications of upper extremity splinting include pressure necrosis, conversion of a closed injury to an open one, and loss of neurovascular function. With the use of air splints there is the additional risk of pressure-induced tissue ischemia and compartment syndrome.⁷⁹

Conclusion

Injuries to the upper extremities, though not life-threatening, may be limb-threatening and can have significant immediate or long-term effects. Maintain a high index of suspicion for underlying neurovascular injury; check neurovascular status before and after applying a splint and frequently during transport. When possible, administration of appropriate analgesia will be greatly appreciated by the patient.

Lower Extremity

Background

Injuries to the lower extremities, including sprains, fractures, and dislocations, are also commonly encountered by prehospital care providers. As with upper extremity injuries, application of a splint is an essential part of the prehospital management of lower extremity injuries (Fig. 46.21). Many of the principles, techniques, and complications discussed for upper extremity splinting also apply to injuries to the lower extremity; the SAM Splint (Sam Medical Products) (see Fig. 46.18D) and pillow splint (see Fig. 46.18F) are just two examples. Table 46.2 provides recommendations for immobilizing a variety of lower extremity injuries. One fundamental difference between splinting upper and lower extremity injuries is use of a traction splint in the management of femoral fractures. The remainder of this section focuses on the use of traction splints (Video 46.4).

The use of traction and countertraction for alignment and reduction of fractures dates from the time of Hippocrates.⁸¹ In the late 1800s, Sir Hugh Owen Thomas developed the first full-ring traction splint for the definitive management of fractured femurs.^{76,81} However, because the Thomas full-ring splint was difficult to apply on the battlefield, it was later modified by his nephew, Sir Robert Jones, and other surgeons to a half-ring design that made it easier to apply during battle.

Figure 46.21 Prefabricated padded leg splint. Similar to the arm splints described earlier, many prefabricated leg splints are commercially available. Their application and use mirror the general principles of splinting described in Fig. 46.18.

TABLE 46.2 Management of Specific Lower Extremity Orthopedic Injuries

SITE	SUGGESTED IMMOBILIZATION TECHNIQUES
Hip	Secure the injured leg to the uninjured leg, ideally padded between, and/or with a long external splint secured proximally and distally Full body immobilization (backboard, Reeves flexible stretcher [Fisher Scientific, Hampton, NH], scoop stretcher, vacuum mattress, etc.), with the limb padded and secured
Midshaft femur	Traction splint, contralateral leg stabilization, or rigid splint
Knee	Cardboard or vacuum splint in the position found
Tibia/fibula	Cardboard, air, or vacuum splint
Ankle	Pillow, cardboard, or air splint
Foot	Pillow or air splint
Toe	Tape to the adjacent toe

During World War I, the modified splint was credited with reducing the mortality rate associated with fractured femurs from 80% to 15%.⁸¹ Since then, several additional modifications that carry the name of their inventors (e.g., Glenn Hare, Joseph Sager, Allen Klippel) have furthered the development of lower extremity traction splints. Today, traction splints are a nearly universal piece of equipment found on most ambulances, and their application is an integral part of the prehospital care provider's skill set. The main purpose of the traction splint is to immobilize a fractured femur.^{82,83}

In the setting of a fractured femur, muscle spasm and overlap of fragments may cause the thigh to lose its cylindrical shape and adopt a more spherical appearance (Fig. 46.22).⁸¹ The resultant decreased tissue pressure and increased volume may allow 1 to 2 L of blood to accumulate at the fracture site.

Figure 46.22 Femur fracture. Anteroposterior and lateral views of the right femur demonstrate a displaced, angulated, and foreshortened femoral fracture. Such injuries may result in substantial hemorrhage into the thigh, even to the point of hemorrhagic shock.

Figure 46.23 Use of a traction splint helps restore femoral fractures to a more natural anatomic alignment, which may reduce hemorrhage, pain, and damage to surrounding neurovascular structures.

Traction splints are designed to align fracture segments and restore the cylindrical shape of the thigh (Fig. 46.23). This in turn increases tissue pressure, decreases the potential space for blood loss, and inhibits further hemorrhage. In addition, traction splints help reduce pain, prevent further damage to neurovascular structures, and reduce the incidence of fat embolism.^{82,83}

Indications

Application of a lower extremity traction splint is indicated whenever an isolated midshaft femur fracture is suspected.^{78,84,85} Clinical signs of a fractured femur include thigh pain associated with limb shortening, angulation, crepitus, swelling, or ecchymosis.

Contraindications

Do not use traction splints on patients with pelvic fractures, hip injuries with gross displacement, significant injuries involving the knee, or avulsion or amputation of the ankle or foot.⁸⁵ Use of traction splints is not recommended in the presence of an associated distal tibia-fibula or ankle fracture in the same extremity. In these circumstances, the amount of traction required to realign the fractured femur can distract the distal fracture site. A variety of rigid splints may be considered in these settings.

There has been some controversy over whether a traction splint should be applied to an open femoral fracture for fear that the use of traction may allow contaminated bone fragments to retract into the wound. A 2011 update to the International Trauma Life Support guidelines recommends use of traction splints on open femur fractures only in the austere environment or when access to definitive care will be significantly delayed.⁸⁶ When possible, providers should use copious irrigation to remove foreign materials prior to application of the splint. If traction does force contaminated bone fragments into the wound, this information must be relayed to the receiving clinician and antibiotics initiated as soon as possible. In those situations where a traction splint is not applied, a variety of rigid splints can be used to immobilize the bony fragments in the position that they were found. In either case, stabilization of the fracture site to prevent further

hemorrhage, neurovascular damage, or soft tissue injury should take precedence, while making every effort to minimize the risk for increased contamination.

Equipment

Regardless of the type or manufacturer, the basic traction splint consists of a metal frame that extends from the proximal end of the thigh to an area distal to the heel. The padded proximal end fits against the ischial tuberosity and serves as the anatomic fixation point. The proximal portion of the splint may be a ring that encircles the proximal end of the thigh, a partial ring, or a padded bar. At the distal end of the splint there is typically a ratchet-type device that when engaged, creates traction on the distal end of the femur. All traction splints also have several soft elastic straps that support the thigh and leg.⁸⁵

Commonly used traction splints include the Hare Traction Splint (Dyna-Med, Lexington, KY), Kendrick Traction Device (Ferno-Washington, Inc.), Sager Emergency Traction Splint (Minto Research and Development, Redding, CA), and the Ferno-Trac Traction Splint (Ferno-Washington, Inc.) (Fig. 46.24). Each of these splints has its own advantages, disadvantages, and unique method of application. For example, traction splints that use a half-ring design apply countertraction to the ischial tuberosity from below the shaft of the femur. This produces flexion at the hip joint of up to 30 degrees and will not allow complete fracture alignment unless the patient is in a reclining position approximately 30 degrees from horizontal or the injured extremity is elevated to create the same angle. Traction splints that do not use a half ring do not cause hip flexion.

Procedure

Application of the Ferno-Trac Traction Splint (Ferno-Washington, Inc.) and the Sager Emergency Traction Splint

Figure 46.24 Traction splints. A wide variety of devices are commercially available, each with its own advantages, disadvantages, and unique methods of application.

Ferno Traction Splint Application

1 Place the ankle hitch around the posterior of the heel so that the traction strap hangs inferiorly, under the foot.

2 Secure the velcro on the ankle hitch (arrow). Ensure that the D-ring is present. This will be used to receive the hook from the traction device.

3 While one rescuer gently applies traction and lifts the leg, slide the splint under the patient. The ischial pad should be firmly seated against the ischial tuberosity. Secure the ischial strap around the proximal end of the femur.

4 Maintain manual traction on the leg, and attach the traction device hook to the D-ring on the ankle hitch. Turn the traction dial counterclockwise to apply traction. Manual traction should be continued until mechanical traction takes over.

5 Stop applying traction once the leg has resumed its normal length (compare with the uninjured side). Secure the 4 remaining Velcro straps (2 above and 2 below the knee). Repeat a neurovascular examination.

Figure 46.25 Application of the Ferno Traction Splint. Note that the splint should be adjusted so that it is 12 inches longer than the uninjured leg before application. (Reproduced and modified with permission from Ferno-Washington, Inc., Wilmington, OH.)

(Minto Research and Development) is illustrated in [Figs. 46.25](#) and [46.26](#), respectively.

When possible, explain the procedure to the patient. Pain is always associated with the application of a traction splint, so make every effort to provide appropriate analgesia (e.g., parenteral opiates) before application of the splint. In addition, reassure the patient that, although the initial application of traction is often quite painful, stabilization of the fracture site will help reduce subsequent discomfort. Expose the injured area and remove the patient's shoe and sock to assess distal neurovascular status before and after splint application. Manage open fractures as discussed previously. If the injured leg is markedly deformed, an assistant should first attempt to straighten it with manual traction and maintain that position until a splint has been applied. The amount of traction necessary to straighten a badly deformed extremity will vary, but rarely exceeds 15 lbs of force. If the patient strongly resists while traction is being applied, stop the procedure and splint the injured extremity in the position in which it was found.

If the splint has an adjustable bar, determine the appropriate length by measuring the uninjured leg. The splint should extend

approximately 6 inches (15 cm) beyond the ankle. With the extremity slightly elevated, place the traction splint (e.g., Ferno-Trac Traction Splint [Ferno-Washington, Inc.]) under the injured leg and rest it firmly against the ischial tuberosity. To ensure that the injured extremity will remain elevated once manual traction has been released, unfold the heel stand and lock it into place. Place the Sager Emergency Traction Splint (Minto Research and Development) between the legs and against the ischial tuberosity, carefully avoiding or protecting the genitalia. Secure only the most proximal ischial strap at this point.

Next, place the ankle harness immediately above the medial and lateral malleoli and attach it to the distal end of the traction splint. Ferno-Trac (Ferno-Washington, Inc.) and other similar traction splints use a ratchet mechanism to apply constant (static) traction on the ankle strap. For dynamic quantifiable splints such as Sager-type devices, gently extend the inner shaft of the splint until the desired amount of traction is achieved, either by comparing leg length or using the quantitative scale to set the desired force. Both static and dynamic traction mechanisms may lose traction as muscle spasm decreases

Sager Traction Splint Application

1

Prior to application of the splint, get a rough measure of the length of splint needed. Extend the splint so that the wheel is at the heel.

2

Grasp the Kydex buckle and slide the thigh strap up under the leg so that the perineal cushion is snug against the perineum and ischial tuberosity.

3

Tighten the Kydex buckle thigh strap to draw the perineal-ischial pad to the lateral portion of the crotch.

4

Apply the ankle harness tightly around the ankle above the medial and lateral malleoli of the ankle. Check the posterior tibial and dorsalis pedis pulses before hitch application and after traction is established.

5

Shorten the loop of the harness connected to the cable ring by pulling on the strap threaded through the square "D" buckle.

6

Extend the inner shaft of the splint by opening the shaft lock and pulling the inner shaft out until the desired amount of traction is noted on the calibrated wheel. As a rough guide to determine the amount of traction needed, apply 10% of body weight to a maximum of 22- to 25-lb (10- to 25-kg) traction.

7

Apply the longest 6-inch wide thigh strap as high up the thigh as possible.

8

Apply the second longest thigh strap around the knee. Use padding as needed. Next, apply the shortest 6-inch wide strap over the ankle harness and lower the leg.

9

Apply figure-eight strap around both ankles. The patient's leg is now secured, traction is controlled, medial and lateral shift of the distal fragment and internal and external rotation is prevented.

Figure 46.26 Application of the Sager traction splint. Note that the splint can alternatively be strapped to the outer portion of the leg. In addition, it is possible to splint both legs with a single splint.

and leg length increases, requiring reevaluation and possible adjustment.^{81,87,88} Regardless of which splint is being used, apply traction gradually to approximately 10% of body weight or a maximum of 7 kg (15 lb) (15 kg [30 lb] for bilateral fractures). Only rarely will more traction be required.^{84,85} The goal is to stabilize the fracture and maintain proper limb alignment. Use the least amount of force necessary to accomplish this task.⁸⁹

Before moving the patient, place supportive straps around the thigh, knee, and distal end of the leg to stabilize the extremity. After application of the splint, be sure to recheck distal neurovascular status and then secure the patient and splint firmly to the ambulance stretcher. Take extra care while moving the patient and when closing any transport vehicle door to avoid unnecessary movement and further injury. If the splint extends beyond the dimensions of the stretcher, additional support for the splint may be needed (e.g., short spine board or cardiopulmonary resuscitation board) to ensure that the injured extremity remains elevated throughout transport. Loss of pulses with application of a traction splint requires that the position of straps and the amount of traction be reassessed immediately. It is also important to recheck the position of the splint and the patient's neurovascular status after moving the patient. Finally, remove the traction splint in reverse order of application.

Special Considerations

The Sager Models S304 (Form III Bilateral) and SX404 (Extreme Bilateral) (Minto Research and Development) offer a unique advantage in confined spaces in that they can be used to immobilize both legs simultaneously with only one splint. In addition, neither splint extends beyond the patient's heels, thus making them more versatile for use in helicopters, fixed-wing aircraft, and smaller van-type ambulances.

Complications

Complications are generally the result of incorrect application and include pain, ongoing hemorrhage, peroneal nerve injury, perineal injury, movement at the fracture site, ligamentous injury, injury to unrecognized fractures elsewhere, or further neurovascular compromise.

Conclusion

When properly applied, traction splints reduce the pain, hemorrhage, and potential injury to adjacent structures that are associated with femoral fractures. Close attention to the manufacturer's application instructions and frequent patient reassessment will help reduce complications.

PELVIC IMMOBILIZATION

Background

Pelvic fractures cause significant morbidity and mortality, especially in the elderly. The decreased bone density in older individuals contributes to the likelihood of sustaining pelvic fractures from low- to moderate-energy mechanisms, such as falls from a standing height. The findings on physical examination may be subtle, such as slight asymmetry of the lower extremities, so a high index of suspicion is important. In younger individuals, pelvic injuries are usually caused by high-energy mechanisms, most commonly motor vehicle collisions.⁹⁰ Major

Figure 46.27 Traumatic internal hemipelvectomy. Major pelvic trauma such as this can lead to uncontrollable hemorrhage and hypovolemic shock. Early stabilization and immediate transport are mandatory. (From Asensio JA, Trunkey DD, editors: *Current therapy of trauma and surgical critical care*, St. Louis, 2008, Mosby.)

pelvic trauma can lead to severe, uncontrollable hemorrhage, hypovolemic shock, and multisystem organ failure (Fig. 46.27).⁹¹

In the prehospital setting, early stabilization of fracture segments to control hemorrhage, gentle handling, and immediate transport to a trauma center are the cornerstones of treatment.⁹² However, even the most experienced prehospital provider may find it difficult to identify pelvic injuries in the field (the exception being an open-book fracture). Hence, prehospital providers should not hesitate to stabilize the pelvis if a fracture is suspected.

Indications and Contraindications

Apply a pelvic circumferential compression device to any patient with significant pelvic pain, tenderness, or evidence of pelvic instability after trauma, especially if the patient is hypotensive.^{93,94} There are no contraindications to pelvic stabilization in patients with presumed pelvic fractures.

Procedure

Stabilization of the pelvis consists primarily of compressing the bony ring. This can be accomplished using a variety of devices, including a simple sheet, commercially available pelvic circumferential compression devices (also known as *pelvic binders*) such as the SAM Sling (SAM Medical Products), the T-POD Pelvic Stabilization Device (Pyng Medical Corp., Richmond, British Columbia, Canada), vacuum “beanbag” mattress splints, and pneumatic antishock garments (PASGs) (Fig. 46.28). With the advent of commercial pelvic binders, use of a PASG for pelvic fracture stabilization is no longer recommended.^{95,96} When using any pelvic stabilizing device remember that aggressively moving patients or aggressively palpating or rocking the injured pelvis can precipitate further vascular injury or clot disruption and lead to life-threatening hemorrhage.

To apply a sheet, place it over a long spine board and then gently logroll the patient by no more than 15 degrees into position on the board.⁹³ Alternatively, slide the sheet under the patient by passing it below the lumbar or thigh area and gently maneuvering it into position. In some cases it may be desirable to lift the patient using a scoop stretcher and then

Figure 46.28 The SAM Sling may be used to stabilize a fractured pelvis. (Courtesy SAM Medical Products, Portland, OR.)

Figure 46.29 Pelvic stabilization using a sheet. Note that the sheet is wrapped firmly around the greater trochanters and tied to compress the bony pelvis.

slide the sheet beneath the patient. Regardless of which method is used, wrap the sheet around the greater trochanters and tie the ends into a knot to compress the bony pelvis (Fig. 46.29). Pelvic binders are designed for quick and easy application in the field or ED. They are easy to maintain, reusable, and sized to fit 95% of the adult population. The pelvic binder acts similar to a bed sheet and, when placed properly over the area of the greater trochanters, provides a safe and effective force to stabilize pelvic fractures.^{97,98} Application of one such device,

the SAM Sling (SAM Medical Products), is illustrated in Fig. 46.30.

Complications

Application of any pelvic compression device can damage the underlying soft tissue, as well as organs enclosed within the bony pelvis, including the bladder, urethra, and vagina.⁹⁹ However, the potential benefits of pelvic stabilization far outweigh these rare potential complications and should not discourage one from applying a pelvic stabilization device.⁹⁹

Conclusion

Pelvic fractures can be quickly and easily stabilized with a sheet or commercially available pelvic circumferential compression device. Early recognition and stabilization of pelvic injuries, gentle manipulation of the patient, and rapid transport will help reduce morbidity and mortality.

REMOVAL OF HELMETS AND PROTECTIVE EQUIPMENT

Background

Though originally developed for protection of the head during combat, helmets are commonly worn by motorcyclists, athletes (e.g., football, hockey, lacrosse, motor sports), and individuals participating in a host of recreational activities (e.g., cycling, skiing, snowboarding, in-line skating, skateboarding). Emergency care providers must therefore be equipped and trained to remove a helmet safely.

The majority of modern sports helmets consist of a hard polycarbonate shell lined with foam padding, adjustable air cells, or both. Density, strength, and rigidity vary depending on the type of impact that the helmet is designed to protect against (Fig. 46.31). Many helmets are considered multisport and meet the requirements for several potential mechanisms of injury and varying degrees of impact.¹⁰⁰

Many helmets are modified with additional padding so that they conform tightly to the individual's head. In addition, helmets used in contact sports (e.g., football, hockey, lacrosse) typically have some type of face mask secured to the front of

SAM Sling Application

Remove objects from the patient's pockets or pelvic area. Unfold the SAM Pelvic Sling with the nonprinted side facing up. Keep the strap attached to the buckle.

Place the nonprinted side of the SAM Pelvic Sling beneath the patient at the level of the buttocks (greater trochanters).

Wrap the nonbuckle side of the SAM Pelvic Sling around the patient.

FIRMLY WRAP the buckle side of the sling around the patient and position the buckle in the midline. Secure by pressing the flap to the sling.

Lift the black strap away from the sling by pulling upward.

With or without assistance, firmly pull the orange and black straps in opposite directions until you hear and feel the buckle click. **MAINTAIN TENSION!**

IMMEDIATELY press the black strap onto the surface of the SAM Pelvic Sling to secure it.
Note: Do not be concerned if you hear a second "click" after the sling is secured.

To remove it, lift the black strap by pulling upward. Maintain tension and slowly allow the SAM Pelvic Sling to loosen.

Figure 46.30 Application of the SAM Sling. (Courtesy SAM Medical Products, Portland, OR.)

Figure 46.31 Types of helmets.

the helmet to provide additional protection for the athlete's eyes and face. These athletes also use a variety of additional pads that may complicate or hinder helmet removal, such as shoulder pads and neck orthoses. Shoulder pad configuration varies from sport to sport and even from player to player. Cervical orthoses limit neck motion when paired with helmets and shoulder pads and protect against spinal and brachial plexus injuries. Commonly used cervical orthoses include neck rolls, cowboy collars, and butterfly restrictors.

Motorcycle helmets may or may not have a full face guard, but in either case they have been shown to reduce the incidence of severe head injury and death and are associated with shorter hospital stays and reduced hospital cost.^{101–103} Although early studies suggested that the use of motorcycle helmets might be associated with an increased incidence of cervical spine injuries,^{104,105} this concern has not been substantiated.^{106–108}

Early research in the area of helmet removal focused primarily on the removal of motorcycle helmets. More recently, the spotlight has turned to football helmet removal because football players commonly sustain head and neck trauma, and their care is frequently complicated by the presence of additional protective equipment.¹⁰⁹ The proper management of a helmeted, spine-injured athlete has prompted much debate and disagreement among various health care professionals. In 1998, the National Athletic Trainers' Association formed the Inter-Association Task Force for the Appropriate Care of the Spine-Injured Athlete, which in 2001 released its first comprehensive set of guidelines and recommendations titled *Prehospital Care of the Spine-Injured Athlete*.¹¹⁰ This consensus document was updated in 2009 and recommended transportation with the helmet and shoulder pads in place for the majority of athletes, to be removed at the hospital following spinal imaging. It did allow for removal of helmet and shoulder pads in limited circumstances where immobilization was inadequate or access to airway was compromised.¹¹¹ These guidelines were widely adopted but remained controversial because of the difficulties in accessing the airway, neck and chest, the degradation of imaging quality, and the lack of experience of hospital personnel with removing equipment. New guidelines are in development at the time of publication, but the executive summary for the 2015 revision notes allows for removal prior to transport to mitigate these issues.^{111a}

Helmet removal requires a careful, methodical approach to avoid compounding a possible injury to the spinal cord.^{112,113} Fluoroscopic studies have detected spinal motion even in the best of circumstances when removing hockey and football helmets.^{112–114} As with all trauma victims, the initial management of an injured athlete is to address the ABCs (airway, breathing,

circulation). However, it is important to note that a properly fitting sports helmet holds the head securely in the neutral position, provided the athlete is also wearing shoulder pads. In this case, removing the face mask but leaving the helmet and shoulder pads in place may allow adequate airway control while maintaining proper alignment of the cervical spine and reduce the risk for further injury.^{109,115} Generally, removal of helmet and pads as a unit in the field is reasonable provided that several providers are available and have sufficient experience in the technique.^{111a}

Motorcycle and motor sport helmets do not usually have a removable face mask, do not always fit properly, and are worn without shoulder pads. Thus motorcycle and motor sport helmets should be removed routinely to properly restrict motion of the spine.¹⁰⁹

Indications

In general, in a highly functioning EMS system, there are few downsides to removal of helmet and shoulder pads (if present) at the scene. This equipment needs to be removed eventually, and hospital staff are nearly always less experienced and practiced than trainers and prehospital personnel.

If the athlete's helmet is not removed, maintain cervical spine immobilization using tape, commercially available foam blocks, and a lifting device designed to maintain spinal motion restriction. Do not remove the helmet or shoulder pads (if present) individually: either remove both or neither, to avoid hyperextension of the cervical spine.^{109,111,112} If in doubt regarding the need for removal of a sport helmet, the National Athletic Trainers' Association suggests remembering two overarching principles: (1) exposure and access to vital life functions (e.g., airway, chest for cardiopulmonary resuscitation or use of an automated external defibrillator) must be established or easily achieved in a reasonable and acceptable manner, and (2) neutral alignment of the cervical spine should be maintained while allowing as little motion of the head and neck as possible.¹¹¹

The potential for helmets to interfere with plain films of the spine was demonstrated in two studies,^{116,117} though nonmetallic helmets were less likely to interfere with computed tomography.¹¹⁸ Thus removal prior to imaging may be indicated depending on the imaging mode available or desired.

Motorcycle and motor sport helmets should be removed in the prehospital setting.⁷⁸ Motorcycle helmets with a full face guard make it very difficult to assess and manage the airway and to evaluate injuries to the head and neck. The helmet's large size and design may cause significant neck flexion if left in place. While decreasing the likelihood of injury, the

Figure 46.32 A, The HANS device. B, The SHR Flex device. (Courtesy HANS Performance Products, Atlanta, GA; B, Courtesy SCH Roth Racing, Mooresville, NC. <https://www.schrothracing.com>.)

increasing use of head and neck restraint devices (e.g., the HANS device [Fig. 46.32A] and the SHR Flex device [Fig. 46.32B]) in professional motor sports has further complicated cervical spine management and helmet removal.

Contraindications

The only absolute contraindications to helmet removal are neck pain or paresthesias associated with the procedure or an inability to remove the helmet because of an impaled object (e.g., deer antler through a motorcycle helmet).^{119,120} Relative contraindications to helmet removal include unfamiliarity with the technique and lack of sufficient assistance.^{121,122}

Procedure

Sport Helmet Removal

When a face mask is present, if not immediately removing the helmet, remove the mask at the earliest opportunity, before transportation and despite the absence of any respiratory complaints.^{110,111,121,123} A variety of tools (e.g., FM Extractor [Collins Surgical, Brockton, MA], Trainer's Angel [Trainer's Angel, Riverside, CA], anvil pruner, polyvinyl chloride pipe cutter, or power screwdriver) and techniques are used for face mask removal.¹¹³ All emergency care providers should have tools for face mask removal readily available and be familiar with their use. The choice of equipment is less important than the skill and experience of the personnel using it.¹²⁴ To remove the face mask of a football helmet, cut the four plastic loop straps that secure the face mask to the helmet. Remove hockey and lacrosse face masks by unscrewing the external screws holding them in place. Maintain in-line stabilization to keep the head and neck in the neutral position during the entire procedure. With practice, the face mask of any helmet can be

quickly and safely removed with minimal movement of the cervical spine.¹¹⁵

The National Athletic Trainers' Association protocol for helmet and shoulder pad removal discussed in this chapter has been shown to effectively limit motion of the cervical spine during removal of equipment.¹²⁵ Proper removal of a helmet and shoulder pads requires at least two (and preferably three or four) individuals, one of whom maintains manual in-line stabilization of the cervical spine throughout the procedure.^{101,121,126}

One rescuer manually stabilizes the head and neck in the neutral position by placing his or her hands on each side of the helmet with the thumbs pointing up (Fig. 46.33, step 1). A second rescuer then removes the chin strap by cutting or unsnapping it (see Fig. 46.33, step 2). Next, this rescuer removes the left or right cheek and jaw pads from the helmet by first slipping the flat blade of a screwdriver or bandage scissors between the pad snaps and the helmet's inner surface and twisting slightly. Once separated from the helmet, remove the pads by sliding them out firmly and slowly. Remove the opposite side in the same manner. Note that some helmet models (e.g., Riddell Revolution [Riddell, Rosemont, IL]) are padded with a number of air-filled bladders that must be deflated (rather than removed) before removal of the helmet (Fig. 46.34).¹²⁷ In this case, the second rescuer deflates the air inflation system by releasing the air at the external ports with the inflation needle that comes with the helmet. Alternatively, an 18-gauge needle or air pump needle may be tried. If an inflation needle is not available (or an 18-gauge needle or air pump needle does not work), directly puncture the bladders with an 18-gauge needle.

The second rescuer then takes over in-line immobilization of the head by using one hand to grasp the patient's mandible between the thumb and the first two fingers while placing the

Football Helmet and Shoulder Pad Removal

1 One rescuer manually stabilizes the patient's head and neck in the neutral position by placing his or her hands on each side of the helmet, with the thumbs pointing up.

2 A second rescuer then removes the chin strap by cutting or unsnapping it.

3 The second rescuer then takes over in-line immobilization of the head by using one hand to grasp the patient's mandible between the thumb and the first two fingers while placing the other hand under the occiput.

4 The first rescuer then places a thumb inside each ear hole of the helmet and curls his or her fingers along the bottom edge of the helmet. Without pulling laterally, the helmet is removed by gently rotating it off the head.

5 The shoulder pads are removed by cutting the straps underneath the arms and the anterior straps holding the pads together.

6 The hands of the second rescuer stabilize the head as the shoulder pads are removed. When possible, the helmet (with the face mask removed) and shoulder pads should remain in place until the initial clinical and radiographic evaluation is completed in the ED.

Figure 46.33 Football helmet and shoulder pad removal. Proper removal of a helmet and shoulder pads requires at least two rescuers. (Note: this figure does not demonstrate removal of the face mask and cheek/jaw pads, which is recommended before helmet removal. See text for details.) ED, Emergency department. (Courtesy AtlantiCare Regional Medical Center, Emergency Medical Services, Atlantic City, NJ.)

other hand under the occiput (see Fig. 46.33, step 3). The first rescuer then places a thumb inside each ear hole of the helmet and curls his or her fingers along the bottom edge of the helmet (see Fig. 46.33, step 4). At this point some experts recommend easing the helmet off by pulling laterally and longitudinally in line with the head and neck.¹²⁶ However, this maneuver may actually tighten the helmet at the occiput and

the forehead.¹²⁸ The Inter-Association Task Force recommends rotating the helmet off the head in a gentle fashion without pulling laterally.¹²³ Remove shoulder pads by cutting the straps underneath the arms and the anterior straps holding the pads together (see Fig. 46.33, step 5). If a cervical orthosis (e.g., neck roll, cowboy collar, or butterfly restrictor) is present, disconnect it from the helmet and shoulder pads before removal.

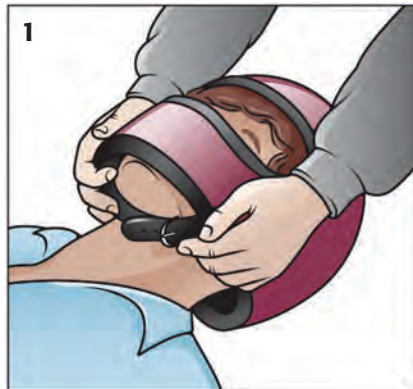

Figure 46.34 Riddell Revolution football helmet. These helmets are padded with a number of air-filled bladders that must be deflated (rather than removed) before removal of the helmet. **A**, Frontal view. **B**, Inside view. See text for details. (Courtesy Riddell, Elyria, OH.)

Motorcycle Helmet Removal

1 One rescuer maintains in-line immobilization by placing his or her hands on each side, of the helmet with the fingers on the victim's mandible. This position prevents slippage if the strap is loose.

2 A second rescuer cuts or loosens the strap at the D-ring.

3 The second rescuer places one hand on the mandible at the angle, the thumb on one side and the long and index fingers on the other. With the other hand the rescuer applies pressure from the occipital region. This maneuver transfers the in-line immobilization responsibility to the second rescuer.

4 The rescuer at the top moves the helmet. Three factors should be kept in mind:

- The helmet is egg-shaped and therefore must be expanded laterally to clear the ears.
- If the helmet provides full facial coverage, glasses must be removed first.
- If the helmet provides full facial coverage, the nose may impede removal. To clear the nose, the helmet must be tilted backward and raised over it.

5 Throughout the removal process the second rescuer maintains in-line immobilization from below to prevent unnecessary neck motion.

6 After the helmet has been removed, the rescuer at the top replaces his or her hands on either side of the victim's head with the palms over the ears.

Figure 46.35 Motorcycle helmet removal. (Reproduced with permission from Norman E. McSwain, Jr., MD, FACS, and Richard L. Garnelli, MD, FACS—American College of Surgeons Committee on Trauma, April 1997.)

Figure 46.36 The Eject Helmet Removal System. This device uses a small air bladder that is neatly folded in an accordion fashion and placed underneath the helmet liner. A small tube runs under the padding and fastens to the bottom of the rim of the helmet to provide easy access. The device may be prefitted into the rider's helmet or inserted at the time of removal by using an insertion tool that allows the airbag to be slid up inside the top of a helmet. (Courtesy Shock Doctor, Minneapolis, MN. <http://www.ejectsafety.com>.)

When possible, remove the shoulder pads and helmet simultaneously to prevent the head from falling into extension. If the shoulder pads cannot be removed simultaneously, manually stabilize the head in the neutral position during the procedure. The hands of the second rescuer can be moved superiorly as the helmet is being removed so that the thumb and first fingers grasp the maxilla at each side of the nose in the maxillary notch (see Fig. 46.33, step 6).

After removal of the helmet, place a c-collar while maintaining in-line stabilization. Remember that if the helmet cannot be removed and access to the chest area is required, remove the anterior half of the shoulder pads and leave the posterior portion to maintain cervical position with the helmet in place.

Motorcycle Helmet Removal

For the reasons described earlier, motorcycle helmets should be removed in the prehospital setting. The removal method endorsed by the American College of Surgeons in 1997 is the method most often used today (Fig. 46.35).¹²⁹ Providers should be aware that significant cervical motion can occur during removal of a motorcycle helmet if the shoulders are not properly elevated; a folded sheet or jacket placed behind the patient's shoulders may help limit any cervical motion associated with the procedure.¹³⁰

If attempts to remove the helmet result in pain or paresthesias, the advanced trauma life support guidelines recommend removing the helmet via a technique described by Aprahamian and coworkers.¹³¹ This technique uses a cast saw to bivalve the helmet in the coronal plane. Following division of the outer rigid shell, incise the inner foam material and remove it while maintaining the head and neck in neutral alignment. Although this approach does provide an alternative method of removing the helmet, the intense vibrations produced during use of the cast cutter may exacerbate an underlying spinal injury. In addition, this technique may be slow and difficult with modern, well-fitting, high-quality helmets.^{121,132,133}

The preferred method of helmet removal in organized motor sports is the Eject Helmet Removal System (formerly the Hats Off System), which consists of an inflatable air bladder that can be placed into the helmet before use or introduced into the crown of the helmet with a specially designed insertion tool. When inflated with a hand pump or CO₂ cartridge, it

purportedly loosens the helmet to allow easy removal (Fig. 46.36).¹³² Despite little scientific data supporting its use, the Indycar Racing League, American Speed Association, and American Motorcycle Association have made the Eject Helmet Removal System mandatory at all of their events. In addition, the Championship Auto Racing Teams and National Association for Stock Car Auto Racing strongly recommend its use.

Complications

It is theorized that underlying cervical spine injuries may be exacerbated by failure to adhere to proper helmet removal techniques, though clinical data is lacking.¹¹³ In a cadaveric model, Donaldson and colleagues¹³³ demonstrated that even when using proper technique, there is a significant amount of motion during removal of helmets and shoulder pads. Larger studies are needed to determine whether there is a real and significant risk in the clinical setting.

Conclusion

Prehospital care providers must take caution when evaluating and treating an athlete with a suspected head and neck injury. In general, athletic helmets and shoulder pads should be removed at the scene when adequate trained personnel are available, though it is reasonable to transport without removal when equipment is maintaining the spine in neutral alignment, and when there are no other emergency conditions that require their removal. Face masks, however, should be removed early in the management of these patients. Motorcycle and motor sport helmets, as well as sports and other helmets worn without shoulder pads, should be removed routinely to provide access to the patient's airway and allow proper spinal motion restriction. When indicated, prehospital helmet removal can be accomplished in a safe and effective manner by well-trained prehospital care providers.

The primary concern of removing helmets and protective padding is causing additional injury to the patient. It may also prolong on-scene time and delay transport to the hospital.

Management of Amputations

Emily Rose

Rapid and appropriate emergency care of a patient with an amputated body part is crucial to the salvage and preservation of function. This chapter discusses the emergency management priorities of patients with amputation injuries, the acute care of amputated parts before they are replanted, and the management of distal digit amputations and dermal “slice” wounds.

Amputation may be partial or complete. Injuries with any interconnecting tissue between the distal and proximal portions, even if it is only a small piece of bridging skin, are considered incomplete (or partial) amputations. The peak incidence of traumatic amputations occurs between the ages of 15 and 40 years and approximately 80% of injuries occur in males. Motor vehicle collisions are the leading mechanism of injury, followed by industrial and agricultural accidents. Local crush injuries occur most commonly, and sharp guillotine amputations are least common. Partial amputations occur as often as total amputations. Seventy percent of amputations overall occur in the upper extremity and distal amputations are more common than proximal.¹

Successful revascularization of amputated parts may ensure viability, but neurologic, osseous, and tendinous healing are critical for ultimate function. If there is incomplete neurologic recovery, limited range of motion, and intolerance to cold, the replanted part may have little functional value for the patient. Rehabilitation from replantation surgery may be prolonged, (often >1 year) and frequently repeat surgical procedures are required. A patient’s preconceived perceptions of medical ability to save an amputated part and well-intentioned promises made by a transferring physician may set up unrealistic expectations for replantation. The emergency clinician should be aware of the limitations of replantation surgery and should not encourage unrealistic expectations in injured patients or their families.

BACKGROUND

Replantation attempts (with rare success) have been described for hundreds of years but the ability to consistently replant amputated parts is now possible with advances in microvascular surgical techniques. Upper limb and hand replants were first described in 1962. The first successful microvascular anastomosis of a digital vessel was described in 1965, and now replantation success rates range from 50% to 90%.^{2,3} Survival of the replanted tissue was the criterion for success for the original pioneers in replant surgery, but with further technological and surgical refinements, today’s surgeons emphasize functional recovery as well as viability. Replantation of a part that is painful or useless or that interferes with function is a disservice to the patient and is less desirable than early restoration of function

Management of Amputations

Indications

- Young stable patient
- Thumb
- Multiple digits injured
- Sharp wounds with little associated damage
- Upper extremity (children)

Contraindications

Absolute

- Associated life threats
- Severe crush injuries
- Inability to withstand prolonged surgery

Relative^a

- Single digit, unless thumb
- Avulsion injury
- Prolonged warm ischemia (>12 hr)
- Gross contamination
- Prior injury or surgery to part
- Emotionally unstable patient
- Lower extremity

Complications

- Infection
- Poor function

Equipment

Review Box 47.1 Management of amputations: indications for reimplantation, contraindications, complications, and equipment. ^aIf the victim is a child or if there are multiple losses, salvage reimplantations are attempted and the relative contraindications are ignored.

without replantation. With advancements in technology, there are also alternatives to replantation such as targeted reinnervation, transplantation of composite tissue, or the potential for upper extremity transplantation to restore upper extremity function.⁴ The operative plan must be tailored to each individual patient with consideration of the patient's underlying health, ability to undergo and comply with rehabilitation, support network, and likely functional outcome.

INDICATIONS

The mechanism of injury is the most important determinant of implant survival. Replantation is more likely to occur with sharp/penetrating injury, distal level of amputation, lack of multilevel involvement, and when the injury is isolated to the extremity.² Preservation of the amputated part is indicated whenever there is a potential for replantation. Revascularization and reanastomosis of partially and completely amputated parts should be provided when there is hope of preservation or restoration of function. Aesthetic considerations, patient avocations, and occasionally the patient's religious or social customs may also influence the decision to proceed with surgery. Ultimately, the microsurgical team and patient must reach the decision together after a rational explanation of the potential results.

Replantation is more commonly performed for upper extremity amputation because a lower extremity prosthesis often provides a good functional outcome and is often superior to outcomes with replantation. Upper extremity prostheses are less able to achieve fine motor activity and a "bad hand" may be more functional than a "good amputation" in the upper extremity.⁵ Additionally, there is less muscle (which is less vulnerable to crush injury and allows a longer ischemia time) and increased collateral circulation in the upper extremity, which improves replantation success.⁵ **Review Box 47.1** summarizes the general indications for replantation. Single-digit amputations that are both proximal to the distal interphalangeal (DIP) joint and distal to the flexor digitorum superficialis may be replanted successfully with good functional recovery (**Fig. 47.1**). The thumb accounts for 40% to 50% of hand function with its utility in pinch and grip. Even if a replanted thumb has a limited range of motion, it is more functional than any other available reconstructive procedure or prosthetic device.⁶ The underlying health of the patient is more important to outcomes than chronologic age. Children consistently have better outcomes due to their superior neuroplasticity, regenerative capacity, and adaptability to rehabilitation,⁷⁻¹⁰ though there are no fixed age limits for replantation. The decision to replant is made on a case-by-case basis by the microsurgical team, who must weigh all the factors involved. In general, patients can expect to achieve 50% of original sensation and motor function of the replanted part, with younger patients and more distal amputations having the best outcomes.⁷

CONTRAINDICATIONS

Absolute contraindications to replantation include life-threatening injury or significant comorbidity that prohibits a lengthy operation.⁷ Relative contraindications include severely crushed or mangled parts or profuse contamination. Contraindications to replantation are listed in **Review Box 47.1** and

Figure 47.1 A and B, Single-digit amputations are not usually replanted unless the thumb is involved. This sharp amputation with little associated damage in a 20-year-old may qualify, but it is best to discuss this with the hand surgery team before giving unrealistic expectations to the patient, who may anticipate a normal result by simply "sewing it back on." Avulsion of the tendons proximal to the amputation greatly complicates this case.

are discussed in the following sections. The amputated part should be treated carefully because portions may be used as a graft even if the entire part will not be replanted. For example, an amputated fingertip not suitable for replantation may be an ideal donor source for a skin graft on the stump. In addition, even when replantation is contraindicated, tissue (e.g., skin, bone, tendon) from the amputated part may be useful in restoring function to other damaged parts. In general, never discard amputated tissue until all possible uses of the severed parts are considered.

GENERAL CONSIDERATIONS

Mechanism of Injury

Severe extremity trauma is a significant cause of morbidity, and the potential for successful replantation in terms of survival, as well as useful function, is directly related to the mechanism of injury. Guillotine-type injuries are the least common but have the best prognosis because of the limited area of destruction. Crush injuries are the most common, but produce more tissue injury and therefore have a poorer prognosis. Avulsion injuries have the worst prognosis because a significant amount of vascular, nerve, tendon, and soft tissue injury invariably occurs.

Ischemia Time

Irreversible ischemic injury occurs in muscle tissue after 2 to 4 hours of warm ischemia and 6 to 8 hours of cold ischemia. Digits have less muscle tissue and are therefore less susceptible to ischemic damage (increasing warm ischemia time to 6 to 12 hours and cold ischemia time to 12 to 24 hours).¹¹ However, ischemic time alone does not preclude replantation attempt as successful replantation after prolonged ischemia time has been reported (hand reimplantation after 54 hours of cold ischemia; digit replantation after 33 hours of warm and 94 hours of cold ischemia).^{12,13} Techniques such as interosseous muscle stripping to prevent necrosis may improve replantation success in scenarios of prolonged ischemia time.

PATIENT ASSESSMENT AND MANAGEMENT

The initial care and treatment of a patient with a traumatic amputation begins with a primary survey and stabilization of the airway, breathing, and circulation. Traumatic limb amputations are less likely to occur in isolation and management of a patient's injuries must be prioritized such that life-threatening head and torso injuries take precedence over limb-threatening conditions (Fig. 47.2).^{1,14} Early hemorrhage control is essential. Bleeding should be controlled initially with direct pressure. If unsuccessful, the judicious use of a tourniquet is endorsed as a temporary adjunct to control extremity hemorrhage.^{15,16} To minimize potential complications, note the time of tourniquet application and limit tourniquet use to the time necessary to control the hemorrhage. Multiple amputations are an independent risk factor for death.¹⁷

After the initial assessment and stabilization of the patient, initiate care of the stump and amputated part (Box 47.1). A thorough neurovascular exam should be performed and documented. Evaluate the extremities for pulses and the presence of a bruit. In partial amputations, note the hard and soft signs of vascular injury (Table 47.1). In patients with soft signs of vascular injury, measure the ankle-brachial index or arterial pressure index (systolic pressure of the injured extremity/systolic pressure of the uninjured extremity). A ratio of less than or equal to 0.9 raises concern for a vascular injury. Reduce and

BOX 47.1 Axioms for Care of Amputations

DO:

- Splint and elevate
- Apply a pressure dressing
- Protect from further trauma or injury
- Protect from further contamination
- Provide analgesia
- Give tetanus prophylaxis and antibiotic therapy
- Obtain radiographs

DON'T:

- Apply dry ice or freeze tissue
- Place tags on tissue
- Place sutures in tissue
- Sever skin bridges
- Initiate perfusion of the amputated part
- Place tissue in formalin or water

immobilize associated fractures and evaluate the patient for associated conditions such as rhabdomyolysis and compartment syndrome.

Obtain a history regarding the exact mechanism, time, and duration of the injury, handedness, general medical status (notably diabetes, vascular disease, and smoking), allergies, medications, illness, previous injury to the affected part, care of the stump and amputated part before arrival in the emergency department (ED), occupation, avocations, tetanus history, and the patient's expectations.

Initiate tetanus prophylaxis (if needed) and broad-spectrum systemic antibiotic therapy (e.g., cephalosporins). Intravenous opioids are recommended for pain; titrate the dose to the clinical condition. Digital or regional nerve blocks are effective adjuncts for pain relief but limit ongoing neurologic evaluation (see Chapters 31 and 32). Obtain preoperative labs and imaging, including radiographs of the amputated part and proximal stump that include at least one joint proximal to the injury site (Fig. 47.3). Contact the regional replantation resource center as soon as possible to arrange transportation and provide adequate time for mobilization of the replantation team.

Patients who have suffered an amputation often experience denial, shock, disbelief, and feelings of hopelessness about their injury; some even become suicidal. Treat patients with supportive and realistic reassurance, and avoid promises of outcome. It is important that the emergency clinician (or other nonreplantation specialist) not speculate on the specifics of the ultimate prognosis.

CARE OF THE STUMP AND AMPUTATED PART

The goals of initial care of the stump and amputated part include control of hemorrhage and prevention of further injury or contamination.

Stump

Examination of the stump may be brief and should primarily be an assessment of the degree of damage to surrounding tissue (Fig. 47.4). Remove all jewelry from the stump and irrigate with normal saline to remove gross contamination; any manual débridement and dissection should be performed only by the replantation team. Do not use local antiseptics, especially hydrogen peroxide or alcohol, because they may damage viable tissue. Do not clamp arterial bleeders. Similarly, surrounding tissue should not be manipulated, clamped, tagged, or further traumatized in any way. Cover the stump wound with a saline-moistened sterile dressing to prevent further contamination and to limit damage from desiccation. Splint

TABLE 47.1 Clinical Signs of Vascular Injury

HARD SIGNS OF VASCULAR INJURY	SOFT SIGNS OF VASCULAR INJURY
Absent distal pulses	Distal nerve deficit
Active pulsatile bleeding	Diminished pulses
Large expanding hematoma	Nonexpanding hematoma
Bruit or thrill	History of pulsatile or significant hemorrhage at time of injury

Figure 47.4 **A**, Blast injury resulting in amputation. Remove gross contamination by irrigating with normal saline. Avoid using antiseptics because they may damage viable tissue. Assess the degree of contamination, the level of the injury, and any concomitant injury. **B**, Obtain radiographs of the amputated part (if available) and the proximal stump to include at least one joint proximal to the injury site. (Courtesy Stephen Pap, MD.)

the stump for protection and to prevent further injury from concomitant fractures or compromised blood flow from a change in position. Splinting and elevation may also reduce swelling and help control bleeding.

Amputated Part

Remove all jewelry and irrigate the amputated part with normal saline to remove gross contamination, similar to care of the stump described previously (Fig. 47.5). The amputated part should be wrapped in saline-moistened gauze and placed in a dry and closed waterproof plastic bag (see Fig. 47.5, step 5). Do not place the amputated part directly in ice or cold saline. The bag containing the specimen wrapped in saline-moistened gauze should be immersed in ice water or refrigerated at 4°C. The amputated part itself should NOT come into direct contact with ice or saline or reach freezing temperatures. Do not discard any tissue as any amputated fragment could be potentially used for skin, bone, or nerve grafting.⁷ Label the tissue containers with the patient's name, the amputated part contained within, the time of the original injury, and the time that cooling began.

Treatment is similar for partial amputations with vascular compromise. Irrigate the wound with normal saline. Place a saline-moistened sponge on the open tissue and wrap the injury in a sterile dressing in which a splint has been incorporated to protect from further injury. Place ice packs or commercial cold packs over the dressing to cool the devascularized area (see Fig. 47.5, step 8).

SPECIAL CONSIDERATIONS

Lower Extremity Amputations

Lower limbs are not commonly replanted because replantation is fraught with potential complications and lower limb prostheses, especially those used below the knee, are well tolerated and functional.^{17,18} Prostheses provide a secure stance and permit locomotion. Lower extremity replantation generally requires skeletal shortening, and distal nerve regeneration is often imperfect, with both deficits producing dysfunction.¹⁹ A patient with a replanted lower extremity, with significant shortening and without sensation, typically has superior functional outcome with a prosthesis. Children are an exception and replantation may be attempted in a child with a lower limb amputation due to their superior replantation functional outcomes.

Hand Function

Fine motor hand function involves pinch and grasp functions. If the index finger is amputated, the middle finger can often adequately perform the pinching function formerly provided by the index finger. Power in grasping and gripping is primarily a function of the fourth and fifth digits. An effective grip that provides the ability to hold a variety of objects is a central function of the ring and middle fingers. In addition to its function in pinching, the thumb is the major opposing force for successful grip and grasp. The thumb is the most important digit for adequate hand function, and its loss results in 40% to 50% disability. Such disability requires aggressive attempts to replant amputated thumbs. If this is impossible or unsuccessful, secondary alternatives are pollicization (creation of a thumb by using another digit) or toe transfers.^{20,21}

Care of the Stump and Amputated Part

1 Irrigate the wound with saline solution.

2 Wrap the wound with Kerlix or Kling for pressure, then elevate.

3 Rinse the amputated part with saline solution.

4 Wrap the amputated part in a moist sterile gauze or towel, and place it in a plastic bag or container. Do not immerse the amputated part in saline.

5 Place the amputated part in a container (preferably Styrofoam) and cool with separate plastic bags containing ice or in a container of ice water.

6 For partial amputations, begin by irrigating the wound with saline solution.

7 Place parts in a functional position, then apply a saline-moistened sterile dressing over the wound.

8 Apply a coolant bag outside of the dressing.

9 Splint and elevate the extremity.

NOTE: Do not scrub or apply antiseptic solution to the wound.

Control any bleeding with pressure.

If a tourniquet is required, place it close to the amputation site.

Figure 47.5 Care of the stump and amputated part. Do not place the amputated part directly in ice or saline.

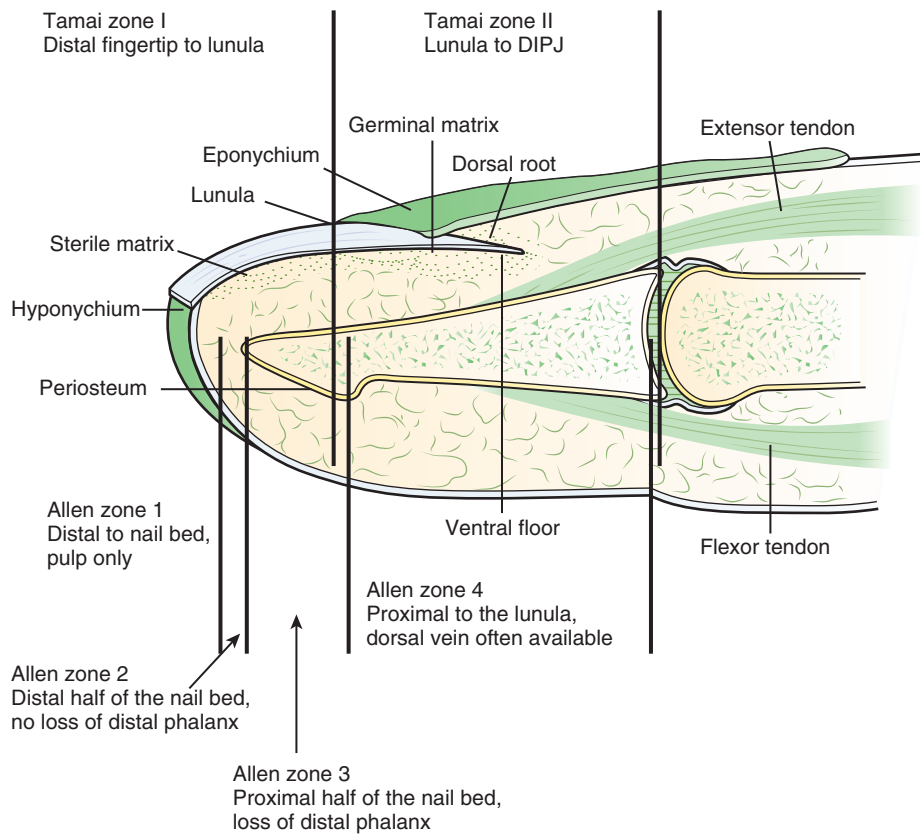

Figure 47.6 The Tamai and Allen classifications of distal fingertip amputations. *DIPJ*, distal interphalangeal joint. (From Lee DH, Mignemi ME, Crosby SN: Fingertip injuries: an update on management, *J Am Acad Orthop Surg* 21(12):756–766, 2013.)

Fingertip Amputations and Dermal Slice Wounds

There are several classification systems for distal fingertip amputations. The Tamai classification is most commonly used, though the Allen classification is the most clinically useful for hand surgeons (Fig. 47.6).

Treatment of distal fingertip injuries remains somewhat controversial, but good results are often achieved with conservative management. Factors that impact management include the amount of soft tissue loss, the integrity of the nail bed, and the patient's age, occupation, and management preference. The basic goals of treatment are to provide tissue coverage, an acceptable cosmetic result, and early functional recovery. Primary closure or healing by secondary intention is preferred when there is adequate soft tissue coverage and no exposed bone (Fig. 47.7). If there is no exposed bone, but significant pulp loss, treatment options include primary closure, healing by secondary intention, completion amputation, full-thickness skin grafting, or split-thickness skin grafting.²²

In general, uncomplicated fingertip wounds less than 1 cm in size heal well with conservative treatment. In children under 2 years of age, fingertip wounds up to 2 cm may be managed conservatively, as children in this age group have superior regenerative capacity.^{7–10} Management is more challenging when there is significant loss of skin and soft tissue from the finger pad.

Volar skin is unique in its combination of toughness and sensitivity. Wounds with a significant loss of volar tissue frequently require additional treatment (Fig. 47.8). If there is

Figure 47.7 This very minimal amputation of the fat pad with a mandolin slicer does not involve bone or the nail bed and is a common injury. It will heal very well with conservative therapy. No skin grafting is required. It will require a few weeks to heal, with periodic cleaning and débridement. Note: The ring should be removed as soon as possible.

significant soft tissue loss on the volar aspect of the distal finger, completion amputation and closure by a hand specialist provides the quickest recovery. In these cases, ablation of the nail bed and digital nerve transection are generally required to prevent hook nail deformity and painful neuroma formation, respectively.²² Alternatives to completion amputation include partial-thickness skin grafts, full-thickness skin grafts, Atasoy-Kleinert V-Y flap,

Figure 47.8 This patient with significant volar tissue loss required microsurgical replantation. **A**, Tamai level 2 volar oblique pulp amputation. **B**, After completion of microsurgical replantation. **C**, Four-month follow-up. (Used with permission from Peterson SL, Peterson EL, Wheatley MJ: Management of fingertip amputations, *J Hand Surg Am* 39(10):2093–2101, 2014.)

Kutler lateral V-Y flap, Moberg flap, or other local and distal flap coverage techniques.^{22–25} A composite graft is another reconstructive option in children, where the amputated part is sutured back to the stump without formal microvascular repair. The tip may potentially necrose, but serves as a biological dressing. In adults, composite graft may be attempted after the amputated portion is defatted but outcomes are inferior to those in children.^{26,27} Although traditionally some type of grafting or advancement techniques have been used for distal guillotine amputations, conservative management is now more common, even if some portion of bone is exposed (Fig. 47.9).

For more significant distal amputations, replanting the amputated tip preserves the nail (which enhances fingertip sensation and two-point discrimination), digit length, and joint motion, and often results in better overall functional outcomes.²⁸ Moreover, survival rates of finger replantation are high (approaching 90%).^{6,29,30} Even amputations distal to the insertion of the flexor digitorum superficialis are often attempted because digit function with preserved proximal interphalangeal joint motion is enhanced by the additional length, even if the DIP joint is stiff or fused.^{6,31,32} Additionally, active range of motion is increased if this insertion site is preserved (82 degrees compared to 25 degrees with a more proximal amputation).⁶ Though young children potentially regenerate the distal tip, functional outcomes are also excellent after replantation.³³

As discussed previously, incomplete transections and small distal amputations without significant soft tissue loss may heal well with conservative therapy initiated by the emergency clinician. It may require a number of weeks to totally heal, but nonoperative treatment in appropriate patients provides excellent functional and cosmetic results, minimizes recovery time, and has few complications. Débride necrotic and grossly contaminated tissue and irrigate the wound thoroughly with normal saline. If bone is left exposed without soft tissue coverage, the patient will probably need an operative procedure. Alternatively, the bone may be rongeuired (shortened) to allow soft tissue coverage and primary healing with better functional recovery. The nail bed tissues should be preserved, if possible, because the presence of a nail improves hand sensation and affects the cosmetic appearance. After cleansing and careful débridement, apply an occlusive dressing directly over the wound and then bandage and splint the finger for protection. Provide tetanus prophylaxis if needed. Amputations that involve the distal phalanx are frequently treated as contaminated open fractures. However, there is no evidence that antibiotics prevent infection or are superior to excellent wound care, and pro-

phylactic antibiotics are generally not recommended.^{34–36} Wound contraction and healing usually result in acceptable cosmetic and functional recovery in 2 to 3 weeks. Arrange appropriate follow-up to ensure adequate healing and recovery.

Partial Fingertip Amputations

The emergency clinician can also manage partial fingertip amputations distal to the DIP joint. These wounds are treated in a manner similar to complete amputations. However, when the amputation has a substantial amount of undamaged tissue connecting the fingertip, use sutures or bandaging and protective splinting to carefully align and stabilize the injured fingertip. Partially amputated fingertips, especially in children, may occasionally survive and regain vascularization and sensation. The patient must be warned that the distal tip may potentially become necrotic and progress to a complete amputation. Injury to the nail bed requires special attention to ensure proper alignment. If the nail bed tissues are not aligned properly, permanently disfigured nails may result. Complete or partial nail removal may be required for the placement of sutures.

Manage dermal slice wounds (see Fig. 47.7) by gently cleansing the wound and applying antibiotic ointment and a nonadherent dressing, followed by a pressure dressing. The patient should return in 48 to 72 hours for the wound to be inspected and the dressing changed. At that time, instruct the patient on the use of nonadherent dressings that should be changed daily until functional epithelialization of the wound takes place (usually approximately 10 to 14 days). A protective finger splint or guard also minimizes the risk for further injury and pain from trauma to the sensitive wound area. Protection also allows earlier return to functional use and employment. Wounds larger than 10 mm² and those with deep loss of digit pulp tissue may be candidates for skin grafting.

Penis, Ear, and Nose Amputations

Replantation of the penis, ear, and nose generally results in better function and cosmesis than a prosthesis or reconstructive surgery. The amputated parts and wounds should be handled in the same manner as digital replantations.

Penile amputations are uncommon; most cases are self-inflicted trauma in patients who are severely psychologically disturbed. Successful replantation with microsurgical techniques has been reported. Preservation or reconstruction of the urethra to maintain a competent urinary stream is critical for success.^{37,38} Ears and noses are frequently partially amputated and

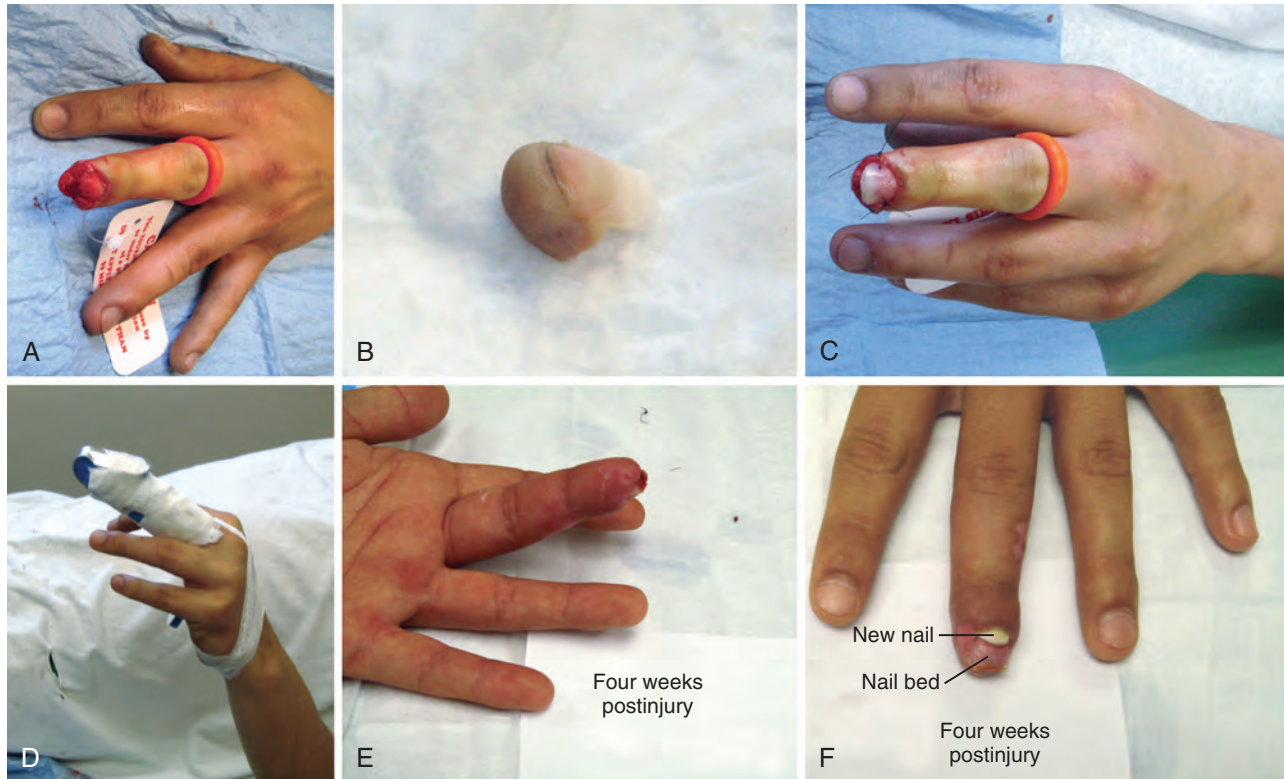

Figure 47.9 A, This young man with no medical problems had his fingertip cut off by a metal press, a guillotine-type amputation that has traditionally been treated with various surgical techniques. A conservative approach is now advocated, especially in children. Note that the nail bed is now exposed because of avulsion of the nail. The distal phalanx was not injured but could be felt in the stump. B, The avulsed tip had skin and the avulsed nail was attached. C, After the tip was cleaned by gentle scrubbing and minor débridement of macerated tissue, the nail was dissected from the tip and sutured back under the eponychium. The amputated tip was discarded. D, A protective splint and a pressure dressing were applied. Cephalexin was given for 7 days. The patient was seen weekly for dressing changes and minor débridement. E, At 4 weeks the finger had healed well with good sensation and an almost normal appearance. F, The old nail was removed to reveal the growth of a new nail. At 8 weeks there was no deformity or problem, except minor shortening of the tip.

occasionally totally amputated. Whenever possible, these body parts should be replanted unless they are severely traumatized and gross contamination is present. These wounds frequently heal well, and patients with such wounds have a high tissue survival rate and a low incidence of total necrosis. Microsurgical repair leads to improved outcomes for replantation of the ear and nose.³⁹⁻⁴³

COMPLICATIONS

Appropriate and expedited ED care facilitates the best possible outcome after an injury. Avoid improper management of the parts or stump and subsequent additional injury to the tissue from overzealous hemostasis or cleansing. Furthermore, avoid desiccation, maceration, or freezing of tissue from improper storage. Expedite the preoperative workup of the patient and immediately notify the replantation team because these are crucial factors in the patient's care.

Despite optimal initial care, replantation itself may be associated with acute or long-term complications. Multiple operations may be required, with prolonged immobilization and rigorous rehabilitation. Early surgical complications include wound infection, and arterial and venous insufficiency. Late

complications include cold intolerance, paresthesias, tendon adhesions, bone malunion/nonunion, neuroma formation, and contractures. Despite advanced microsurgical techniques, patients typically recover only 50% of their original function and sensation of the replanted parts, which may have negative psychosocial and economic consequences.⁴⁴

FIELD AMPUTATIONS

Emergency physicians may be called on to perform field amputation of an extremity as a lifesaving intervention. The typical scenario is a victim who is trapped or unable to be extricated from the scene because an extremity is covered or held immobile due to debris or other heavy objects or is lodged in a narrow space. The procedure is not detailed in this text but is contained in the video library (Videos 47.1-47.3).

Extensor and Flexor Tendon Injuries in the Hand, Wrist, and Foot

Peter E. Sokolove and David K. Barnes

EXTENSOR TENDONS

Extensor tendons are quite superficial, covered only by skin and a thin layer of fascia, and are thus highly susceptible to injury by commonly experienced trauma. Such injuries may result from lacerations, bites, or burns, but they may also be caused by closed injury or with even seemingly superficial lacerations. Whereas some extensor tendon injuries must be managed by a hand surgeon, others may be treated in the emergency department (ED). The emergency provider must understand the anatomy, principles of treatment, repair technique, and postrepair care of these injuries to ensure the best possible patient outcome. The authors suggest that all flexor tendon lacerations be referred to a hand surgeon.

Functional Anatomy

There are 12 extrinsic extensor muscles of the wrist and digits, all of which are innervated by the radial nerve. The muscles that give rise to these tendons originate in the forearm and elbow (Fig. 48.1). The extrinsic extensor tendons reach the hand and digits by passing through a fibro-osseous tendon sheath (retinaculum) located at the dorsal surface of the wrist. This synovium-lined sheath provides smooth gliding of the tendons and prevents bowstringing when the wrist is extended.¹ The dorsal retinaculum contains six compartments or subdivisions (Fig. 48.2). These compartments are numbered from the radial to the ulnar side of the wrist.

The first compartment contains two tendons, the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB). The APL tendon is the most radial of the extensor tendons and inserts on the base of the thumb metacarpal. It can be palpated just distal to the radial tubercle. The APL tendon causes thumb abduction and extension and some radial wrist deviation. The EPB travels with the APL through the first compartment but inserts at the base of the proximal phalanx of the thumb. The EPB tendon can be palpated over the dorsum of the first metacarpal when the thumb is extended against resistance. Both tendons can be tested by having the patient spread the fingers apart against resistance.

The second compartment also contains two tendons: the extensor carpi radialis brevis (ECRB) and the extensor carpi radialis longus (ECRL). These two tendons arise from the lateral epicondyle of the elbow. The ECRL inserts on the base of the index finger metacarpal, and the ECRB inserts on the base of the long (middle) finger metacarpal. Both tendons are powerful wrist extensors, and the ECRL also allows some radial wrist deviation. Wrist extension plays an especially

important role in the mechanics of the hand because hand-grip strength is maximal only when the wrist is extended.

The third compartment contains only one extensor tendon, the extensor pollicis longus (EPL). This tendon crosses over the ECRB and ECRL and travels along the dorsum of the thumb to insert on the distal phalanx. The EPL forms the top of the anatomic “snuffbox,” and the bottom is formed by the EPB. The EPL can be visualized when the thumb is extended, and its strength can be tested by having the patient hyperextend at the interphalangeal (IP) joint against resistance. The intrinsic extensor of the thumb can provide some degree of extension at the IP joint. Therefore, if an EPL injury is suspected, it is important to compare extension at the IP joint with that of the unaffected thumb.

The fourth and fifth compartments contain the six tendons that extend the index through the little fingers. Each finger has its own extensor digitorum communis (EDC) tendon. The index and little fingers have an additional independent extensor tendon, the extensor indicis proprius (EIP) for the index finger and the extensor digiti minimi (EDM) for the little finger. The fourth compartment contains the EIP and EDC tendons, and the fifth compartment contains only the EDM tendon. These six tendons can be seen over the dorsum of the hand, where they are poorly protected and prone to injury. In this region the tendinous, ligamentous, and fascial connections between these tendons are known as the *juncturae tendinum*. Because of these redundant interconnections, a patient may be able to extend a digit, albeit weakly, even when there is a complete laceration of its EDC tendon. To avoid missing a tendon injury on the dorsum of the hand, it is important that the examiner test for tendon strength and not just for active extension.

The course of the extensor tendons along the fingers is more complex, but a basic understanding of this anatomy is essential for the emergency provider to evaluate and treat extensor tendon injuries (Fig. 48.3). The EIP tendon joins the EDC tendon at the level of the metacarpophalangeal (MCP) joint in the index finger; the EDM tendon parallels the course of the EDC tendon. The four EDC tendons eventually insert at the base of the proximal, middle, and distal phalanges. The most proximal insertion of the EDC tendon is at the level of the base of the proximal phalanx. The tendon actually inserts in two ways. First, there is a loose dorsal insertion just distal to the MCP joint. In addition, the EDC tendon inserts into the volar plate via the sagittal band. The sagittal band is a circumferential ligament at the level of the metacarpal head that serves to keep the EDC tendon centered over the metacarpal head, as well as to provide a stable connection with the volar plate located on the palmar side of the hand. After its primary insertion at the level of the MCP joint, the EDC tendon then extends dorsally along the digit. The EDC trifurcates over the proximal phalanx (Fig. 48.4). Its major central slip inserts on the base of the middle phalanx (Fig. 48.5). The lateral branches of the EDC tendon join with the lateral bands from the interossei and lumbricals to form the conjoined lateral bands. The two conjoined lateral bands then fuse together over the middle phalanx to form the terminal extensor mechanism (TEM) that inserts on the base of the distal phalanx (Fig. 48.6). The triangular ligament is a connection between the two conjoined lateral bands that assists in keeping these structures on the dorsal aspect of the digit.

The sixth dorsal compartment of the wrist contains only one tendon, the extensor carpi ulnaris (ECU). This tendon

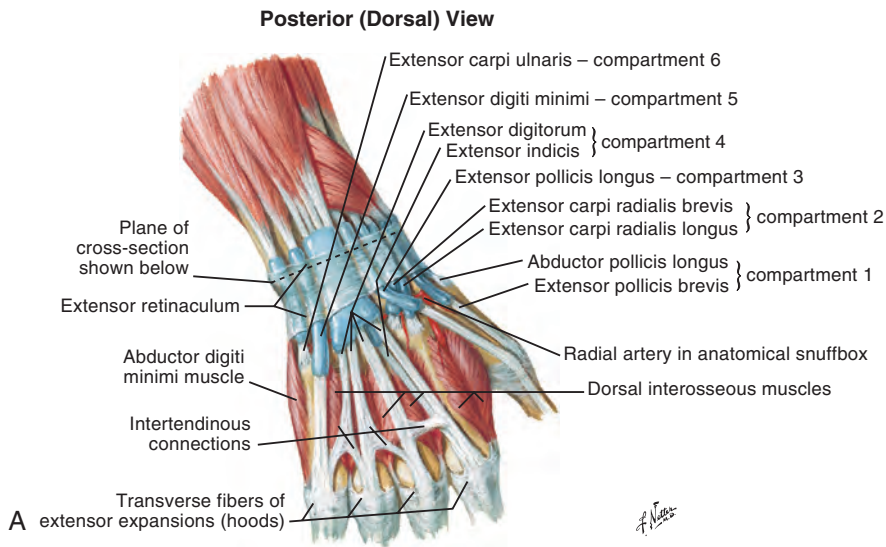

Figure 48.1 Extensor muscles and tendons of the right wrist and hand. **A**, Posterior (dorsal) view. **B**, Cross-section of the most distal portion of the forearm. **C**, Radial nerve in the forearm: posterior view. Figure 48.2 **A**, The extensor mechanism at the wrist and dorsum of the right hand. The six extensor compartments at the wrist contain (1) the abductor pollicis longus (APL) and extensor pollicis brevis (EPB), (2) the extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB), (3) the extensor pollicis longus (EPL), (4) the extensor digitorum communis (EDC) II to V and the extensor indicis proprius (EIP), (5) the extensor digiti quinti (EDQ), and (6) the extensor carpi ulnaris (ECU). An important anatomic detail is the presence of a synovial sheath around each tendon unit within each fibro-osseous canal. Note that the EDQ is also called the extensor digiti minimi by some authors. **B**, Note that the juncturae tendinum allow some weak extension of the finger when the proximal extensor is completely lacerated. (A, Adapted from Thomas JS, Peimer CA: Extensor tendon injuries: acute repair and late reconstruction. In Chapman MW, editor: *Operative orthopaedics*, ed 3, Philadelphia, 2001, JB Lippincott, p 1487.)

originates at the lateral epicondyle of the elbow and inserts at the base of the small finger metacarpal. The ECU functions as a wrist extensor and ulnar deviator. It can be palpated just distal to the tip of the ulna, and its strength can be tested by forced ulnar deviation of the wrist.

General Approach to Extensor Tendon Injuries

The key to detecting extensor tendon injuries in the ED is to perform a careful and thorough history and physical examination. These injuries are easy to miss with a cursory examination. Closed injuries may appear innocuous at first but can result in tendon injuries that may lead to severe deformities or dysfunction if undetected (Figs. 48.7–48.9). Closed injuries are also commonly associated with fractures. A hand radiograph is recommended for closed-hand injuries when a fracture is suspected or for open-hand injuries in which a fracture or foreign body is suspected. It is generally accepted that all open injuries that result from glass should be radiographed. Plain radiographs have a sensitivity of approximately 98% for detecting radiopaque foreign bodies (e.g., gravel, glass, metal).²

Injuries to extensor tendons from lacerations are quite common, especially on the dorsum of the hand where they are located superficially. All dorsal wrist, hand, and digit lacerations should be assumed to have an underlying tendon laceration until proved otherwise. Digital extension, albeit weak, can still occur with partial tendon lacerations of up to 90%, so visualization of the tendon and careful strength testing are required to definitively rule out a partial injury. In some cases the specific diagnosis simply cannot be made on the first examination (see later). Complete laceration of an EDC tendon on the dorsum of a hand can still allow digital extension through the juncturae tendinum.

After assessing the strength and neurovascular status of the injured hand it is imperative that the emergency provider visually inspect the wound thoroughly. Inspection should include an assessment of the degree of wound contamination, as well as a search for foreign bodies and occult tendon lacerations. It is often necessary to extend the skin laceration to aid in the visualization of a possible tendon injury. Because an extensor tendon is a mobile structure, it is imperative to visualize it in its entirety through a full range of motion if it is exposed. It is especially important to examine the tendon in the position

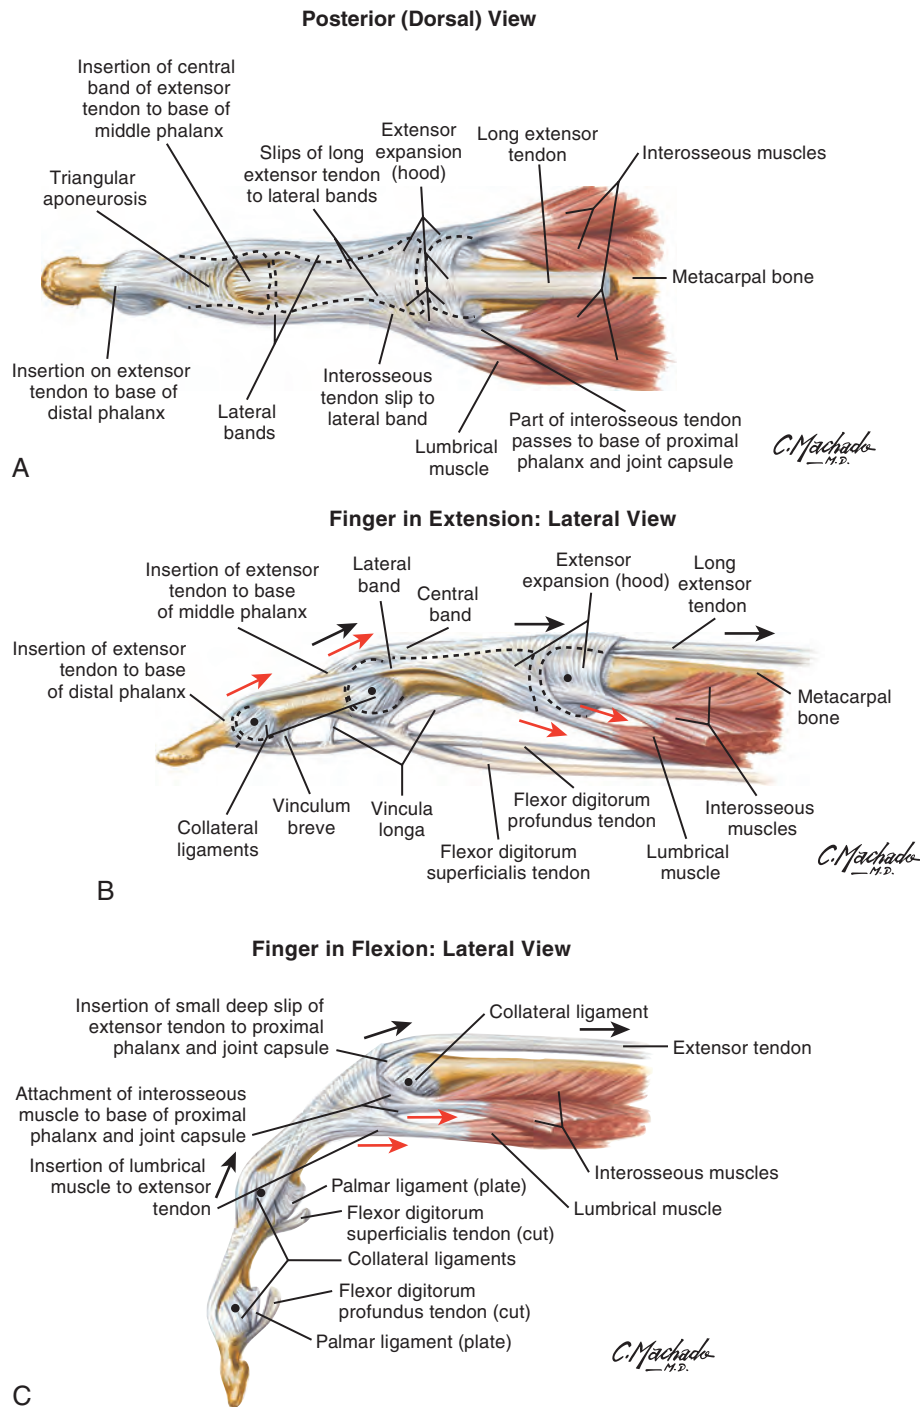

Figure 48.3 Flexor and extensor tendons in the fingers. **A**, Posterior (dorsal) view. **B**, Finger in extension: lateral view. **C**, Finger in flexion: lateral view. Note the directions of force when the extensor tendon is activated (*arrows*). (A–C, Netter illustrations used with permission of Elsevier Inc. All rights reserved.)

that it occupied at the time of injury because the tendon injury frequently does not lie directly under the external skin wound (see Fig. 48.8).

Some investigators have advocated the use of ultrasound in the diagnosis of suspected extensor (and flexor) tendon lacerations in the hand.³ This is a potentially attractive tool because it is easy to use, noninvasive, and provides point-of-care analysis. Ultrasound has the added advantage of facilitating dynamic evaluation of tendons through their range of motion.⁴

In a study of 34 patients with upper extremity tendon injuries treated by emergency physicians, ultrasound was faster and more accurate than exploration, magnetic resonance imaging (MRI), and specialty consultation.⁵ Accuracy of sonography for detection of hand and digit tendon injuries greatly depends on operator experience and is not a routine component of emergency medicine ultrasound practice.

Definitive examination of any wound must occur under the best possible conditions, with a good light source, a bloodless

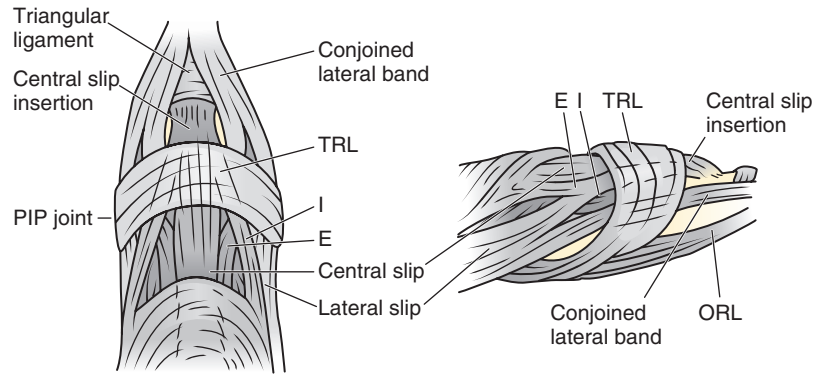

Figure 48.4 Zone of convergence of the digital extensor mechanism, which begins at approximately the midportion of the proximal phalanx and ends at the level of the insertion of the central slip into the dorsal base of the middle phalanx. Proximal to the zone of convergence, the extrinsic and intrinsic components of the extensor mechanism are separate: the central slip is extrinsic, whereas the lateral slips are intrinsic. Within the zone of convergence there is complete reciprocal crossover of fibers from the central slip and lateral slips. The products of the completed convergence are the central slip insertion and the conjoined lateral bands, both of which have dual muscular activity. *E*, Extrinsic contribution to the conjoined lateral bands; *I*, intrinsic contribution to the insertion of the central slip; *ORL*, oblique retinacular ligament; *PIP*, proximal interphalangeal; *TRL*, transverse retinacular ligament. (From Thomas JS, Peimer CA: Extensor tendon injuries: acute repair and late reconstruction. In Chapman MW, editor: *Operative orthopaedics*, ed 3, Philadelphia, 2001, JB Lippincott, p 1500.)

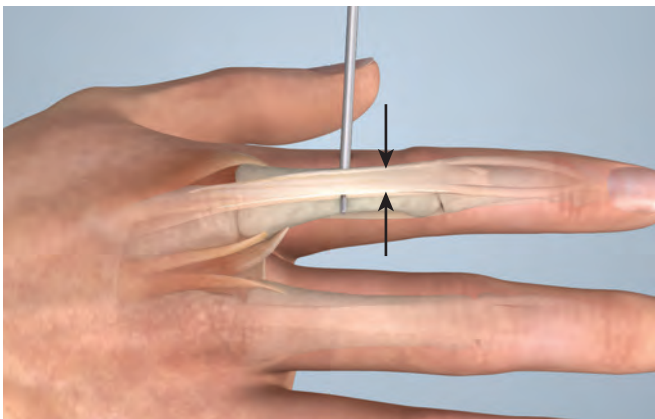

Figure 48.5 The extensor mechanism on the dorsum of a finger. Arrows point to the radial and ulnar lateral band portions of the extensor mechanism, and the probe is lifting the entire structure up off the phalanx.

Figure 48.6 The terminal extensor mechanism.

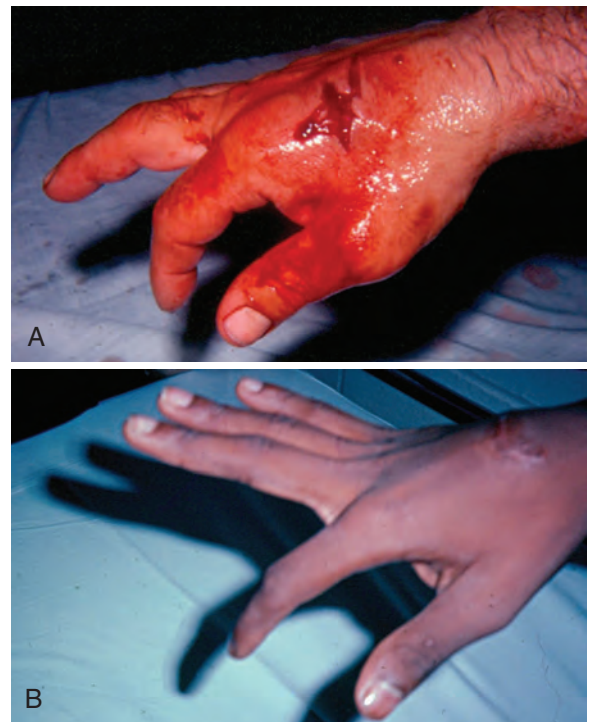

Figure 48.7 Because of their superficial location, it is difficult to avoid at least partial injury to the extensor tendons with even superficial lacerations of the dorsum of the wrist, hand, or fingers. **A**, This complete extensor tendon laceration is obvious because the index finger cannot be extended. **B**, This partial tendon laceration was not appreciated on initial examination, which seemingly demonstrated full tendon function. The entire tendon could not be visualized because of an uncooperative patient. The unappreciated partial laceration progressed to a complete rupture by the time of suture removal. Expedient delayed primary repair resulted in a good outcome.

Figure 48.8 To examine for a tendon injury, use a bloodless field. Note the sterile glove on the patient to maintain a clean field. It is almost impossible to cut the dorsum of the hand or fingers and avoid at least a partial tendon injury. **A**, The location and depth of this laceration suggest an extensor tendon injury. On examination, the patient had full extension. **B**, No tendon injury is visualized when the laceration was examined with the fingers in extension. When the laceration was extended and probed with the finger flexed, a 60% laceration of the extensor tendon could be viewed in the depths of the wound. **C** and **D**, Note the typical shiny white appearance of the fully exposed tendons (*arrows*).

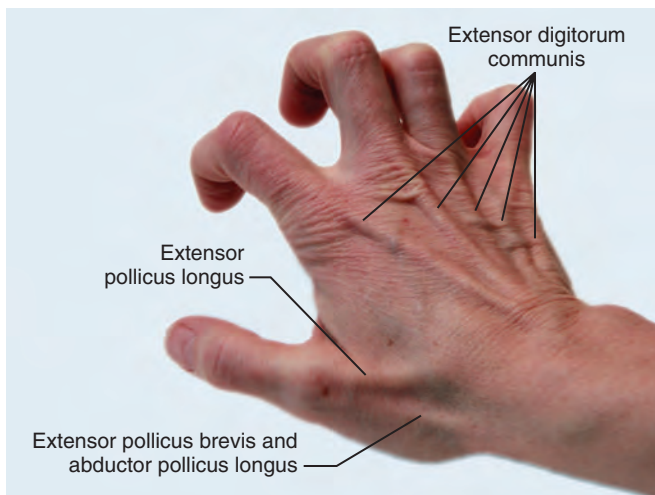

Figure 48.9 Given the superficial location of extensor tendons, suspect a tendon injury even with seemingly superficial lacerations of the dorsum of the hand and fingers. Full function is possible with a significant tendon laceration, and delayed total rupture can occur days to weeks later if the injury is not repaired or splinted. Most partial extensor tendon lacerations do well with 3 to 4 weeks of splinting and no surgical repair. When in doubt, clean the laceration, suture the skin, splint, and refer for subsequent examination in a few days.

field, adequate local anesthesia, and a cooperative patient. It may be impossible to adequately assess some patients completely during the first ED visit. In this case, final diagnosis must be delayed until the proper circumstances permit the required conditions. Occasionally, patient noncompliance thwarts even the most carefully planned follow-up. Frequently, the patient's pain, swelling, anxiety, or degree of intoxication or altered sensorium limits the clinician's diagnostic ability. Therefore it would not be considered standard to diagnose the presence or the full extent of all extensor tendon injuries immediately. Whenever logistically possible, emergency providers should consult a specialist when an extensor tendon injury is suspected by mechanism, location of the wound, or tendon dysfunction. Under most circumstances, however, there is no value in obtaining an immediate on-site consultation with a hand or orthopedic surgeon because the scenario would similarly limit any clinician's diagnostic acumen.

If the examining clinician suspects but is unable to locate a tendon laceration, or if a patient is uncooperative with the examination and the circumstances prohibit ideal initial care, patients should be referred for follow-up in 1 to 3 days for a repeat examination. Close the skin and apply a splint for interim wound care. A delay of a few days for definitive diagnosis, surgical repair, or both does not result in any significant alteration in the final outcome. Delayed primary repair, without

the need for tendon grafting or tendon transfer, is a well-accepted technique. In fact, many hand surgeons are reluctant to immediately repair even a complete extensor tendon laceration in a contused, potentially contaminated wound. The exact time frame under which such delayed repair results in an outcome similar to that of immediate repair is not well defined and depends on the clinical scenario. Usually, repair delayed for up to 10 days will still ensure an outcome similar to that of an immediate repair, but this varies depending on the injury. Providers should clearly document the inability to rule out a tendon injury in the ED and the mandate for follow-up within a specified time frame on the medical record and discharge instructions.⁶

Use of Antibiotics

There are no data to support or refute the use of prophylactic antibiotics as a routine adjunct after tendon injury. In general, prophylactic antibiotics have not been demonstrated to reduce infection rates after soft tissue injury in the setting of proper wound cleaning. Nor have they been proved to reduce infection rates in the absence of gross contamination, retained foreign material, extensive contusion, or a delay in cleaning. Many clinicians opt for antibiotics with gram-positive (e.g., anti-staphylococcal) coverage if the tendon has been injured or sutured, but no universally accepted standard of care exists.⁷ An individualized approach is advocated. Prophylaxis is generally used for only 3 to 5 days after injury unless there are extenuating circumstances such as immunocompromise, diabetes, a human bite, an unusual source of contamination, or peripheral vascular disease. If the sterility of a wound is in doubt, do not attempt tendon repair.

Preparation for Repair

Before attempting repair of an open extensor tendon injury in the ED, be prepared and have the proper equipment available. Place the patient supine on a gurney that ideally has an arm board attached. Bright overhead lighting is important for wound exploration so that the presence of tendon injuries and foreign bodies can be adequately assessed. Instruments should include, at a minimum, a needle holder, two skin hooks and retractors, sharp (i.e., iris) and blunt-nosed scissors, several small hemostats, and one pair of small single-toothed (i.e., Adson) forceps.

The choice of suture material depends on the location of the tendon injury. For repair of complete tendon injuries on the dorsum of the hand, non-absorbable, synthetic braided suture is preferred.⁸ Polyester suture, such as Ethibond (Ethicon, Somerville, NJ) or Mersilene (Ethicon), is recommended. Nylon suture is acceptable but is less ideal because colored nylon may be visible under the skin. Chromic and plain gut should be avoided because it may dissolve before adequate tendon healing has occurred. Silk is not desirable because of its reactivity. Most extensor tendons on the dorsum of the hand will accommodate 4-0 suture, but 5-0 suture material may be needed for smaller tendons. Small, “plastic repair” tapered needles should be used to avoid tearing the tendon. Partial tendon injuries in the digits are best repaired with fine, synthetic absorbable suture such as polyglactin (Vicryl [Ethicon]). Complex lacerations that involve tissue loss and fraying of the tendon margins (e.g., table-saw injuries) represent a particularly challenging clinical scenario that may make an otherwise straightforward tendon repair very difficult. In these cases, Lalonde and Kozin recommend closing the lacerated skin and tendon together (i.e., dermatotenedosis). Take large, composite bites of skin

and tendon together, 5 to 10 mm on either side of the wound, with 3-0 or 4-0 nylon suture tied outside the skin. Tighten the suture until the digit is in full extension.⁹

Before repairing a tendon injury, it is imperative that the provider use adequate anesthesia so that thorough wound exploration can occur. A field block or regional nerve block can be used on the dorsum of the hand, whereas local anesthesia or a digital nerve block can be used on the fingers. The choice of anesthetic composition has been the subject of long-standing controversy. Traditional teaching admonishes the use of epinephrine-containing anesthetic for fear of digital ischemia; however, many clinicians readily use lidocaine with epinephrine in the hand and fingers without complications. There is ample anecdotal and clinical evidence supporting the safety profile of epinephrine in digital anesthesia. Epinephrine has the benefit of prolonging the anesthetic effect and promoting a bloodless field during wound exploration and repair.¹⁰ It is important that the digits be fully anesthetized or, in the case of more proximal wounds on the hand, that the area around the wound be liberally anesthetized because many lacerations must be extended to afford access to the surgical field. It is a common error to avoid extending a laceration and to attempt examination, cleaning, or repair through a small initial skin laceration.

Following the administration of an anesthetic, place a tourniquet on the involved limb if hemostasis is problematic (see Fig. 48.8). It is absolutely essential that adequate control of blood flow be obtained before attempting to repair a tendon laceration. It is very difficult to find the proximal end of a retracted tendon in a bloody field. Before applying a tourniquet, wrap the patient's arm in several layers of cast padding as a comfort measure and elevate the arm for at least 1 minute to allow blood to drain by gravity. Place a blood pressure cuff on the middle to upper part of the arm, wrap several more layers of cast padding around the cuff, and then inflate it to 260 to 280 mm Hg. Once inflated, clamp the tubes tightly with a hemostat. The use of cast padding during inflation helps avoid premature opening of the cuff. Use of a hemostat to clamp the blood pressure cuff tubes helps avoid cuff deflation. A blood pressure cuff tourniquet is generally well tolerated by patients for approximately 15 to 20 minutes. If tendon repair cannot be accomplished in this time it is likely that the injury is too complex for repair in the ED. When necessary, use parenteral analgesia or anxiolysis to help the patient tolerate a longer tourniquet time. For finger examination, placing a rubber ring tourniquet at the base of the finger should give excellent hemostasis.

Atraumatic technique is essential for minimizing adhesions and scar tissue formation. Tendons should be handled delicately, avoiding crushing force or excessive punctures with forceps and needles. Forceps should be used only on the exposed, cut end of the tendon whenever possible.¹¹

Patterns of Injury and Management

Treatment of extensor tendon injury (Video 48.1) depends primarily on whether the injury is open or closed, as well as the anatomic location of the injury. The most widely accepted classification system is that developed by Verdan,¹² which divides the hand and wrist into eight anatomical zones (Fig. 48.10). It is quite useful for emergency providers to become familiar with this classification because in many instances the zone of injury can help determine whether tendon repair should be attempted in the ED. One must keep in mind that repair of

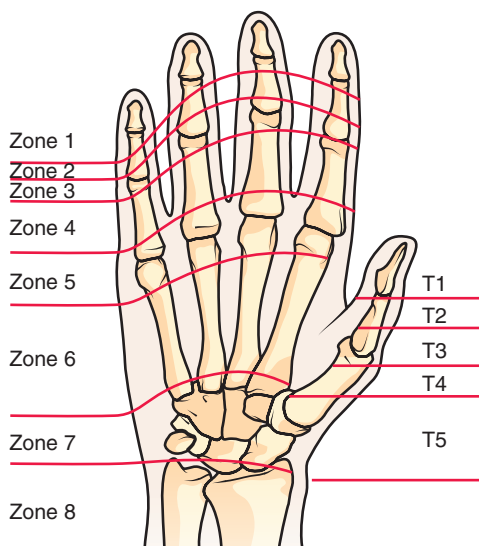

Figure 48.10 Dorsum of the left hand. The injury classification system recommended by Verdan¹² includes eight anatomically based zones. (Adapted from Blair WF, Steyers CM: Extensor tendon injuries. *Orthop Clin North Am*, 23:142, 1992.)

Figure 48.11 An effective way to fully immobilize a finger with a tendon laceration is to incorporate an aluminum foam splint into the middle layers (arrow) of a standard dorsal plaster/fiberglass short-arm dorsal splint.

lacerated extensor tendons within 72 hours of injury is still considered primary closure. Therefore although emergency providers may repair many extensor tendon injuries immediately, some injuries are best managed with delayed repair. In these cases, initial care in the ED should consist of sterile skin preparation, copious wound irrigation and inspection for foreign bodies, skin closure, splint application, and referral to a hand specialist for further care in 1 to 5 days. A plaster, metallic, or fiberglass dorsal splint in which a metal foam finger splint is incorporated is an ideal way to totally immobilize a finger (Fig. 48.11) (see Chapter 50).

Zone 7 and 8 Injuries¹

Zones 7 and 8 consist of the area over the wrist and the dorsal aspect of the forearm, respectively. Extensor tendon lacerations in these regions can be quite complex and therefore should not be repaired in the ED. Because of the proximity to extensor tendons in the distal part of the forearm, lacerations such as stab wounds may appear innocuous but often result in multiple tendon lacerations. At the wrist level, the extensor tendons are covered by a retinaculum that is lined with synovium. Although this tissue allows smooth gliding of tendons during

normal activity, the presence of synovium increases the risk for adhesions after tendon repair. In addition, lacerated tendons in the wrist and distal part of the forearm may retract away from the site of initial injury. This may make tendon retrieval and repair quite difficult and necessitate incision of the retinaculum and exploration of one or more compartments.

As a result of the potential complexity of these injuries, all tendon lacerations in zones 7 and 8 require formal surgical exploration and repair. ED management of these patients includes local wound care with primary repair of the skin and placement of a volar splint in 35 degrees of extension at the wrist and 10 to 15 degrees of flexion at the MCP joints. Promptly refer these patients to a hand surgeon so that repair may be undertaken within 1 week of injury.

Zone 6 Injuries^{1,8,13}

Zone 6 consists of the area over the dorsum of the hand. Extensor tendon injuries in this region are frequently caused by lacerations from broken glass or another sharp object. Common pitfalls in ED management of these injuries are usually related to failure to recognize that the tendon has been injured. It is important to remember that these tendons are superficially located, partial tendon lacerations may occur, and weak extension of a digit is possible with a complete tendon laceration because of transfer of extensor function through the juncturae tendinum. Lacerations of the EIP or EDM tendons are evidenced by an inability to extend independently the index or little finger, respectively. In most cases, missing zone 6 injuries can be avoided if a careful physical examination is performed, including thorough wound exploration under sterile conditions using a tourniquet, adequate local anesthesia, and good lighting.

Extensor tendon injuries in zone 6 are generally appropriate for repair in the ED. Because of the juncturae tendinum, extensor tendons in zone 6 are less likely to retract than those in zones 7 or 8; however, the severed tendon may retract when the injury is more proximal. The distal end of a severed tendon is usually easy to find by passively extending the patient's affected digit to bring the end into view. Retrieval of the proximal portion of a severed tendon is sometimes required and can usually be accomplished in the ED. Before searching for the proximal end of the tendon, the clinician should have a 4-0 nylon suture loaded onto a needle holder. When the proximal end is located, place this suture as a holding suture as far proximal as possible so that the tendon is not lost again. It is often necessary to use a scalpel to extend the skin wound proximally in a direction parallel to the course of the injured tendon to obtain adequate exposure. One should then begin to search for the tendon by lifting up this overlying skin with forceps and inspecting the proximal portion of the wound. Sometimes the blood-stained end of a tendon tunnel can be seen; this may contain the proximal end of the tendon. By gently placing a small hemostat or toothed forceps up this tunnel, the tendon stump can often be pulled into view.

Once both ends of the injured tendon have been located, the technique used for repair depends on the size and shape of the tendon. Whereas larger, round tendons can accommodate sutures that pass through the core of the tendon, smaller or flat tendons are difficult to repair with this technique. Most of the tendons in zone 6 can be repaired using one of several published techniques that maximize the strength of repair and minimize the risk of adhesions and catching. A detailed description of all available tendon repair techniques is beyond the

scope of this text. Emergency providers should be familiar with some of the more common approaches such as the modified Kessler, modified Bunnell, modified (or augmented) Becker (aka Massachusetts General Hospital), and Krackow-Thomas techniques, and be prepared to apply one or more depending on the injury pattern.^{6,14,15}

Both the modified Bunnell and modified Kessler techniques involve first placing a single suture in one end of the cut tendon, usually made of 3-0 or 4-0 non-absorbable material. Place the suture in the tendon core by inserting the suture needle into the exposed, cut end and then weaving the suture through the lateral tendon margins. Next, place the same suture through the core of the opposite half of the cut tendon. Tie the suture ends in a square knot in between the cut ends of the tendon to bring the two halves together. To improve the tensile strength of the repair, a number of other suture techniques may be used.⁸ One option is to increase the number of suture strands that cross the repair site (e.g., four strands rather than two). A cadaver study comparing various four-strand tendon repair techniques concluded that the Massachusetts General Hospital technique was more resistant to gap formation than either the Krackow-Thomas or the four-strand modified Bunnell techniques.¹⁶ However, this cadaver model could not assess tendon shortening or subsequent range of motion.¹⁷ Another way to improve tensile strength is to place a peripheral suture in addition to the core suture. Place a running cross-stitch suture of synthetic, absorbable material (e.g., 5-0 polyglycolic acid, polyglactin, or polydioxanone) circumferentially around the repair site or just on the dorsal surface of the tendon across the laceration site. Alternatively, place sutures laterally along both sides of the tendon starting at approximately 1 cm of either side of the repair site.

The running interlocking horizontal mattress (RIHM) is a newer technique recommended by some authors for primary extensor tendon repair (Fig. 48.12). Using 4-0 non-absorbable suture, the RIHM begins with a simple running suture directed

away from the surgeon. Then, using the same suture, the operator places a running mattress directed towards the examiner, interlocking each returning throw underneath the previously crossed suture to secure each pass. Tie the suture at the near end on the outside of the tendon to complete the repair. In a cadaver model of zone 6 injuries, the RIHM repair was significantly stiffer, resulted in significantly less shortening, required less tendon exposure, and took less time to perform than both the augmented Becker and modified Bunnell techniques. There was no significant difference in failure rates. This technique has the added benefit of being able to withstand the forces of early active motion during the postoperative period. It also preserved more tendon length and decreased flexion loss, potentially improving grip strength after repair.^{18,19}

Smaller tendons may be repaired with a figure-of-eight or horizontal mattress suture (Fig. 48.13). Small, tapered needles should be used to avoid tearing the tendon. In a cadaver study comparing multiple suture techniques, it was found that the modified Bunnell technique provided the strongest extensor tendon repair.²⁰ In addition, this technique produced no gapping between the repaired tendon ends and minimized the postrepair restriction of flexion at the MCP and proximal interphalangeal (PIP) joints. Alternatively, some experts recommend the RIHM for extensor tendon repairs. There are no studies that clearly show superiority for any particular technique, and not all hand surgeons agree on the repair approach, even for the same or similar injuries. The ultimate choice of repair technique will depend largely on the treating providers' familiarity with extensor tendon repair, as well as the size of the tendon. Regardless of the chosen suture technique, it is important to test the degree of flexion passively at the MCP joint after a zone 6 tendon repair to be certain that the tendon has not been excessively shortened.

The approach to partial extensor tendon lacerations is not well defined and no definitive standard of care exists. One evidence-based analysis identified 141 relevant papers, but none

Figure 48.12 The running interlocking horizontal mattress suture (RIHM). **A**, Begin the repair with a simple running suture directed away from the clinician. **B**, Complete the repair by placing a running mattress suture back toward the clinician, interlocking each returning throw underneath the previously crossed suture to lock each throw. (From Lee SK, Dubey A, Kim BH, et al: A biomechanical study of extensor tendon repairs: introduction to the running-interlocking horizontal mattress extensor tendon repair technique, *J Hand Surg Am* 35(1):19–23, 2010.)

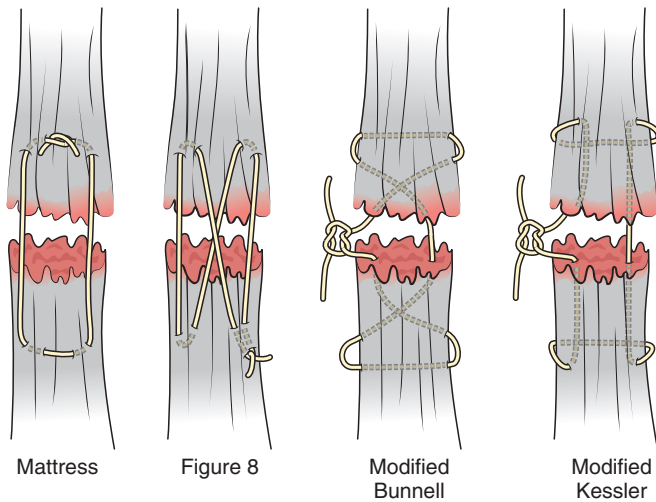

Figure 48.13 Suture techniques used for extensor tendon repair.

were germane to the question of repair of partial extensor tendon injuries.²¹ The authors concluded that there is no direct evidence to assist in answering this question. Given the lack of literature on the subject, a reasonable approach may be to extrapolate from data on flexor tendon injuries. It has been demonstrated that many partial flexor tendon lacerations do well without repair,²² but hand surgeons still disagree on the need for repair of these injuries. In a survey of hand surgeons, 30% of respondents repaired all partial flexor tendon lacerations and 45% repaired only lacerations with greater than 50% involvement of the cross-sectional area.²³ Except at the wrist level, extensor tendons are not covered with synovium and are therefore less likely than flexor tendons to form adhesions after repair. This encourages some authors to recommend repair of most partial extensor tendon lacerations. Although the ideal approach to these injuries is not known, it is reasonable to consider repair of partial extensor tendon lacerations to be optional if less than 50% of the cross-sectional area is involved. However, if not repaired, such injuries must be splinted for 3 to 4 weeks to ensure that a partial laceration is not converted into a complete injury. Skin closure, splinting, and referral for follow-up is a standard approach to unrepaired partial extensor tendon lacerations.

After repair of a lacerated EDC tendon in zone 6, apply a volar splint so that the wrist is in 30 to 45 degrees of extension, the affected MCP joint is neutral (0 degrees of flexion), and the unaffected MCP joints are in 15 degrees of flexion. The PIP and distal interphalangeal (DIP) joints should be allowed full range of motion. After 10 days, the MCP joints are allowed 20 to 30 degrees of flexion. If there is an isolated EIP or EDM tendon injury, only the index or little finger must be included in the splint. Dynamic extension splinting may be used as early as 2 days after tendon repair, so close follow-up is recommended.²⁴

Zone 5 Injuries^{25,26}

Zone 5 consists of the area over the MCP joint. Open injuries in this region should be considered secondary to a human tooth bite until proved otherwise (Fig. 48.14), especially if the injury occurs over the first or second MCP joint because this is frequently the location of a clenched-fist (“fight-bite”) injury. ED evaluation must begin with a careful and persistent history

Figure 48.14 Regardless of this patient’s history, this wound is infected and highly suggestive of a human bite injury, which was vehemently denied by this patient. Human bites cause extensor tendon injuries, fractures, and joint capsule injuries and can harbor foreign bodies.

Figure 48.15 This patient stated that he sliced his hand on a piece of metal at work (expecting a workers’ compensation claim) but was unable to explain the chipped bone and piece of tooth that was found in the wound on exploration. Note that this puncture-type wound had to be significantly extended to adequately visualize the extent of the injury.

and physical examination, although patients may be reluctant to admit to punching someone in the mouth. The wound should be inspected through its full range of motion because the positions of the EDC tendons change with hand position. It is generally recommended that radiographs be obtained for all these injuries to evaluate for metacarpal head fractures, air in the joint space, or the presence of a foreign body such as a tooth fragment (Fig. 48.15).²⁴

If, after a thorough evaluation, it is determined that a human bite in this region has resulted in a superficial skin laceration only, without injury to the underlying tendon or joint, outpatient management is appropriate. The wound should be copiously irrigated and left open, a volar splint applied with the wrist in 45 degrees of extension, the MCP joints in neutral position (0 degrees of flexion), and the hand dressed with a bulky dressing. The use of prophylactic antibiotics for these “low-risk” human bites on the hand is controversial and clinical trials have yielded mixed results.^{27,28} Despite the lack of compelling clinical evidence for either approach, many authors recommend

Figure 48.16 Traumatic ulnar dislocation of the extensor digitorum tendon at the metacarpophalangeal (MCP) joint of the long finger. **A**, No swelling or tenderness. The tendon is centralized. Tendon instability is not evident with the MCP joint extended. **B**, Ulnar displacement of the extensor tendon increases with MCP joint flexion. (From Skirven TM: *Rehabilitation of the hand and upper extremity*, ed 6, St. Louis, 2011, Mosby.)

that 3 to 5 days of prophylactic antibiotics be given to these patients. Regardless of whether antibiotics are prescribed, patients should be seen in 24 to 36 hours for a repeat examination to evaluate for wound infection.

If a human bite results in tendon damage, including partial or complete laceration, some clinicians opt for admission and intravenous antibiotics. However, no specific standard of care exists. Outpatient therapy is acceptable in a reliable patient who has access to follow-up. Delayed closure with evaluation and repair of the tendon should be undertaken by a hand surgeon after 7 to 10 days of antibiotic therapy.^{8,24} Primary closure of even seemingly clean and well-irrigated human bites in this region is not advisable because of the increased risk for wound infection, as well as the potential for septic destruction in cases of traumatic MCP joint arthrotomy. If an open joint is noted on physical examination, a more aggressive approach is warranted. Such patients are generally admitted for intravenous antibiotics after copious irrigation.^{8,24}

If a patient suffers a zone 5 tendon injury, and it can be determined with complete certainty that it was caused by a relatively clean, sharp object rather than a human bite, primary closure is appropriate. Referral of these injuries to a hand surgeon is common practice given the complexities of the injury and possible sequelae. Careful repair of lacerations involving both the EDC tendon and the sagittal band is necessary to prevent subluxation of the EDC tendon away from the center of the metacarpal head. Initial ED management of non-human bite injuries is often limited to skin closure, splinting as described earlier, and referral to a hand surgeon within 1 to 5 days.

Closed extensor tendon injuries in zone 5 usually result from the acute or recurrent application of compressive force to the MCP joint capsule. Closed injuries in this region are sometimes referred to as a *boxer's knuckle* (Video 48.2). Repetitive closed injury to the MCP joint region can produce small tears in the EDC tendon, the sagittal band, or the joint capsule. These patients tend to have chronic and recurrent pain and swelling in the MCP joint region but usually have normal radiographic findings. Acute trauma may result in the same injuries or cause more severe damage to the extensor hood.

Such patients may have complete disruption of the extensor mechanism including damage to the central tendon and the sagittal band. The MCP joint is swollen, has decreased mobility, and may exhibit an extensor lag. Traumatic subluxation of an EDC tendon may be present and usually involves the middle finger with subluxation to the ulnar side (Fig. 48.16). Dislocation to the radial side is less common, probably because of the juncturae tendinum on the ulnar side that can compensate for injuries to the sagittal band.²⁹ The subluxation becomes more prominent with flexion at the MCP joint. Controversy exists regarding the initial management of closed injuries in this region. Whereas some authors prefer initial surgical repair,²⁶ others use an initial trial of extension splinting in some or all cases.^{8,24,25,29} Splinting the MCP joint in neutral or slight flexion for 6 weeks has been recommended for dislocations initially seen within 3 weeks of injury. Operative repair is usually reserved for more delayed manifestations or patients who fail splint therapy.²⁴

Zone 4 Injuries²⁵

Zone 4 consists of the area over the dorsal aspect of the proximal phalanx between the MCP and PIP joints. The extensor tendon is a broad, flat structure in this region and is relatively easy to repair. Because the extensor tendon is flat and conforms to the roundness of the proximal phalanx, tendon injuries in this area generally result from a laceration and are almost always incomplete. As a result, extension at the PIP joint is not usually impaired. It is therefore imperative that all these wounds be explored carefully while remembering that the extensor tendon lies immediately beneath the thin overlying skin. Tendons tend to not retract in this area, so close inspection will usually result in location of the injured tendon.

Hand surgeons generally repair central slip lacerations or any laceration that results in an extension lag at the PIP joint. The decision to repair a partial tendon laceration in zone 4, and whether it should be repaired by the emergency provider, is best discussed with the consulting hand surgeon. In general, because of the duality of the extensor system in this region, lacerations of a single lateral slip can either be repaired with 5-0 nonabsorbable suture or left unrepaired and splinted.

Placement of running sutures or simple interrupted sutures with buried knots is appropriate for this area. As placement of core sutures is technically difficult or impossible here, other techniques such as the RIHM are recommended.¹⁸ Postrepair splinting depends on the presence of tension at the repair site. Minor lacerations in zone 4 that do not result in tension on the repair site can be treated with a finger guard for 7 to 10 days and early range of motion. Treat larger lacerations or those that result in tension at the repair site with a splint that extends from the forearm to the digit for 3 to 6 weeks. Apply the splint so that the wrist is in 30 degrees of extension, the MCP joint is at 30 degrees of flexion, and the PIP joint is in neutral position. Group the fingers so that either the index and long fingers, or the long, ring, and little fingers are immobilized.

It is important to recognize that complex partial tendon lacerations (e.g., laceration of a lateral slip with a saw) in zone 4 may result in damage to the gliding layer located between the tendon and the bone. If the patient is still able to actively extend the digit at the PIP joint, these complex partial tendon lacerations are best managed by débriding the frayed tendon ends and splinting the digit in extension rather than attempting to suture the damaged tendon. The splint should be worn for 10 days, followed by active range of motion.

Zone 3 Injuries^{1,24,26}

Zone 3, the area over the PIP joint, is a common site of both closed and open injuries. An open injury usually results from laceration with a sharp object. It is imperative that these wounds be carefully explored in the ED to rule out penetration of the joint capsule (i.e., arthrotomy). Patients with wounds that are suspected of penetrating the joint are generally taken to the operating room for surgical exploration, irrigation, and treatment with intravenous antibiotics, but protocols vary.

Zone 3 tendon lacerations can result in long-term deformity if not carefully repaired, and patients with such injuries are commonly referred to a hand surgeon. Partial lacerations of the central slip or lateral bands are managed variably, and it is advisable to discuss these injuries with the consulting hand surgeon. Lacerations in this area may sometimes result in a complete central slip injury. This may manifest as an acute boutonnière (“buttonhole”) deformity in which the PIP joint rests in 60 degrees of flexion. The signs may be subtle, however, and may be noticeable only by weakened extension at the PIP joint or incomplete extension by only a few degrees.

A boutonnière deformity develops when the central slip is ruptured by an open or closed mechanism that leads to unopposed action of the flexor digitorum superficialis tendon. This results in flexion at the PIP joint, protrusion of the head of the proximal phalanx between the two lateral bands, and disruption of the triangular ligament. When this occurs, the lateral bands are displaced volar to the axis of motion of the PIP joint. The lateral bands then paradoxically become flexors of the PIP joint (Fig. 48.17). In addition, the extensor hood mechanism is pulled more proximally, which results in increased tension on the TEM and hyperextension at the DIP joint. Thus, a boutonnière deformity consists of flexion of the PIP joint with hyperextension of the DIP joint.

Open central slip injuries are usually managed operatively, and complex injuries may require direct attachment of the tendon to bone or tendon reconstruction. If the consulting hand surgeon chooses not to repair the tendon injury immediately, close the skin and apply a splint in the same fashion

Figure 48.17 Boutonnière deformity. This can be an open or a closed injury. Note the flexion of the proximal interphalangeal joint and extension of the distal interphalangeal joint from a laceration of the central slip mechanism.

as described for zone 4 injuries. Thermoplastic splints allow immobilization of the hand without involvement of the wrist but may not be available in the ED setting. Promptly refer these patients to a hand surgeon so that repair may be undertaken within 1 week of injury.

Patients with closed injuries in zone 3 are commonly encountered in the ED. They may complain of a direct blow to the dorsal PIP joint or a “jammed” finger. This injury occurs when an object such as a ball delivers a sudden axial loading force with forced flexion of the PIP joint while it is extended. These patients commonly complain of a painful, swollen PIP joint, which often makes the examination difficult. Some of these injuries may represent PIP joint dislocations that were spontaneously or manually reduced before the arrival of the patient at the ED. The tendon injury that is important to recognize in this setting is an occult isolated central slip rupture. Patients may have decreased extension at the PIP joint, but extension is generally normal because the lateral bands are the primary extensors of this joint. With forced extension against resistance, patients usually have pain and may have decreased strength. To eliminate pain as the cause of the decreased mobility, it may be helpful to test PIP extension against resistance after performing a digital block. With acute central slip rupture, PIP joint extension may be particularly weak when the MCP and wrist joints are held in maximal flexion. In this position, a 15-degree or greater loss of active extension is highly suggestive of a central slip injury.²⁶ The Elson test may also help identify this injury (Fig. 48.18).³⁰

A boutonnière deformity does not usually develop in patients with closed zone 3 injuries until 10 to 21 days after injury unless the central slip and triangular ligament are both disrupted and the lateral bands subluxate toward the volar plate. To prevent the deformity from occurring, the provider should have a high index of suspicion for its presence and treat these patients conservatively. It is advisable that all patients with a swollen, tender PIP joint and pain with flexion or extension be splinted and referred for close follow-up.³¹ Apply a dorsal splint overlying the PIP joint while keeping it in full extension. This can be accomplished with an aluminum foam-backed splint or a Bunnell (“safety pin”) splint, although the latter

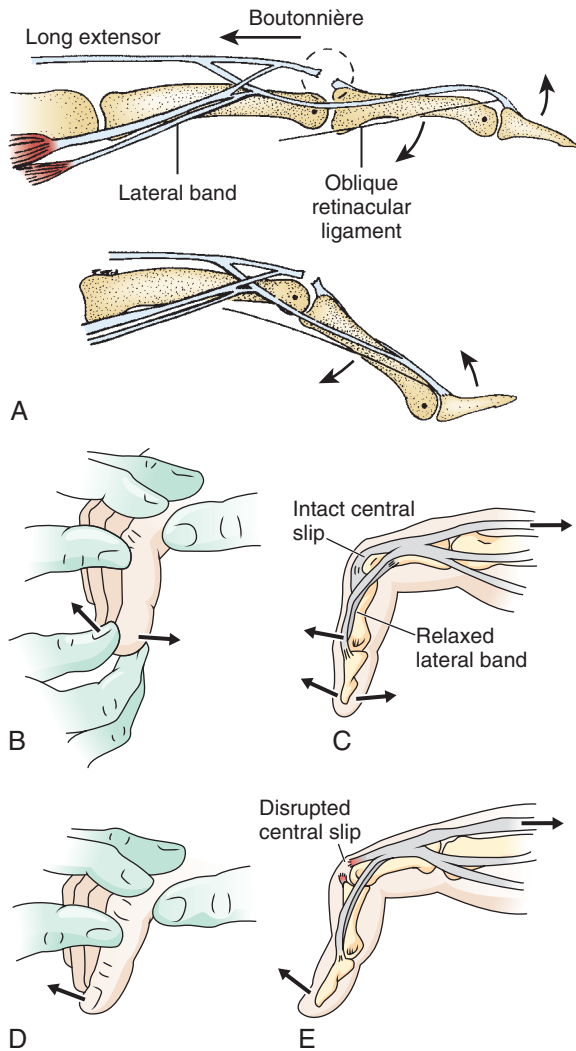

Figure 48.18 A, Diagram of a boutonniere deformity. B–E, The Elson test for early diagnosis of an acute rupture of the central slip of the extensor digitorum communis tendon. Such rupture results in a boutonniere deformity in which the distal interphalangeal joint is hyperextended, as shown. B, With the patient's finger flexed (over a straight edge) at the proximal interphalangeal (PIP) joint, palpate the dorsal surface of the middle phalanx. C, If the central slip is intact, PIP joint flexion causes the slip to tighten distally, thereby relaxing the lateral bands and leaving the distal phalanx flail (arrows). Thus, when the patient is asked to extend the digit, the examiner feels pressure that is being exerted by an intact central slip. D and E, If the central slip is disrupted, however, the examiner feels no pressure on the dorsum of the middle phalanx as the patient tries to extend the digit. It is possible for the patient to extend the injured finger successfully only by hyperextending (by action of the lateral bands) (arrows).

may not be available in the ED.²⁴ The MCP and DIP joints should be left free to have full, active range of motion (Fig. 48.19). If a central slip attachment fracture is present, orthopedic consultation is recommended because these patients may require surgical internal fixation.³²

Zone 1 and 2 Injuries^{1,8,24,26}

Zones 1 and 2 consist of the area over the DIP joint and the middle phalanx, respectively. In zone 2, the conjoined lateral bands come together to form the TEM and are held together,

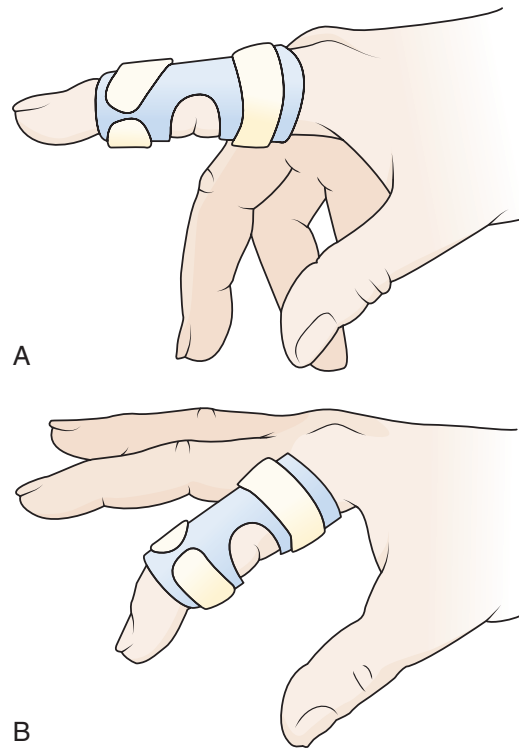

Figure 48.19 A, Boutonniere splint. B, This splint allows active flexion at the metacarpophalangeal and distal interphalangeal joints.

in part, by the triangular ligament. The TEM inserts on the base of the distal phalanx and allows extension at the DIP joint. Complete disruption of the TEM results in an inability to extend at the DIP joint. Because of the unopposed action of the flexor digitorum profundus (FDP) tendon, the DIP joint rests in the flexed position. The most common closed tendon injury of the hand is known as a *mallet deformity* of the finger (Fig. 48.20A). When evaluating DIP motion, it is important to isolate the function of the extensor tendon by holding the PIP joint in full extension (see Fig. 48.20B and C). Normally, full active extension is possible.

Tendon lacerations in zones 1 or 2 that result in a partial or complete mallet deformity generally warrant discussion with a hand surgeon (Fig. 48.21). Management consists of repair of the lacerated tendon and postrepair immobilization. Some surgeons will use only an external splint; others prefer placement of a Kirschner wire (K-wire) through the distal phalanx into the middle phalanx to help stabilize the joint. One technique for tendon repair is dermatotendodesis, which involves placement of a single, running roll-type suture through the tendon and overlying skin (Fig. 48.22).^{1,24} The DIP joint is then splinted in full extension for at least 6 weeks. Occult partial tendon lacerations are important to recognize to prevent the development of a mallet deformity. If there is a partial tendon laceration in zone 1 or 2 that does not result in any extension lag, the approach to repair is variable, and it is advisable to discuss the repair with the consulting hand surgeon. In general, partial tendon lacerations involving less than 50% of the tendon area that do not result in an extension lag may be splinted in extension for 7 to 10 days with or without repair of the tendon itself.²⁴ Partial tendon lacerations involving more than 50% that do not result in an extension lag may be repaired by a hand surgeon or an emergency clinician who is experienced

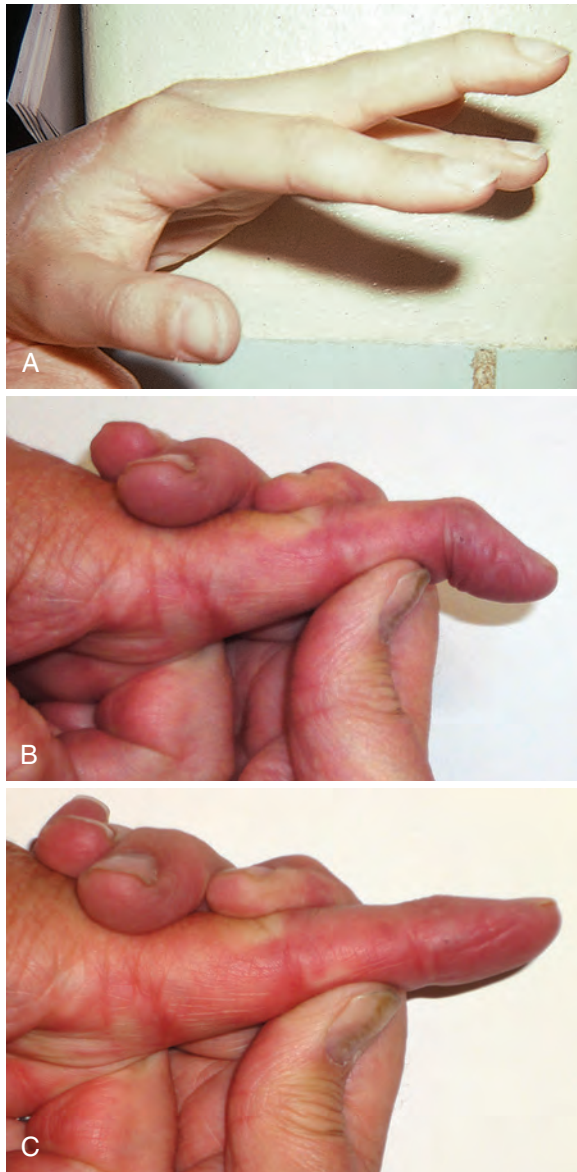

Figure 48.20 **A**, Mallet finger deformity. **B** and **C**, When evaluating distal interphalangeal (DIP) motion for a mallet finger, isolate the function of the extensor tendon by holding the proximal interphalangeal (PIP) joint in full extension. This minimizes the contribution of the central slip to DIP extension. With the PIP joint stabilized, test active extension at the DIP joint. **B**, A patient with a mallet finger will be unable to extend the distal phalanx actively, but the joint can usually be extended passively. **C**, Normal extension with the PIP joint stabilized rules out a mallet finger. See Fig. 50.18 for splinting techniques for a mallet finger. (A, From Leddy JP, Dennis TR: Tendon injuries. In Strickland JW, Rettig AC, editors: *Hand injuries in athletes*, Philadelphia, 1992, Saunders, p 180.)

in the repair of these injuries. In either case it is advisable to discuss with the consultant hand surgeon whether the tendon will be repaired in the ED or the operating room.

If a zone 1 or 2 partial tendon laceration is repaired in the ED, it can be approximated by using a combination of running and cross-stitch sutures²⁴ using 5-0 nonabsorbable (e.g., Prolene [Ethicon]) suture material. In general, given the diminutive size of the extensor tendon in this region, placement of core sutures is not possible. It is important that the tendon ends

Figure 48.21 An open mallet finger can be repaired surgically.

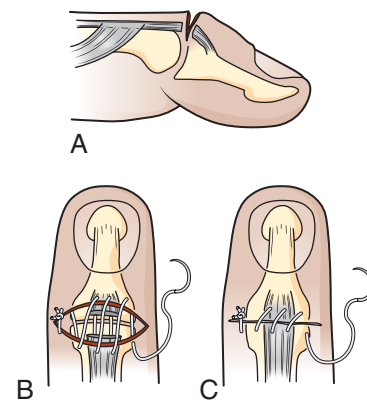

Figure 48.22 Dermatotenodesis technique for zone 1 extensor tendon repair. **A**, Fresh lacerations of the extensor mechanism over the distal joint with a mallet finger deformity are repaired with a running-type suture, which simultaneously approximates the skin and tendon (**B** and **C**). A small dressing is applied along with a splint to maintain the joint in full extension. The sutures are removed at 10 to 12 days, but the splint is continued for a total of 6 weeks. (**A–C**, Adapted from Baratz ME, Schmidt CC, Sugar AM, et al: Extensor tendon injuries. In Green DP, editor: *Operative hand surgery*, ed 5, Philadelphia, 2005, Churchill Livingstone p 190.)

be approximated but not pulled too tightly; otherwise, joint stiffness and limitation of flexion will occur. After repair of a partial tendon laceration, splint the DIP joint in extension for 6 to 8 weeks followed by 2 to 4 weeks of night splinting and active range-of-motion exercises. Patients should be warned after tendon repair that there is likely to be some residual loss of flexion at the DIP joint, even in the best case.

Closed injuries in zones 1 and 2 may result in a partial or complete mallet deformity, depending on the injury pattern. These injuries are usually caused by an axial loading force with forced flexion of the DIP joint while it is being held in extension. A common ED scenario involving this injury is a patient who complains of pain and swelling at the DIP joint after a ball strikes the fingertip.

Closed tendon injuries in this region can generally be classified into three types. The first type of injury consists of closed rupture of the TEM. The second type of injury is an avulsion fracture of the dorsal lip of the distal phalanx. This fracture is intraarticular, but there is no volar displacement of

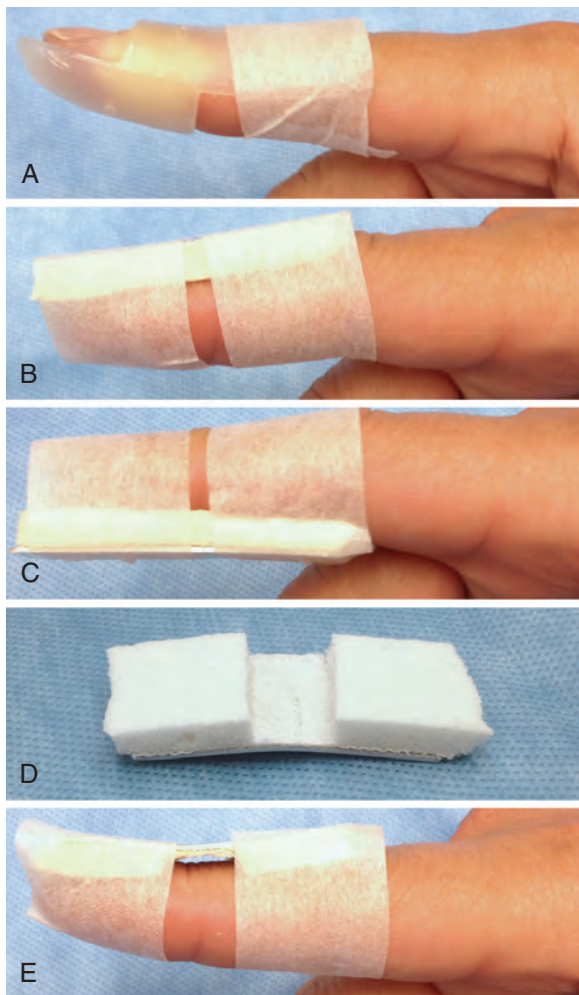

Figure 48.23 Mallet finger splints. Be careful to avoid sustained pressure from the splint on the skin in the area of the distal interphalangeal (DIP) joint. Excessive pressure or hyperextension can cause skin necrosis. The splint should allow easy motion of the proximal interphalangeal joint with no flexion of the DIP joint. Immobilize the DIP joint in full extension or slight hyperextension (5 to 10 degrees). Splints are maintained continually for 6 to 8 weeks, including during sleep, with strict avoidance of any flexion during hand washing or splint changes. **A**, Commercially available and an ideal and preferred volar plastic splint (Stack mallet finger splint). **B**, Dorsal aluminum foam splint. **C**, Volar aluminum foam splint. **D** and **E**, Kleinert mallet finger splint. The Kleinert splint provides modest hyperextension and avoids pressure on the skin by removing the middle third of the foam padding, thereby eliminating all direct pressure on the injury site. All give good results.

the remaining portion of the distal phalanx. Avoid attempting to reduce displaced fractures before splinting because any reduction is unlikely to be maintained without surgery; mallet fingers with associated fractures are best splinted and referred. Treat both type 1 and type 2 injuries by splinting in full extension for 6 to 8 weeks. Either a dorsal or palmar splint should hold the DIP joint in extension or slight hyperextension (5 to 10 degrees) while allowing free range of motion of the PIP joint (Fig. 48.23). With a properly fitted splint, no flexion of the DIP joint should occur. The splint can be constructed from aluminum, foam-backed splint material, or from a pre-fabricated stack splint (Stax, North Coast Medical, Inc. Gilroy, CA). A Cochrane review of mallet finger injury treatments

Figure 48.24 A mallet fracture with volar subluxation of the distal phalanx. Avoid attempts to reduce any displaced fractures before splinting because any reduction is unlikely to be maintained without surgery; mallet fingers with associated fractures are best referred.

found inadequate data to establish the most effective type of splint, but the stack splint is the editor's preference for ease of application and patient comfort.³³ Be careful to avoid excessive sustained pressure from the splint on the DIP joint area because skin necrosis may occur. Strictly maintain the DIP joint in full extension for 6 to 8 weeks, including during sleep and splint changes. Adherence to this instruction is essential because patients have a tendency to test its function on their own, thus tearing the healing tendon fibers. The most common reason for treatment failure is patient noncompliance with prolonged splinting. Patients should support the distal fingertip in full extension whenever the splint is removed. Should DIP joint extension be lost at any point during the initial treatment period, reset the treatment clock for an additional 6 weeks.

The third type of closed injury is an intraarticular avulsion fracture of the dorsal lip of the distal phalanx with volar displacement of the remaining portion of the distal phalanx (Fig. 48.24). Such injuries are best referred for definitive treatment consisting of either surgery or more complex splinting. Normally, the DIP collateral ligaments hold the distal phalanx in place; however, if there is a large enough fracture fragment (usually >50% of the articular surface), the remaining distal phalanx fragment displaces in the volar direction secondary to unopposed action of the FDP tendon. When volar displacement of the distal phalanx occurs, this injury may require more aggressive treatment to achieve an optimal outcome.²⁶ Unfortunately, there are no adequate randomized, controlled trials comparing operative versus conservative treatment of these injuries.³³ Operative repair usually involves open reduction (Video 48.3) and internal fixation of the fracture with placement of a K-wire for additional stabilization. It is important to remember that it is the presence of volar subluxation, not the size of the avulsion fracture, that is most often considered when determining the need for operative management.

Any injuries, whether open or closed, that result in complete disruption of the TEM may result in a swan neck deformity (Figs. 48.25 and 48.26). This deformity consists of flexion at the DIP joint (a mallet finger) and hyperextension at the PIP joint. It results from increased extension force on the middle phalanx caused by dorsal and proximal displacement of the lateral bands. This complication can often be avoided if disruption of the TEM is diagnosed and treated correctly in the ED.

Complications

All extensor tendon repairs are subject to the usual complications of wound infection and skin breakdown secondary to prolonged

Figure 48.25 Swan neck deformity. (From Skirven TM: *Rehabilitation of the hand and upper extremity*, ed 6, St. Louis, 2011, Mosby.)

Figure 48.26 Diagram of the swan neck deformity. Lateral bands have displaced dorsal to the axis of the proximal interphalangeal joint, where they extend the joint and allow the distal interphalangeal joint to flex. (From Rizio L, Belsky MR: Finger deformities in rheumatoid arthritis, *Hand Clin* 12:531, 1996.)

splinting. Tendon rupture is a rare complication after tendon repair and may result from inadequate suture technique or premature motion against resistance. When extensor tendons are repaired, it is important to use at least five throws and to tie a square knot. All extensor tendon repairs require some period of complete immobilization during tendon healing, and the emergency provider must stress the necessity for patient compliance.

Extensor tendon injuries in zone 7 tend to have the worst prognosis. Because of the presence of a synovial lining, postrepair adhesions may develop. Adhesions may lead to decreased excursion of the extensor tendons with resultant decreased mobility at the wrist. There may also be limitation of finger flexion when the wrist is flexed, as well as limitation of finger extension when the wrist is extended. Because of the lack of synovium, the low risk for adhesions, greater tendon excursion, the relatively simple anatomy, and the usual lack of associated injuries, zone 6 tendon injuries tend to have fewer complications than other areas of the hand. The tendons in zone 6, however, do have a tendency to shorten if the ends are approximated too tightly. This may result in restriction of PIP and MCP joint flexion. In addition, worse outcomes may occur with complex zone 6 tendon injuries when additional soft tissue or bony injuries are present.^{24,34}

Zone 5 injuries are particularly prone to infection because injuries in this region commonly occur from a human bite. In addition, if the extensor hood covering the MCP joint is not repaired carefully, subluxation of the EDC tendon may occur.¹³ Tendon shortening and stiffness may result if complex partial tendon lacerations in zone 4 are managed too aggressively. As

discussed previously, these injuries are often best managed by splinting alone. A common complication of zone 3 extensor tendon injury is the development of a boutonnière deformity, which usually results from failure to diagnose or adequately immobilize a central slip injury. Similarly, undiagnosed or improperly treated extensor tendon injuries in zones 1 and 2 may lead to either a swan neck or a chronic mallet deformity of the digit. DIP joint splinting itself may result in skin ulceration or tape allergy, often occurring in the second week of treatment.²⁴ Skin breakdown may ensue if the DIP joint is splinted in hyperextension because of decreased skin perfusion.

Postrepair Care and Rehabilitation

Proper care after diagnosis and repair of an extensor tendon injury is extremely important for optimal patient outcome. Even the best initial tendon repair can have a poor result if subsequently treated improperly. Rehabilitation of tendon injuries has evolved since 1980 to include dynamic splinting and active range-of-motion exercises to achieve maximal motion of the affected digit.

Zone 1 and 2 injuries are usually treated with static splinting, as described previously. After 6 to 8 weeks, active range-of-motion exercises should begin. Night splinting is recommended for an additional 2 to 6 weeks after initial immobilization.^{1,6,24,26} Some authors also recommend wearing the splint during the day when performing heavy tasks.²⁴ It is advisable to give the patient a number of extra splints so that the patient (or family) can change the splint frequently to avoid pressure injury. During splint changes it is important that the DIP joint be held in full extension either by using the other hand or by placing the finger against a table. If an extension lag develops at any time, continuous splinting must be repeated. Closed injuries of the central slip (zone 3) are often treated with a boutonnière splint for 4 to 6 weeks, followed by 2 to 6 weeks of gradual flexion exercises and night splinting. During the initial period of immobilization, the patient should be instructed to passively flex the DIP joint every hour to maintain gliding and proper position of the lateral bands.

Lacerations in zones 3 and 4 have traditionally been treated with static splinting from the forearm to the digits. An alternative approach is to splint only the DIP and PIP joints in extension and begin a “short-arc-motion” protocol within 1 to 2 days of repair.³⁵ This consists of active motion at the PIP joint progressing from 0 to 30 degrees in the first 2 weeks, then to 0 to 50 degrees in the third and fourth weeks. When compared with static splinting, this protocol may lead to better PIP and DIP joint flexion without resulting in tendon rupture or a boutonnière deformity. Dynamic extension splints are also proving to be useful for rehabilitation of zone 3 and 4 tendon injuries.^{24,35,36}

Early motion after extensor tendon repair has been found to be most useful in zones 5 through 7. A dynamic extension splint in which the wrist is extended 45 degrees and all finger joints rest in the neutral position is commonly used. A volar block allows 30 to 40 degrees of MCP joint flexion, whereas a dynamic traction mechanism passively extends the digits. Dynamic splinting is started 1 to 3 days after repair. Active motion is added at 3 to 4 weeks, and resistance is added at 7 weeks. A randomized, controlled trial of zone 5 and 6 extensor tendon repairs found total active motion with dynamic splinting was superior to static splinting at 4 to 8 weeks, but not at 6 months. However, grip strength in the affected hand was

improved at 6 months with dynamic splinting.³⁷ A short-arc-motion protocol with controlled active motion at the MCP joint has also been shown to be safe and effective when started 24 to 48 hours after repair.¹³ One comparative trial reported that dynamic extension splinting and controlled active mobilization worked equally well for zone 5 and 6 tendon injuries.³⁸ All early range-of-motion protocols are most beneficial when managed closely by a skilled hand therapist. Patient age, associated injuries, suture type, and repair technique all affect the choice of rehabilitation protocol.¹³ Most importantly, patients must be reliable and motivated to take advantage of early range-of-motion techniques. It is best to refer patients to a hand surgeon or hand therapist as soon as possible after repair so that rehabilitation can begin in a timely manner.

EXTENSOR TENDON INJURIES OF THE FOOT

The extensor tendons of the foot are less commonly injured than the extensor tendons of the hand and wrist. The most important extensors of the foot and ankle that may be injured and encountered in the ED are the tibialis anterior, extensor hallucis longus (EHL), and extensor digitorum longus (EDL) tendons.

The tibialis anterior muscle originates on the shaft of the tibia and interosseous membrane and inserts on the medial

cuneiform and the base of the first metatarsal. The tibialis anterior extends (dorsiflexion) the foot at the ankle joint and inverts the foot at the subtalar and transverse tarsal joints. Spontaneous rupture of the tibialis anterior tendon may be seen in both elderly and young patients who have been injured during athletic activity. Injury to this tendon commonly results from forceful attempted dorsiflexion of the ankle while it is held fixed in the plantar-flexed position.³⁷ Patients generally have decreased strength of foot dorsiflexion because the toe extensors are used to accomplish this motion. Rupture or laceration of the tibialis anterior tendon should be promptly referred to an orthopedic surgeon for consideration of formal operative repair. In some cases, closed injuries of the tibialis anterior tendon may be managed nonoperatively depending on the extent of the patient's symptoms and functional impairment.³⁹

The EDL and EHL tendons both originate from the shaft of the fibula and interosseous membrane. The EHL tendon inserts on the base of the distal phalanx of the great toe, whereas the EDL tendon divides into four branches that insert on toes 2 through 5 (Fig. 48.27). Both the EHL and the EDL tendons primarily result in extension of the toes and dorsiflexion at the ankle. The extensor digitorum brevis (EDB) and extensor hallucis brevis (EHB) muscles originate from the upper part of the calcaneus. The EHB tendon joins the lateral aspect of the EHL tendon before inserting on the great toe. The EDB

Figure 48.27 Muscles of the dorsum of the foot: superficial dissection. (Netter illustrations used with permission of Elsevier Inc. All rights reserved.)

muscle gives rise to three tendons that join the lateral side of the EDL tendons going to toes 2 through 4 (see Fig. 48.27).

Injury to the EHL and EDL tendons may result from a sharp object lacerating the dorsum of the foot. Patients may have weakness of, or an inability to extend, the involved toe or toes. The examiner may be unable to palpate the injured tendon. Whether one should repair EHL or EDL tendon lacerations is controversial. However, many authors favor repair because failure to repair EDL tendons may result in a claw deformity of the adjacent toes.⁴⁰ Lacerations of the EHL and EDL tendons at the level of the ankle are usually repaired, whereas lacerations on the dorsum of the foot and the toe are variably managed. Repair is favored if the patient has significant pain or any flexion deformity of the involved toe. Repair is also favored when both ends of the tendon are easily visualized in the wound and the patient is willing to undergo prolonged immobilization after repair.⁴¹ Because management of these injuries is controversial, it is advisable to discuss the care of these patients with the consulting orthopedic surgeon or podiatrist. Extensor tendon repair of the foot is not usually performed in the ED setting. Superficial cutaneous nerves are easily injured on the dorsum of the foot during wound exploration, which can lead to the formation of a chronic, painful neuroma. If the injury is repaired in the ED, the technique for repair is similar to that used for the dorsum of the hand (zone 6). A posterior splint that includes the toes should be applied after tendon repair. Splint the ankle at 90 degrees with the toes in the neutral position, and recommend non-weight bearing status until specialty follow-up.

FLEXOR TENDON INJURIES

Flexor tendon injuries are more difficult to diagnose and more challenging to treat than extensor tendon injuries. In general, emergency providers do not repair flexor tendons. Anatomic and biomechanical issues, the physiology of flexor tendons and tendon healing, and follow-up rehabilitation and physical therapy are complex and formidable. A satisfactory outcome is more difficult to achieve with an injured flexor tendon than with a similar degree of injury to an extensor tendon. Unlike extensor tendons, flexor tendons are influenced by a number of complex pulley mechanisms. Flexor tendons glide through delicate tendon sheathes, so even a minor defect in tendon integrity is physiologically magnified (Fig. 48.28). In addition, flexor tendon injuries are often associated with nerve and vascular injuries.

The main clinical mandates for emergency providers are to diagnose or consider flexor tendon injuries, provide initial proper wound care, and expedite appropriate consultation and follow-up. Unlike the more superficial extensor tendons, flexor tendons are often buried deep within the hand and forearm, and it is frequently not possible to visualize the tendon in the recesses of a wound. Puncture wounds of the palm often injure flexor tendons, but deep puncture wounds prohibit visualization of injured structures (Fig. 48.29). Therefore a partial flexor tendon injury may be clinically silent until rupture occurs days or weeks later. Delayed repair of undiagnosed flexor tendons may be complicated by tendon retraction or scar formation, and tendon transfer and grafting may be necessary.

It may not be possible on the initial visit for the emergency provider to diagnose the presence of all flexor tendon injuries, nor the full extent of such injuries. Help may be obtained from

a specialist if logistically possible, but generally there is no mandate for such immediate on-site examination when questions about tendon integrity exist. Even though consultation is advised before definitive disposition, the same limitations in the examination would similarly confront a specialist. Individual scenarios and local protocols will guide the timing and degree of consultation in the ED.

Notwithstanding the previous discussion, complete flexor tendon injuries are often apparent on physical examination, either by testing individual tendons or by the resting posture of the injured hand. In contrast, partial tendon lacerations are commonly clinically unappreciated because no functional deficit is evident. Clinical clues to a potential flexor tendon injury are weakness of flexor tendon function (difficult to evaluate in an acutely injured extremity), pain at the site of injury when performing active range of motion against resistance, and an abnormal resting position of the hand (Fig. 48.30A and B), which can be determined by careful examination but is always difficult in a child or uncooperative patient (see Fig. 48.30C and D). The emergency provider may not be able to arrive at a complete or accurate diagnosis without surgical exploration. However, it is counterproductive and potentially harmful to attempt extensive exploration of the deep recesses of the hand or forearm in the ED merely to visualize a suspected flexor tendon injury.

A specialist, usually on an elective outpatient basis, surgically repairs completely transected flexor tendons. Most hand surgeons are reluctant to perform primary repair of a flexor tendon injury on ED patients and prefer to have the wound cleaned, the skin closed, and the patient scheduled for subsequent definitive repair. The final outcome of flexor tendon surgery depends on multiple factors; however, surgical repair of most flexor tendons accomplished within 10 to 21 days of injury (delayed primary repair) generally produces final outcomes similar to those repaired immediately.⁴²⁻⁴⁴ Therefore, if a partial tendon laceration is not diagnosed at the initial visit and rupture is noted at the time of removal of the skin sutures or inspection of the wound, immediate referral to a hand surgeon would be expected to provide a similar result had the injury been diagnosed at the time of the initial ED visit.

It is appropriate to treat partial flexor tendon lacerations, if appreciated, with careful wound cleaning, skin closure, splinting, and referral for reevaluation in 1 to 5 days. Definitive treatment of partial lacerations remains quite controversial. Some surgeons will repair all partial tendon lacerations, whereas others take a more conservative approach. The conservative approach is supported by experimental evidence suggesting that surgical repair of partially lacerated tendons results in weaker tendons than if the tendons were not surgically repaired.⁴⁵ Wray and colleagues suggest forgoing suturing in favor of splinting, followed by early mobilization of tendons with lacerations involving 25% to 95% of the cross-sectional area.⁴⁶ Without conclusive evidence either way, a reasonable approach would be to suture tendon lacerations involving greater than 50% of the cross-sectional area with special surgical techniques, suture tendon lacerations involving 25% to 50% of the cross-sectional area with simple or special suture techniques, and simply trim injuries that affect less than 25% of the cross-sectional area to promote normal gliding function.⁴⁴ All decisions concerning the type and timing of repair should be made in concert with a consultant, while keeping in mind that some decisions regarding surgical repair of partial injuries cannot be made for weeks or months.

Figure 48.28 A, Muscles of the forearm (deep layer): anterior view. B, Muscles of the forearm (intermediate layer): anterior view.

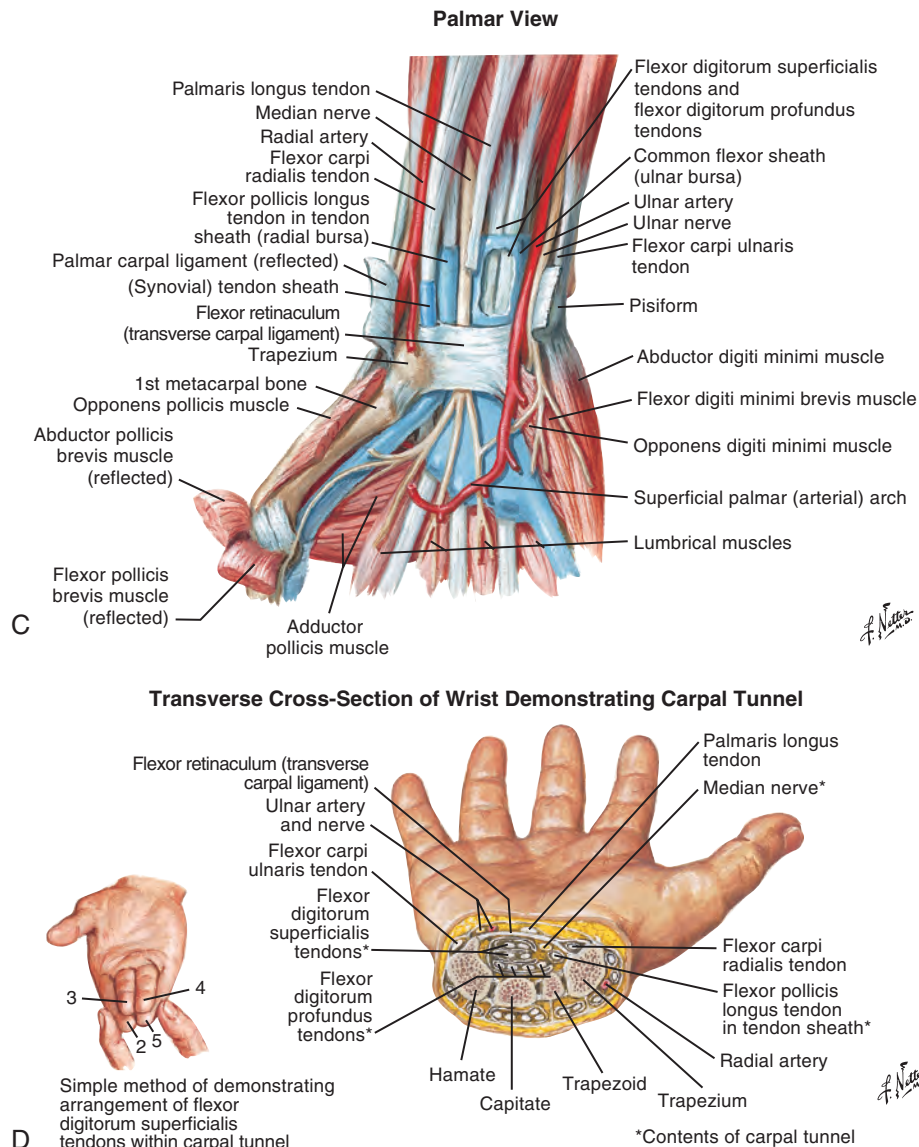

Figure 48.28, cont'd C, Flexor tendons, arteries, and nerves at the wrist: palmar view. D, Transverse cross-section of the wrist demonstrating the carpal tunnel. (A–D, Netter illustrations used with permission of Elsevier Inc. All rights reserved.)

Following evaluation of a known or suspected flexor tendon injury, suture the skin and splint the hand to protect the tendon and minimize retraction. Techniques vary, and the initial splinting positions are probably inconsequential to the final outcome if the duration of splinting does not exceed 7 to 14 days. As a guideline, splinting the wrist in 30 degrees of flexion, the MCP joints in 70 degrees of flexion, and the IP joints in 10% to 15% of flexion has been recommended.⁴⁷ No data exist to support or refute the value of prophylactic antibiotics for any soft tissue injury that has been properly cleaned. Although no definitive standard of care has been promulgated, many clinicians prescribe 3 to 5 days of antibiotics effective against gram-positive organisms (including *Staphylococcus aureus*) if a tendon is injured. Antibiotics are recommended if the degree of contamination is significant, cleaning has been delayed, there are unusual sources of injury, or the patient is immunocompromised. Specific written instructions with a definite follow-up time frame outlined and assistance in patient referral

will probably improve the final outcome, but flexor tendon injuries often produce lifelong disability despite even ideal care in the ED.^{7,48}

ACHILLES TENDON RUPTURE

An Achilles tendon rupture can lead to serious morbidity. Although definitive care of such injuries is not performed in the ED, it is important to make the correct diagnosis and institute proper and prompt referral. This injury is easy to miss, and it is not always diagnosed on the first visit. Initially considered a minor ankle sprain by both the patient and provider, the diagnosis was missed in more than 20% of cases in a 2008 case series.⁴⁹ Rupture often occurs with steroid use, with degenerative conditions, and in the elderly, but Achilles tendon rupture can also occur in healthy athletic patients with no history of heel pain and often with seemingly minor trauma.

Figure 48.29 Deep puncture wounds of the palm may injure the flexor tendons. **A**, The depth of this wound precludes extensive exploration to visualize the tendon. Partial tendon lacerations may still initially allow full function. Clues to a partial flexor tendon laceration include weakness of flexion or pain with attempts at flexion against resistance, but many partial lacerations are clinically silent. Despite full function, this wound's location and depth suggest the possibility of at least a partial tendon injury. The prudent course would include meticulous wound care, splinting, skin closure, and contact with a hand specialist to arrange reexamination in a few days, while cautioning the patient that a flexor tendon injury may be present and delayed repair for up to 1 to 3 weeks yields results comparable to immediate repair. Immediate repair is often eschewed because of swelling and wound contamination. Further care may be required. **B**, This palm laceration from the sharp top of a metal can seemed superficial. Function was normal. **C**, When examined with the fingers in extension, the tendon was readily visualized, a surprise to the clinician given the benign and superficial appearance of the laceration. The visualized tendon was intact. **D**, However, when the fingers were flexed (*arrow*), the position of the hand when the injury occurred, a 20% to 30% laceration of the tendon was demonstrated. **E**, This injury will do well with 3 weeks of splinting and no tendon repair. Follow-up with a hand surgeon in a few days is prudent. Note the outrigger aluminum splint incorporated into a short-arm plaster splint (*arrow*; see [Fig. 48.11](#)).

Fluoroquinolone antibiotics have been implicated in Achilles tendon rupture, especially in the elderly. This led the Food and Drug Administration to issue a “black box” warning on the use of all fluoroquinolones for this condition in 2008.⁵⁰ The common mechanism of rupture is sudden overload of the tendon by forceful plantar flexion of the foot, as in recreational sports involving jumping (basketball), pushing a heavy object, or stepping up. The injury is usually a complete as opposed to a partial tear, and rupture commonly occurs in a region 2 to 6 cm proximal to the tendon's insertion on the calcaneus. Occasionally, the patient may appreciate an audible snap or

pop. Pain may not be perceived in the tendon itself; instead, heel or diffuse ankle pain may be experienced. Because multiple structures plantar flex the foot, the initial result is weakness of the ankle, but importantly, complete loss of motion of the foot may not occur. Characteristic ecchymosis may be evident in 48 to 72 hours after injury.

The diagnosis may be suggested by a palpable defect in the tendon, but this can be subtle or absent ([Fig. 48.31](#)). The calf squeeze test (Thompson's test) is a physical finding that is 96% to 100% sensitive. To perform this test, have the patient lie prone with the feet overhanging the edge of the examination

Figure 48.30 **A**, Note the obvious abnormal resting posture of the hand. This boy's palm laceration involved the flexor tendons to his index finger. With his hand at rest, his index finger lies in extension, in contrast to his other fingers, which are partially flexed. **B**, Loss of the digital cascade in the middle finger illustrated here should be indicative of a flexor tendon laceration without further examination. The small glass laceration in the palm accounts for the profundus laceration, apparent only at follow-up. Children are difficult to fully examine in the emergency department. Splinting and follow-up in a few days are prudent based on the injury mechanism and location. **C**, The flexor digitorum profundus tendon is examined by immobilizing the digit in question and asking the patient to flex the distal interphalangeal joint against resistance. **D**, The flexor digitorum superficialis tendon is examined by immobilizing the digits not being tested and asking the patient to flex the proximal interphalangeal joint against resistance. Pain and weakness associated with flexion against resistance may suggest a partial tendon laceration, but this is often a very subtle or inaccurate evaluation that must be repeated when the pain and swelling have subsided. (**A**, Courtesy Robert Hickey, MD, Children's Hospital of Pittsburgh.)

table. Squeeze the calf and observe for strong passive plantar flexion of the foot. If the foot does not move, a complete tear is diagnosed (Fig. 48.32). When the diagnosis is not clinically certain, or when the possibility of other injuries exists, emergency imaging should be performed. With isolated Achilles tendon rupture, standard radiographs will be normal. MRI is diagnostic but not usually indicated in the ED. Point-of-care ultrasound has emerged as a useful tool to diagnose both

complete and partial tendon ruptures.⁵¹ Sonography is appealing because of its relatively low cost, portability, safety profile, the ability to perform static and dynamic evaluations, and the ability to compare the contralateral side easily. The sensitivity and specificity of ultrasound for Achilles tendon rupture, as reported in the radiology literature, are 96% to 100% and 83% to 100%, respectively.^{52,53} Although no studies have directly evaluated the diagnostic accuracy of ultrasound performed by

Figure 48.31 This patient complained of a sprained ankle of 3 days' duration after jumping in a basketball game. There was moderate weakness of plantar flexion, but not complete loss. A defect in the Achilles tendon may be appreciated in some cases of Achilles tendon rupture, but not in this case. Note the characteristic bruising.

Figure 48.32 **A**, To perform the calf squeeze test (Thompson's test) place the patient prone on the stretcher with the feet overhanging the edge. **B**, Squeeze the calf and look for forceful passive plantar flexion of the foot. In this case the left foot (note the swelling and ecchymosis) did not move, thus confirming a complete Achilles tendon rupture.

Figure 48.33 Longitudinal ultrasound of a complete Achilles tendon rupture. There is a 2.6-cm separation between the proximal (left) and distal (right) torn tendon ends (indicated by the dotted line between plus marks). The calcaneus is located far to the right. Herniated echogenic fat can be seen between the injured tendon edges. (From Fessell DP, Jacobson JA: *Ultrasound of the hindfoot and midfoot*, *Radiol Clin North Am* 46:1027, 2008.)

emergency physicians for Achilles tendon ruptures, bedside ultrasound performed by emergency physicians for tendon injuries in other body areas had a sensitivity, specificity, and accuracy of 100%, 95%, and 97%, respectively.⁵ A *sonographic Thompson's test* can be performed by directly visualizing the Achilles tendon with the high-frequency linear ultrasound probe while the calf muscle of the prone patient is gently squeezed. The Achilles tendon is assessed, proximally to distally, for synchronous movement, using dynamic sonography during passive dorsiflexion and plantar flexion of the ankle with the probe over the area of interest. Complete tears are recognized by retraction of the proximal tendon end, and echogenic adipose tissue (Kager's fat) may be seen to herniate between the torn ends of the tendon (Fig. 48.33).⁴⁹ The provider will see continuous tendon movement at the rupture site in the case of a partial rupture because some intact fibers remain.⁵⁴ Treatment is variable, ranging from conservative splinting to surgical repair. Splinting the foot in mild plantar flexion (gravity equinus) can protect the tendon until follow-up in 1 to 5 days.

KNEE EXTENSOR TENDON RUPTURE⁴¹

The extensor mechanism of the knee is composed of the four strong quadriceps muscles, the femoral quadriceps tendon, the patella, the patellofemoral and patellotibial ligaments, the medial and lateral retinacula, the patellar tendon, and the tibial tubercle. Both the quadriceps and patellar tendons are subject to rupture, and the condition occurs predominantly in males. Quadriceps tendon rupture is more common in the elderly and in those with systemic degenerative disease, arthritis, and steroid use, and is associated with significant morbidity regardless of treatment. It may also be seen in younger patients, such as after taking a basketball jump shot. Performance-enhancing steroid use is likewise a risk factor in these patients. Patellar tendon rupture is also a serious injury but occurs more commonly in healthy patients, younger than 40 years, participating in sporting events.⁵⁵

As with Achilles tendon rupture, rupture of the knee extensor mechanism is not always initially suspected or diagnosed; it is missed on initial evaluation in nearly 40% of cases.⁵⁶ The mechanism of quadriceps tendon rupture is usually a deceleration injury with the knee partially flexed, coupled with a strong quadriceps muscle contraction when the foot is fixed. The trauma may be seemingly minor, such as missing a step or jumping from a low height. A common history is an elderly patient who is descending steps or walking off a curb, misses a step, and attempts to keep from falling. A popping or tearing

Figure 48.34 **A**, This elderly man lost his footing going down the stairs and missed only a single step. He felt a pop and was unable to walk. Arthrocentesis yielded a grossly bloody effluent. An obvious suprapatellar soft tissue defect and an inability to perform a straight-leg raise while supine made the diagnosis of a complete quadriceps tendon rupture obvious. **B**, This man landed on both feet while jumping off a low curb and then collapsed. Pain was minimal and malingering was suspected. Diffuse soft tissue swelling, bilateral knee effusions, normal radiographic findings, and the ability to walk with bilateral knee immobilizers delayed the diagnosis of bilateral quadriceps tendon rupture until follow-up. **C**, A step-off above the knee readily identified a complete quadriceps tendon rupture. The patient was unable to lift the leg off the stretcher, an activity that made the soft tissue defect obvious.

sensation may be elicited. The pain may be deceptively minor. The rupture may be partial but is more often complete. Quadriceps tendon rupture usually occurs transversely, just proximal to the patellar insertion, with or without an avulsion fracture of the superior pole of the patella. A suprapatellar gap may be palpated. The mechanism of patellar tendon rupture is usually an excessive load on the flexed knee during athletic activities. The patient complains of pain and inability to extend the knee or ambulate. Patellar tendon rupture generally occurs at the inferior pole of the patella. Athletic patients may continue to play with a partial tear, but a complete rupture does not allow ambulation. Bilateral complete rupture has been described, but the condition is generally unilateral.

With either type of rupture, a large hemarthrosis is usually produced and often prompts the incorrect diagnosis of a ligamentous injury such as an anterior cruciate ligament rupture. A palpable defect superior or inferior to the patella may be appreciated, but diffuse swelling can mask this finding (Fig. 48.34). Lack of the expected defect can be misleading in the presence of a large hemarthrosis. When the history consists of only minor trauma, and the findings on physical examination are subtle, the provider may incorrectly suspect malingering or noncooperation with the examination. With complete rupture, a supine patient is unable to actively extend the knee or lift a straightened leg off the stretcher, and the knee flexes when posterior thigh support is removed from the raised leg. Weak extension, especially in the sitting position, may be possible if portions of the medial and lateral retinaculæ are intact, even with a complete rupture of the central rectus femoris. With complete rupture, the patient cannot walk and the knee gives way immediately. As one would intuit, however, a knee immobilizer allows the patient to apparently walk normally. Partial tears may allow the patient to walk with a

peculiar forward-leaning gait that helps support the knee in extension.

Plain radiographs may show the occasional patellar avulsion fracture. With quadriceps tendon ruptures, a low-riding patella (*patella baja*) may be present as the patella falls inferiorly. Conversely, a high-riding patella (*patella alta*) is often seen with patella tendon ruptures as the quadriceps tendon and patella retract superiorly. MRI is definitive for identifying nuances of the process. As with Achilles tendon rupture, sonography is an emerging diagnostic imaging tool used by some ED providers to assess for ruptures of the quadriceps and patellar tendons.⁵¹ Complete tendon ruptures yield hypoechogenicity over the entire length and thickness of the tendon, whereas a hypoechoic line with a wedge-shaped separation may be seen with a partial laceration. The use of dynamic ultrasound will demonstrate the separated tendon ends moving away from each other with intervening echogenic or echolucent fluid.⁵⁷ Partial tears of either tendon may be treated surgically, or nonoperatively if there is no functional impairment. Complete tears require surgical repair, usually as soon as possible after the diagnosis is made.⁵⁵ Although definitive treatment is not undertaken in the ED, early diagnosis may improve the long-term outcome. There is no consensus regarding the timing of repair, although delays are correlated with tendon retraction and atrophy. Therefore most authors recommend early repair.⁵⁸ The postoperative period of recovery for the elderly is prolonged and difficult. Acute injuries diagnosed in the ED should be treated with the knee fully extended in a knee immobilizer and crutches with a 1- to 2-day follow-up, but admission is often warranted to expedite definitive intervention.⁴⁵

Management of Common Dislocations

Robin M. Naples and Jacob W. Ufberg

Joint dislocations are frequently encountered in patients seen in the emergency department (ED). They can range from a simple finger joint dislocation to limb- or life-threatening consequences of high-energy trauma. Keys to clinical assessment and radiographic evaluation of these injuries are discussed along with methods of reduction. The emphasis of the chapter is on simple dislocations that should be diagnosed and initially managed in the ED (Videos 49.1 to 49.22). Fracture-dislocations that commonly require operative intervention and emergency orthopedic consultation are not discussed.

PREPARATION OF THE PATIENT

Although many authors claim that their reduction method is well tolerated without premedication, they have not usually measured the discomfort of their patients quantitatively.¹⁻⁵ There are no rigid, generally accepted guidelines for the use of pharmacologic adjuncts in the management of dislocations. Each patient and each dislocation is unique, and the treating clinician must use judgment regarding whether premedication is required, which agent or agents to use, and what dose to give. In general, the authors suggest the routine judicious use of analgesia with or without sedation for the majority of reductions performed in the ED. A calm, cooperative patient may tolerate attempts at gentle reduction of a major joint such as the shoulder, but even the most stoic of patients may be quite uncomfortable with the manipulations necessary for reduction of a dislocated finger. A radial head dislocation in a child is usually easily treated without analgesia; however, reduction of a hip dislocation is unlikely to be successful without a significant amount of sedation and analgesia. Attempting any reduction technique in an extremely anxious patient without premedication will generally frustrate the operator and further upset the patient and may hinder a successful outcome. When multiple attempts are required and significant force must be exerted because of muscle spasm or an uncooperative patient, there is an additional chance of producing complications during the reduction.

Verbal techniques for alleviating anxiety and discomfort are not to be discounted because they can be of great assistance during joint reduction. In field settings, simple hypnosis techniques have been used successfully for major joint dislocations.⁶ In the ED, verbal reassurance and distracting conversation are useful adjuncts. Additionally, the use of handheld tablets has shown to aide a variety of painful procedures in the pediatric population and may be a useful adjunct.^{7,8}

In most circumstances, analgesia or sedation of some sort, or both, will be required; the intravenous (IV) route of drug administration is usually the method of choice because it allows

rapid relief of patient discomfort and facilitates repetitive dosing for titration to the desired effect (see [Chapter 33](#)). Alternatives to procedural sedation and analgesia include intraarticular injection of local anesthetics, hematoma blocks, peripheral nerve blocks, and regional anesthesia (see [Chapters 29, 31, and 32](#)).

GENERAL PRINCIPLES

Clinical assessment of a patient with a dislocation must include a search for fractures or other serious injuries, especially if the mechanism involved high energy. This is most important for hip, knee, and posterior sternoclavicular dislocations. For all dislocations, perform a detailed neurovascular examination of the extremity before focusing attention on the injured joint.

Although many dislocations are clinically obvious, some may escape detection for some time as other injuries or issues dominate the clinical picture. A knee dislocation may be quite obvious in a 170-lb man who displays a deformity of the knee, but in a 400-lb patient, the knee may look deceptively normal on first glance. The history and mechanism of injury can be quite helpful in certain circumstances. For example, a painful shoulder joint in a seizure patient should prompt assessment for a posterior shoulder dislocation, whereas a history of the knee striking the dashboard is a clue to a potential hip dislocation.

Some dislocations can be difficult to identify on plain radiographs. One should keep a high index of suspicion for dislocation when indicated. Carpal dislocations in the wrist may be subtle, but are clinically suggested by severe pain and swelling. Similarly, superior dislocation of the patella may be mistaken for high riding patella typical of patellar tendon rupture. Unlike anterior shoulder dislocations, which are often easily detected on plain films, posterior shoulder dislocations may be missed on initial radiographs.

Some dislocations will have been reduced before clinician assessment. A careful history will uncover these injuries and prompt the necessary assessment of the ligamentous integrity and the possibility of an associated vascular injury and guide proper immobilization and follow-up care. A dislocated and then spontaneously reduced knee is a severe injury that often escapes detection by even a seasoned clinician's initial evaluation. Other dislocations that are commonly first seen in a reduced state include finger dislocations, patellar dislocations, and radial head subluxations.

Although the chance that a gentle attempt at reduction will cause a fracture or neurovascular injury is extremely low, careful evaluation before and after reduction, as well as documentation of the patient's neurovascular status, is important. Frequently, the initial pain of the dislocation is distracting, and paresthesias or a weak pulse may not be readily apparent until the joint has been reduced. When the integrity of the pulse is in question, *blood pressure* at the wrist or foot may be compared with that in the uninjured extremity, or a *pulse oximeter* may be applied to the distal end of the fingers ([Fig. 49.1](#)).

Pre-reduction radiographs are generally recommended. Reasons include difficulty distinguishing a fracture-dislocation by clinical examination and the potential for medicolegal problems if the fracture is not identified before attempts at reduction. More importantly, certain associated fractures predict a poor outcome with closed reduction and make orthopedic consultation a consideration before such attempts. Exceptions

Figure 49.1 Significant vascular injuries from dislocations, such as knee, elbow, or ankle dislocations, are usually obvious, but impaired distal circulation may be subtle or delayed because of a slowly increasing intimal flap arterial lesion. Standard techniques to assess vascular injury are the strength of the pulse and capillary refill; this should detect most arterial injuries. **A**, Taking a blood pressure reading distal to the injury with a cuff and Doppler ultrasound, or **B**, applying a pulse oximeter distal to the injury and comparing the results with those of the uninjured extremity may give some helpful clues to underlying vascular injuries.

to this rule include suspected radial head subluxation in young children and clinical circumstances in which radiographs are not readily available (e.g., in the wilderness). Clinical conditions (i.e., vascular compromise or threatened skin penetration) may dictate the need for immediate reduction without radiographs; however, the few minutes required for initial radiographic evaluation rarely increases vascular or neurologic complications and provides very useful information to the consultant.

Some authors question the need for pre-reduction films in certain patients with obvious or recurrent anterior shoulder dislocation.^{9,10} Although post-reduction radiographs are traditionally obtained, the need for this in a clinically obvious successful shoulder joint relocation has been questioned.^{10,11} The authors suggest that post-reduction films be taken in virtually all patients who have had a dislocation reduced in the ED. Patients who have received sedatives and opioids may not remember the actual successful reduction or the immediate post-reduction period. Re-injury after release from the ED without radiographic corroboration of a successful reduction can raise questions about the adequacy of the initial procedure. Occasionally, a fracture is detected on post-reduction radio-

graphs that was not obvious on the initial films, or a previously noted minor fracture may be found to reside in an intraarticular location.¹⁰ Point of care ultrasound is being used more frequently by emergency medicine physicians for musculoskeletal complaints. A growing body of research is revealing the safety and efficiency of using this modality for diagnosing dislocations and confirming successful reduction and will be discussed later in this chapter. As practitioners gain confidence and experience with ultrasound in this capacity, the need for both pre- and post-reduction radiographs may be supplanted by the performance of ultrasound.

In general, dislocations of all types are less common in children than in adults because of the relative weakness of the epiphyseal growth plate with respect to the ligamentous support of the joint. Therefore, in children the epiphysis will tend to fracture before dislocation occurs, except in the case of radial head dislocation (nursemaid's elbow). Reduction techniques for pediatric dislocations are generally similar to those used for adults.

The proper terminology for dislocations describes the relationship of the distal (or displaced) segment relative to the proximal bone or the normal anatomic structure. The terms *anterior* and *posterior* are used for most dislocations. Therefore, if the head of the humerus lies anterior to the glenoid fossa, the injury is an anterior shoulder dislocation. Similarly, if the olecranon lies behind the distal end of the humerus, the injury is a posterior elbow dislocation. In the hand, wrist, and foot, one uses the terms *dorsal* and *volar*. *Palmar* and *plantar* are sometimes used in place of volar to describe the position of the dislocated part. Dislocations can be *open* or *closed* and may have associated fractures, which require a separate description.

It is generally accepted that the sooner a dislocation is reduced, the better. This alleviates the patient's discomfort and corrects distortion of the surrounding soft tissues. In some studies the success rate of reduction is higher when attempted closer to the time of injury.² However, there is no reason to forego an attempt at closed reduction of an "old injury" in the vast majority of dislocations. Although chronic dislocations persisting several days, weeks, or longer are often difficult to reduce in a closed manner, such cases are infrequent and should not deter the physician from attempting closed reduction.

A certain percentage of all types of dislocations are not amenable to closed reduction. Inability to complete a closed reduction is generally the result of interposition of soft tissue structures or fracture fragments and not necessarily due to improper technique. If sedation and analgesia are adequate to permit relaxation of the patient's muscle tone, reduction should be relatively straightforward. When reduction under adequate sedation and analgesia is unsuccessful after several attempts, further attempts at closed reduction are inappropriate. Generally, orthopedic consultation should be obtained after two or three failed attempts.

Once an attempt at reduction is completed, recheck the neurovascular status that was documented before the reduction was performed. For the elbow, hand, and forefoot joints, perform passive range of motion to assess the stability of the reduction and to ensure a smoothly gliding joint that is free of intraarticular obstruction. For the shoulder, one must be cautious after reduction as full passive range of motion may cause repeated dislocation. Testing the ability to place the palm of the ipsilateral hand on the contralateral shoulder can safely assess successful range of motion and confirmation of reduction.

Figure 49.2 A and B, Because the distal pulse is weak and the toes are numb, it may be tempting—and is commonly advocated and acceptable—to immediately reduce these obvious dislocations while the patient is still on the ambulance stretcher. Because proper analgesia or sedation (or both) is required, it is often prudent, although not mandatory, to take a few minutes to also obtain at least a portable radiograph. C, Note the very significant fracture-dislocation on the pre-reduction radiograph. D, Once the reduction is accomplished, there is a remarkable difference that suggests a less impressive injury. *The specific initial injury will be impossible to reconstruct from the post-reduction physical examination alone.* The few minutes required to properly prepare the patient for reduction and to document the initial injury will not result in a more serious adverse outcome than has been prognosticated by the initial injury. However, when the patient has sustained multiple trauma and extremity films are a low priority, early reduction without radiographs may be warranted.

In addition to close monitoring of the medicated patient, proper aftercare involves adequate immobilization of the injured joint for comfort and to prevent repeated dislocation. Recommendations for follow-up care depend on the injury and its severity.

Timing of Reduction

Questions often arise concerning the necessity of immediate versus delayed reduction, with the clinician fearing disastrous neurovascular consequences if a dislocation is not manipulated immediately on arrival at the ED. In reality, there is rarely an instance in which pre-reduction radiographs, even portable films, cannot be obtained before treatment. Even if the pulse is weak or the fingers are numb, a few minutes' delay is usually acceptable to gain important radiographic information on the

type of dislocation and the presence of an associated fracture and to provide documentation for follow-up clinicians. Important clinical information may be difficult to obtain, or the specific initial injury may be impossible to reconstruct once the joint has been reduced (Fig. 49.2). Of equal importance, a dislocation with concomitant neurovascular injury should be reduced with the least amount of trauma possible, which often requires a few minutes for induction of analgesia and sedation, a time during which radiographs can be obtained. If a vascular or neurologic abnormality is documented before reduction, the joint should be reduced by the timeliest and least traumatic procedure available. Each case should be handled individually by taking the specific injury, available resources, and the clinician's experience into account. Although multiple unsuccessful or forceful attempts at reduction in the ED should be avoided with all dislocations, this is especially important in patients

with vascular or neurologic compromise. Occasionally, the more prudent course is reduction under general anesthesia, but this decision must take into consideration the availability of consultation and other resources.

The remainder of this chapter covers dislocations of the various joints with the exception of carpal (wrist) dislocations, which are complex and require orthopedic consultation, and temporomandibular joint dislocations, which are discussed in Chapter 63.

SHOULDER DISLOCATIONS

The human shoulder joint is remarkable for its degrees of motion. The glenohumeral joint has the greatest range of motion of any joint in the body, largely because of the loose joint capsule and the shallow nature of the glenoid fossa.¹² However, these anatomic features that allow for great mobility contribute to its instability, making it the most frequently encountered large joint dislocation. Posterior dislocation is uncommon, mainly because of the anatomic support of the scapula and the thick muscular support in this area. Anterior support is less pronounced, with the inferior glenohumeral ligament serving as the primary restraint to anterior dislocation.¹³ The depth of the glenoid fossa is somewhat increased by the fibrocartilaginous glenoid labrum, which forms the rim of this structure.

Most shoulder dislocations are anterior (i.e., the humeral head becomes situated in front of the glenoid fossa). Posterior dislocations are the next most common, but they generally account for less than 4% of shoulder dislocations.¹⁴ Less common variations include inferior (luxatio erecta), superior, and intrathoracic dislocations.

Anterior Shoulder Dislocations

As stated earlier, shoulder dislocations are the most common major joint dislocation encountered and reduced in the ED, with anterior dislocations comprising the vast majority. The usual mechanism of injury is indirect and consists of a combination of abduction, extension, and external rotation.^{12,13} Only rarely is the mechanism a direct blow to the posterior aspect of the shoulder. Occasionally, especially with recurrent dislocations, the mechanism is surprisingly minor and can be puzzling to the clinician. An anterior dislocation can be induced by mere external rotation of the shoulder while rolling over in bed or reaching behind oneself for the seat belt. When the first dislocation occurs at a younger age, the recurrence rate is higher. If the first dislocation occurs before 20 years of age, there is an 80% to 92% rate of recurrence. If the first dislocation takes place after 40 years of age, the rate of recurrence is 10% to 15%.¹² Rotator cuff injuries, however, occur more frequently in older patients with anterior shoulder dislocations.¹⁵

The four types of anterior dislocations are classified according to where the humeral head comes to rest. Subcoracoid dislocations account for more than 75% of anterior dislocations. The other anterior shoulder dislocations include subglenoid dislocation and the uncommon subclavicular and intrathoracic dislocations (Fig. 49.3).¹²

Clinical Assessment

The presence of an anterior shoulder dislocation is usually obvious (Fig. 49.4). A posterior dislocation is more subtle in

Figure 49.3 Types of anterior shoulder dislocations.

terms of both clinical and radiographic findings. It can be misdiagnosed as a severe contusion (Table 49.1). A patient with an anterior shoulder dislocation supports the injured extremity and leans toward the injured side while holding the arm in abduction and slight external rotation. The patient cannot adduct or internally rotate the shoulder. Visual inspection reveals loss of the rounded appearance of the shoulder because of absence of the humeral head beneath the deltoid region. The acromion is prominent and an abrupt drop-off below the acromion can be seen or palpated. An anterior fullness in the subclavicular region is visible in thinner individuals and is easily palpable in most others. Comparison with the uninjured side is a useful aid for both visual examination and palpation. Any attempt at internal rotation is quite painful and resisted by the patient. An inability to place the palm from the injured extremity on the uninjured shoulder is consistent with an anterior shoulder dislocation; after reduction, this maneuver should be possible.

Careful assessment of the neurovascular status of the affected extremity is essential (Figs. 49.5 and 49.6). Injury to the axillary artery is rare. It usually occurs in the elderly¹⁵ and can be quickly assessed by a decreased or absent radial pulse or by the appearance of an expanding hematoma. It is important to evaluate the status of the axillary nerve because this is the most common nerve injury resulting from anterior dislocations.¹⁶ Assess the sensory component of the axillary nerve by testing for sensation over the lateral aspect of the upper part of the arm in the “regimental badge” area over the deltoid muscle. Testing the motor component of the axillary nerve is a difficult undertaking in a patient with a dislocated shoulder, as it requires activation of the deltoid muscle. Less commonly, the brachial plexus may be injured by a stretch injury and produce variable

Figure 49.4 A, Typical manifestation of an anterior right shoulder dislocation. The shoulder is very painful, and thus the patient resists movement. The outer round contour of the shoulder is obviously flattened, and the displaced humeral head may be appreciated in the subcoracoid area. Frequently, the patient abducts the arm slightly, bends the torso toward the injured side, and supports the flexed elbow on the injured side with the other hand. B, Obvious left shoulder dislocation. This chronic dislocation occurred frequently with minimal trauma, and the patient was able to dislocate it at will, feign a new injury, and obtain narcotics from multiple emergency departments.

nerve deficits. Perform a complete assessment of all the major nerves to the arm because other nerve injuries may occur, such as injuries to the ulnar and radial nerves.¹⁶ A neurologic deficit does not preclude closed reduction, but in patients with a nerve injury, avoid multiple forceful attempts at reduction.

Brachial plexus injuries require an especially atraumatic reduction. If generous sedation and analgesia do not permit easy reduction in the ED, reduction of a dislocation with a nerve injury may be more prudently performed in the operating room with the patient under general anesthesia. Nerve injuries in this setting generally have a good prognosis, but the patient should be informed of the findings and the need for follow-up. The symptoms may require many months to resolve.

Vascular injuries, such as axillary artery disruption, are rare but usually quite obvious because of dysaesthesias and coolness of the involved arm. An expanding axillary hematoma, pulse deficit, peripheral cyanosis, and pallor can be seen. Collateral circulation may produce a faint pulse in the extremity, so comparison with blood pressure on the uninjured side may be helpful. Specific lesions include complete disruption, linear tears, and thrombosis. Axillary artery injuries can occur at all ages, but they are more common in the elderly. The artery is particularly at risk with anterior dislocations, and dislocation with spontaneous reduction can produce the injury. Arteriography with surgical repair of the artery is required, occasionally with fasciotomy of the forearm if the ischemia is long-standing.¹⁷

In many shoulder dislocations, some portion of the rotator cuff will be injured. Rotator cuff tears are easier to evaluate after reduction, when the pain and swelling have subsided.

Radiologic Examination

Associated fractures are detected in 15% to 35% of anterior shoulder dislocations, with fractures of the greater tuberosity being the most common.¹² The presence of a fracture of the greater tuberosity does not change the initial management of anterior shoulder dislocations, and these fractures usually heal well after closed reduction in routine fashion.¹² The Hill-Sachs deformity, a sign of repeated dislocations, produces a groove

TABLE 49.1 Comparison of Anterior and Posterior Shoulder Dislocations: Classified According to Displacement of the Humeral Head

in the posterolateral aspect of the humeral head and may be seen on pre-reduction or post-reduction films (Fig. 49.7). The Hill-Sachs deformity is caused by impaction of the humeral head against the glenoid rim after dislocation. It rarely has any clinical significance but may result in a loose body within the joint.¹⁵ Impaction of the humeral head against the glenoid during dislocation may also cause disruption of the anteroinferior portion of the cartilaginous labrum of the glenoid or the inferior aspect of the bony glenoid, an injury known as a *Bankart lesion*. It has been implicated as one source of recurrent dislocations but does not affect immediate ED management.¹⁵

Fractures of the humeral neck are frequently displaced with attempts at closed reduction, which can lead to avascular necrosis of the humeral head.¹⁸ The fact that humeral neck fractures are a known complication of shoulder relocation¹² supports the value of pre-reduction radiographs of anterior shoulder dislocations. However, some argue that clinically obvious recurrent dislocations and first-time anterior dislocations without a blunt traumatic mechanism (information usually

offered by the patient) can be reduced without prior radiographs because fracture is quite unlikely in these situations.^{9,10} Hendeby and coworkers¹⁹ performed a prospective validation study of an algorithm for selective radiography that incorporated the mechanism of injury, previous dislocations, and the clinician’s certainty of joint position. In this study, 24 patients with recurrent atraumatic anterior shoulder dislocations who received neither pre-reduction nor post-reduction radiographs had no clinically significant fractures found on follow-up. These patients had much shorter ED lengths of stay than did patients who received only pre-reduction or post-reduction films, or both.¹⁹

One retrospective case-control study found that the presence of any of three risk factors (age >40 years, first episode of dislocation, traumatic mechanism of injury defined as a fall greater than one flight of stairs, a fight or assault, or a motor vehicle collision) predicted clinically important fractures with a sensitivity of 97.7%.²⁰ However, in a prospective study by Atef and colleagues, associated injuries were found in 60% of patients with anterior shoulder dislocation, a much higher frequency than previously thought; most commonly noted was a rotator cuff tear but the injuries ranged from axillary nerve injury to greater tuberosity fracture.²¹

Anterior dislocations are not subtle on routine anteroposterior (AP) radiographs, and this view detects the most important fracture to identify, that of the humeral neck (Fig. 49.8). An adequate AP view, when combined with the typical clinical examination, allows successful detection of most anterior shoulder dislocations. A true AP view of the shoulder is taken at a right angle to the scapula and requires rotation of the patient to 30 to 45 degrees.

The typical lateral views obtained include a scapular Y view (see Fig. 49.8), a transthoracic view, and an axillary view. These views rarely add to the AP film in patients with an obvious anterior dislocation, but they are of value in posterior dislocations (Fig. 49.9). The usefulness of additional views for anterior shoulder dislocations is primarily to detect fractures, and the previously mentioned lateral views (especially the transthoracic view) are quite limited in this respect.²² The apical oblique view has been found to be more valuable than the oblique scapular projection for acute shoulder trauma.²² This view is obtained by angling the beam 45 degrees caudad with the patient in a 45-degree oblique position (Fig. 49.10).

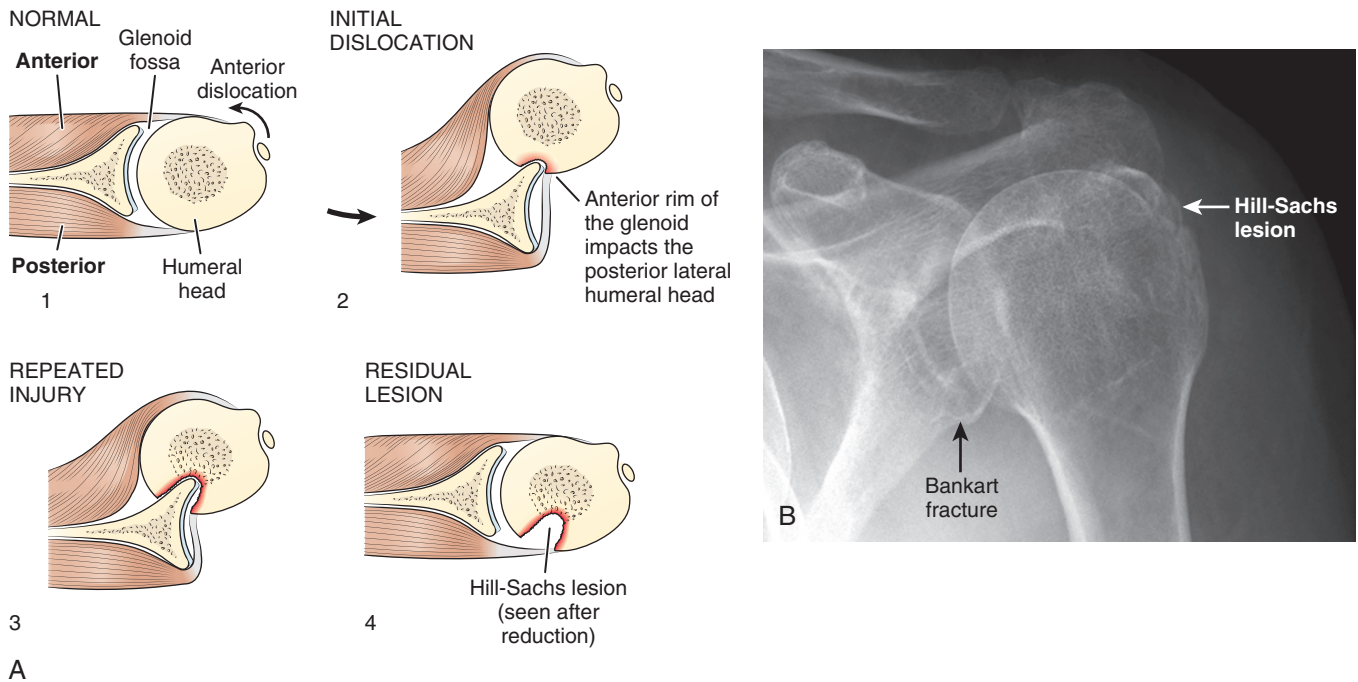

Figure 49.7 **A**, 1, Normal. With repeated anterior shoulder dislocations, a Hill-Sachs lesion may form. 2, During dislocation, the humeral head is damaged by the sharp anterior rim of the glenoid. 3, With repeated dislocation, a lesion called the “hatchet sign” develops. 4, On the reduction film the lesion is apparent. **B**, Radiograph demonstrating a Hill-Sachs lesion and a Bankart fracture: a fracture of the inferior glenoid rim from impaction of the dislocated humeral head.

Post-reduction radiographs are obtained to document the success of the reduction. Occasionally, they will reveal a fracture not detected on pre-reduction radiographs. In one series, 8% of patients with anterior shoulder dislocations had Hill-Sachs deformities noted only on post-reduction films.¹⁰ A more recent prospective observational study (2007) found 37.5% of detected fractures associated with anterior shoulder dislocation were only seen on post-reduction radiographs; none however changed clinical management.²²

Recent advances in the use of point-of-care ultrasound by emergency physicians have resulted in its growing use for diagnosis^{23–27} and confirmation of successful reduction^{27,28} of shoulder dislocations and for administration of local anesthetic to facilitate closed reduction. A study by Abbasi and colleagues found that ultrasound had identical results as plain radiographs for both the detection of shoulder dislocation as well as complete reduction, with a sensitivity of 100%.²⁷ Whereas further validation studies, as well as studies to determine the ability of ultrasound to recognize associated fractures, still need to be performed, we expect ultrasound to continue to become an ever-increasingly useful tool in the treatment of shoulder dislocations. One disadvantage of using only ultrasound diagnosis is difficulty in maintaining a permanent record of a successful reduction.

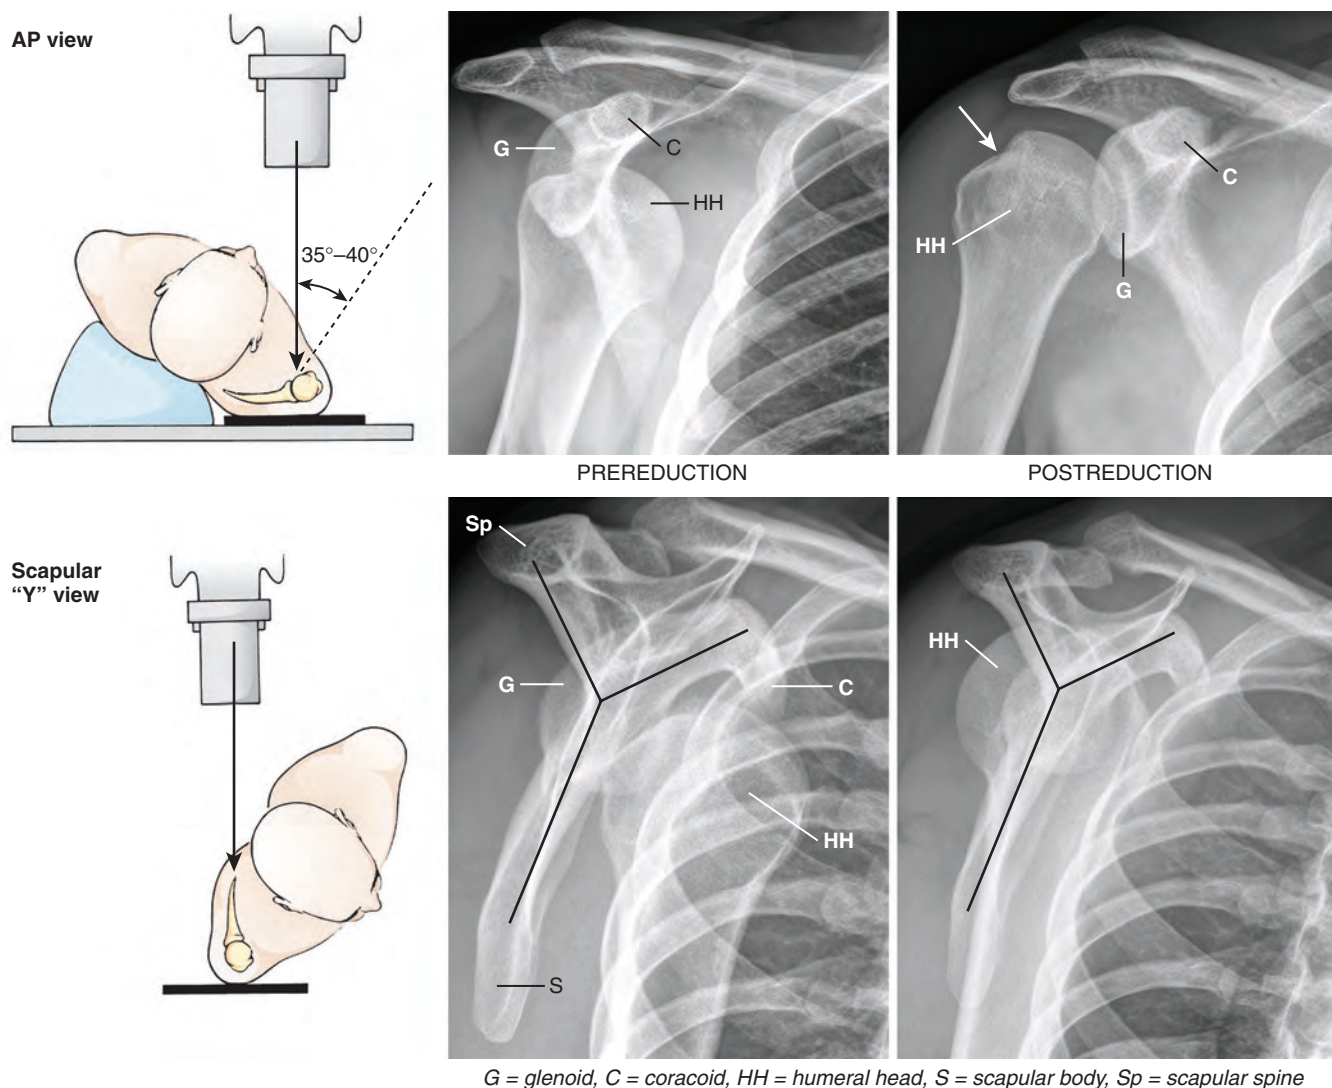

Reduction Techniques

Hippocrates (450 BC) is generally credited with the first detailed description of reduction techniques, and it is believed that a drawing in the tomb of Upuy (1200 BC) is the earliest depiction of such a method.¹² The Hippocratic technique involves placement of the operator’s foot in the axilla to allow countertraction. This technique is problematic and not recommended by some

authors.^{3,13} Likewise, the Kocher method, which involves forceful leverage of the humerus, is associated with an increased rate of complications and is generally discouraged in favor of other techniques.^{12,13}

This section discusses several methods of reduction that are well studied, proven to be safe, and easy to master. Regardless of the reduction technique used, gradual, gentle application of the technique is essential. Although all the techniques discussed are generally acceptable and many authors state that their techniques are quite painless,^{1–5} few studies have quantified the actual pain reported by patients.²⁹ As noted previously, intraarticular lidocaine may also be used to reduce the pain accompanying reduction (Fig. 49.11). In studies by Matthews and Roberts³⁰ and Kosnick and colleagues,³¹ intraarticular injection of lidocaine was found to offer significant relief of pain during reduction of anterior shoulder dislocations. In addition, a 2014 meta-analysis showed that intraarticular lidocaine had similar success rates as procedural sedation and led to decreased length of stay and complication rates, thus making it a useful alternative to procedural sedation and analgesia.³² A previous prospective study and Cochrane review reported similar results.^{33,34} Ultrasound may be used to assist intraarticular lidocaine injection in both adults and pediatric patients.^{35,36} When using intraarticular lidocaine, any blood present should be aspirated from the glenohumeral joint before injecting the anesthetic. Note that 10 to 20 mL of 1% lidocaine has been used with the intraarticular technique and that it may take as long as 15 to 20 minutes for adequate analgesia.

The use of regional nerve blocks (suprascapular and scalene) under ultrasound guidance have also been used to provide analgesia for closed reduction of anterior shoulder dislocations. Studies have demonstrated similar analgesia and reduction

G = glenoid, C = coracoid, HH = humeral head, S = scapular body, Sp = scapular spine

Figure 49.8 Anteroposterior (AP) and scapular “Y” views of an anterior subcoracoid dislocation. The AP views (*top row*) are fairly easy to interpret. On the pre-reduction film, the humeral head is clearly dislocated from the glenoid fossa and is seen underneath the coracoid process. The correct anatomic relationship of the humeral head and glenoid is demonstrated on the post-reduction film. Note the presence of a Hill-Sachs lesion (*arrow*) on the superior aspect of the humeral head. The scapular “Y” view (*bottom row*) is more difficult to understand. The limbs of the “Y” are composed of the scapular spine, the coracoid process, and the scapular body (*gray lines*). The glenoid fossa is found at the convergence of these limbs in the center of the scapula. On the pre-reduction view, the humeral head is found *anterior*, or *medial*, to the glenoid and under the coracoid, thus confirming the presence of an anterior dislocation. In a posterior dislocation, the humeral head is *posterior*, or *lateral*, to the glenoid (see [Fig. 49.9](#)). On the post-reduction view, the humeral head is correctly positioned in the middle of the “Y,” over the glenoid. C, Coracoid process; G, glenoid fossa; HH, humeral head; S, scapular body; Sp, scapular spine. (Diagrams from Heppenstall RB: *Fracture treatment and healing*, Philadelphia, 1980, Saunders, p 374.)

success rates when compared to procedural sedation, but with significantly less one-on-one practitioner time and a lower ED length of stay³⁷⁻³⁹ (see [Chapter 31](#)).

It is important to note that neither local nor regional anesthesia produces muscle relaxation, but they may obviate the need for IV access and prolonged observation. Operator judgment is an important part of the decision as to whether reduction should be attempted without premedication. Advantages of such an approach include avoidance of potential complications from drug therapy, reduced staff requirements, and theoretically, more rapid patient disposition. Certainly, a patient who is

markedly intoxicated may require little, if any supplemental sedative therapy. However, all patients who are reluctant or too anxious to cooperate with an attempt at reduction without medication and those with a high degree of muscle spasm should receive premedication. Generally, only one attempt is made; if unsuccessful, further attempts at reduction are made after the IV administration of sedatives. When in doubt, it is best to use pharmacologic adjuncts (see [Chapter 33](#)).

Several factors will help in deciding which reduction technique is best in each clinical situation. Do not use forceful techniques such as traction-countertraction in patients who

Figure 49.9 Posterior shoulder dislocation. **A**, Anteroposterior (AP) view of a patient with a posterior dislocation. A posterior dislocation may be difficult to appreciate on an AP view because it is *not inferiorly displaced and may appear to be in the glenoid fossa*. Note the space between the glenoid fossa and the humeral head (*arrow*). It does not look normal. **B**, The scapular Y view reveals that a posterior dislocation is present. Note that the humeral head lies *posterior, or lateral, to the glenoid fossa* rather than being centered over it. G, Glenoid; HH, humeral head.

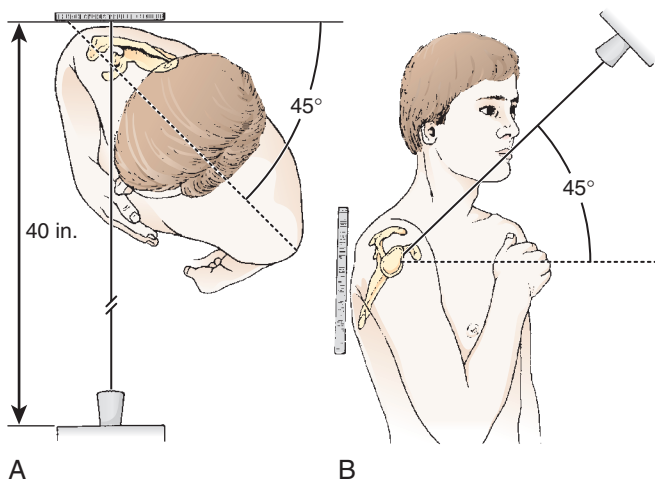

Figure 49.10 **A** and **B**, Positioning for an apical oblique view. The affected shoulder is placed at a 45-degree oblique position and the central ray is angled 45 degrees caudad. The affected arm is adducted. **C**, Normal apical oblique view. (From Heppenstall RB: *Fracture treatment and healing*, Philadelphia, 1980, Saunders, p 392. Reproduced with permission.)

are not being sedated. The clinician's comfort level with a given technique is always a factor as the greatest success rates will probably result from techniques with which the clinician is most familiar. The time and resources available to the clinician must also be considered because methods such as the Stimson maneuver require more time and the availability of weights and straps. In addition, certain reduction techniques can be performed without assistance, whereas others require an additional person to apply countertraction or to help with manipulation of the scapula or humeral head. Ideally, the emergency clinician should become familiar with a number of different techniques for reducing anterior shoulder dislocations because no single method has a 100% success rate nor is any technique ideal in every situation.

Stimson Maneuver (Fig. 49.12A)

The Stimson maneuver is a classic technique that offers the advantage of not requiring an assistant. Place the patient prone on an elevated stretcher and suspend approximately 2.5 to 5.0 kg (5 to 10 lb) of weight from the wrist.^{12,13} The weights can be strapped to the wrist, or a commercially available Velcro wrist splint can be placed and the weights hung from the strap with a hook.⁴⁰ The slow, steady traction produced with this method often permits reduction, but 20 to 30 minutes may be required. If needed, facilitate reduction by externally rotating the extended arm.

Variations of this method include the recommendation for flexion of the elbow to further relax the biceps tendon and the application of manual traction instead of weights.^{41,42} Rollinson⁴³

Figure 49.11 A, Intraarticular injection for the reduction of an acute anterior shoulder dislocation can be very effective. After aspirating blood from the joint, 10 to 20 mL of 1% plain lidocaine is injected slowly through the lateral sulcus. Allow 15 to 20 minutes for the lidocaine to take effect. B, The empty glenoid fossa is easily identified when considering an injection of lidocaine into the joint to facilitate reduction of a dislocated shoulder.

allowed the arm to hang under its own weight after a supraclavicular block and reported a 91% success rate with usually no more than a gentle pull on the arm after 20 minutes in this position. Each variation of the Stimson method can be used in combination with the scapular manipulation technique described later. Indeed, a success rate of 96% has been reported with the combined prone position, hanging weights, IV analgesia and sedation, and scapular manipulation.⁴⁰

Disadvantages of the Stimson method include the time required to achieve reduction and possible dangers to the patient associated with the positioning required for this technique. There is a potential danger of patients slipping off the elevated bed. A “seat belt” strap or bedsheet may be placed around the patient and stretcher to avoid movement of the patient off the stretcher. Airway access to a patient in the prone position may be more difficult in the setting of an overly intoxicated patient or one who becomes overly sedated. Logistically, the Stimson method may be difficult. One must have a bed that elevates to a suitable height for length of the patient’s arm and a convenient method to hang the weights. Sometimes locating the weights themselves can be challenging in a busy ED.

Scapular Manipulation Technique (See Fig. 49.12B)

This method is popular because of its ease of performance, reported safety, and acceptability to patients. To date, no complications from the scapular manipulation technique have been reported in the literature.^{29,40,44} Shoulder reduction via this method focuses on repositioning the glenoid fossa rather than the humeral head, and less force is required than with many other methods.³⁰ Its success rate is high, generally greater than 90% in experienced hands.^{40,44,45} Some studies report higher success rates in patients who have had repeated dislocations and lower rates in patients with an associated greater tuberosity fracture.⁴⁵ The initial maneuver for scapular manipulation is traction on the arm as it is held in 90 degrees of forward flexion. This may be performed with the patient prone and the arm hanging down, as described for the Stimson method, with or without flexion of the elbow to 90 degrees. Alternatively, this traction may be applied by placing an

outstretched arm over the seated patient’s midclavicular region while pulling the injured extremity with the other arm. Regardless of the means of arm traction, slight external rotation of the humerus may facilitate reduction by releasing the superior glenohumeral ligament and presenting a favorable profile of the humeral head to the glenoid fossa.⁴⁶

The prone patient position is recommended for those not familiar with the technique because it facilitates identification of the scapula for manipulation (medial rotation of the tip). Nonetheless, the technique can be performed with the patient supine given that the patient’s shoulder is flexed to 90 degrees and the scapula is exposed during gentle upward traction on the humerus.⁴⁷ Although seated scapular manipulation offers the advantage of not requiring the patient to go through the awkward and potentially uncomfortable assumption of the prone position, it is a technically more difficult variation of scapular manipulation, especially if sedation is going to be necessary. When using the prone position, place the injured shoulder over the edge of the bed to allow the arm to hang perpendicular for the application of traction (see Fig. 49.12A).⁴⁴

After the application of traction, manipulate the scapula to complete the reduction. Anderson and associates⁴⁴ recommended manipulation of the scapula after the patient’s arm is relaxed; however, success is possible with no delay in performing this second step.²⁹ Manipulate the scapula by stabilizing the superior aspect of the scapula with one hand and pushing the inferior tip of the scapula medially toward the spine. Place the thumb of the hand stabilizing the superior aspect of the scapula along the lateral border of the scapula to assist the pressure applied by the thumb of the other hand. A small degree of dorsal displacement of the scapular tip is recommended as it is being pushed as far as possible in the medial direction.⁴⁴

When the patient is properly positioned with the affected arm hanging perpendicularly, the lateral border of the scapula may be difficult to find in larger patients. This border is generally located quite laterally with the patient in this position, and it must be properly located before any attempt at reduction. The reduction itself is occasionally so subtle that it may be missed by both the patient and operator. A minor shift of the arm may be the only clue that reduction has been successful.

Careful palpation of the subclavicular area to locate the position of the humeral head before repositioning the patient may be used to determine the success of the reduction.

Best of Both (BOB) Technique (See Fig. 49.12C)

A variation of the seated scapular manipulation technique is the “best of both” (BOB) maneuver.⁴⁸ To perform the BOB maneuver, position the patient seated sideways on the stretcher with the unaffected shoulder and hip against the fully elevated head of the stretcher. Stand on the foot end of the gurney at the patient’s affected side and use one hand to apply downward force on the proximal end of the patient’s bent forearm. Use the other hand to grasp the patient’s hand and gently rotate the arm internally or externally as needed. Once downward force is being applied, ask an assistant to perform the scapular manipulation maneuver described earlier.⁴⁸

External Rotation Method (See Fig. 49.12D)

This method offers the advantage of requiring only one person and no special equipment. The technique needs no strength or endurance on the part of the operator and is well tolerated by patients.³ The actual pain experienced by patients with this technique has not been quantified, but Plummer and Clinton³ stated that it can be performed with “little, if any sedation.” In this technique, the basic maneuver is slow, gentle external rotation of the fully adducted arm. In 1957, Parvin described a self-reduction external rotation technique in which the patient sits on a swivel-type chair and grasps a fixed post positioned waist high and slowly turns the body to enact external rotation.⁴⁹ Parvin reported that the reduction usually takes place at 70 to 110 degrees of external rotation.⁴⁹

Since Parvin’s initial study, this method has been described with the patient supine and the affected arm adducted tightly to the patient’s side.^{1,50} Flex the elbow to 90 degrees and hold it in the adducted position with the operator’s hand closest to the patient. Use the other hand to hold the patient’s wrist and guide the arm into slow and gentle external rotation. The procedure may require several minutes because each time the patient experiences pain, the procedure is halted momentarily. Although the report of Mirick and coworkers¹ mentioned using the forearm as “a lever,” a later description clearly recommends allowing the forearm to “fall” under its own weight.³ No additional force should be applied to the forearm, and no traction is exerted on the arm.

The end point of the reduction may be difficult to identify because reduction is frequently very subtle. It is therefore recommended that external rotation be continued until the forearm is near the coronal plane (lying on the bed, perpendicular to the body), a process that usually takes 5 to 10 minutes.³ If the patient’s dislocation persists after full external rotation, apply steady gentle traction at the elbow. Reduction may occasionally be noted when the arm is rotated back internally.⁵⁰ The success rate of this technique in three series performed by emergency clinicians was approximately 80%.^{1,50,51}

Milch Technique (See Fig. 49.12E)

Proponents of this method praise its gentle nature, high success rate, lack of complications, and tolerance by patients.^{2,5} It can be described as “reaching up to pull an apple from a tree.” The basic steps of this technique are abduction, external rotation, and gentle traction of the affected arm. Finally, if needed, the humeral head can be pushed into the glenoid fossa with the thumb or fingers.

In describing this technique, Milch⁵² wrote that the fully abducted arm was in a natural position in which there was little tension on the muscles of the shoulder girdle. He postulated that this was related to our ancestral “arboreal brachiation” (swinging from trees). The primary step in this technique is to abduct the affected arm to an overhead position. Russell and colleagues⁴⁶ had their patients raise their arm and put their hand behind their head as a first step. Although this seems odd, patients can usually do this quite readily with little assistance and be quite comfortable in this position. Alternatively, abduct the arm by grasping the patient’s elbow or the wrist. Lacey and Crawford⁵³ found that the prone position, with the patient’s shoulder close to the end of the bed, facilitated this step.

Once the arm is fully abducted, apply gentle longitudinal traction with slight external rotation. If reduction does not occur quickly, push the humeral head upward into the glenoid fossa with the thumb or fingers of the other hand. Beattie and associates² reported a success rate of 70% with the Milch technique, but others have achieved success rates of 90% or greater.^{5,46} In a comparison study of external rotation and the Milch technique for reduction of anterior shoulder dislocations without sedation, success rates were equivalent but external rotation was noted to be easier and less painful for the patient.⁵⁴

Traction-Countertraction (See Fig. 49.12F)

This method is commonly used in the ED, largely because of tradition, clinician comfort, and a high success rate. Clinician familiarity is an advantage of this technique, but it requires more than one operator, some degree of force, and occasionally, endurance. This technique is usually quite uncomfortable for the patient, and premedication is recommended before any attempt. In a 2014 comparison study of traction-countertraction versus modified scapular manipulation, modified scapular manipulation was better tolerated by patients and had a better success rate on first attempt; traction-countertraction was more successful on second attempt.⁵⁵

With the patient supine, wrap a sheet or strap around the upper part of the patient’s chest and under the axilla of the affected shoulder. Ask an assistant to hold the sheet, preferably by wrapping it around the assistant’s waist to take advantage of body weight rather than arm strength to apply the countertraction. Traction may then be applied onto the extended arm by the clinician, but this generally results in operator fatigue, especially if the operator relies on biceps strength to provide continuous traction. Instead, flex the elbow of the affected side to 90 degrees and wrap a sheet or strap around the proximal part of the forearm and then around the operator’s waist. Elevate the bed to the point at which the sheet can sit at the level of the operator’s ischial tuberosities. This allows the operator to comfortably lean back and use body weight to supply the force of traction, thereby reducing the possibility of operator fatigue. The portion of the sheet that is positioned on the patient’s forearm has a tendency to ride up; flexion of the elbow beyond 90 degrees will minimize this problem. Alternatively, the operator merely leans backward with the arms fully extended, again using the continuous weight of the body rather than the strength of the biceps to provide constant traction.

Once traction has been applied, the operator must be patient because the procedure may take a number of minutes to be successful. The premedication is probably inadequate if the patient resists the procedure or is notably uncomfortable during

Anterior Shoulder Dislocation Reduction

A. Stimson Maneuver

Place the patient prone on the edge of the stretcher. Be careful that a sedated or intoxicated patient does not fall off the table. Belts or sheets can be used to secure the patient to the stretcher, 5-kg weights are attached to the arm, and the patient maintains this position for 20 to 30 minutes, if necessary.

The addition of scapular manipulation and/or gentle external and internal rotation of the shoulder with manual traction may aid in reduction.

B. Scapular Manipulation

Rotate the inferior tip of the scapula medially and dorsally toward the spine with the tips of your thumbs.

The procedure can take place with the patient prone (as in the Stimson technique) or with the patient seated. For the latter, have an assistant apply traction on the arm while applying countertraction on the ipsilateral clavicle.

C. Best-of-Both Technique

Position the patient seated sideways with the unaffected shoulder and hip against the upright head of the stretcher. Apply downward force on the patient's flexed forearm, and gently rotate the arm internally or externally as needed.

Once downward force is applied, instruct an assistant to perform scapular manipulation as described previously.

Figure 49.12 Anterior shoulder dislocation reduction methods. ED, emergency department.

Continued

Anterior Shoulder Dislocation Reduction

D. External Rotation

Fully adduct the arm and flex the elbow to 90 degrees. Hold the patient's wrist and guide the arm into slow and gently external rotation. Halt momentarily if the patient experiences pain. Continue the rotation until the forearm is laying on the bed. No traction is applied.

E. Milch Technique

First abduct the arm to an overhead position by grasping the patient's arm at the elbow or wrist. Once fully abducted, apply gentle longitudinal traction with slight external rotation. If reduction does not occur quickly, push the humeral head upward into the glenoid fossa.

F. Traction-Countertraction Method

Wrap one sheet around the affected axilla and the assistant's waist. The assistant leans back to apply countertraction. Wrap another sheet around the patient's flexed arm and your waist. Lean back to apply traction.

Reduction can be facilitated by gently adducting the arm (after traction is applied) while a second assistant provides gentle lateral traction on the humerus.

G. Spaso Technique

With the patient supine, gently lift the arm toward the ceiling while applying gentle vertical traction. Instruct an assistant to apply countertraction. Apply gentle external rotation during the procedure.

H. Eskimo Method

While the patient lies on the unaffected side, lift him a short distance off the ground by grasping the abducted arm of the injured side. This is a field technique and should not be used in the ED.

Figure 49.12, cont'd

attempts at reduction. Do not hesitate to order supplementary medications. Gentle, limited external rotation is sometimes useful to complete the reduction.¹² Applying traction to an arm that is slightly abducted from the patient's body is often successful, but some operators prefer to slowly bring the arm medial to the patient's midline while maintaining traction or to have an assistant apply a gentle lateral force to the midhumerus to direct the humeral head laterally. Successful reduction is usually presaged by slight lengthening of the arm as relaxation occurs, and a noticeable "clunk" may occur at the point of reduction. A brief wave of fasciculations in the deltoid may also be seen at the time of reduction.

Spaso Technique (See Fig. 49.12G)

This technique was first reported by Spaso Miljesic as a simple, single-operator technique requiring minimal force.⁵⁶ One published series reported an 87.5% success rate in premedicated patients when performed by junior house officers.⁵⁷ A 2015 study comparing the Spaso technique to external rotation found both to be equally efficacious, however the Spaso technique was faster, more efficient, and more easily performed.⁵⁸ Place the patient in the supine position and grasp the affected arm around the wrist or distal end of the forearm. Gently lift the affected arm vertically toward the ceiling and apply gentle vertical traction. While maintaining traction continuously, externally rotate the arm. Reduction may be subtle but is generally signaled by hearing or feeling a "clunk." Completion of this technique may require several minutes of gentle traction to allow the muscles of the patient's shoulder to relax.⁵⁷

Other Methods

Poulsen⁵⁹ reported a method termed the *Eskimo technique* that may be performed in field settings (see Fig. 49.12H). In this technique the patient lies on the unaffected side and is lifted a short distance off the ground by grasping the abducted arm on the injured side. The patient's body weight acts to effect the reduction. Poulsen's success rate was 74% in a series of 23 patients, all of whom were premedicated. However, the author⁵⁹ also postulated that this technique could place undue stress on the brachial plexus or axillary vessels. Use of this technique, when other options are available, should probably be reserved until more data are obtained.

Noordeen and coworkers⁶⁰ reported a simple method in which the patient sits sideways in a chair with the affected arm draped over the backrest. The operator holds the arm with the wrist supinated, and the patient is instructed to stand up. The success rate was 72% in 32 patients treated in this manner. A variation of the chair technique, which was successful in 97% of 188 anterior shoulder dislocations, involves operator-applied traction on the patient's flexed elbow by means of a cloth loop or stockinette.⁶¹ Standing beside the patient, the operator holds the involved elbow in 90 degrees of flexion while stepping down on the cloth loop. The patient sits in the chair, and an assistant may help support the patient by applying countertraction under the involved arm.

Post-reduction Care

After an attempt at reduction, the neurovascular status of the affected extremity should be rechecked and the results documented in the patient's medical record. Indirect evidence that the reduction has been successful includes an immediate decrease in pain, restoration of the round shoulder contour, and increased passive mobility of the shoulder. No harm is done by putting

Figure 49.13 A, If a patient with a shoulder injury can place the palm of the injured arm on top of the contralateral shoulder, it is unlikely that a shoulder dislocation is present. Alternatively, completion of this maneuver after an attempt at reduction provides strong evidence that the reduction was successful, even if the patient is still sedated. B, The best way to immobilize any reduced shoulder dislocation is uncertain and unlikely to be of consequence for a few days (see text). A typical shoulder immobilizer or a simple sling is appropriate pending orthopedic referral and follow-up.

the joint through a limited range of motion. If the patient can tolerate placement of the palm from the injured arm on the opposite shoulder, it is quite likely that the shoulder reduction was successful (Fig. 49.13A). For patients with possible axillary nerve injury, close to 90% will recover with expectant management. Nevertheless, it is prudent to refer these patients for early orthopedic follow-up.⁶²

Post-reduction radiographs are often recommended to make a careful search for new fractures. Although most greater tuberosity fractures do not alter patient management, patients with greater tuberosity fractures displaced more than 1 cm after closed reduction almost always have an associated rotator cuff tear⁶³ and should receive prompt orthopedic consultation because they may require operative repair.

Traditional post-reduction treatment focuses on the importance of preventing the shoulder from dislocating again after the patient is discharged. This is best accomplished by immobilizing the joint with a commercially available shoulder immobilizer or a sling and swath to limit external rotation and abduction (see Chapter 50). Orthopedic follow-up is recommended for all anterior shoulder dislocations because the

incidence of rotator cuff injury is as high as 38% and it might complicate restoration of normal function.⁶⁴ As a general rule, the older the patient, the shorter the recommended time of immobilization.¹² Those older than 60 years should have early follow-up (e.g., 5 to 7 days) to allow early mobilization and avoid persistent shoulder joint stiffness or adhesive capsulitis. Younger patients are usually immobilized for approximately 3 weeks and can be instructed to follow up within 1 or 2 weeks of the event. As mentioned earlier, young age confers risk of recurrent dislocation, but it is not clear if prolonged immobilization decreases recurrence rates. A 2010 meta-analysis found that immobilization for more than 1 week did not reduce recurrence rates.⁶⁵

Since the early 2000s, the wisdom of immobilization in internal rotation has been questioned. Several studies have shown that placing the arm in internal rotation actually increases labral detachment from the glenoid rim, whereas some degree of external rotation maximizes contact between the detached labrum and the glenoid rim.^{66–68} In one study, cadavers were used to measure the force of contact between the labrum and the glenoid rim in different arm positions. The authors of this study found that maximum contact force was actually generated in 45 degrees of external rotation, whereas no contact force was generated with the arm in internal rotation.⁶⁸ Unfortunately, the question of which position (e.g., internal versus external rotation) is superior for post-reduction immobilization remains unanswered.⁶⁹ Clinical studies thus far have shown conflicting results.^{70–75} Nevertheless, in the most recent systemic review and meta-analysis comparing recurrence rates and patient-based quality of life assessments between external and internal rotation immobilization (2014), Liu and colleagues found that immobilization in external rotation did not reduce recurrence rates or improve quality of life.⁷⁶ As a result, it is not unreasonable to immobilize the extremity in a manner consistent with the recommendations of the orthopedic surgeons at one's institution until further evidence is presented. When in doubt, a simple sling or the traditional shoulder immobilizer will certainly suffice pending 5- to 7-day follow-up (see Fig. 49.13B).

Discharge the patient with oral analgesics (either nonsteroidal antiinflammatory drugs or narcotics) to minimize discomfort and instruct them to return if the clinical condition worsens. Periodically, one may encounter a return visit from a successfully treated patient who is in severe pain from hemiarthrosis. In one series of patients older than 60 years, Trimmings⁷⁷ reported excellent pain relief by aspirating the hemiarthrosis 24 to 48 hours after shoulder reduction. This can be accomplished by using the technique of arthrocentesis described in Chapter 53. In addition, intraarticular instillation of 10 to 20 mL of 1% lidocaine (or a longer-acting local anesthetic) may be helpful for further pain relief.

Posterior Shoulder Dislocations

Posterior shoulder dislocations account for less than 4% of all shoulder dislocations.¹⁴ Because they are so uncommon, posterior dislocations have the potential to be missed. In fact, delays in diagnosis for weeks to months have been reported.^{78,79} This may lead to increased rates of dislocation arthropathy and chronic pain.¹⁵ The mechanism of injury is almost always indirect and consists of a combination of internal rotation, adduction, and flexion.¹² Classic precipitating events include seizure, electrical shock, and falls. Some patients may not be seen until at a point well past the original event.⁷⁹ In addition,

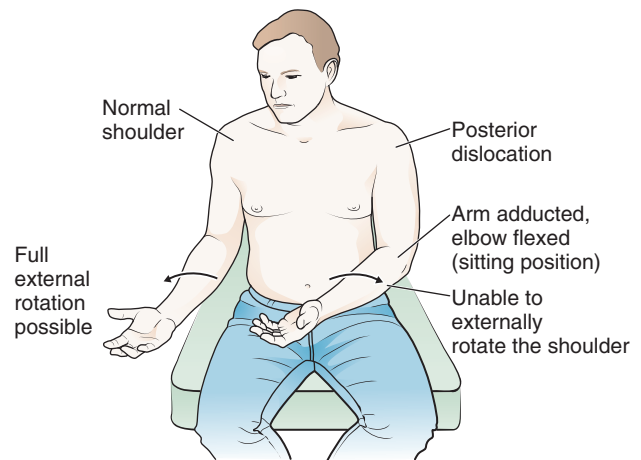

Figure 49.14 A posterior dislocation may be difficult to appreciate on radiographs. A clue to a posterior shoulder dislocation is the arm locked in adduction and internal rotation and the patient's inability to rotate the shoulder externally with the elbow flexed at 90 degrees.

patients with seizures may not complain of pain or a limited range of motion in the immediate postictal period because of their altered mental status.

Clinical Assessment

Though clinically less obvious than anterior dislocations, posterior shoulder dislocations do occur in a typical, recognizable manner. Mistakes may be made if the clinician is overly reliant on AP radiographs, which are potentially misleading⁷⁹ and may result in misdiagnosing the injury as a soft tissue contusion or acromioclavicular (AC) strain. The principal sign of a posterior dislocation is an arm that is somewhat fixed in adduction and internal rotation (Fig. 49.14). Abduction and external rotation are limited, and attempts to perform these movements generally elicit pain.^{12,14} Inspection and palpation reveal loss of the normal anterior contour of the shoulder, as well as a prominent coracoid and acromion. The shoulder is flattened anteriorly and rounded posteriorly, and the humeral head may be palpable.^{12,14}

Comparison with the opposite shoulder should be undertaken with caution because this injury may occasionally occur bilaterally. Perform a neurovascular assessment in the standard manner, but such complications are unusual with posterior dislocations.

Radiologic Examination

The key point regarding radiographs for posterior shoulder dislocations is the subtle nature of this dislocation on a single AP film (Figs. 49.15A and 49.16A) and the diagnostic importance of the scapular Y view (see Fig. 49.15B) or the axillary view (see Fig. 49.16B). Diagnosis of posterior shoulder dislocation is quite easy with the axillary view, whereas the routine AP and lateral views are difficult to interpret in approximately half the cases.⁷⁹ The axillary view is generally available in the radiology department and can be obtained with as little as 20 to 30 degrees of abduction and the plate placed on the shoulder.⁷⁹ In addition to easy visualization of the posteriorly situated humeral head, the axillary view often reveals an impression fracture of the humeral head (see Fig. 49.16B). The scapular Y view is produced by superimposing the head of the humerus over the coracoid, acromion, and body of the scapula, which form a Y shape. In the event of a posterior shoulder dislocation,

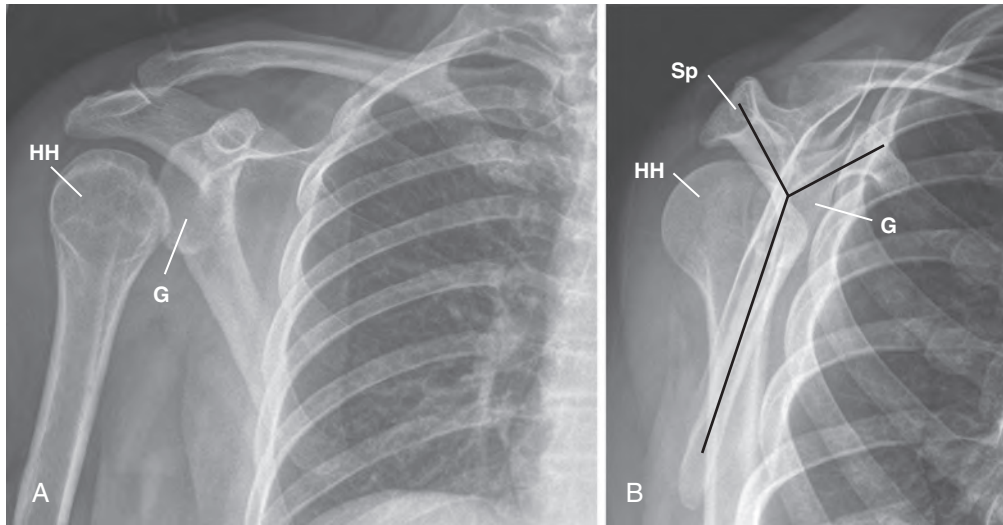

Figure 49.15 Posterior shoulder dislocation seen on a scapular Y view (see also Figs. 49.8 and 49.9). **A**, The anteroposterior view does not definitively show the dislocation. Because the dislocation is directly posterior, there is no superior or inferior displacement of the humeral head. On superficial observation, the head of the humerus appears to maintain a normal relationship with the glenoid fossa and the acromion process. However, definite abnormalities exist on this film. The space between the humeral head and the glenoid fossa is abnormal, and because of the extreme internal rotation of the humerus, the head and neck are seen end on and resemble a light bulb. **B**, On the scapular Y view it becomes obvious that the humeral head is posteriorly dislocated. It projects posteriorly under the scapular spine rather than in its normal location, centered over the glenoid fossa. *G*, Glenoid fossa; *HH*, humeral head; *Sp*, scapular spine.

Figure 49.16 Posterior shoulder dislocation, seen on axillary view. **A**, The dislocation is not immediately evident on the anteroposterior view. The humeral head appears as a light bulb, which indicates internal rotation and is a subtle sign that a posterior dislocation might be present (*arrow*). **B**, On the axillary view the humeral head is seen to lie posteriorly and is impacted on the rim of the glenoid (*arrow*). When viewing axillary films, use the coracoid process to orient yourself to anterior and posterior (the coracoid is an anterior structure). (From Andrews JR, Wilk PE, Reinold MM: *The athlete's shoulder*, ed 2, Philadelphia, 2008, Churchill Livingstone.)

the head of the humerus will lie posterior to the glenoid (away from the chest wall) (see Figs. 49.9B and 49.15B).

Even though axillary and scapular Y views are diagnostic, clues to posterior dislocation do exist on AP films. The internally rotated humeral head appears symmetric on an AP film and is in the shape of a light bulb, as opposed to the normal club-

shaped appearance created by the greater tuberosity (Fig. 49.17).⁶¹ With posterior dislocation, the space between the articular surface of the humeral head and the anterior glenoid rim is widened, and there is a decrease in the half-moon-shaped overlap of the head and the fossa.^{78,80} There may also be a compression fracture on the medial aspect of the humeral

Figure 49.17 Anteroposterior views comparing posterior dislocation and a normal shoulder joint. Posterior shoulder dislocation causes internal rotation of the humeral head, which makes the head appear as a light bulb rather than its normal club-shaped appearance. In addition, note that the space between the articular surface of the humeral head and the anterior glenoid rim is widened (*arrows*), and there is a decrease in the overlap between the head and the fossa.

Posterior and Inferior Shoulder Dislocation Reduction

A. Posterior Dislocation

Apply traction, internal rotation, and adduction to the affected arm. Instruct one assistant to apply countertraction (with a sheet wrapped around the waist) and another assistant to apply anteriorly directed pressure on the posterior aspect of the humeral head.

B. Inferior Dislocation (Luxatio Erecta)

Apply overhead traction with the arm in abduction. With your free hand, exert cephalad pressure over the humeral head. Instruct an assistant to apply countertraction toward the patient's feet with a sheet placed over the injured shoulder.

Figure 49.18 Posterior and inferior shoulder dislocation reduction methods.

head, as indicated by a dense line. This is known as the trough sign.⁸⁰ A fracture of the lesser tuberosity should always prompt a search for the presence of a posterior shoulder dislocation.

As mentioned earlier in this section, ultrasound is being used increasingly for the diagnosis of shoulder dislocations, including posterior shoulder dislocations and may be useful as an adjunct to the physical exam when dislocation is clinically suspected but not radiographically apparent.^{22,25,26}

Reduction Technique (Fig. 49.18A)

Reduce an acute posterior dislocation by applying traction on the internally rotated and adducted arm combined with anteriorly directed pressure on the posterior aspect of the humeral head.^{12,79} Generous premedication is usually indicated, and countertraction may be applied with a sheet looped in the affected axilla, similar to the procedure described for anterior dislocations. Kwon and Zuckerman¹² recommended applying

lateral traction on the upper part of the humerus if the humeral head is locked on the posterior glenoid. Hawkins and colleagues⁷⁹ suggested that posterior dislocations with an impression defect of the humeral head greater than 20% of the articular surface require open reduction. Posterior dislocations that have been diagnosed late are difficult to reduce in a closed manner, but an attempt with adequate premedication is generally indicated.⁷⁹

Post-reduction Care

As with anterior dislocations, neurovascular examination and radiographs should be repeated after attempts at reduction. Successful reduction is suggested by a patient's ability to place the palm of the injured arm on the opposite shoulder. Given the rarity of these injuries, orthopedic consultation is often sought early in the care of these patients. In a training environment, involvement of orthopedic residents is of benefit to their education and should be considered early. An analysis and review of the literature of posterior dislocations suggests the majority (65%) of posterior shoulder dislocations will have an associated injury (fracture, reverse Hill-Sachs injury, or rotation cuff tear) underscoring the importance of orthopedic consultation.⁸¹

Unusual Shoulder Dislocations

Luxatio Erecta

Inferior dislocations of the shoulder, known as *luxatio erecta*, are quite rare but also quite obvious. The patient has the arm locked in marked abduction with the flexed forearm lying on or behind the head⁸² (Fig. 49.19). Occasionally, the humerus may have less abduction, thus potentially obscuring the diagnosis.⁸³ The humeral head can be palpated along the lateral chest wall. With this injury, the inferior capsule is almost always torn. Associated injuries include fractures of the greater tuberosity, acromion, clavicle, coracoid process, and glenoid rim. Neurovascular compression may be present, but this is usually reversed once reduction is accomplished.¹² Long-term complications include adhesive capsulitis and recurrent dislocations.

To reduce an inferior shoulder dislocation, apply overhead traction (generally with the arm in full abduction) in the longitudinal direction of the arm, and exert cephalad pressure over the humeral head much as with the Milch technique (see

Fig. 49.18B).^{12,83} If needed, apply countertraction toward the patient's feet by using a sheet placed over the injured shoulder. After reduction, bring the abducted arm into adduction against the body and supinate the forearm.⁸⁴

Alternatively, use the "two-step" maneuver described by Nho and associates,⁸⁵ in which the luxatio erecta is first converted to an anterior dislocation. To perform this maneuver, place one hand on the medial condyle of the elbow and the other hand around the shaft of the humerus. Push anteriorly on the shaft of the humerus while stabilizing the medial condyle of the elbow, and rotate the humeral head from an inferior to an anterior position. The authors then describe using the external rotation method to reduce what is now a typical anterior dislocation.⁸⁵

Scapular dislocation or "locked scapula" is a rare condition characterized by obvious protrusion of the lateral border of the scapula and significant swelling of the medial border because of tearing of the musculature.⁸⁶ To reduce the scapula, apply traction on the abducted arm and apply medial pressure on the scapula.⁸⁶

AC JOINT SUBLUXATION AND DISLOCATION

The AC joint is a true diarthrodial joint that consists of a synovial cavity surrounded by a relatively lax capsule and the weak AC ligament. This structure allows the gliding motion necessary for shoulder movement. The major stability of the AC joint comes from two ligaments. The AC ligament is primarily responsible for joint stability in the AP direction. The coracoclavicular ligament, which has posterior (conoid) and anterior (trapezoid) components, anchors the distal end of the clavicle to the coracoid process of the scapula and therefore supports the joint in a superior-inferior direction. In general, AC injuries arise from a direct force such as a fall on the point of the shoulder with the arm adducted.⁸⁷ AC joint injuries are categorized according to the Rockwood classification (types I to VI) (Fig. 49.20).

First Degree (Type I)

This injury consists of a minor tear in the AC ligament. The coracoclavicular ligament is intact. The clinical findings are

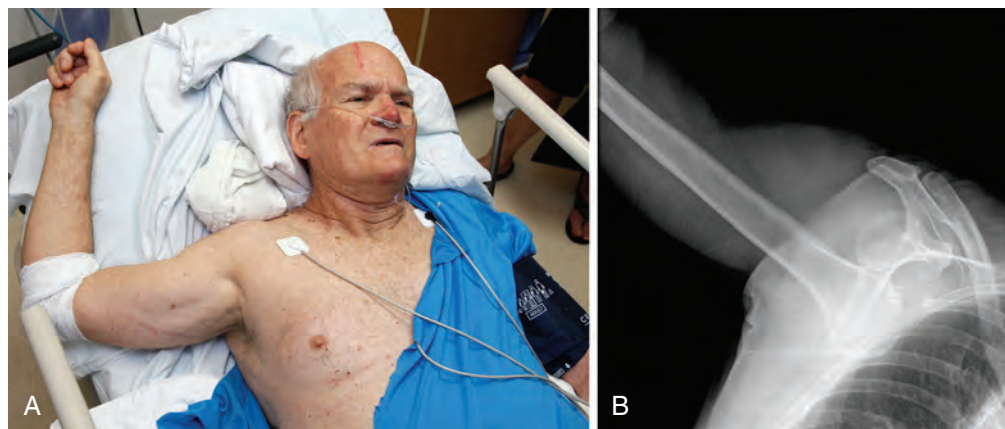

Figure 49.19 Luxatio erecta. **A**, This is a rare inferior shoulder dislocation, and patients may hold their arm in marked abduction with the elbow flexed and the forearm resting on their head. **B**, Radiographic appearance of luxatio erecta.

Figure 49.20 Grade I to III acromioclavicular separation. (See text for description.) (From Heppenstall RB: Fractures and dislocations of the distal clavicle, *Orthop Clin North Am* 6:480, 1975.)

limited to tenderness in the area of the AC joint. Radiographs show little, if any change in position of the clavicle in relation to the acromion.⁶³ Management of this condition consists of a sling for comfort, ice, and mild analgesics. Generally, the symptoms subside with 7 to 10 days of rest.¹² Orthopedic referral is not usually necessary unless return to normal function is delayed beyond 2 weeks.

Second Degree (Type II)

In addition to a complete tear of the AC ligament, the coracoclavicular ligament is stretched or incompletely torn.⁶³ The patient generally supports the injured arm and has slight swelling and definite tenderness over the AC joint. Radiographs demonstrate a definite change in the relationship of the distal end of the clavicle to the acromion. However, in type II injuries the inferior edge of the clavicle should not be separated from the acromion by more than half its diameter,⁶³ and the coracoclavicular distance is the same as that on the uninjured side.¹² This injury can be treated in closed fashion with a sling.¹² Orthopedic referral is recommended, and some still recommend a sling-strap device that elevates the arm and depresses the clavicle for these injuries.⁶³

Third Degree (Type III)

In this injury, the distal end of the clavicle is essentially free floating because both the AC and coracoclavicular ligaments are completely disrupted.⁶³ The arm is supported by an uncomfortable-appearing patient, and the distal end of the clavicle is usually seen to be riding high above the acromion. The diagnosis is generally obvious, and radiographs are used mainly to rule out an associated fracture. Radiographic criteria for this degree of injury include the inferior border of the clavicle raised above the acromion or a discrepancy in the coracoclavicular distance between the normal and affected sides (Fig. 49.21).¹² These injuries require orthopedic referral, and a fair bit of controversy exists regarding their subsequent management.^{2,88} Larsen and coworkers⁸⁹ conducted a prospective, randomized trial of conservative versus operative management of significant AC separations and concluded that conservative management was generally better, with possible exceptions made for patients with significant cosmetic deformity and for those who frequently keep their arm at 90 degrees of abduction. Even though optimal therapy is still unclear, a logical

Figure 49.21 Third-degree acromioclavicular (AC) separation. In a third-degree AC separation, the clavicle is seen riding high above the acromion. This is due to disruption of both the AC and coracoclavicular ligaments.

approach includes ED treatment with a sling and early orthopedic referral.

Fourth, Fifth, and Sixth Degrees (Types IV to VI)

In type IV injury, the distal end of the clavicle is free floating and posteriorly displaced into or through the trapezius muscle. Type V injury is characterized by inferior displacement of the scapula with a marked increase (two to three times normal) in the coracoclavicular interspace.¹² Type IV and V dislocations generally require surgery, and orthopedic referral is necessary. Type VI injury involves dislocation of the distal end of the clavicle inferiorly. Because this is usually the result of major trauma, other fractures are often present and should be sought.¹²

Radiographic Examination

The diagnosis of AC dislocation is usually made clinically by noting pain and local tenderness at the AC joint in the absence of other findings. Radiographs are generally indicated to rule out associated fractures and to aid in assessing the degree of injury. A single radiograph of the injured shoulder often suffices,

Figure 49.22 Sternoclavicular joint: posterior dislocation. **A**, Frontal chest radiograph showing asymmetry in the position of the medial margins of the clavicle, with the right clavicle (on the injured side) being located inferior to the left clavicle. **B**, An axial computed tomography scan confirms posterior dislocation of the right sternoclavicular joint. (From Resnick D Kransdorf MJ, editors: *Bone and joint imaging*, ed 3, Philadelphia, 2005, Saunders.)

but some clinicians prefer to obtain views of the opposite shoulder for comparison. Although their efficacy has never been proved, it has traditionally been recommended that “weighted” films be obtained for suspected type I or II injuries. Weighted films are generally performed after routine “unweighted” radiographs and are obtained by strapping approximately 4.5 to 7.0 kg (10 to 15 lb) of weight to the patient’s wrists and repeating the radiographs. Weighted films are of questionable value in mild injuries and superfluous in obvious type III to VI injuries. In a prospective study of 70 type I or II injuries,⁹⁰ the use of weights was associated with less evident separation in 7 cases, essentially producing a false-negative study in comparison to plain unweighted films. Only three injuries were re-categorized as type III after the performance of weighted films. The authors of this study recommend abandoning the use of weighted films in patients with AC dislocation.⁹⁰

STERNOCLAVICULAR DISLOCATIONS

Despite the fact that the sternoclavicular joint is the least stable joint in the body, sternoclavicular dislocations are rare.⁹¹ The primary supports of this joint are the sternoclavicular and costoclavicular ligaments. Anterior dislocations are much more common and usually the result of an indirect mechanism involving a blow thrusting the shoulder forward,⁶³ or they may be atraumatic, caused by ligamentous laxity in teens and young adults.⁹¹ Posterior dislocations also usually result from a blow to the shoulder but can also be caused by a direct superior sternal or medial clavicular blow.⁹¹ Athletic injuries and those resulting from motor vehicle accidents account for the vast majority of sternoclavicular dislocations.^{62,92} Posterior sternoclavicular dislocation (also known as retrosternal dislocation because the medial end of the clavicle dislocates both posteriorly and medially) is potentially life-threatening because injury to the great vessels or compression of the airway might occur.⁹¹ Patients may complain of dyspnea, choking, or hoarseness with tracheal compression; dysphagia with esophageal

compression; ipsilateral upper extremity pain and swelling with subclavian vessel occlusion; or paresthesias if the brachial plexus is compromised.⁹² Any suggestion of these complications should prompt immediate surgical consultation.

The clinical manifestation of these injuries is usually straightforward and consists of pain, swelling, tenderness, and deformity of the joint. Patients may complain of pain that is worse with arm movement and when they are supine. Plain radiographs of this joint are difficult to interpret and generally include an apical lordotic-type view with the radiographic tube angled 45 degrees cephalad. Confirmation of the diagnosis is best made with a thoracic computed tomography (CT) scan, which may also identify high rib fractures, pulmonary contusion, or pneumothorax (Fig. 49.22).^{91,93} CT angiography should be obtained to identify associated vascular injury when indicated. Children may have epiphyseal disruption with retrosternal displacement of the medial aspect of the clavicle.⁹⁴

To reduce both types of sternoclavicular dislocation, place a rolled blanket or a sandbag between the scapula and spine to separate the medial aspect of the clavicle from the manubrium. Apply traction on the 90-degree abducted, 10-degree extended arm in line with the clavicle and then push (anterior dislocation) or lift (posterior dislocation) the clavicle back into position.⁹¹ Posterior dislocations may be difficult to reduce and to maintain via closed reduction. Therefore some authors recommend reduction in an operating suite unless complications necessitate immediate reduction.⁹¹ Given the rarity of this injury and the potential for major underlying complications, early consultation is recommended for suspected posterior sternoclavicular dislocations. Once reduced, a clavicle strap may be used to immobilize both anterior and posterior dislocations for up to 6 weeks.⁹²

ELBOW DISLOCATIONS

The elbow is second only to the shoulder as a site of major joint dislocations in adults; it is the most commonly dislocated joint in children. Anatomically, the principal articulation of

Figure 49.23 Classification of elbow dislocations.

the humerus and ulna is a stable hinge joint with the intercondylar groove of the distal end of the humerus nestled in the olecranon fossa. Because of the stability of the elbow, any dislocation is expected to be accompanied by considerable soft tissue damage. Associated fractures of the radial head and coronoid process of the ulna are common. Elbow dislocations are usually simply divided into posterior and anterior dislocations (Fig. 49.23). However, there are actually several additional types of elbow dislocations, including lateral, divergent, and isolated dislocations of the radius.⁹⁵ In the rare divergent dislocations, the radius and ulna are dislocated in opposite directions, either anterior and posterior or medial and lateral.⁹⁵

Studies have shown that many patients report long-term problems including residual pain and joint stiffness after elbow dislocation.^{96,97} However, the most serious complication of elbow dislocation is injury to the brachial artery. This injury is possible with any type of elbow dislocation and is a frequent occurrence with open dislocations.⁹⁵ Vascular compromise can be delayed in onset and result from either unsuspected arterial injury or progressive soft tissue swelling. The circulatory status of the arm must be carefully monitored even after successful reduction.⁹⁵ In most cases, orthopedic consultation should be sought before disposition. Patients with any variety of elbow dislocation who have significant or immediate soft tissue swelling or hematoma formation or those who have questionable vascular integrity or neurologic findings are often admitted to the hospital or ED observation unit.

Injury to the median and ulnar nerves may be the result of stretch, severance, or entrapment. It is difficult to clinically distinguish these causes; therefore management of nerve injuries is frequently expectant.⁹⁵ It is imperative to conduct a careful neurologic examination before and after reduction because any increase in findings may indicate entrapment and the need for surgical intervention.⁹⁵ Myositis ossificans is also a potential complication of elbow dislocations secondary to hemarthrosis, which underscores the advisability of orthopedic consultation early in the course of care.

Posterior Dislocations

Posterior dislocations make up the vast majority of elbow dislocations.⁶³ The usual mechanism is a fall on an outstretched hand with the elbow in extension. Findings on clinical examina-

Figure 49.24 Posterior elbow dislocation. *Top row*, pre-reduction films; *bottom row*, post-reduction films. *AP*, Anteroposterior; *LAT*, lateral.

tion are usually diagnostic unless severe soft tissue swelling is present. The patient has a shortened forearm that is held in flexion, and the olecranon is prominent posteriorly. The normally tight triangular relationship of the olecranon and the epicondyles of the distal end of the humerus is disturbed in a posterior dislocation. A defect may also be palpated above the prominence of the olecranon.

Radiologic Examination

Two radiographic views, an AP and a true lateral, should be obtained (Fig. 49.24). The diagnosis is obvious with proper radiographs. A careful search for fractures of the distal end of the humerus, radial head, and coronoid process must be undertaken because they commonly occur in this injury.⁹⁵ In children younger than 14 years, the fracture is usually a separation of the medial epicondyle because the epiphyseal plate gives way before the medial collateral ligament of the elbow. Post-reduction radiographs are also necessary to confirm reduction and disclose any associated fractures.⁹⁸

Reduction Techniques and Post-Reduction Care

As with shoulder reductions, some authors claim that their method of elbow reduction is virtually painless,^{49,99} but this has not been objectively documented. In general, patients with posterior elbow dislocations are quite uncomfortable, and it is beneficial to administer IV analgesics early in the course of care, preferably before positioning for radiographs. In addition to or in lieu of parenteral sedation and analgesia, some clinicians inject the elbow joint with a local anesthetic (e.g., 3 to 5 mL of 2% plain lidocaine) before attempting reduction. Before injection, aspirate the joint to remove any blood.

Recommended Initial Approach

A prone technique is advantageous because patients tolerate this position quite well. Hang the flexed elbow over the edge of the bed and position an assistant with his or her back toward the patient such that the patient's humerus can be encircled

Posterior Elbow Dislocation Reduction

A. Initial Recommended Approach

1, Position the patient prone and hang the flexed elbow over the bed. Instruct an assistant to grasp the humerus with both hands and apply pressure on the olecranon with the thumbs (black arrow). Apply longitudinal traction on the humerus (white arrow).

2, If reduction is not accomplished, try to further flex the elbow while applying traction (white arrows), or instruct the assistant to lift the humerus while pushing down on the olecranon (black arrows). Reduction is generally noted by a definitive “clunk.”

B. Traction-Countertraction

With the patient supine, instruct an assistant to stabilize the humerus. Grasp the wrist and apply in-line traction. Slightly flex the elbow, and hold the wrist supinated as traction is applied.

C. Chair/Back of Bed Method

Hang the patient's arm over the padded back of a chair or over the edge of the bed. Apply pressure to the posterior aspect of the olecranon to achieve reduction. Traction may be applied to the forearm.

Figure 49.25 Posterior elbow dislocation reduction methods.

with both hands and pressure applied with the thumbs on the posterior aspect of the olecranon (Fig. 49.25A). This pressure on the olecranon is intended to lift it up and away from the humerus. Apply longitudinal traction on the arm with the elbow in slight flexion. If reduction is not accomplished, an attempt may be made to further flex the elbow, or the assistant can be instructed to lift the humerus. Reduction is generally noted by a definite “clunk.”

Traditional Traction Method

Place the patient in the supine position and have an assistant stabilize the humerus with both hands¹⁰⁰ (see Fig. 49.25B). Grasp the wrist and apply slow and steady in-line traction. Slightly flex the elbow to keep the triceps mechanism loose, and hold the wrist supinated while applying traction. Reduction is usually signified by a “clunk” that is heard or felt. If this method is not successful after a reasonable period of traction

(10 minutes), gently flex the forearm to effect reduction. Alternatively, apply downward pressure on the proximal volar surface of the forearm to free up the coronoid process.

Alternatives

Several authors have described variations of a prone method of reduction that are reportedly well tolerated by patients.^{49,99,100} In the method described by Minford and Beattie,⁹⁹ position the patient with the arm hanging over the padded back of a chair or over the edge of the bed (see Fig. 49.25C). Apply pressure to the prominent posterior aspect of the olecranon to achieve reduction. Alternatively, apply traction with the elbow flexed over the edge of a chair. Pull down on the hand while using the thumb to guide the olecranon into place.¹⁰⁰ Parvin⁴⁹ positioned the patient as for the Stimson method of shoulder relocation, prone on a stretcher with the arm hanging down, and applied gentle downward traction on the wrist.

Anterior Elbow Dislocation Reduction

Apply in-line traction and backward pressure on the proximal end of the forearm while an assistant provides countertraction on the humerus. A clunk usually indicates that reduction is achieved.

Flex the arm beyond 90 degrees to ensure that the joint has been reduced. Splint the elbow in at least 90 degrees of flexion with a posterior long-arm splint.

Figure 49.26 Anterior elbow dislocation reduction method.

Post-Reduction Care

Once reduction is achieved, put the elbow through a gentle range of motion to ensure that the reduction is stable and there is no mechanical block to movement.⁹⁵ An inability to move the elbow through a smooth range of motion after reduction is often caused by an entrapped medial epicondyle fracture fragment, which requires operative intervention.⁹⁵ Immobilize the elbow in at least 90 degrees of flexion with the forearm in slight pronation by using a long arm posterior splint (see [Chapter 50](#)). After immobilizing the joint, recheck the neurovascular status of the extremity and obtain post-reduction radiographs.

After reduction, any signs of delayed vascular compromise are first addressed by loosening the splint and decreasing the degree of flexion. This may restore adequate blood flow.⁹⁵ If not, immediate surgical consultation is necessary for emergency arteriography, exploration of the brachial artery, or both.⁹⁸ Brachial arterial injury may not be immediately apparent because of the presence of collateral circulation. The risk for vascular compromise is a reason to consider in-hospital observation. Alternatively, observe the patient in the ED or ED observation unit for 2 to 3 hours after reduction to evaluate for delayed neurovascular compromise before discharge.

The optimal duration of immobilization is unknown. However, a recent randomized multicenter trial (2017) found early range of motion to be safe and associated with faster recovery time and return to work when compared to plaster immobilization for 3 weeks.¹⁰¹

Anterior Dislocations

Anterior dislocations of the elbow are quite rare; they usually result from a direct posterior blow to the olecranon with the elbow flexed.⁹⁵ On physical examination, the arm is elongated and extended with anterior tenting of the proximal end of the forearm and prominence of the distal end of the humerus posteriorly.⁹⁵ These injuries are the result of a great deal of

force; they are frequently open and accompanied by significant neurovascular injury. An avulsion of the triceps mechanism may also occur.⁹⁵

To reduce anterior dislocations of the elbow, apply in-line traction and backward pressure on the proximal end of the forearm ([Fig. 49.26](#)). An assistant provides countertraction by grasping the humerus with both hands. Given the infrequent nature of anterior dislocations and the high probability of a severe associated injury, the emergency clinician should consider early orthopedic consultation.

RADIAL HEAD SUBLUXATION (NURSEMAID'S ELBOW)

Radial head subluxation is a common pediatric orthopedic issue that generally occurs between the ages of 1 and 3 years. The mean age is just older than 2 years, but this entity has been reported in infants younger than 6 months^{102,103} and in older children up to the preteen years.¹⁰⁴ There is a slight predilection for this injury to occur in girls and in the left arm.^{103,105} The classic mechanism of injury is longitudinal traction on the arm with the wrist in pronation, as occurs when the child is lifted up by the wrist ([Fig. 49.27A](#)).¹⁰³ There is no support for the common assumption that the relatively small head of the radius in relation to the neck of the radius predisposes the young to this injury.¹⁰⁶ The pathologic lesion is generally a tear in the attachment of the annular ligament to the periosteum of the radial neck, with the detached portion becoming trapped between the head of the radius and the capitellum (see [Fig. 49.27B](#)).¹⁰⁶

Clinical Assessment

The history offered by the caretaker may not be that of the classic pulling-type mechanism. Schunk,¹⁰³ in a series of 83 patients, reported that only 51% described such a mechanism

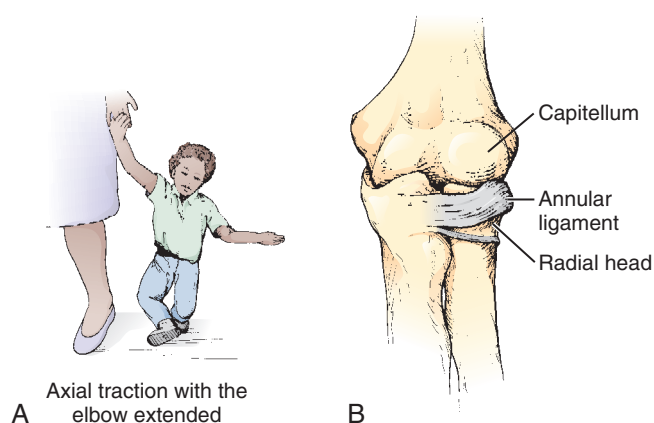

Figure 49.27 Radial head subluxation (nursemaid's elbow). **A**, The classic mechanism for this injury is longitudinal traction on the arm with the wrist in pronation. **B**, The pathologic lesion is usually a torn piece of the annular ligament becoming trapped between the radial head and the capitellum of the humerus. (From Fleisher GR, Ludwig S, editors: *Textbook of pediatric emergency medicine*. Baltimore, 1988, Williams & Wilkins p 1322. Reproduced by permission.)

Figure 49.28 Typical findings in a child with subluxation of the right radial head (nursemaid's elbow). It may be difficult to determine exactly where the pathology exists, and the wrist is often thought to be the area of injury. This child will not use the injured right arm but has minimal discomfort as long as the elbow is not manipulated. **A**, The affected arm hangs down at the side, slightly flexed and pronated. **B**, Once the subluxation is reduced, full activity is generally regained in a matter of minutes.

whereas 22% reported a fall. In patients younger than 6 months, the mechanism in the majority of cases is simply rolling over in bed.¹⁰² Therefore isolated radial head subluxation in children younger than 6 months does not automatically necessitate a child abuse investigation. The typical patient with radial head subluxation is in no distress and holds the involved arm slightly flexed and the wrist pronated at the side (Fig. 49.28). This has been termed the *nursemaid's position*.¹⁰⁷ The exact area of pain is often difficult to locate. The child will refuse to use the arm, and this may be the chief complaint.¹⁰⁴ An older child will usually point to the dorsal aspect of the distal end of the forearm when asked where it hurts, which may mislead the clinician to suspect a distal radial buckle fracture.

Although tenderness about the elbow has been reported occasionally, there is often little tenderness or swelling in the elbow region.^{103,104} In a cooperative child, the arm and shoulder are carefully palpated to discern any tenderness. Areas of focus on palpation should include the clavicle and distal end of the radius because these are common sites for pediatric fractures. When patient anxiety interferes with reliable assessment of tenderness in a child whose arm is in the classic nursemaid's position, the examiner can stand at a distance and have the parent or caretaker palpate the extremity to ascertain tenderness. This may also be done with a cooperative patient to reassure a doubtful parent regarding the absence of a fracture. If no tenderness is noted on palpation, it is appropriate to attempt reduction without prior radiographs.¹⁰⁸

Although resistance to or pain with supination is a frequent finding in patients with radial head subluxation,¹⁰³ one need not test for this finding until the time of reduction.

Radiographic Examination

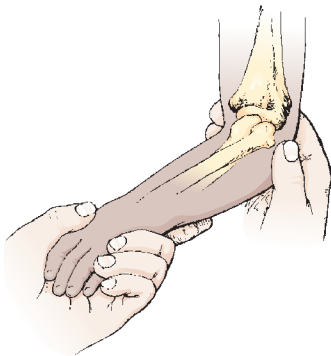

Radiographs are not generally needed with the classic findings of a child with an arm in the nursemaid's position that is not tender (or minimally tender in the radial head area) on palpation and an appropriate history.¹⁰⁸ In these cases, findings on radiographs are generally normal, and if obtained, the positioning of the child's arm by the x-ray technician often effects reduction.¹⁰³ Nevertheless, Frumkin¹⁰⁶ described three cases of nursemaid's elbow in which a line drawn through the longitudinal axis of the radius did not normally bisect the capitellum on pre-reduction radiographs but did so after reduction. Radiographs are sometimes recommended if the child is not moving the arm normally 15 minutes after reduction.¹⁰⁷ However, this time frame may be too short because reuse can be delayed for more than 30 minutes, particularly in children initially seen some time after the injury. Quan and Marcuse¹⁰⁴ recommended an approach in which no radiographs are obtained on the first visit, including in children released from the ED before regaining full use of the arm. At the time of a 24-hour follow-up visit, radiographs are obtained only if repeat attempts at manipulation are not successful.

Even though this condition does not generally require radiographs, they can be valuable if external signs of trauma are present (e.g., swelling, abrasions, ecchymoses) or if the child does not use the arm normally within 24 hours after the subluxation is thought to be reduced. Other less common conditions that can have similar findings are fractures, joint infections, tumors, and osteomyelitis.

Ultrasound is an additional tool that may be used to help exclude an alternate etiology of elbow pain or confirm the presence of a suspected radial head subluxation. A study performed by Rabiner and colleagues evaluated the use of ultrasound to exclude a posterior fat pad, a finding associated with supracondylar fracture, in patients with suspected radial head subluxation.¹⁰⁹ All patients with normal elbow ultrasound had successful reduction of the radial head subluxation with return to full function.¹⁰⁹ Ultrasound may also be diagnostic in radial head subluxation. The "hook sign," caused by the hyperechoic J-shaped supinator muscle above the radial head, has been shown to be 100% sensitive for the diagnosis of radial head subluxation.^{110,111} As with other conditions, ultrasound can be a useful radiation-sparing adjunct to the physical exam and may additionally assist in reassuring an anxious caregiver of the diagnosis prior to reduction attempts.

Nursemaid's Elbow Reduction

1

Grasp the elbow with one hand and place your thumb over the region of the radial head.

2

Grasp the wrist with your other hand and supinate the extended forearm in a steady and deliberate manner. Apply slight traction to the arm.

3

Once supinated, flex the arm. An audible or palpable click signifies successful reduction but is not always noted.

Figure 49.29 Nursemaid's elbow (radial head subluxation) reduction. (From Fleisher GR, Ludwig S, editors: *Textbook of Pediatric Emergency Medicine*. Baltimore, 1988, Williams & Wilkins, p 1322. Reproduced by permission.)

Reduction Techniques

Supination Method

Reduction of nursemaid's elbow (Fig. 49.29) is generally performed without premedication. If the subluxation has been present for hours, oral or nasal midazolam can be a useful adjunct to overcome the child's anxiety related to manipulation (see Chapter 33). It is important to explain to the caretaker that the reduction will probably cause the child discomfort and precipitate crying, but that this is transient and a clue to the diagnosis. Position the child seated on the lap of an assistant (often a parent) who stabilizes the arm by holding the humerus adducted to the side. Grasp the elbow with one hand and place the thumb over the region of the radial head. Although it has been stated that the thumb can apply pressure on the radial head, this positioning is mainly useful for palpation of the reduction "click." Grasp the child's wrist with the other hand and supinate the extended forearm in a steady, deliberate manner. Slight traction before supination is generally recommended, but it is unclear whether this increases the likelihood of successful reduction. Once supinated, flex or extend the arm; however, flexion is the most common maneuver and may actually be somewhat more successful than extension.¹⁰³ An audible or palpable click signifies successful reduction but is not always noted. Once the reduction has been performed, the child usually cries for a few minutes. Generally, the operator should leave the room and then return in 10 to 15 minutes to repeat the examination. Full use of the arm should be evident (see Fig. 49.28B).

Pronation Method

This technique is performed with the child positioned as for the supination method. However, the forearm is not supinated. Instead, the forearm is rapidly hyperpronated and flexed.

Multiple studies have found a variable combination of improved success and less pain with this method.¹¹²⁻¹¹⁵ Similarly, a 2012 Cochrane review concluded hyperpronation to be more successful and less painful than the supination method.¹¹⁶

After Attempted Reduction

If a click is detected, the child will generally regain use of the affected arm quickly (almost always by 30 minutes).¹⁰⁴ Therefore, if a definite click is detected, it is reasonable to observe the child for up to 30 minutes before further intervention. If there is still no use at 30 minutes, the operator may try to determine whether supination is still painful, which would suggest the need to repeat the attempt. In children in whom a click is not detected, the majority will not use the arm by 30 minutes.¹⁰⁴ Therefore a repeated attempt at reduction is recommended after 10 to 15 minutes of nonuse in children who did not have a click during the primary reduction. Two or more attempts are required to produce the click in up to 30% of patients.¹⁰⁴

If the child has not regained use of the arm after a few attempts and a reasonable period of time, some authors recommend that radiographs be obtained.¹⁰⁷ Radiographs may also help relieve parental anxiety. Alternatively, instructions may be given for 24-hour follow-up if normal function is not restored, with consideration of radiographs at the time of follow-up.¹⁰⁴ In two series of patients with nursemaid's elbow, 6 of 10 patients released without normal arm use had spontaneous restoration of function, whereas the other 4 required remanipulation (which successfully restored function).^{103,104} Delayed use of radiographs may decrease overall radiation exposure in a child with a radial head subluxation.

The use of a posterior splint to protect the elbow of a child who refuses to use the affected arm after a presumed reduction is of uncertain value. However, some form of immobilization (e.g., splint, sling, or both) may be valuable in a child with

significant residual discomfort after a prolonged period of subluxation or in whom recurrent subluxations have taken place.

On occasion, a successful reduction painfully resubluxates with movement; in this case, immobilization and referral may be necessary.¹⁰⁶ If reduction has been achieved clinically and maintained in the ED, analgesics or a follow-up visit is unnecessary. Because other pathology can rarely mimic this condition (e.g., occult fracture, osteomyelitis, joint infection, tumor), full, unrestricted, and painless use of the arm must be evident by 24 hours. If not, further workup is warranted.

The emergency clinician should consider parental education regarding prevention of radial head subluxation. Parents or caregivers should be instructed to lift toddlers who are at an age most at risk for these injuries from beneath their axilla, as opposed to forcibly lifting or pulling them by the wrist or hand.

HAND INJURIES

The hand is extremely susceptible to dislocation injuries because of its frequent use and exposed nature. Proper motion and function of the hand are intimately related to normal anatomic alignment.¹¹⁷ The emergency clinician must therefore be skilled in the diagnosis and management of dislocations involving the hand. An improperly managed hand injury can result in significant long-term or permanent disability.

Anatomically, the joints of the digits are quite similar and consist of a hinged joint with a tongue-in-groove-type arrangement.¹¹⁷ The soft tissue support includes two collateral ligaments attached to a volar plate (Fig. 49.30). The volar plate is composed of dense fibrous connective tissue that is thickened at its distal attachment and thinner at its proximal attachment

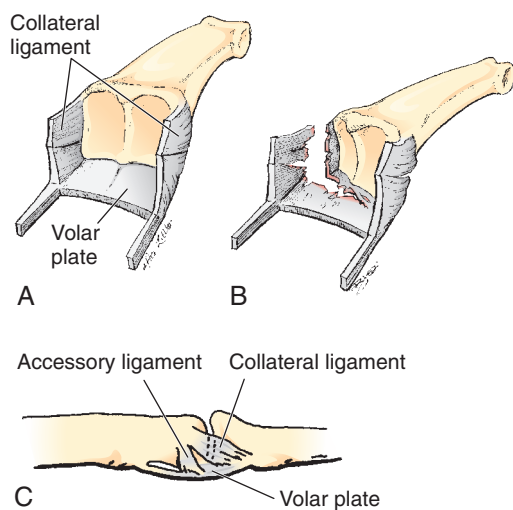

Figure 49.30 A and B, The collateral ligament–volar plate relationship. The metacarpophalangeal and interphalangeal joints derive their strength from a combination of the two collateral ligaments and the volar plate. Dislocations of these joints require tearing of at least two parts of this three-part structure. C, Lateral view demonstrating the collateral ligament–volar plate relationship. (A and B, From Carter P, editor: *Common hand injuries and infections*. Philadelphia, 1983, Saunders, p 114. Reproduced by permission; C, redrawn from Eaton RG: *Joint injuries of the hand*. Springfield, IL, 1972, Charles C Thomas.)

to allow folding with joint flexion.^{117,118} Dorsal dislocation of a digit requires failure of the volar plate, whereas lateral dislocation disrupts a collateral ligament and induces at least a partial tear in the volar plate.

Radiographic examination of all hand injuries is relatively straightforward and includes at least two views (AP and lateral) of the injured area (Fig. 49.31). The most important radiographic error in evaluating joint injuries in the hand is failing to get a true lateral view of the injured joint.¹¹⁸ This may lead to missing a fracture or a loose body in the joint.

Anesthesia is generally required for proper management of dislocations involving the hand. It is most often accomplished with a finger or wrist block (see Chapter 31), although a more proximal regional or Bier block may be used on occasion (see Chapter 32). Getting a secure grip on the digits may be difficult and could complicate the reduction. Wearing rubber gloves or wrapping gauze around the fingers may be useful.

Figure 49.31 Phalangeal dislocations. A, Dorsal dislocation of the metacarpophalangeal (MCP) joint of the thumb. B, Dorsal dislocation of the proximal interphalangeal (PIP) joint of the middle finger. Note the presence of a small volar plate fracture (arrow). C, Dorsal dislocation of the distal interphalangeal (DIP) joint of the little finger. Dorsal dislocations are much more common than volar ones. AP, Anteroposterior; LAT, lateral.

Thumb Dislocations

The opposable thumb is an essential structure for countless activities. Despite its strong ligamentous and capsular support, the exposed positioning of the thumb makes it a frequent site of dislocations and subluxations. The metacarpophalangeal (MCP) joint in the thumb is similar to the MCP joints in the fingers but has a stronger volar plate and collateral ligaments.¹¹⁸

Interphalangeal Joint Dislocation of the Thumb

The single IP joint of the thumb has strong cutaneous-periosteal attachments, and dislocations of this type are therefore frequently open.¹¹⁸ Dislocations at the IP joint are generally dorsal and can be reduced in a manner similar to that for IP dislocations of the finger (Fig. 49.32A and B). First, re-create the

mechanism of injury by applying longitudinal traction and hyperextension to distract the phalanges. Next, flex the IP joint with continued traction and apply direct pressure on the base of the distal phalanx to complete the reduction.¹¹⁸

After reduction, test the range of motion and stability of the joint and obtain post-reduction radiographs. If adequate reduction has been achieved, splint the thumb in slight flexion for 3 weeks.¹¹⁸ Orthopedic or hand specialist referral is advisable.

Metacarpophalangeal Joint Injury of the Thumb Dorsal Dislocation

The MCP joint of the thumb can be dislocated dorsally by a hyperextension injury. The proximal phalanx will come to rest in a position dorsal to the first metacarpal (Fig. 49.33; also see Fig. 49.31A). There are two basic types of MCP dislocation

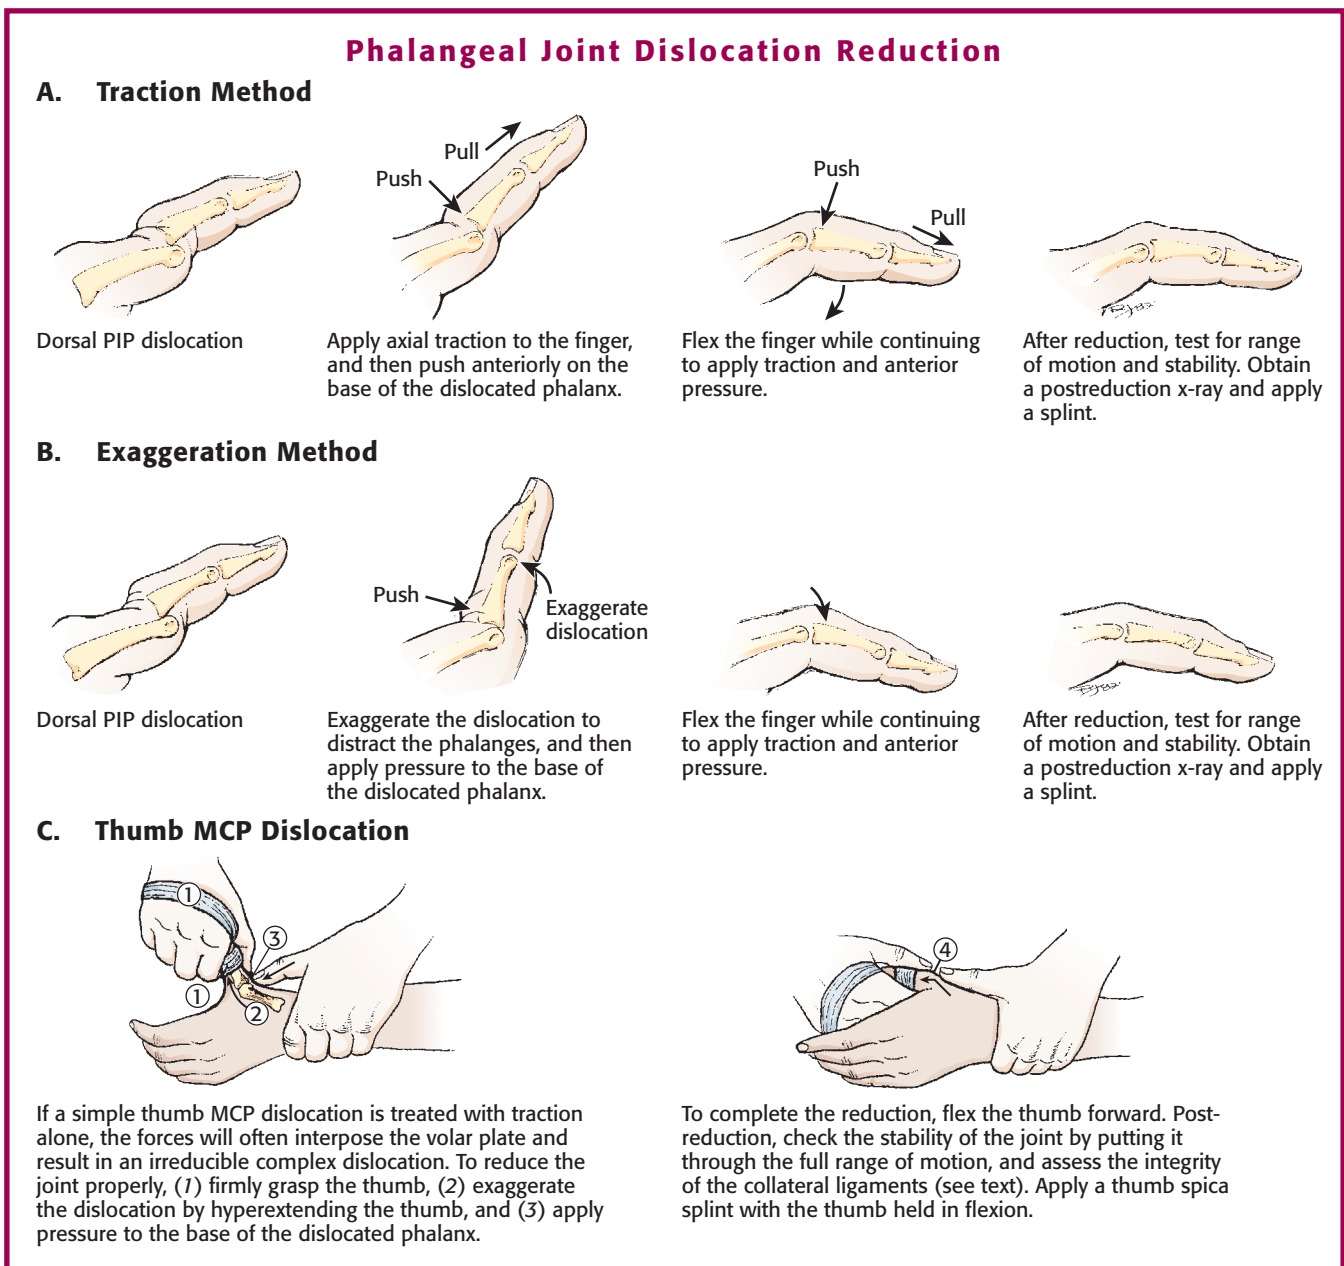

Figure 49.32 Phalangeal dislocation reduction. MCP, Metacarpophalangeal

Figure 49.33 Dorsal dislocation of the metacarpophalangeal joint of the thumb.

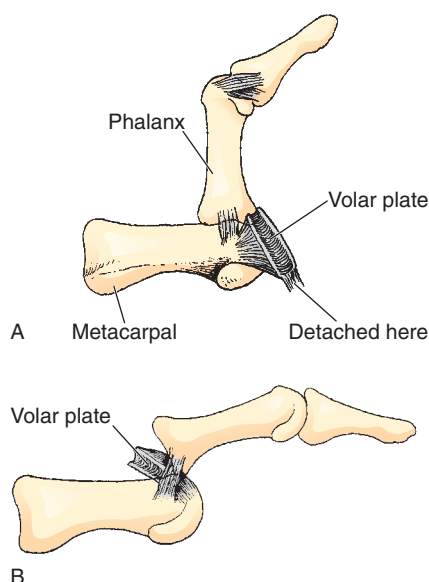

Figure 49.34 **A**, In a simple dorsal metacarpophalangeal joint dislocation (note the right angle between the phalanx and the metacarpal), the volar plate remains in front of the metacarpal head, although it is detached from its weaker metacarpal insertion. **B**, In a complex dislocation (note the more parallel alignment between the phalanx and the metacarpal), the volar plate becomes entrapped in the joint, and this makes reduction by closed methods impossible. (**A** and **B**, From DePalma AF: *Management of fractures and dislocations: an atlas*. Philadelphia, 1970, Saunders, p 1177. Reproduced by permission.)

(this applies to the fingers also): simple and complex. In a complex MCP dislocation, the volar plate becomes entrapped dorsal to the metacarpal head (Fig. 49.34), with the flexor tendons and lumbricals acting to completely entrap the metacarpal head.¹¹⁸ The simple type is amenable to closed reduction, whereas the complex type requires operative reduction because of the interposed soft tissue.^{117,118} It is important to note that a simple MCP dislocation can be converted into a complex one during reduction.¹¹⁷

Clinical features that suggest a complex MCP dislocation include a proximal phalanx that is less acutely angulated than with a simple dislocation (i.e., < 60 degrees).¹¹⁸ Dimpling may also be noted over the thenar eminence as a result of pressure

Figure 49.35 Irreducible metacarpophalangeal joint dislocation of the thumb. Note the sesamoid bone (arrow), which indicates interposition of the volar plate between the two ends of the bone and may prevent closed reduction. (From Carter P, editor: *Common hand injuries and infections*. Philadelphia, 1983, Saunders, p 115. Reproduced by permission.)

from the entrapped metacarpal head.¹¹⁷ On radiographs of simple dislocations, the joint surfaces are in close contact, whereas they are separated in complex dislocations. The presence of a sesamoid bone in the joint space is diagnostic of a complex MCP dislocation (Fig. 49.35).¹¹⁷

To reduce a simple MCP dislocation, hyperextend the joint as far as possible with the wrist in flexion to relax the tendons (see Fig. 49.32C). Once maximal hyperextension is achieved, push the base of the proximal phalanx distally while bringing the joint back into flexion.¹¹⁷ Applying simple traction alone as an initial maneuver risks trapping the volar plate and creating a complex dislocation.¹¹⁷ After reduction, test the stability of the joint by putting it through a full range of motion. Assess the integrity of the collateral ligaments with the MCP joint in flexion (see later). Simple MCP dislocation injuries generally require casting for 3 weeks with the joint in moderate flexion.¹¹⁸

Volar Dislocation

Volar dislocations are rare and generally associated with collateral ligament ruptures. They are commonly irreducible because of interposition of one or both extensor tendons and the dorsal capsule.¹¹⁷ Orthopedic consultation is required.

Ulnar Collateral Ligament Rupture

Also known as *gamekeeper's* or *skier's thumb*, this injury results from a laterally directed force at the thumb MCP joint causing rupture of the ulnar collateral ligament (Fig. 49.36). The usual mechanisms include falling with a ski pole in the hand or having the thumb alone draped over the steering wheel in an auto crash. These injuries are most often initially seen in the reduced state with just a complaint of pain in the area. Early recognition of this injury is essential to prevent further disability because this ligament is important for the grasping function of the thumb. A strain or partial tear probably cannot be diagnosed in the ED. It is therefore prudent to immobilize all significantly “sprained thumbs” in a thumb spica splint for a few days and reexamine those with significant injuries. A complete or severe ligamentous tear is generally diagnosed by stress testing of the MCP joint (Fig. 49.37). Radiographs occasionally demonstrate an avulsion-type fracture. The exact positioning of the thumb for stress testing is debatable, but the metacarpal should be stabilized with the thumb and index

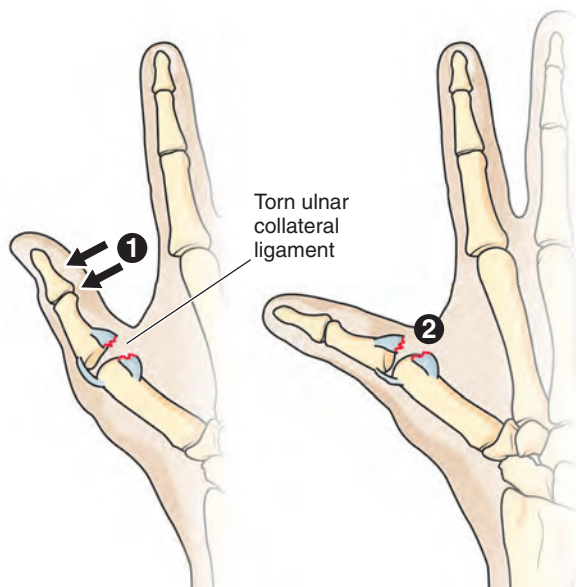

Figure 49.36 Rupture of the ulnar collateral ligament (gamekeeper's thumb). 1, This injury is caused by forcible abduction. If unrecognized and untreated, progressive metacarpophalangeal (MCP) subluxation may occur (2), which interferes with grasping and causes significant permanent disability. Suspect this injury when there is a complaint of pain in this region. Look for tenderness on the medial side of the MCP joint. (Modified from McRae R: *Practical fracture treatment*. Edinburgh, UK, 1981, Churchill Livingstone, p 162. Reproduced by permission.)

Figure 49.37 Stress testing of the ulnar collateral ligament of the thumb. This is done both clinically and with an anteroposterior radiograph. A, A line is drawn on the skin with a pen. The line is along the long axis of the metacarpal and the proximal phalanx. B, Deviation of the straight line during stress indicates instability. The metacarpal is fixed with the operator's other hand. Note: With acute injuries of the thumb, a simple sprain may be diagnosed when an ulnar collateral ligament injury is partial or severe and stress tests are negative because of swelling and spasm. Therefore it is prudent to splint all significantly sprained thumbs and reexamine them in a few days if the symptoms persist.

finger of one hand while applying stress with the other hand. Louis and associates¹¹⁹ recommended stressing the joint in full flexion because virtually no lateral movement of the MCP joint should be noted in this position. Instability in full flexion of greater than 35 degrees is indicative of a complete rupture. Hossfeld and Uehara¹¹⁸ suggested testing the MCP joint in

Figure 49.38 Carpometacarpal (CMC) dislocation of the thumb (arrows in A and B). A, Anteroposterior (AP) and lateral (LAT) radiographs of a CMC dislocation of the thumb, which is an uncommon injury. The patient sustained this injury when an air bag deployed during a motor vehicle collision. These dislocations are not generally amenable to closed reduction and usually require Kirschner wires. B, Pre- and post-reduction films of a CMC dislocation.

20 to 30 degrees of flexion to lessen the stabilizing effects of the volar plate; the results should be compared with stability on the other side.

Cast partial injuries to the ulnar collateral ligament for 3 weeks; complete rupture usually requires operative repair.¹¹⁹ An associated nondisplaced fracture may be treated in closed fashion, whereas a displaced fracture is an indication for operative repair.¹¹⁹

Carpometacarpal (CMC) Dislocations of the Thumb

CMC dislocations of the thumb are uncommon (Fig. 49.38); when present, they often occur with an associated fracture. Because closed reduction is generally unstable, operative stabilization by percutaneous placement of Kirschner wires (K-wires) is usually required.¹¹⁸

Finger Dislocations

The basic anatomic structure of the fingers is similar to that of the thumb with the exception that the fingers have more lateral support from the MCP joints, which makes collateral ligament injury here much less common than in the thumb. The treatment principles are also similar. It is advisable to

Figure 49.39 Fracture-dislocations of the proximal (PIP) and distal interphalangeal (DIP) joints. True lateral radiographs are required to maximize sensitivity for small avulsion fractures. **A**, A volar avulsion fracture (arrow) is readily seen on this dorsal DIP dislocation. **B**, The fractures are more difficult to appreciate on this unfortunate patient who sustained dislocations of both the DIP and PIP joints in a fall (arrows).

order radiographs for a specific finger (not just “hand” films). Complete views of the finger will include an AP view, a true lateral view, and an oblique view. A true lateral view is extremely important for detection of subtle dislocations or small avulsion fractures on the volar surfaces (Fig. 49.39).

Proximal Interphalangeal (PIP) Joint Dislocations

The PIP joint is extremely important, and any loss of motion in this joint may severely restrict normal function.¹¹⁷ This joint is also prone to stiffness, so careful treatment of injuries in this area is essential. Injuries to the PIP joint are generally slow to heal and often result in an increase in joint size as a result of scar tissue formation.¹¹⁷ Because of this propensity for a less-than-perfect outcome, it is advisable to refer PIP injuries after emergency care.

Proper examination of the PIP joint (Fig. 49.40) includes the application of ulnar and radial stress to test the integrity of the collateral ligaments and hyperextension to determine the integrity of the volar plate. Inability to actively extend the flexed PIP joint against resistance suggests a central slip rupture, which may progress to a boutonnière deformity (see Chapter 48).¹¹⁷ Such an examination should be carried out *after* any successful joint reduction. This examination should also be conducted on a painful PIP joint that is radiographically normal to detect soft tissue injury in a spontaneously or field-reduced dislocation. This is extremely important in athletes because coaches often reduce these injuries.¹¹⁷

Dorsal PIP Dislocations

Dorsal PIP dislocations are among the most common types encountered in the ED (Fig. 49.41; also see Fig. 49.31B). The mechanism is usually a blow to the end of the finger, such as from a thrown ball, that creates an axial load and hyperextends the finger.¹¹⁸ The middle phalanx comes to rest dorsal to the proximal phalanx (Fig. 49.42). An associated disruption of the volar plate is generally present.^{117,118} The deformity is obvious

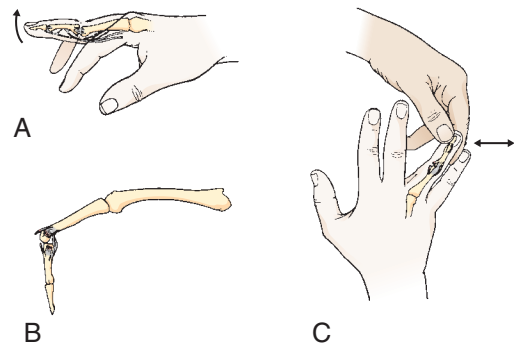

Figure 49.40 Post-reduction stress applied to a dislocated proximal interphalangeal (PIP) joint. **A**, If the volar plate has been completely disrupted, the PIP joint will hyperextend with both passive and active motion. **B**, Inability to actively extend the PIP joint indicates rupture of the central slip of the extensor tendon. **C**, Passive lateral stress is applied to check the integrity of the collateral ligaments. (A–C, From DePalma AF: *Management of fractures and dislocations: an atlas*. Philadelphia, 1970, Saunders, pp 1203–1204. Reproduced by permission.)

Figure 49.41 Dorsal proximal interphalangeal joint dislocation.

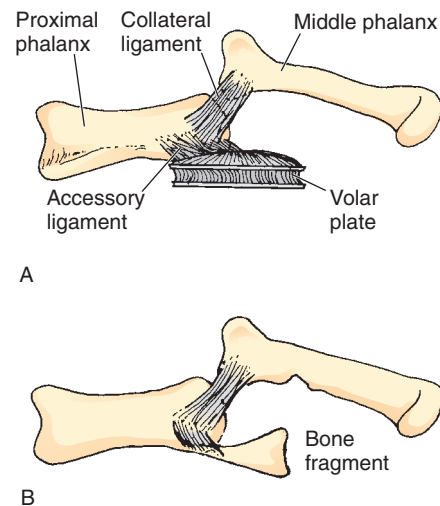

Figure 49.42 A dorsal proximal interphalangeal joint dislocation **A**, may involve rupture of the volar plate itself or **B**, may involve avulsion of varying amounts of bone from the middle phalanx. If a large fragment of bone is avulsed from the base of the phalanx, the dislocation is unstable after reduction. The collateral ligaments will tear in varying degrees and should be assessed with stress testing after reduction.

on clinical examination, and radiographs clearly demonstrate the injury. An associated fracture of the volar lip may be detected. If this fracture affects greater than 33% of the joint surface, closed reduction will be unstable because the collateral ligament is attached to the bony fragment. In these cases, operative repair will be necessary.¹¹⁸

A dorsal PIP dislocation can be reduced after a digital block. The usual method (see Fig. 49.32*A* and *B*) is to exaggerate the injury by slight traction and hyperextension, thereby distracting the middle phalanx. Apply pressure to the base of the middle phalanx as the finger is brought into flexion. These injuries usually reduce fairly easily, and failure of routine attempts should raise suspicion of interposed soft tissue, for which orthopedic consultation should be sought.

After reduction is completed, place the joint through a range of motion to ensure stability of the reduction. If stable, splint the joint in 20 to 30 degrees of flexion for 3 weeks.^{117,118} Alternatively, buddy taping to an adjacent finger for 3 to 6 weeks allows early active motion and prevents hyperextension, which should be avoided.¹¹⁸ Because PIP injuries can be slow to heal and are complicated by stiffness, it is advisable to refer these patients for orthopedic follow-up.

Volar PIP Dislocations

Volar PIP dislocations are uncommon injuries and virtually always accompanied by injury to the central slip of the extensor tendons. If the dislocation is reduced before the ED visit and there is no indication that the dislocation was volar, this injury may be incorrectly treated by splinting in mild flexion as though it were the more common dorsal dislocation. However, with disruption of the central slip of the extensor tendons, immobilization in flexion will lead to the development of a boutonnière deformity.^{117,120} Even when this injury is recognized and treated properly, some impairment of mobility may occur. It is generally best to seek early orthopedic consultation for these injuries because some require operative repair. If the emergency clinician accomplishes a closed reduction, post-reduction films must demonstrate normal congruity of the joint surfaces, and a central slip attachment fracture must be excluded.¹²⁰ If so, splinting of only the PIP joint in full extension should be undertaken for 3 weeks and early orthopedic follow-up ensured.¹¹⁷

Lateral PIP Dislocations

Lateral PIP dislocations are fairly common and often reduced in the field. The patient will frequently describe dramatically how the finger was pointing in an unnatural manner (Fig. 49.43). The injury can be detected by applying ulnar and radial stress to the PIP joint. If still dislocated, re-create the injury and then apply longitudinal traction to reduce the dislocation. Treat partial tears of the collateral ligaments by buddy taping the finger for 3 to 6 weeks.¹¹⁷ Management of complete tears is controversial, with some advocating operative therapy for all such injuries and others using varying durations of immobilization or buddy taping.¹¹⁷ Referral is suggested for all but the mildest of PIP collateral ligament injuries.

Distal Interphalangeal (DIP) Dislocations

As in the thumb, the distal phalanx is attached firmly to skin and subcutaneous tissue by osteocutaneous fibers. For this reason, dislocations of the DIP joint are frequently open.¹¹⁷ A DIP dislocation is usually dorsal, and the mechanism is a blow to the end of the finger. Despite the dislocation, the DIP joint

Figure 49.43 Lateral proximal interphalangeal dislocation. These injuries are fairly common and will have dramatic and obvious clinical findings. The dislocation is often reduced in the field, before emergency department evaluation.

may retain some range of motion, so it is important to not overlook these injuries.¹²¹ Lateral radiographs are diagnostic.

Management of a dorsal DIP dislocation involves reduction in a fashion similar to that described for other IP joint injuries (see Fig. 49.32). Hyperextend the finger and apply traction to distract the joint, and then apply pressure on the base of the distal phalanx during flexion. Following reduction, check the joint for stability and place the finger in a dorsal splint for 10 to 12 days.¹¹⁷

An injury to the DIP joint that may be confused with a dislocation is the mallet finger (Fig. 49.44). This injury is often caused by forced flexion of an extended finger (e.g., struck by a baseball). The patient is unable to extend the fingertip, but the joint appears normal on passive extension by the examiner. The injury is a rupture of the extensor tendon, with or without avulsion of a small piece of bone. Unless the injury is properly splinted or surgically immobilized, permanent deformity will occur (see Chapter 48).

MCP Dislocations

The pathology and management of finger MCP dislocations are identical to those of the thumb, as discussed earlier. The same classification of simple and complex applies; the complex type requires operative repair. Dimpling on the palmar surface suggests the presence of a complex dislocation. It is important to remember that application of traction alone for a simple MCP dislocation may convert it to a complex dislocation. For dorsal dislocations, flex the wrist to relax the tendons and hyperextend the joint as far as possible. Then apply pressure on the base of the proximal phalanx to effect reduction. After reduction of a simple dorsal MCP dislocation, buddy taping is generally sufficient to secure the reduction.¹¹⁷ Volar dislocations are rare and require orthopedic consultation.

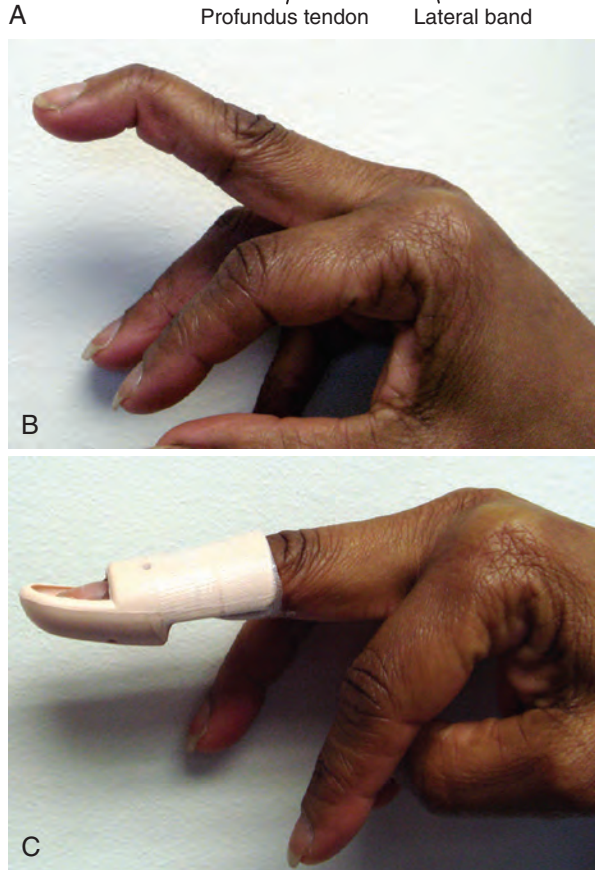

Figure 49.44 A, A mallet finger injury is not a dislocation; it is a rupture of the extensor tendon to the distal phalanx. It can occur with or without (demonstrated here) an avulsion fracture after seemingly minor trauma. B, This mallet deformity was caused by a baseball striking the fingertip end on and producing acute flexion of the joint. C, A stack splint, with the proximal interphalangeal joint left free to allow relaxation of the distal interphalangeal joint, is kept in place for 6 to 8 weeks. Caution the patient to avoid flexing the joint to “test it out” during splint changes. Wire fixation may be required.

CMC Dislocations

CMC dislocations are rare injuries that are frequently misdiagnosed. The usual site of injury is the fifth CMC joint, which is dorsally dislocated.¹¹⁸ The injury is generally the result of a high-energy mechanism, such as a motor vehicle crash or a fall. The diagnosis can be quite difficult to make because the appearance may be subtle even on a lateral radiograph. Associated fractures and other injuries are frequently present, and percutaneous fixation is usually required.¹¹⁸

Carpal Dislocation/Dissociation

Dislocation and dissociation of the carpal bones are significant injuries that require identification in the ED and expeditious immobilization and reduction to ensure the best ultimate outcome. Nonetheless, these injuries often produce significant

Figure 49.45 With this much soft tissue swelling 2 days after a fall on an outstretched hand, something more than a sprain or bruise is likely. If no fracture is seen on radiographs, consider carpal bone fracture or dissociation as the culprit. Scaphoid fracture, scapholunate dissociation or lunate or perilunate dislocation should be considered. Computed tomography or magnetic resonance imaging may be required to define the exact pathology. Note that patients with such injuries hold the wrist in flexion, worsening the edema by compression of dorsal hand veins.

long-term disability, such as chronic pain and weakness, premature arthritis, and avascular necrosis. Specific intervention to establish anatomic alignment is usually undertaken on diagnosis or within a few days of the injury, so identification in the ED, initial splinting, and proper referral are paramount. Definitive treatment is beyond the scope of this chapter and is performed by a consultant, often a hand surgeon.

The most common carpal injuries are scapholunate dissociation and perilunate dislocation, although a number of variations exist. These injuries are often sustained by a fall on an outstretched hand. Carpal dislocations and dissociations produce pain, weakness, decreased range of motion, and often significant soft tissue swelling, with many symptoms seemingly out of proportion to the radiographic findings. Specific radiographic diagnosis is frequently difficult, and it is not uncommon for definitive diagnosis to be missed on initial ED evaluation. CT or magnetic resonance imaging may be required to delineate the specifics of the injury. Marked swelling on the dorsal surface of the hand or wrist, in the absence of a definitive fracture on plain radiographs, is a common scenario, and such findings should prompt consideration of carpal dislocation or dissociation (Fig. 49.45). If a diagnosis is not forthcoming, splinting and reevaluation of a markedly swollen and painful hand or wrist in 2 to 3 days is prudent.

Scapholunate dissociation is a serious, frequently missed injury that is characterized by a widened space (>3 mm) between the scaphoid and lunate bones on a plain radiograph. This is best visualized on a posteroanterior view with the hand closed in a fist and the wrist in ulnar deviation (Fig. 49.46). It is indicative of disruption of ligaments stabilizing the two carpal bones. Even though the symptoms and swelling may be impressive, the radiographic findings are subtle and often overlooked, with initial and subsequent complaints being attributed to a severe bruise or sprain. When identified, the hand and wrist are immobilized in the ED by a splint in neutral position or in 10 to 15 degrees of wrist dorsiflexion. Referral should also be initiated.

Lunate dislocation and perilunate dislocation (Figs. 49.47 and 49.48) can also occur as a result of trauma and produce pain, swelling, and disability. Plain radiographs will usually

Figure 49.46 Scapholunate disassociation is easy to miss on a plain film. **A**, A posteroanterior view of the wrist demonstrates a widened space between the scaphoid (S) and the lunate (L) (*arrow*) because of ligamentous disruption from an impaction injury. Orthopedic consultation is required for this injury. **B**, A normal wrist shows that the typical distance between the scaphoid and lunate should be approximately the same as that between the scaphoid and the radius.

Figure 49.47 Perilunate dislocation. **A**, A posteroanterior view of the wrist does not show the normal two crescentic rows of carpal bones but rather shows significant overlap of the hamate (H) and the lunate (L), as well as the capitate (C) with the scaphoid (S). **B**, A lateral view shows that the lunate remains in alignment with the end of the radius (R) but the remainder of the carpal bones have been dislocated.

delineate the pathology. Identification, splinting in a neutral position or in 10 to 15 degrees of wrist dorsiflexion, and referral are the mainstays of ED treatment.

HIP DISLOCATIONS

The hip is generally a stable ball-and-socket joint. The head of the femur is deeply situated in the acetabulum, and liga-

mentous and muscular support is very strong. Therefore hip dislocations are usually the result of significant force, and a careful search for other limb- or life-threatening injuries must be undertaken. Common mechanisms of hip dislocation include motorcycle or car accidents, vehicles striking pedestrians, and falls.¹²²

Associated fractures are quite common with hip dislocations. In fact, up to 88% of hip dislocations are accompanied by an associated fracture.¹²³ If a fracture complicates the dislocation,

Figure 49.48 Lunate dislocation. **A**, On a posteroanterior view of the wrist, significant overlap is seen of the capitate (C) and scaphoid (S), as well as the hamate (H) and lunate (L). Furthermore, clear overlap appears between the scaphoid and the radial styloid. All these findings suggest dislocation. **B**, On the lateral view, the carpal bones remain in alignment with the distal end of the radius (R), but the lunate has rotated and dislocated in the palmar direction (arrow). (From Mettler FA, editor: *Essentials of radiology*, ed 2, Philadelphia, 2005, Saunders.)

orthopedic consultation is generally indicated. However, the emergency clinician should be able to reduce simple hip dislocations, which are dislocations without an associated fracture or with a very minor fracture.¹²⁴

Hip dislocations may occasionally be missed in the setting of severe trauma because other injuries garner more attention. A missed diagnosis can also occur when a fracture of the femur obscures the clinical picture of hip dislocation.¹²⁴ Common complications of hip dislocation include sciatic nerve injuries and avascular necrosis of the femoral head. Sciatic nerve injuries are seen with 10% to 14% of posterior hip dislocations.¹²⁴ Avascular necrosis of the femoral head is one of the more disabling complications associated with hip dislocation. Although it is generally stated that early reduction will reduce the frequency of this complication, evidence for this statement is hard to find. Dreinhofer and coworkers¹²³ noted poor outcomes despite early (i.e., <6 hours) reduction of type I hip dislocations (dislocation without a significant associated fracture). Yang and colleagues¹²² found that reduction beyond 24 hours was associated with a worse prognosis, but they could not find a significant time factor for those reduced in less than 24 hours. Nevertheless, it is still advisable to reduce hip dislocations as soon as feasible to decrease soft tissue distortion. If evidence of nerve injury exists, the dislocation should be treated as an emergency and reduced as early as possible.

Radiographic Examination

Dislocation of the hip is generally obvious on the standard AP pelvic film that is often taken during trauma resuscitation (Fig. 49.49). A lateral or oblique view of the hip may help clarify the type of dislocation and allow detection of associated fractures.

Figure 49.49 This patient was in a motor vehicle accident and has both an anterior and a posterior dislocation of the hips. Posterior dislocation occurs 90% of the time and is seen here on the left, with the femoral head displaced superior and lateral to the acetabulum. On the right is an anterior dislocation with the femoral head displaced inferiorly and medially. This patient also has a fracture of the pelvis and possibly the left acetabulum and will require a computed tomography scan to unravel the extent of all injuries. (From Mettler FA, editor: *Essentials of radiology*, ed 2, Philadelphia, 2005, Saunders.)

Analgesia and Anesthesia

Dislocation of a prosthetic hip can usually be managed with moderate amounts of IV premedication in the ED. Premedication recommendations for other acute traumatic dislocations run the gamut from general anesthesia for all reductions¹²³ to

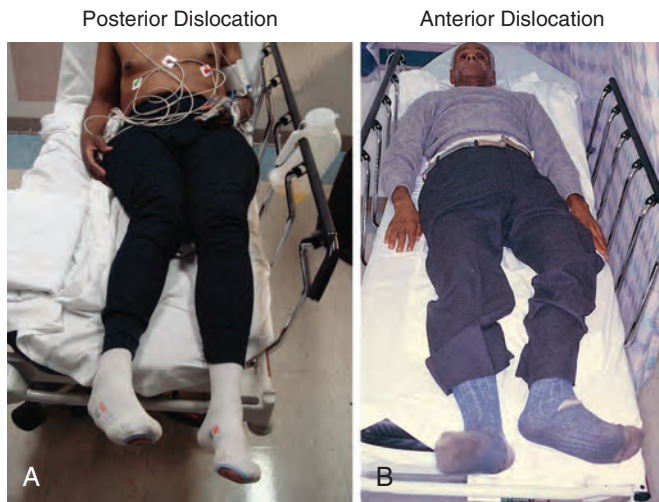

Figure 49.50 **A**, Posterior hip dislocation in a patient with a hip prosthesis. The right leg is adducted, flexed at the knee, shortened, and internally rotated. **B**, The much less common anterior dislocation. The left leg is shortened, abducted, flexed at the knee, and externally rotated, similar to the appearance of a hip fracture.

IV sedation only.¹²⁵ A 2013 case report described the use of a fascia iliaca compartment block to successfully reduce a dislocation of a total hip arthroplasty.¹²⁶ Most clinicians would agree that some type of IV premedication is necessary, and patients often require deep sedation if the procedure is to be successful in the ED. One should not hesitate to opt for spinal or general anesthesia if reasonable attempts at reduction in the ED fail.

Posterior Hip Dislocation

Posterior dislocation is the most common type of hip dislocation. Posterior dislocations generally occur secondary to a blow to the flexed knee with the hip in varying degrees of flexion (e.g., a knee striking the dashboard in a head-on motor vehicle collision). The greater the amount of flexion of the hip at the time of the injury, the less the chance of an associated fracture.¹²⁴ The femoral head is forced out of the acetabulum and rests behind it. The sciatic nerve is located just behind the hip joint and may be injured with a posterior hip dislocation. The clinical picture includes a shortened, internally rotated, and adducted leg (Fig. 49.50A).

Reduction Techniques

Several basic methods of hip reduction have been reported. Some techniques involve placing the patient in the prone position (e.g., the Stimson technique), whereas others require that the patient be supine with downward stabilization of the pelvis performed by an assistant. The supine position may be preferable in multiply injured patients because of the difficulty involved in closely monitoring a critically ill patient in the prone position.

Stimson Technique (Fig. 49.51A)

In the prone or gravity method described by Stimson, the patient is positioned so that the distal portion of the pelvis overhangs the edge of the stretcher. Flex the hip, knee, and ankle to 90 degrees and apply downward pressure on the posterior aspect of the proximal end of the tibia.¹²⁴ Gently

rotate the hip internally and externally to facilitate reduction. If needed, an assistant may apply direct downward pressure on the femoral head. An alternative and more comfortable way to provide downward pressure on the tibia is to grasp the patient's ankle, place your knee on the patient's calf, and use your body weight to apply pressure.¹²⁵ This method is believed to be the least traumatic; however, associated thoracoabdominal injuries or a need for deep sedation, which may pose an airway risk, may make the prone position risky for the patient.¹²⁴

Allis Technique (See Fig. 49.51B)

For the Allis technique, place the patient supine and have an assistant stabilize the pelvis by applying downward pressure at the anterior superior iliac spines. Exert upward traction in line with the deformity and flex the hip to 90 degrees. Gently rotate the hip internally and externally until it is reduced.¹²⁴ Some prefer to stand on the patient's stretcher so that body weight can be used for leverage. Howard¹²⁷ suggested modifying this technique by applying lateral traction on the flexed upper part of the femur to disengage the head of the femur from the outer lip of the acetabulum.

Whistler Technique (See Fig. 49.51C)

Another method known as the Whistler technique was described by Walden and Hamer.¹²⁸ Place the patient in the supine position with both knees flexed to 130 degrees. While an assistant stabilizes the pelvis, stand beside the affected limb. Place an arm under the affected knee and grab the unaffected knee. With the other hand, anchor the ankle of the affected leg firmly against the stretcher. Using the arm placed under the knee as a lever, raise your shoulder to elevate the affected knee. This allows the femoral head to move anteriorly around the acetabular rim and relocate.¹²⁸ Although experience with this technique is limited, it appears to be a promising, gentle reduction method.

Captain Morgan Technique (See Fig. 49.51D)

Another gentle method for reducing posterior hip dislocations is similar to the Whistler technique but uses the clinician's knee as opposed to the arm. To perform the Captain Morgan technique, place the patient supine with the affected knee flexed. Stand on the affected side and place your flexed knee underneath the patient's flexed knee. Apply force with your leg in an upward direction. Internal or external rotation can be added as needed. One case series described an extremely high success rate with this method of reduction, with only one failed attempt secondary to bony fragments in the joint space, which required open reduction.¹²⁹

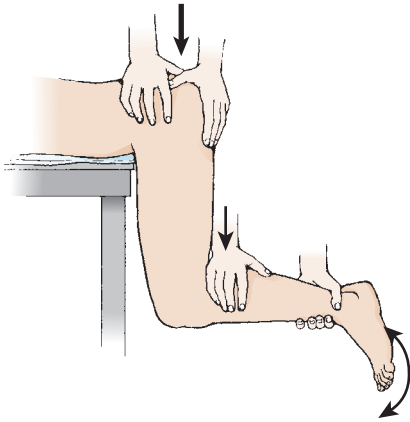

Once reduction is achieved, the legs are immobilized in slight abduction by placing an abduction pillow or another object between the knees. Radiographs should be repeated to confirm reduction, and the patient should be admitted to the hospital.

Dislocations of Hip Prostheses

Dislocation of a hip prosthesis is a separate issue (Fig. 49.52). Unlike primary dislocations, which require significant trauma, a prosthetic hip may dislocate with minimal force, such as rolling over in bed or trying to get out of a chair. Most dislocations occur in the first 3 to 4 months after surgery, but recurrent dislocation may take place much later. The majority of dislocations are posterior. The emergency physician should consider

Posterior Hip Dislocation Reduction

A. Stimson Technique

Place the patient prone with the distal part of the pelvis overhanging the edge of the stretcher. Flex the hip, knee, and ankle to 90 degrees. Apply downward pressure on the posterior aspect of the proximal end of the tibia. Internally and externally rotate the hip to facilitate reduction. Instruct an assistant to apply downward pressure on the femoral head.

C. Whistler Technique

Position the patient supine with the knees flexed to 130 degrees. Instruct an assistant to stabilize the pelvis, and place your arm under the affected knee and grab the other knee. Anchor the ankle to the bed with your other hand. Using your arm under the knee as a lever, raise your shoulder and elevate the affected knee.

B. Allis Technique

Instruct an assistant to apply downward pressure on the anterior superior iliac spines. Exert upward in-line traction on the femur and flex the hip to 90 degrees. Gently rotate the hip internally and externally until it is reduced. Standing on the bed helps increase your leverage.

D. Captain Morgan Technique

Place the patient supine with the knee flexed. Place your flexed knee under the patient's knee. Apply force with your leg in an upward direction. Internally and externally rotate the hip as needed to facilitate reduction.

Figure 49.51 Posterior hip dislocation reduction methods. (A, From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP, editors: *Fractures in adults*, ed 2, Philadelphia, 1991, Lippincott, p 1588. Reproduced by permission.)

consultation with the orthopedic surgeon who placed the prosthesis.

The three major causes of prosthetic hip dislocations include (1) assumption of a position that exceeds the stability of the prosthesis, (2) soft tissue imbalances, and (3) component malposition.¹³⁰

Emergency clinicians have been shown to be highly successful in reducing prosthetic hip dislocations.¹³¹ Reduction techniques are similar to those described earlier; however, the urgency is not as paramount because problems with bone necrosis do not exist. Although complications are occasionally unavoidable, the clinician must be aware that forceful reduction of a dislocated hip prosthesis may dislodge the acetabular cup, fracture underlying osteoporotic bone, or loosen the prosthesis. Unlike

other hip dislocations, patients with prosthetic hip dislocations will often not require hospital admission and may be discharged after discussion with the consulting orthopedic surgeon. The most common way to reduce such dislocations is shown in [Fig. 49.53](#).

Anterior Hip Dislocation

Anterior hip dislocations are less common than posterior dislocations and account for 10% to 15% of all hip dislocations.¹²⁴ There are three general types of anterior hip dislocations that are defined by the place where the femoral head comes to rest ([Fig. 49.54](#)): iliac or subspinous, pubic, and inferior or obturator dislocation. Anterior hip dislocations generally

Figure 49.52 Prosthetic hip dislocation. **A**, This patient has bilateral hip replacements. This posteroanterior radiograph shows left-sided dislocation, with the femoral component displaced in a superior direction. **B**, A cross-table lateral view demonstrates that this is a posterior dislocation (posterior is at the *bottom* of the image, anterior at the *top*). The majority of prosthetic dislocations are posterior.

result from forced abduction of the thigh, which may occur with a fall or motor vehicle crash.¹²⁴ The clinical picture varies with the type of dislocation. With the obturator (inferior) type, the leg is abducted and externally rotated with varying degrees of flexion. In the other types, the hip is usually extended and externally rotated.¹²⁴

Reduction Techniques (Fig. 49.55)

The Stimson gravity method may work for anterior hip dislocation, although it is not recommended for the pubic type.¹²⁴ Alternatively, the Allis maneuver can be applied in a modified fashion. Place the patient in a supine position and have an assistant stabilize the pelvis while applying lateral countertraction on the thigh. Flex the hip slightly and apply traction along the long axis of the femur. Gently adduct and internally rotate the leg to affect reduction.¹²⁴

For the reverse Bigelow technique, place the hip in partial flexion and abduction. Apply traction in the line of the deformity, and adduct, sharply internally rotate, and extend the hip. Caution should be exercised when using this technique because the sharp internal rotation may result in fracture of the femoral neck in patients with osteoporotic bone.¹²⁴ As with posterior dislocations, admission to the hospital is required for patients with these injuries.

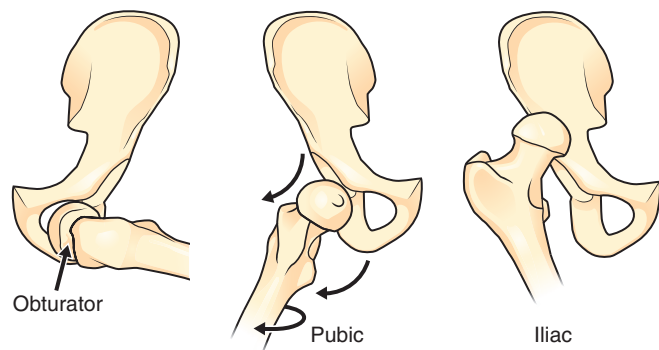

Figure 49.54 Anterior dislocations of the hip: obturator, pubic, and iliac. (From Simon R, Koenigsknecht S: *Orthopedics in emergency medicine*. New York, 1982, Appleton-Century-Crofts, p 367. Reproduced by permission.)

Figure 49.53 **A**, A common method of reducing a posterior hip dislocation is to stand on the bed as shown. Apply traction with external rotation to move the femoral head away from the metallic cup. Assistants protect the operator and provide countertraction. **B**, After reduction, a knee immobilizer prevents dislocation again as hip motion is hampered.

KNEE (FEMUR, TIBIA) DISLOCATIONS

Although the knee is a simple hinge joint, dislocations are quite rare because of its strong ligamentous support. The major ligaments include the anterior and posterior cruciate and the collateral ligaments. The usual mechanism of a knee dislocation involves a great deal of force, such as a motor vehicle crash

Anterior Hip Dislocation Reduction

Modified Allis Technique

Place the patient supine and instruct an assistant to stabilize the pelvis. Flex the hip slightly and apply traction along the long axis of the femur.

Gently adduct and internally rotate the leg to reduce the dislocation.

Figure 49.55 Anterior hip dislocation reduction.

Figure 49.56 **A**, In an obese patient, a dislocated knee may not be obvious on initial inspection. This patient stated that she stepped into a hole and twisted her knee (a classic mechanism for dislocation), which caused the clinician to suspect only ligamentous injury or a sprain with a hemarthrosis. **B**, A radiograph demonstrated the seriousness of this seemingly benign injury. If spontaneous reduction occurs before evaluation in the emergency department, this diagnosis may not even be considered. Arterial injury (especially popliteal artery) is a serious complication of a knee dislocation. Note the equipment for Doppler pulse/ankle blood pressure evaluation in **A**. An arteriogram is the gold standard for evaluation of arterial injuries, which can initially be subtle or delayed (see [Fig. 49.59](#)).

or a sporting injury. However, knee dislocation has been reported after minor mechanisms, such as stepping off a curb or into a hole, usually in association with a twisting action.¹³² Obese patients may be more likely to dislocate a knee with surprisingly minor trauma, coined low-velocity or ultra-low velocity injuries, such as when stepping into a hole causes

a twisting motion ([Fig. 49.56](#)). These patients are more commonly women and are at increased risk of vascular injury when compared to high-energy mechanism multi-ligament disruptions.^{133–135} As with other joint dislocations, knee dislocations are described with respect to the position of the distal bone in relation to the proximal one (i.e., tibia in relation to

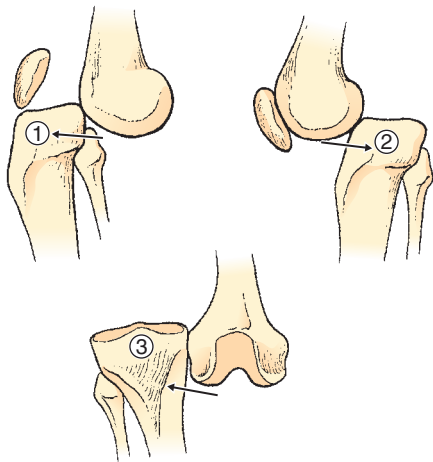

Figure 49.57 The three most common types of knee dislocations: anterior (1), posterior (2), and lateral (3). (From DePalma AF: *Management of fractures and dislocations: an atlas*. Philadelphia, 1970, Saunders, p 1621. Reproduced by permission.)

Figure 49.58 Anterior knee dislocation seen on a lateral radiograph. The patient sustained this injury when he was struck by a vehicle.

the femur).¹³⁶ The more common types are shown in Fig. 49.57. There are five general types of knee dislocation, including anterior (Fig. 49.58), posterior, lateral, and the less common medial and rotatory. Rotatory dislocations may be anteromedial, anterolateral, posterolateral, or posteromedial.¹³⁷

Clinical Assessment

Knee dislocations are usually clinically obvious; however, in some cases the dislocation may have spontaneously reduced before evaluation in the ED and be manifested only as severe knee pain with hemarthrosis. When a spontaneously reduced knee dislocation is associated with other major trauma, the diagnosis can be missed. Obese patients may have a seemingly normal appearance of their knee, but an obvious deformity will be visible on the initial radiographs (see Fig. 49.56). A grossly unstable knee that does not appear to be dislocated is probably a reduced dislocation and carries the same risk for vascular and other complications as a dislocated knee.¹³⁸ A

Figure 49.59 Complete occlusion of the popliteal artery after posterior knee dislocation. This injury can be subtle or delayed. (From Valji K, editor: *Vascular and interventional radiology*, ed 2, Philadelphia, 2006, Saunders.)

severely unstable knee can be defined as one that has greater than 30 degrees of recurvatum (hyperextension) on lifting the leg off the stretcher by the heel¹³⁸ or one that exhibits gross instability after reduction.¹³⁶ Because pain and muscle spasm may limit the physical examination for stability, a knee hemarthrosis, usually a large one with signs of posterior or calf hemorrhage, is a potential tip-off to a reduced dislocation.

An impressive effusion may not be present with a knee dislocation because the joint capsule is often disrupted and extravasation occurs into the surrounding tissue, usually posteriorly. The most important part of the clinical assessment is the vascular status of the extremity (see the next section). Nerve injury is less common, but peroneal nerve injury is a recognized complication, particularly with a posterolateral dislocation.¹³⁶ Peroneal nerve injury should be suspected if the patient is unable to dorsiflex the ankle (footdrop) or has decreased sensation on the dorsum of the foot. Posterolateral dislocations may be irreducible because the medial femoral condyle buttonholes through the joint capsule.¹³⁶ A clue to this injury is the presence of a dimple sign at the medial joint line.

Vascular Injury

The most feared complication of a knee dislocation is severance or internal injury of the popliteal artery (Fig. 49.59). Injury

to the popliteal artery may complicate both anterior and posterior knee dislocations and occurs because the artery is relatively fixed both proximally and distally.¹³⁶ If popliteal artery injury occurs, it is often due to transection with posterior dislocations or intimal tearing due to traction forces during anterior dislocations.¹³⁷ In addition, Varnell and associates¹³⁸ noted that vascular injury was as common in a severely unstable knee (e.g., field reduced) as in an acutely dislocated knee. The incidence of popliteal artery injury in a dislocated knee is approximately 20% in most series.¹³⁸⁻¹⁴⁰ However a 2014 database review of 8050 patients with knee dislocation found an overall frequency of vascular injury of 3.3%.¹⁴¹ The seriousness of this complication is largely due to the fact that the collateral circulation about the knee is poor,⁶³ and the end result of injury to the popliteal artery (or vein) may be amputation, particularly if recognition is delayed.^{142,143} It should also be noted that nerve injuries are more common in patients with a vascular injury.^{144,145}

It has previously been stated that popliteal artery disruption may be present despite a normal pulse.¹⁴⁶ Such statements have led to recommendations to perform arteriography or exploration of all knee dislocations.¹³⁶ However, some studies question this perspective. Varnell and associates¹³⁸ reported a pulse deficit or absent pulse in all patients with vascular injury. Kendall and coworkers¹³⁹ also reported clear clinical evidence of all popliteal artery injuries in knee dislocations. This group recommended exploration for obvious ischemia, angiography for patients with ischemia whose pulse is restored after relocation, and observation for all others.¹³⁹ Dennis and colleagues¹⁴⁷ reported that physical examination alone had 100% accuracy in predicting the need for surgical intervention in patients with posterior knee dislocations. Miranda and associates¹⁴⁸ reported that popliteal artery injury can be safely and reliably predicted by a physical examination that includes specific evaluation for active posterior hemorrhage (expanding hematoma, absent pulse, or the presence of a thrill or bruit). However, it is noted that the hard physical signs of arterial injury might be delayed for 24 to 48 hours. Thus, although focused clinician examination may be quite accurate in the vast majority of cases, any dislocated knee should prompt serious concern about the vascular integrity of the leg given the sometimes subtle or delayed manifestation of vascular injuries.

Simple palpation of the artery may not be sensitive enough to detect a decreased pulse. An ankle-brachial arterial pressure

index (ABI) should be considered to compare blood pressure in the ankle with that in the arm. In addition, consider digit pulse oximetry to compare the uninjured leg with the injured one. Mills and coworkers¹⁴⁵ reported the results of a prospective study of 38 patients with knee dislocation to evaluate the accuracy of ABI in identifying vascular injury. Patients with an ABI of less than 0.90 underwent arteriography, whereas those with an ABI of 0.90 or greater underwent serial examination and delayed arterial duplex evaluation. Eleven (29%) of the patients had an ABI of less than 0.90, and all of them had arterial injuries requiring surgical intervention. Of the remaining 27 patients with an ABI of 0.90 or greater, none had a vascular injury noted on serial examination or duplex ultrasonography. No patient in this group was found to have vascular compromise at follow-up (range, 4 to 36 months).¹⁴⁵

Knee dislocations are usually clinically obvious or easily visible on plain radiographs. Therefore it is occult knee dislocations (i.e., dislocated and spontaneously reduced) that are problematic for the emergency clinician to diagnose. Internal derangement with a knee hemarthrosis (often of the size noted with a torn anterior cruciate ligament) is a common first sign that the knee had previously been dislocated and spontaneously reduced. Therefore all knee injuries with significant swelling, hemarthrosis, or a dislocating mechanism of injury should be evaluated with the specific intent of ruling out vascular injury.

If vascular compromise is detected on clinical assessment, it is appropriate to reduce the knee dislocation without obtaining radiographs, although a few minutes to obtain portable radiographs and to administer IV medication would be unlikely to make a difference in the final outcome.¹³⁶ Use of Doppler ultrasound for pulse checks and ABI should also be considered with these injuries (see Chapter 1). Early consultation should be sought for knee dislocations because of the high incidence of complications and the frequent need for operative intervention. The decision to pursue angiography in a patient with a dislocated knee is best made in consultation with an orthopedic surgeon.

Reduction Technique (Fig. 49.60)

The need for IV sedation and analgesia depends on the clinical situation, but it should be considered routine whenever possible (see Chapter 33). The basic initial approach for all types of knee dislocation is to apply traction to the extremity. This

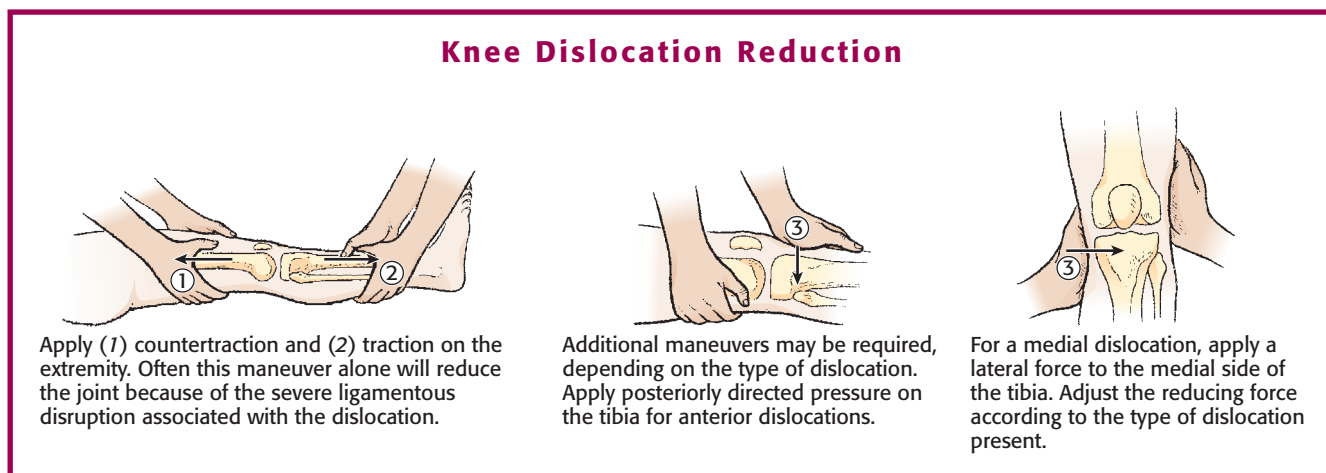

Figure 49.60 Knee dislocation reduction.

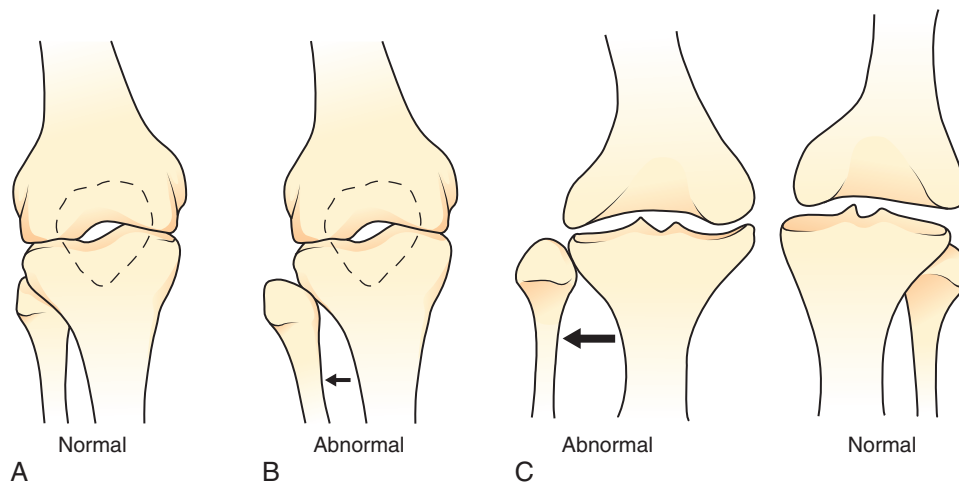

Figure 49.61 Anterolateral fibular head dislocation compared with a normal knee. The interosseous distance is widened and the proximal end of the fibula is displaced laterally. **A**, Normal anteroposterior projection of the knee. **B**, Lateral displacement of the proximal end of the fibula. **C**, Use of bilateral comparison views to highlight the fibular displacement.

alone is often all that is required for reduction because of severe disruption of the ligamentous support of the knee.⁹⁸ For anterior dislocations, lift the distal end of the femur to effect reduction. For posterior dislocations, lift the proximal end of the tibia to complete the reduction.⁶³ For medial, lateral, and rotatory dislocations, a similar approach is acceptable, with pressure exerted in the medial or lateral direction as needed.

After reduction, splint the extremity in 15 degrees of flexion. A posterolateral dislocation may be irreducible, and operative intervention should be considered if reduction is not easily accomplished.⁶³

Post-reduction Care

Appropriate aftercare for knee dislocations requires serial reassessment of the neurovascular status of the extremity, post-reduction films, and admission to the hospital. Use a knee immobilizer to provide stabilization and comfort. These injuries cause severe ligamentous and other derangements in the knee and generally require operative stabilization with a long period of recovery and physical therapy.

DISLOCATIONS OF THE FIBULAR HEAD

The fibula can be dislocated at its proximal articulation in the knee joint. This is most commonly an anterolateral dislocation.¹³⁶ The fibular head is normally nestled in a stable manner behind the lateral tibial condyle with two supporting tibiofibular ligaments.¹⁴⁹ The tibiofibular joint has a separate synovial cavity, and therefore a typical knee joint effusion will not be seen with this dislocation. When the knee is flexed, the stability of this joint is decreased because of relaxation of the fibular collateral ligament.¹⁴⁹ The typical mechanism of injury is a fall on a flexed, adducted leg, often combined with ankle inversion. This mechanism is seen in sports and parachute landings.¹⁴⁹ Posterior dislocations can result from a twisting mechanism or a direct blow to the area while the knee is flexed.¹³⁶

Anterolateral dislocation is the most common type. It is accompanied by obvious prominence of the fibular head anteriorly; no associated neurovascular problems are noted. The less common posterior dislocation may be accompanied by peroneal nerve injury.¹³⁶ Patients have varying degrees of disability, and some may walk on the leg with only mild discomfort.¹⁴⁹ On radiographic examination the three cardinal signs of anterolateral dislocation are lateral displacement of the fibula on an AP film, a widened proximal interosseous space, and anterior displacement of the fibular head on a lateral view (Fig. 49.61).¹²³ If high clinical suspicion exists for fibular head dislocation and radiographs are nondiagnostic, CT is the next study of choice.^{150,151}

Reduction Technique

To reduce an anterior fibular head dislocation, place the patient supine and flex the affected knee to 90 degrees to relax the biceps femoris tendon. Dorsiflex and externally rotate the foot and apply direct pressure to the fibular head; reduction is usually signified by a snap.¹³⁶ The method for reduction of a posterior dislocation is the same except that direct pressure is applied in a forward direction. Patients should not bear weight for 2 weeks and should receive orthopedic referral. Immobilization is probably unnecessary.¹³⁶

PATELLAR DISLOCATION

Patellar dislocations are fairly common, especially in adolescents. The usual mechanism is a powerful quadriceps contraction combined with a strong valgus and external rotation component.¹⁵² This may be seen in activities such as making a “cut” in sports or with dancing. The patella may also dislocate with a direct blow to the flexed knee.⁶³ Factors predisposing to patellar dislocation include chronic patellofemoral abnormalities such as genu valgum and femoral anteversion.¹⁵² Patellar dislocation is described by the relationship of the patella to the knee joint. Lateral dislocations are the most common by far. Other types include superior, medial, and intercondylar (Fig. 49.62).

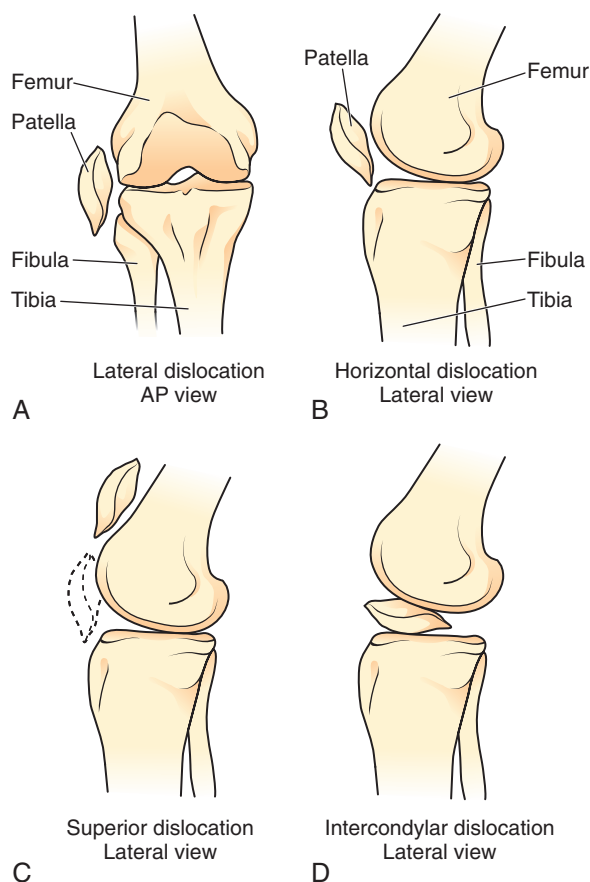

Figure 49.62 A–D, Various types of patellar dislocation. Lateral dislocation is the most common. AP, Anteroposterior.

Figure 49.63 Lateral patellar dislocations are usually clinically obvious. The knee is held in flexion, and the patella (*arrow*) can be seen and palpated along the lateral aspect of the knee.

Clinical Assessment

Lateral dislocation of the patella is generally clinically obvious (Fig. 49.63). The knee is held in some degree of flexion and the patella can easily be seen and palpated on the lateral side of the knee. Tenting of the patella is often detectable unless significant soft tissue swelling is present.

The patella may be spontaneously reduced in the field with simple leg straightening. The patient will report that the leg “went out” and may describe actually seeing the lateral deformity caused by the displaced patella. Clinical clues to a spontaneously reduced patella include the presence of a knee effusion and tenderness along the medial edge of the patella. Fairbank’s test or the patellar “apprehension” sign is elicited when the patella is pushed laterally and the patient grabs for the knee, a response indicative of the sensation of repeated injury.⁶³

Radiographs

Pre-reduction films are difficult to obtain because the patient’s knee is usually in flexion. Some recommend pre-reduction films when possible in all patients⁶³; however, it is easy to reduce these injuries before radiographs are obtained. The diagnosis is usually obvious, and there are no reports in the literature of complications from gentle reduction. Osteochondral fractures are detectable in approximately half the patients with patellar dislocations, but many of these fractures are visible only on arthroscopy.¹⁵² Post-reduction radiographs are recommended, as are pre-reduction studies, when the diagnosis is uncertain. The clinical diagnosis of patellar dislocation in an older patient should be made with caution because these are primarily injuries involving the young.

Reduction Technique and Post-Reduction Care

Reduction of a lateral patellar dislocation is usually quite simple. Premedication is often not required if the patient can be verbally reassured. If the patient is anxious or in great discomfort, premedication should be considered (see Chapter 33). The two basic maneuvers for patellar relocation are extension of the knee and gentle medial pressure applied to the patella while lifting the most lateral edge of the patella over the femoral condyle (Fig. 49.64).⁶³

Immobilize the leg in extension with a splint or commercially available knee immobilizer (see Chapter 50). Orthopedic follow-up is necessary because of the need for physical therapy and the high rate of persistent instability.¹⁵² However, hospitalization is not required for routine lateral dislocations of the patella. Recurrent dislocations and those associated with an osteochondral fracture might require operative repair.

Patellar dislocations in other locations are often irreducible, and orthopedic consultation should be sought. Intracondylar, superior, and vertical axis (dorsal fin) dislocations are extremely rare and require operative reduction. The rare horizontal dislocation may relocate with closed reduction, but surgical reduction is often necessary.

ANKLE DISLOCATIONS

The ankle joint is a modified saddle joint in which the talus is nestled in the mortise formed by the distal ends of the tibia and fibula.⁶³ The ligamentous support of the ankle is quite strong, and pure dislocations are uncommon. Usually, there are associated fractures of the ankle joint (Fig. 49.65). Ankle dislocations are described by the relationship of the talus to the tibia. Posterior dislocations of the ankle are more common than anterior dislocations, and they usually result from a fall on a plantar-flexed foot. Patients with posterior dislocations often

Lateral Patellar Dislocation Reduction

Gently extend the knee (*white arrow*) and apply medial pressure on the patella (*black arrow*) while lifting up the most lateral edge of the patella over the femoral condyle.

Reduction is usually quite simple and the knee will regain a normal appearance. Immobilize the leg in extension with a splint or knee immobilizer. Arrange for orthopedic follow-up.

Figure 49.64 Lateral patellar dislocation reduction.

Anterior

Posterior

Lateral

Superior ("diastasis")

Figure 49.65 Types of ankle dislocation. Note that there are usually associated fractures of the tibia, fibula, or both.

have an associated fracture of one or more of the malleoli,⁶³ occasionally seen only after reduction (Fig. 49.66). The clinical picture usually consists of significant deformity and disability.

Anterior dislocations generally result from forced dorsiflexion or a blow directed posteriorly onto the distal end of the tibia while the foot is fixed. The talus is prominent anteriorly, and the dorsalis pedis pulse may be lost secondary to pressure from the talus. Superior dislocations are uncommon and result in diastasis of the tibiofibular joint. These injuries are usually the result of a significant axial force, such as a fall from a significant height. Therefore clinicians should search for concomitant calcaneal or low spine fractures. Lateral dislocations of the

ankle are always associated with fractures of the malleoli or distal end of the fibula.

Radiographic Examination

Because of the high rate of associated fractures and the clinical difficulty in assessing for the presence or the exact nature of a dislocation, it is recommended that pre-reduction radiographs be obtained for all suspected ankle dislocations (see Figs. 49.2 and 49.65). It is acceptable to reduce the dislocation without a radiograph if severe vascular compromise is present but, for the vast majority of cases, the few minutes taken to obtain

Figure 49.66 Isolated posterior tibial lip fracture (*arrow*), seen only after reduction of a posterior ankle dislocation. (From Harris JH Jr, Harris WH: *Radiology of emergency medicine*, ed 2, Baltimore, 1981, Williams & Wilkins, p 629. Reproduced by permission.)

bedside radiographs and administer IV medications rarely affect the final outcome. It may be impossible to accurately determine the exact type of dislocation unless pre-reduction films are obtained. AP and lateral views usually suffice for emergency management; other views can be ordered if necessary after the joint is relocated.

Reduction Techniques (Fig. 49.67)

Unless a strong contraindication is present, it is advisable to administer IV sedation and analgesia to patients with an ankle dislocation early in their care, preferably before conducting any manipulations or radiologic studies. Reduction is always painful in an awake patient, and sufficient premedication must be administered. For posterior dislocations, place the patient supine and flex the *knee slightly* to relax the Achilles tendon. An assistant can do this, or the patient can be positioned such that the knee hangs over the end of the bed. Grasp the foot with both hands; place one hand on the heel and the other on the forefoot. Apply traction on the slightly plantar-flexed foot. Have a second assistant apply downward pressure on the distal end of the tibia and move the heel anteriorly to affect reduction.¹⁵²

For anterior dislocations, the initial steps and positioning are the same as those for posterior dislocation. However, instead of plantar flexion, dorsiflex the foot to free the talus. The second assistant applies upward pressure on the distal end of the tibia while the operator applies traction and pushes the foot in a posterior direction.⁶³

Lateral dislocations are really fracture-dislocations, and orthopedic consultation is generally required as part of the ED course. The emergency clinician will often need to reduce these injuries because of the extreme lateral deformity and occasional compromise of the dorsalis pedis artery by stretch. Open dislocations (in the absence of vascular compromise) may be better handled by operating room washout before attempting reduction (Fig. 49.68). If a lateral fracture-dislocation is to be reduced in the ED, the approach is quite similar to that for posterior ankle dislocations. However, instead of pressure in the AP direction, the foot is moved medially after the application of traction.⁶³

Post-reduction Care

After reduction, splint the ankle at 90 degrees with a long leg posterior splint. Application of a stirrup splint in addition to the posterior splint will provide additional stability (see Chapter 50). The necessity of admission to the hospital must be determined in consultation with an orthopedic surgeon. Many patients with these injuries have associated fractures that require surgical intervention.

DISLOCATIONS OF THE FOOT

The importance of the foot is recognized by anyone who has had to spend time ambulating with an injury in this area. For purposes of this discussion, dislocation injuries of the foot can be divided into those of the hindfoot and those of the forefoot.

Hindfoot Injuries

Injuries to this area are uncommon and usually result from high-energy transfer. The major dislocations are subtalar and talar dislocations and midtarsal fracture-dislocations (Lisfranc injury). Although x-ray findings are often subtle and easily overlooked, a Lisfranc injury is complex and always a fracture-dislocation because of the rigid nature of the region (Figs. 49.69 and 49.70). These injuries require orthopedic management and are not discussed here.

Subtalar Dislocation

This uncommon injury generally occurs secondary to sports, falls from heights, or motor vehicle crashes. The calcaneus, navicular, and forefoot are displaced from the talus (Fig. 49.71).¹⁵³ The primary mechanisms are severe inversion causing medial dislocation or severe eversion resulting in lateral dislocation. The medial type occurs so commonly during basketball that it has been termed *basketball foot*.¹⁵⁴ This injury is usually seen in young adult males. Medial dislocations constitute the majority (85%) of these injuries, with lateral dislocations making up the rest.¹⁵⁴

The diagnosis is usually obvious because the talus is prominent and often tents the skin of the proximal part of the foot. The medial type has been termed an *acquired clubfoot*; the lateral type as an *acquired flatfoot*.¹⁵⁴

Some authors recommend spinal or general anesthesia for all such injuries¹⁵⁴; however, it is usually possible to reduce these injuries with IV premedication. Position the patient in a supine fashion and flex the hip and knee much as for reduction

Ankle Dislocation Reduction

A. Posterior Dislocations

(1) Slightly flex the knee. (2) Instruct an assistant to provide countertraction on the leg. (3) Grasp the heel with one hand and the dorsal metatarsals with the other. (4) Slightly plantarflex the foot and apply straight downward counterpressure on the foot.

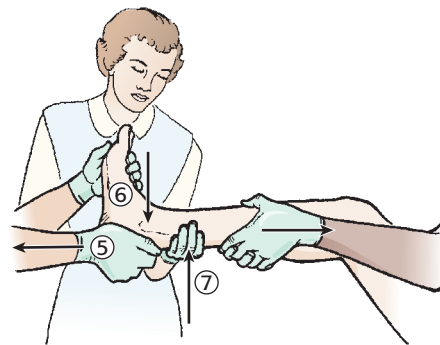

(5) Pull the foot forward with longitudinal traction on the heel. (6) Dorsiflex the foot. (7) Instruct a second assistant to provide counterpressure on the front of the lower part of the leg.

B. Anterior Dislocations

(1) Flex the knee. (2) Grasp the forefoot with one hand and the heel with the other. (3) Dorsiflex the foot to disengage the talus. (4) Instruct an assistant to provide countertraction on the leg.

(5) Apply straight longitudinal traction. (6) Push the foot directly backward. (7) Instruct a second assistant to apply countertraction on the back of the lower part of the leg.

Figure 49.67 Ankle dislocation reduction.

Figure 49.68 A seemingly minor laceration is evidence of the fractured bone previously protruding through the skin (arrow). Compound fractures such as this require antibiotics and open débridement.

of a posterior ankle dislocation. Place one hand on the forefoot and grasp the heel with the other hand. Apply firm longitudinal traction to effect reduction. Dangling the leg over the end of the bed allows the operator to use body weight to assist in traction. Once traction is applied, the deformity is initially increased (inversion for medial; eversion for lateral) and then reversed to effect reduction.¹⁵⁴

Dislocation of the Talus

In this extremely rare injury, the talus is essentially extruded from its normal position and comes to lie anteriorly. This injury is generally open,¹⁵⁴ is not amenable to closed reduction, and virtually always progresses to avascular necrosis.¹⁵⁵ Talcotomy and arthrodesis are often required,¹⁵⁴ and orthopedic referral should be undertaken on an emergency basis if vascular compromise of the foot is present.

Forefoot Dislocations

Much of what is pertinent to the diagnosis and management of forefoot dislocations has already been discussed in the management of dislocations of the finger and hand MCP joints. Anatomically, the joints are quite similar.

Metatarsophalangeal (MTP) Dislocations

These uncommon injuries are generally the result of hyperextension resulting in dorsal dislocation of the great toe MTP joint (Fig. 49.72A).¹⁵⁶ Among the lesser toe MTP joints, lateral or medial displacement of the digit on the metatarsal head is more common and usually the result of jamming the toe on a piece of furniture.¹⁵⁴ As with MCP dislocations, they can be simple or complex. Complex dislocations of the first toe can be suspected by the presence of sesamoid bones in the joint

Figure 49.69 A, A Lisfranc fracture-dislocation is a serious and debilitating injury that is easily missed. This patient complained of extremely severe pain in the foot and was unable to walk after falling down the steps while intoxicated, so the mechanism was unclear. Drug seeking was suspected; however, *note the significant soft tissue swelling of the right foot suggestive of internal injury.* B, This radiograph was initially read as a minor avulsion fracture around the base of the second metatarsal, but a closer review shows widening of the space between the first and second metatarsals and *lateral displacement of the rest of the metatarsals (arrows)*. This injury often requires operative repair, and permanent disability is common in the best of circumstances.

Figure 49.70 Lisfranc fracture-dislocation. Note that the first through fifth metatarsals are shifted laterally with respect to the tarsal bones. This is termed a homolateral dislocation. Poor alignment between the first metatarsal and medial cuneiform and between the fifth metatarsal and cuboid is a clue that this substantial injury is present (*arrows*). Also note the irregularities at the bases of the second through fifth metatarsals, which may represent fractures in this region. Computed tomography or magnetic resonance imaging may be needed to fully assess this subtle, yet complex injury.

Figure 49.71 Medial subtalar dislocation. Note that the tibia, talus, and fibula retain a normal anatomic relationship but that the calcaneus, navicular, and forefoot are displaced medially.

Figure 49.72 Toe dislocations. A, Dorsal dislocation of the first metatarsophalangeal joint (*arrow*). B, Lateral dislocation of the fourth proximal interphalangeal joint (*arrow*). Reduction of toe dislocations follows the same technique as described for finger dislocations (see Fig. 49.32).

space on pre-reduction radiographs.¹⁵⁴ Complex MTP dislocations are often irreducible.

For simple MTP dislocations, reduction is accomplished by increasing the deformity through hyperextension and then applying traction while exerting thumb pressure over the base of the dislocated proximal phalanx. Plantar flexion of the foot may be used to relax the flexor tendons.¹⁵³ Operative intervention is required after reduction if crepitus is present on motion, the joint is unstable, or an intraarticular loose body is noted on post-reduction radiographs.¹⁵⁴

Interphalangeal Dislocations

In the foot, IP dislocations result from an axial load on the toe, such as from kicking a wall (see Fig. 49.72B). These dislocations are generally dorsal and can be reduced as in the hand. Specifically, the toe should be dorsiflexed to exaggerate the

deformity and then undergo traction followed by plantar flexion. Dislocations of the first toe IP joint are usually buddy-taped to the second toe for 2 to 3 weeks, whereas those of lesser toes can be taped for 10 to 14 days.¹⁵⁴ Reduction of dorsal dislocations may be difficult because of entrapment of the plantar plate inside the joint.¹⁵⁷ As in the hand, complex dislocations or those failing closed reduction may occur. Such dislocations require open reduction and internal fixation.¹⁵⁷

CONCLUSION

The following points are important regarding the assessment and management of dislocations:

1. A search for other more serious injuries should be undertaken when there is a high-energy mechanism of injury.
2. Neurovascular assessment should be performed early in the evaluation and appropriately documented.
3. Radiographs and IV premedication are generally indicated before attempts at reduction.
4. Reduction attempts should involve gentle, gradual application of force and patience on the operator's part.
5. After completing reduction, the operator should recheck the patient's neurovascular status, request post-reduction radiographs (except with radial head subluxations), and in certain circumstances, assess the stability and range of motion of the joint.
6. A definite percentage of dislocations are irreducible, and the need for multiple attempts should halt prolonged and forceful attempts in the ED and prompt orthopedic consultation.
7. Dislocations accompanied by neurologic injury should be reduced by the most expeditious and least traumatic method.

Splinting Techniques

Carl R. Chudnofsky and Arielle S. Chudnofsky

Splints are used frequently in the emergency department (ED) for temporary immobilization of fractures and dislocations and for definitive treatment of soft tissue injuries.^{1,2} Patients with a variety of nontraumatic musculoskeletal disorders (e.g., gout, inflammatory joint diseases, infections, burns) also benefit from short-term immobilization. Immobilization is the mainstay of fracture therapy, but though intuitively beneficial, it is difficult to find firm scientific data that support the use

of splinting for soft tissue injuries.^{3,4} Although the general principle of immobilizing sprains and contusions is strongly supported by custom and personal preference, its exact influence on healing, number of complications, and ultimate return to normal activity is not known. In most studies of ankle sprains, for example, the function and pain of the injured joint are similar at 6 weeks' follow-up, regardless of whether treatment consisted of ad lib walking, a simple elastic bandage, a posterior splint, or a formal cast.^{5,6} A systematic review of 22 clinical trials comparing various treatments of acute lateral ankle sprains (cast, splint, or early mobilization with support) found no favorable effect of immobilization.⁷ The current data support functional management for most acute ankle sprains.⁷

Patients are routinely seen in the ED with injuries that are amenable to splinting to relieve pain and augment healing (see [Review Box 50.1](#)). Although a strict standard of care cannot be promulgated, the use of short-term splinting in the ED for acutely painful conditions remains a common practice.

Splinting Techniques

Indications

- Immobilization of a variety of clinical conditions:
 - Fractures and dislocations
 - Deep lacerations that cross joints
 - Tendon lacerations
 - Inflammatory disorders (e.g., gout, tenosynovitis)
 - Deep space infections of the hands or feet
 - Cellulitis overlying a joint
 - Selected puncture or bite wounds

Contraindications

- No absolute contraindications

Complications

- Ischemia
- Heat injury
- Pressure sores
- Infection
- Dermatitis
- Pruritis
- Joint stiffness
- Cast pain
- Compartment syndrome

Equipment

Equipment for plaster splints

Equipment for preformed fiberglass splints

Review Box 50.1 Splinting techniques: indications, contraindications, complications, and equipment.

Emergency clinicians have virtually abandoned the use of circumferential casts in favor of premade commercial immobilizing devices or splints constructed of plaster of Paris or fiberglass. The impetus for this change is primarily related to the complications occasionally associated with circumferential casts, liability issues, and ease of application brought about by new technology. In most instances, properly applied splints provide short-term immobilization equal to that of casts while allowing continued swelling and thus reducing the risk for ischemic injury. Other obvious advantages of splints are that patients can take them off when immobilization is no longer needed or can remove them temporarily to bathe, exercise the injured part, or perform wound care.

▶ Most splinting techniques (Videos 50.1 to 50.6) are handed down from house staff or experienced clinicians, but the procedure is often suboptimal and haphazard.⁸ This chapter presents guidelines for adequate immobilization of injuries commonly encountered by emergency clinicians. Details of the construction and application of commonly used custom-made plaster splints are provided.

INDICATIONS AND CONTRAINDICATIONS

Theoretically, immobilization facilitates the healing process by decreasing pain and protecting the extremity from further

injury. Other benefits of splinting are specific to the particular injury or problem being treated (Fig. 50.1). For example, in the treatment of fractures, splinting helps maintain bony alignment. Splinting deep lacerations that cross joints reduces tension on the wound and helps prevent wound dehiscence. Immobilizing tendon lacerations may facilitate the healing process by relieving stress on the repaired tendon. The discomfort of inflammatory disorders such as tenosynovitis or acute gout is greatly reduced by immobilization. Deep space infections of the hands or feet, as well as cellulitis over any joint, should similarly be immobilized for comfort. Limiting early motion may also reduce edema and theoretically improve the immune system's ability to combat infection. Hence, selected puncture wounds and mammalian or human bites of the hands and feet may be immobilized until the risk for infection has passed. Splinting large abrasions that cross joint surfaces prevents movement of the injured extremity and reduces the pain produced when the injured skin is stretched. Finally, victims of multiple trauma should have fractures and reduced dislocations adequately splinted while other diagnostic and therapeutic procedures (e.g., fluid resuscitation, airway control, computed tomography [CT] scans, tube thoracostomy) are completed. Immobilization decreases blood loss, minimizes the potential for further neurovascular injury, reduces the need for opioid analgesia, and may decrease the risk for fat emboli from long-bone fractures.

Figure 50.1 Indications for splinting. Splinting is traditionally thought of as a treatment of fractures, such as the comminuted distal radius fracture depicted in **A**. However, splinting is also beneficial in a wide variety of other conditions, such as **B**, acute gout, **C**, human and mammalian bites of the hand, and **D**, tendon injuries. Other indications include inflammatory disorders such as tenosynovitis, deep lacerations that cross joints, and deep space infections of the hands and feet.

EQUIPMENT (See Review Box 50.1)

Support Materials

Plaster of Paris

Plaster of Paris is the most widely used material for ED splinting.⁹ Its name originated from the fact that it was first prepared from the gypsum of Paris, France. When gypsum is heated to approximately 128°C, most of the water of crystallization is driven off and a fine white powder is left behind—plaster of Paris. When water is added to the plaster, the reaction is reversed, and the plaster recrystallizes or “sets” by incorporating water molecules into the crystalline lattice of the calcium sulfate dehydrate molecules.

Today, plaster is impregnated into strips or rolls of a crinoline-type material. The crinoline allows easy application, helps keep the plaster molded to the proper form during the setting process, and adds support to the finished splint. Plaster rolls and sheets are available in a variety of setting times and widths (2-, 3-, 4-, or 6-inch widths). The distinct advantage of plaster over commercially available premade splints is that plaster can more easily be molded and tailored to the individual’s anatomy, thereby negating the “one-size-fits-all” approach. In addition, plaster rolls and strips are generally less expensive than premade splints.

Prefabricated Splint Rolls

The use of plaster splints in the form of prefabricated splint rolls (e.g., OCL, BSN Medical, Hamburg, Germany) is very popular among emergency clinicians. These splint rolls have 10 to 20 sheets of plaster enclosed between a thick layer of protective foam padding on one side and a thin layer of cloth on the other. Like custom-constructed splints, they are secured to the extremity with an elastic bandage. The major advantage of prefabricated splint rolls is that significant time is saved because the splint and padding come ready to apply. In addition, prefabricated splint rolls are ideal for intermittent splinting and can be removed and reapplied by the patient as needed. However, prefabricated plaster splint rolls are more expensive than simple plaster rolls, and they lack some of the versatility and custom-fit qualities of self-made plaster splints.

Prefabricated splint rolls composed of layers of fiberglass between polypropylene padding (e.g., Ortho-Glass [BSN Medical], 3M Scotchcast One-Step [3M St. Paul, MN]) are now commonplace in many EDs. Fiberglass splint rolls offer the same time-saving aspect as prefabricated plaster splint rolls but require only 3 minutes to set, thus making application faster. In addition, splints made of prefabricated fiberglass rolls cure more rapidly (20 minutes), have no messy residue (i.e., they can be hydrated in a conventional sink without a special trap), can be washed and reapplied, and are stronger and lighter than splints constructed of prefabricated plaster rolls. Another advantage is the polypropylene padding, which wicks moisture away from the skin better than polyester, nylon, or cotton padding does.¹⁰ Prefabricated fiberglass splint rolls are more expensive than both simple plaster rolls and prefabricated plaster splint rolls and, like prefabricated plaster splints, lack some of the versatility and custom-fit qualities of self-made plaster splints.

Woodcast Composite Splinting Material

A new synthetic material that has had a limited presence in the United States, but looks promising in European studies is

Figure 50.2 Woodcast splint. After heating, Woodcast splints are applied in the same manner as conventional splints. (Courtesy Onbone Oy, Helsinki, Finland.)

Woodcast (Onbone Oy, Helsinki, Finland).^{11–13} Woodcast is made from spruce tree chips and biodegradable plastic, making it nontoxic and environmentally friendly. The material comes in slabs ranging from 1-to-4 mm thick from which the provider can cut out the desired shape for a specific splint. Woodcast splints are applied in the same manner as conventional splints (Fig. 50.2) and have comparable stiffness.¹¹ Like splints made from plaster of Paris and fiberglass, increasing the thickness of the splint increases its ultimate strength. The composite material is easily molded to the contour of an extremity or digit by heating for 15 minutes to a temperature of 65°C using one of the Woodcast heating devices (Fig. 50.3). The material takes approximately 15 minutes to set, providing sufficient time for applying and molding the splint. If needed, setting time can be reduced to 5 to 10 minutes with application of ice packs. Woodcast splints can be rewarmed and remolded after application and gloves are not required when handling the material. Compared to conventional splinting materials, Woodcast splints cause fewer skin reactions, and are associated with similar rates of healing and patient satisfaction.^{12,13}

Protective and Miscellaneous Equipment

Stockinette

A single layer of stockinette is commonly used over the skin and under cotton (Webril, Medtronic, Minneapolis, MN) padding, circumferential casts, and splints. It protects the skin and, when folded back over the ends of the plaster, creates a smooth, professional-looking, padded rim. Stockinette is available in 2-, 3-, 4-, 8-, 10-, and 12-inch widths.

Padding

Padding under the splint protects the skin and bony prominences and accommodates swelling of the injured extremity. Most commercially available splints contain adequate padding in the premade product, but in some instances, additional padding is prudent. In general, the older thin cotton padding known as sheet wadding has been replaced by newer material such as Webril (Curity) and Specialist (Johnson & Johnson, New Brunswick, NJ) cast padding. Webril is soft cotton with a much coarser weave than sheet wadding; consequently, it has greater tensile strength, adheres better, and can be applied more evenly. Specialist padding uses micropleated cotton fibers

Figure 50.3 Woodcast heating devices. **A**, Woodcast standard heating device is designed for heating all flat Woodcast materials. **B**, Woodcast express heating device can be used to heat flat material to create a new splint and to reheat a split that has already been applied to improve its fit. The express device heats the material much faster than the standard device. (Courtesy Onbone Oy, Helsinki, Finland.)

Figure 50.4 Elastic bandages. **A**, An elastic bandage is a popular home treatment of many painful conditions, such as sprains and contusions. An actual medical benefit is unproven. **B**, Wrapping an extremity too tightly may cause additional injury or distal swelling. This patient complained of a swollen hand after an elbow injury. Note the grooves in the skin (*arrows*) indicating that the wrap was the culprit that caused the hand swelling. **C**, A markedly swollen foot after application of a useless elastic bandage on the lower part of the leg.

that relax when moistened. This results in uniform, felt-like padding that conforms to the surface being wrapped. Felt (0.5-inch thick) may also be used to pad bony prominences.

Elastic Bandages

Elastic bandages are used to secure the splint in place. Elastic bandages are available in 2-, 3-, 4-, and 6-inch widths. Some bandages use metal clips, whereas others use a Velcro-type mechanism to secure the bandage in place. Metal clips should be taped in place to avoid inadvertent removal.

Patients often use or request an elastic bandage for many soft tissue injuries. Although applying an elastic bandage to an injured part is popular, it is of minimal benefit alone. The downside is that the bandage may be wrapped too tightly and cause additional injury or distal swelling (Fig. 50.4).

Adhesive Tape

Use adhesive tape to prevent slippage of the elastic bandages, to line the cut edges of a bivalved cast, and to buddy-tape digits. Coban tape can be used in a similar manner and has the advantage of adhering only to itself.

Utility Knife, Scalpel, and Plaster or Trauma Scissors

Use a utility knife, a No. 10 scalpel blade, or plaster or trauma scissors to cut and shape dry plaster.

Bucket

Use a large bucket (preferably stainless steel) for wetting plaster. Do not prepare the plaster in the sink unless it is equipped with a special drain designed to accept plaster residue without clogging. A bucket is not required for the minimal amount of water used to soften premade fiberglass splints. They can be activated by placing them directly under the faucet.

Protective Gear

Use gowns or sheets to prevent soilage of both the patient's and the clinician's clothing. Use gloves (vinyl or latex) and safety glasses to prevent skin or eye damage from plaster dust, wet plaster, or uncured fiberglass polymer. Wearing gloves also decreases clean-up time for the clinician.

GENERAL PROCEDURE OF CUSTOM SPLINT APPLICATION

This following text refers to the application of custom-made plaster splints unless otherwise stated (Figs. 50.5 and 50.6). If periodic wound care is required, apply a more easily removable splint (e.g., OCL [BSN Medical], Ortho-Glass [BSN Medical], Velcro-type splint [described later]) in lieu of the standard splint (Fig. 50.7). Address the issue of removability before the

Plaster Splint Application: Standard Method

1 Measure the length of plaster to be used against the area to be splinted. Roll out the appropriate layers of plaster (roughly 8 layers for upper extremities, 12–15 for the lower).

2 Place a single layer of stockinette over the extremity. The stockinette should extend 10–15 cm beyond both ends of the area to be splinted. Generally, use a 3-inch stockinette for the arm, and a 4-inch for the leg.

3 Wrap 2 to 3 layers of Webril around the entire area to be splinted, overlapping each pass by 25 to 50%. Avoid wrinkling, which may cause pressure sores. See text for precautions regarding potential ischemic injury.

4 Submerge the plaster strips in a bucket of water until the bubbling stops. Do not use water hotter than 24°C (75°F). Using warmer water may cause thermal injury, because the plaster releases heat when activated.

5 Smooth the plaster between your fingers and remove all excess water. Lay the plaster out on a table and smooth further to remove all wrinkles and ensure uniform lamination of all layers.

6 Apply the plaster over the Webril and smooth it over the extremity. Avoid using your fingertips, which may leave indentations in the plaster. A layer of Webril may be placed over the plaster to prevent it from sticking to the elastic wrap.

7 Fold the stockinette over the edge of the plaster and Webril. This helps to hold the splint in place, and provides a smooth padded edge.

8 Secure the splint to the extremity with an elastic wrap by proceeding in a distal-to-proximal fashion. Do not wrap the elastic bandage too tightly.

9 If metal clips are used to secure the elastic wrap, cover them with tape to prevent them from falling off. Alternatively, the wrap can simply be secured with tape.

10 Place the extremity in the desired position, and use the palms of your hands to mold the splint to the contour of the extremity. Again, avoid using your fingertips, which may leave indentations that result in pressure sores.

Figure 50.5 Plaster splint application: standard method (volar wrist splint depicted here).

Plaster Splint Application: Alternative Method

1 Measure the splint and apply stockinette as depicted in steps 1 and 2 of Fig. 50.3. Additionally, premeasure 5 to 6 layers of Webril of the same length as the plaster. Soak and prepare the plaster.

2 Lay out 3 to 4 layers of Webril, which will serve as padding for the splint. Place the plaster (which has already been smoothed) on top of these layers of Webril.

3 Place an additional layer of Webril on top of the plaster, which will prevent it from sticking to the elastic wrap. Essentially, you are sandwiching the plaster between layers of Webril.

4 Apply the splint to the extremity. Enlist the help of an assistant to hold the splint in place.

5 Secure the splint to the extremity with elastic bandages by wrapping in a distal-to-proximal fashion. Remember to fold the stockinette over the edges of the plaster and Webril.

6 Position the extremity as desired, and then gently mold the splint using the palms of your hands.

Figure 50.6 Plaster splint application: alternative method (sugar-tong splint depicted here). This technique may be used if significant swelling is anticipated as Webril (the same diameter as the plaster) is placed directly over the wet plaster rather than wrapped circumferentially around the extremity.

Prefabricated Fiberglass Splint Application

1 Measure the length of splint to be used against the area to be splinted. These splints are available in a variety of lengths and widths.

2 Cut the splint to length using a pair of trauma shears. Round the corners of the cuts to avoid sharp edges of fiberglass.

3 Stretch the cotton padding several inches beyond the edge of the fiberglass on both ends of the splint to assure that there will be no fiberglass in contact with the skin.

4 Prefabricated fiberglass splints require minimal wetting. Simply open one end of the pouch and run tap water over the fiberglass. When water exits the bottom, it is ready to apply. Excess water may be wrung out.

5 Apply the splint to the extremity. If stockinette is used (optional though recommended), fold the edges of the stockinette over the splint. This provides comfort and also holds the splint in place during application.

6 Secure the splint to the extremity using elastic bandages wrapped in a distal-to-proximal fashion.

7 For splints that involve the hand, cut a hole in the center of the elastic bandage, in the loop that is in the region of the thumb.

8 Bring the thumb through the hole. This provides a perfect fit, reduces bunching of the elastic in the web space, and allows for more thumb mobility.

9 Place the extremity in the desired position, and mold the splint with your palms to the contours of the body. Avoid using fingertips, which may leave indentations in the fiberglass.

10 After splint application, observe for vascular compromise or increased patient discomfort. If either occur, loosen the elastic wrap. Never discharge a patient with increasing pain after splint application.

Figure 50.7 Prefabricated fiberglass splint application (volar wrist splint depicted here).

BOX 50.1 Caveats for Proper ED Splinting

- Always use cool, clean water.
- Do not oversaturate the plaster splint. Minimal water is required for fiberglass splints.
- Make the splint *smooth* when placing it on the patient to avoid bumps and pressure points.
- Smooth and mold the splint without squeezing. Use the palms of the hands, not the fingers, to mold the splint to fit the contour of the body part.
- Place the padded side against the skin. Extra cotton padding is optimal.
- Simply roll elastic bandages over the extremity without undue tension.
- Protect or pad the edges.
- Leave the fingertips exposed to check for circulation and sensation.
- Keep the patient still until the splint has dried and hardened.
- The postsplint check includes function, arterial pulse, capillary refill, temperature of the skin, and sensation (FACTS).
- Emphasize and demonstrate splint elevation to the patient.
- Tape over the metal clips used to fasten the elastic bandage to keep them in place and avoid ingestion by a child.

ED, Emergency department.

splint is applied. In addition, use of Webril (Curity) cast padding is described, but other suitable cast padding may be substituted. Caveats for proper ED splinting are listed in [Box 50.1](#).

Patient Preparation

If the clinical situation permits, cover the patient with a sheet or gown to protect clothing and the surrounding area from water and plaster. Nursing staff and housekeeping also appreciate this courtesy. Properly drape hallway patients if areas of the body are exposed. Carefully inspect and examine the involved extremity before splinting, and clearly document the presence of all skin lesions and soft tissue injuries. Clean, repair, and dress all wounds in the usual manner. When open fractures or joints are to be immobilized, cover the soft tissue defect with saline-moistened sterile gauze.

Padding

When the splint involves the digits, place padding between the fingers and toes to prevent maceration of the skin. This can be done with pieces of Webril or gauze cut to the appropriate length.

Following placement of padding between the fingers and toes in self-made splints, use a stockinette over the skin as the first protective layer (see [Fig. 50.5, step 2](#)). Extend the stockinette at least 10 to 15 cm beyond the area to be splinted at both ends of the extremity. Later, after the plaster has been applied, fold the stockinette back over the ends of the splint to create smooth, padded rims and to help hold the splint in place when applying elastic bandages (see [Fig. 50.5, step 7](#)). To avoid pressure damage, do not pull the stockinette too tightly over bony prominences such as the heel. In addition, prevent wrinkling

BOX 50.2 Areas of the Upper and Lower Extremity That Require Additional Padding**UPPER EXTREMITY**

Medial and lateral malleoli

over flexion creases by slitting and overlapping the stockinette at bony prominences. One may also use two separate pieces of stockinette (one at each end of the splint) to produce the smooth padded rims. As a general rule, use 3-inch-wide stockinette for the upper extremity and 4-inch-wide stockinette for the lower extremity.

After the stockinette has been properly positioned, wrap Webril around the entire area that will be exposed to plaster. Apply at least two or three layers of Webril, with each turn overlapping the previous turn by 25% to 50% of its width (see [Fig. 50.5, step 3](#)). Make sure that the Webril extends 2.5 to 5.0 cm beyond the ends of the splint so that it, too, can be folded back over the splint to help create smooth, well-padded edges. Place extra padding over areas of bony prominence, such as the radial condyle or the malleoli ([Box 50.2](#)). Although this can be done with Webril, Mother's Cotton adds an additional measure of protection without the worry of wrinkling or ischemic injury. If significant swelling is anticipated, use three or four layers of Webril. Be careful to avoid wrinkling because this can result in significant skin pressure when a tight splint is worn for a long period. Prevent wrinkles by proportionately stretching or even tearing the side of the Webril that must wrap around the larger portion of an extremity. Joints that must be immobilized in a 90-degree position, such as the ankle, make continuous Webril wrapping difficult. To avoid wrinkles around the ankle, place the joint in the proper position before padding. Wrap the Webril around the malleolar and midtarsal regions first, and then cover the bare calcaneal region with overlapping vertical and horizontal Webril strips until the entire heel region is evenly padded. Use the same approach in similar areas such as the elbow. Choose a width of Webril appropriate for the extremity to be splinted. In general, use the 2-inch width for the hands and feet, the 3- or 4-inch width for the upper extremity, and the 4- or 6-inch width for the lower extremity.

A final caveat when using Webril is to be aware of the potential for ischemic injury. This rare complication is most likely to occur in an extremity that continues to have significant swelling after the patient is released from the ED. Ischemia may result because the concentrically placed Webril can become a constricting band. If this situation is anticipated, it can easily be prevented. Cut through the Webril along the side of the extremity that is opposite the plaster splint. Then, secure the splint to the extremity in the usual manner. Alternatively, place two or three layers of Webril (the same diameter as the plaster)

TABLE 50.1 Setting Times of Fast- and Extra-Fast-Drying Plaster

directly over the wet plaster (see Fig. 50.6). Position the Webril-lined splint over the area to be immobilized and secure it in place with an elastic bandage.

Plaster Preparation

The choice of plaster setting time depends on the nature of the injury and the expertise of the clinician. Use extra-fast-setting plaster when rapid hardening is desired to help maintain alignment of an acutely reduced fracture. However, for the majority of ED splints, plaster with slower setting times (e.g., Specialist Plaster Bandage Fast Setting, BSN Medical) is recommended.¹⁴ Plaster that sets more slowly is easier for some clinicians to use because it affords more leeway in applying and molding the splint. Furthermore, plaster with a longer setting time produces less heat, thus reducing both patient discomfort and the risk for serious burns.¹⁵ Table 50.1 lists the setting times for commonly used plaster. These setting times can be adjusted by adding different substances to the plaster during the production process (Box 50.3). Given plaster with equal setting times, the most important variable affecting the rate of crystallization is water temperature. Warm water hardens a splint faster than cold water does and should not be used when extra time is needed for splint application.

The ideal length and width of plaster depend on the body part to be splinted and the degree of immobilization required. The best way to estimate length is to lay the dry splint next to the area to be splinted. It is best to use a generous length because wet plaster shrinks slightly from its dry length. In addition, if the wet splint is too long, the ends can be folded back easily. Plaster width varies according to the type of splint being made and the body part that is injured, but generally, it should be slightly greater than the diameter of the limb to be splinted. Specific recommendations regarding splint length and width are discussed in the sections describing individual splints.

BOX 50.4 Variables That Increase Heat Production During Crystallization**MAJOR**

Increased splint thickness
Setting time^a
High dip water temperature^b
Wrapping the extremity for support while drying

MINOR

High humidity
High ambient temperature
Reusing the dip water

^aFaster setting times produce more heat.

^bDip water temperature has been a minor determinant of heat production in some studies. Use room-temperature not hot water to make a splint.

The thickness of a splint depends on the size of the patient, the extremity that is injured, and the desired strength of the final product. An ankle splint may crack quickly and become useless if only eight layers are used, but this thickness may be ideal for a wrist splint. In general, it is best to use the minimum number of layers necessary to achieve adequate strength. Thicker splints are heavier and more uncomfortable. It is also important to note that plaster thickness is a major determinant of the amount of heat given off during the setting process. More than 12 sheets of plaster create an increased risk for significant burns, especially when using extra-fast-drying plaster, when using dipping water with a temperature higher than 24°C, or when a pillow is placed under or around the extremity for support during the setting process (Box 50.4). For an average-sized adult, splint the upper extremities with 8 sheets of plaster and the lower extremities with 12 to 15 sheets. Such layering usually provides the strength necessary for adequate immobilization while reducing the patient's discomfort and the risk for significant burns. In a 136-kg (300-lb) patient, however, up to 20 layers may be required to make a durable ankle splint.

Keep the dipping water clean and fresh. Reusing water that has been used previously for wetting plaster increases the amount of heat given off during crystallization and causes the plaster to set more quickly. As a rule of thumb, keep the temperature of the water at approximately 24°C. This temperature allows a workable setting time and has not been associated with increased risk for significant burns. As the temperature of the dipping water approaches 40°C, the potential for serious burns increases, even with splint thicknesses consisting of fewer than 12 plies. It is interesting to note that water temperature has been shown to be only a minor consideration in heat production in some studies (see Box 50.4).

Splint Application (see Fig. 50.5)

Completely submerge the dry splint in the water bucket until the bubbling stops. Remove the splint and gently squeeze out excess water until the plaster has a wet and sloppy consistency. Place the splint on a hard table or countertop (a protective covering is recommended to prevent water or plaster damage) and smooth out the splint (with gloved hands) to remove any

wrinkles and ensure uniform lamination of all layers. Lamination helps increase the final strength of the splint. Position the splint over the Webril and gently smooth it over the extremity. Plaster is usually somewhat adherent to Webril, but an assistant may be required to hold the splint in place during positioning. Once the splint has been properly positioned over the extremity, fold back the underlying stockinette and Webril to help hold it in place. Secure the splint with an appropriately sized elastic bandage by wrapping in a distal-to-proximal direction. Finally, place the extremity in the desired position and mold the wet plaster to the contour of the extremity with only the palms of the hand. Finger indentations may cause ridges, which can produce pressure points.

Molding the wet splint to conform to the body's anatomy is probably the most important, yet the most frequently overlooked step to ensure adequate immobilization. The act of molding may cause some pain, so be sure to forewarn the patient. Mold with the palm or flat side of the fingers to avoid putting ridges or indentations in the underlying plaster. Complete all manipulation of the wet plaster before it reaches a thick, creamy consistency. Any movement after this time, which is known as the critical period, results in an imperfect crystalline network of calcium sulfate molecules and greatly weakens the ultimate strength of the splint. While the plaster is setting, do not wrap a pillow or blanket around the extremity for support because this leads to inadequate ventilation around the splint and greatly increases the amount of heat produced (see [Box 50.4](#)).

If an elastic bandage is applied directly over wet plaster, it may be incorporated into the drying plaster, thus making subsequent removal of the bandage difficult. To make it easier for patients to remove and reapply the splint, wrap a single layer of Webril or roll gauze around the wet plaster loosely before applying the elastic bandage. This prevents the wet plaster from becoming stuck to the elastic bandage. Use only one layer of Webril over the plaster because multiple layers are associated with high drying temperatures.

Before the patient is released from the ED, check the extremity for adequate immobilization and evaluate the patient for any evidence of vascular compromise or significant discomfort. If either occurs, loosen the elastic bandage. If the discomfort persists, place additional padding over the painful areas. If this measure, too, is unsuccessful, make a new splint while paying special attention to proper molding so that the wet plaster does not become indented. By resting tender tissue, splinting usually relieves the discomfort quickly, and patients generally say that they feel better soon after the splint has been applied. In general, a splint should decrease the patient's pain, not increase it; hence, do not readily release a patient who complains of increased pain after a splint has been placed. Such complaints may be due to manipulation during splinting, but increased pain should be further addressed or explained.

After a properly fitting, comfortable splint has been applied, place two strips of tape along each side of the splint to prevent the elastic bandage from slipping. It is also prudent to place tape over any metal fasteners used to secure the elastic bandages because these objects can fall off and be swallowed or aspirated by infants and small children. Use enough tape to include the entire circumference of the area under the fasteners, not just small pieces of tape that may not adhere to the moist splint. Finally, provide a sling for patients with upper extremity injuries and, if required, crutches (and instructions for their proper use) for those with lower extremity injuries.

Patient Instructions

Give patients both verbal and written instructions on splint care and precautions. Stress the importance of elevation in helping to decrease pain and swelling. Demonstrate this as well because most patients do not understand the medical definition of elevation. At night, wrap and secure a pillow around the injured extremity to help the patient keep it satisfactorily elevated. If the injury is less than 24 hours old, encourage the application of ice bags or cold packs. It is useless to apply cold packs over plaster, but it can be beneficial to apply them over Webril or an elastic bandage directly over an injury. It may be necessary to remove the splint to ice the injury. In theory, cold therapy stiffens collagen and thus reduces the tendency for ligaments and tendons to deform. Cold therapy also decreases muscle spasm and excitability, reduces blood flow (thereby limiting hemorrhage and edema), raises the pain threshold, and decreases inflammation. Because the thermal conductivity of subcutaneous tissue is poor, apply cold packs for at least 30 minutes at a time. This guideline is in contrast to the popular recommendation of "ice 20 minutes on, 20 minutes off," which often does nothing more than cool the skin. Do not use cold packs for more than the first 24 to 48 hours because cold can interfere with long-term healing. Instruct the patient to not stress the splint for at least 24 hours because plaster does not approach optimal strength until evaporation has reduced the water content of the plaster to approximately 21% of its initial hydrated level. This process of removing excess water by evaporation is called *curing*, and it generally takes several days to be completed. However, by 24 hours the water content of the plaster has usually been reduced enough to produce a strong, resilient splint. In addition, because the chemical process involved in the formation of plaster is reversible, the patient should avoid getting the splint wet. If the injury permits, the splint can be removed for showering and then reapplied. Alternatively, one or more plastic bags may be placed over a splint before showering.

Splints may crack, break, or disintegrate with wear, and a useless splint should be removed or replaced. Give patients general guidelines for length of immobilization and appropriate follow-up care. Avoid long-term immobilization, particularly in the elderly, because this can produce permanent disability. It is extremely important for the patient to continue to check for signs of vascular compromise. If the patient experiences a significant increase in pain, numbness or tingling of the digits, pallor of the distal end of the extremity, decreased capillary refill, or weakness, instruct the patient to return to the ED or to see his or her primary clinician without delay. As with casting, increased pain after splinting is a warning sign that should prompt a return visit, not telephone advice. Avoid giving excessive doses of opioids during the first 2 to 3 days after splinting to allow pain to prompt a follow-up visit.

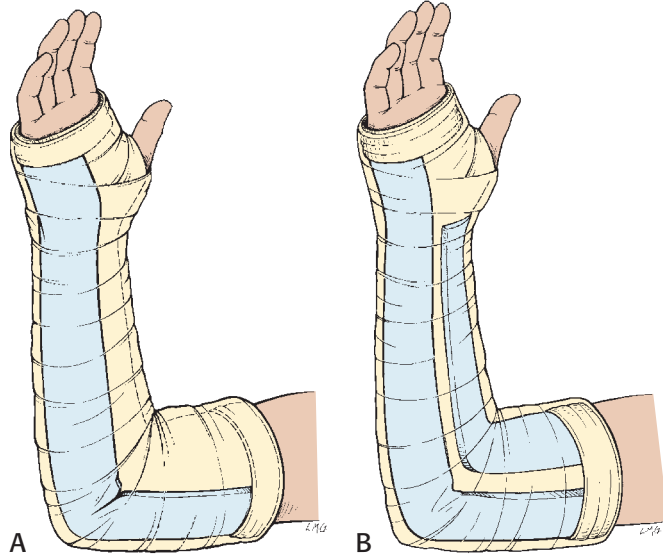

UPPER EXTREMITY SPLINTS

Long Arm Splints

Long Arm Posterior Splint

Indications. Use a long arm posterior splint ([Figs. 50.8 and 50.9](#)) to immobilize injuries to the elbow and proximal end of the forearm. It completely eliminates flexion and extension of the elbow but does not entirely prevent pronation and supination

Long Arm Posterior Splint

Application

A, Extend the splint from the posterior aspect of the humerus to the elbow and then along the ulnar aspect of the forearm to the distal metacarpals. Flex the elbow to 90°, maintain the forearm in the neutral (thumb-up) position, and place the wrist in a neutral or slightly extended (10° to 20°) position.

B, An anterior splint that mirrors the posterior splint may be used to increase stability and prevent supination and pronation. An anterior splint is never used alone.

Indications

Injuries of the elbow and distal end of the forearm, including:

- Distal humerus fractures (shown above)
- Supracondylar fractures
- Olecranon fractures
- Elbow dislocations

Figure 50.8 Long arm posterior splint.

Figure 50.9 When preparing a splint (such as a long arm splint) that involves a right angle, cut out a notch (*arrow*) to allow a smooth bend. Note that padding needs to be applied before splinting.

of the forearm. Therefore it is not recommended for immobilization of complex or unstable distal forearm fractures unless used in conjunction with a long arm anterior splint (see later in this section). Alternatively, a double “sugar-tong” splint can be applied (see later in this section).

Construction. Construct a long arm posterior splint with 8 to 10 layers of 4- or 6-inch-wide plaster. Start the splint on

the posterior aspect of the proximal end of the arm. Extend it down the arm to the elbow and then along the ulnar aspect of the forearm and hand to the level of the metacarpophalangeal (MCP) joints.

Application. Apply a stockinette and Webril as described previously. Cut a hole in the stockinette to expose the thumb, and place extra padding over the olecranon to prevent pressure injury. Position the arm with the elbow flexed to 90 degrees, the forearm neutral (thumb upward), and the wrist neutral or slightly extended (10 to 20 degrees). Ask an assistant to hold the wet splint in place, particularly when applying both a posterior and an anterior splint. Once the splint has been properly positioned, fold the ends of the stockinette and Webril back and secure the splint in place with 2-, 3-, or 4-inch elastic bandages. Finally, fold the sides of the splint up to create a gutter configuration and carefully mold the plaster around the extremity with the palms of the hand. The fingers and thumb should remain free to prevent stiffness from unnecessary immobilization.

Long Arm Anterior Splint

Indications. A long arm anterior splint is never used alone but, rather, as an adjunct to a long arm posterior splint to improve immobilization by increasing stability and preventing pronation and supination of the forearm (see [Fig. 50.8B](#)).

Construction. Construct a long arm anterior splint in the same manner as described for a long arm posterior splint. It mirrors the posterior splint by running down the anterior aspect of the arm to the antecubital fossa, where it continues along the radial aspect of the forearm to the distal end of the radius.

Application. Use stockinette, Webril, and positioning similar to the way described for the application of a long arm posterior splint. When using both an anterior and a posterior long arm splint, have an assistant available to hold the wet splint in place. Place the anterior splint first and then position the posterior splint. Once both splints have been properly positioned, fold the ends of the stockinette and Webril back and secure the splint in place with 2-, 3-, or 4-inch elastic bandages. Finally, fold up the sides of the splint to create a gutter configuration and carefully mold the plaster around the extremity with the palms of the hands. Keep the patient's fingers and thumb free to prevent stiffness from unnecessary immobilization.

Double Sugar-Tong Splint

Indications. Use a double sugar-tong splint (Fig. 50.10) like a long arm posterior splint to immobilize injuries to the elbow

and forearm. However, because it prevents pronation and supination of the forearm, it is preferable for some distal forearm and elbow fractures.

Construction. The splint consists of two separate pieces of plaster, a forearm splint and an arm splint. Construct each piece with eight layers of 3- or 4-inch plaster. The forearm portion of the splint runs from the metacarpal heads on the dorsum of the hand along the dorsal surface of the forearm around the elbow. It continues along the volar surface of the forearm to the palm of the hand and stops at the level of the MCP joints. The arm portion of the splint begins on the anterior aspect of the proximal end of the humerus. It runs down the arm over the forearm splint and around the elbow. It then continues up the posterior aspect of the arm, once again going over the forearm splint, until it reaches the starting point.

Application. Use a stockinette, Webril, and positioning similar to the way described for the application of a long arm posterior splint. Secure the two splints in place with 2-, 3-, or 4-inch elastic bandages starting with the forearm splint at the hand. Once the forearm splint is secured in place, wrap the arm

Double Sugar-Tong Splint

Application

Apply the forearm portion of the double sugar-tong splint first. Begin the splint at the metacarpal heads on the dorsum of the hand, and then extend it along the dorsal surface of the forearm and around the elbow. Continue along the volar surface of the forearm and stop at the level of the metacarpophalangeal joints.

Begin the arm portion on the medial aspect of the proximal part of the arm, and then run it down over the forearm splint and around the elbow. Continue up the lateral aspect of the arm (once again going over the forearm splint) until it reaches the starting point.

Keep the elbow flexed at 90°, the forearm in the neutral (thumb-up) position, and the wrist in a neutral or slightly extended (10° to 20°) position. Allow the fingers and thumb to remain free to avoid stiffness.

Olecranon fracture

Indications

Injuries of the elbow and distal part of the forearm, including:
 Distal humerus fractures
 Supracondylar fractures
 Olecranon fractures (shown above)
 Elbow dislocations

Indications are similar to those for the long arm splint. Since the double sugar-tong splint prevents supination and pronation, it may be preferable for some fractures of the distal humerus and of the forearm and elbow.

Figure 50.10 Double sugar-tong splint.

portion of the splint beginning at its proximal end. Keep the patient's fingers and thumb free to prevent stiffness.

Forearm and Hand Splints

Volar Splint

Indications. Use a volar splint (Fig. 50.11) to immobilize a variety of soft tissue injuries to the hand and wrist. It is also used for temporary immobilization of triquetral fractures, lunate and perilunate dislocations, and second through fifth metacarpal head fractures. For these more serious injuries, some clinicians prefer to add a dorsal splint to create a more stable bivalve effect (see Fig. 50.11B). Because a volar splint does not completely eliminate pronation and supination of the forearm, it may not be ideal for distal radial and ulnar fractures, although many clinicians use this splint for nondisplaced or minimally displaced distal ulnar and radial fractures.

Construction. Construct the splint with 8 to 10 layers of 3- or 4-inch-wide plaster. The splint begins in the palm at the metacarpal heads and extends along the volar surface of the forearm to just proximal to the elbow. If there is an injury to any of the fingers, extend the splint to incorporate the involved digit or digits.

Application. Apply a stockinette and Webril as described previously. Cut a hole in the stockinette to expose the thumb.

If the splint is going to incorporate one or more digits, insert a piece of Webril or gauze between the digits to prevent skin maceration. Place the forearm in the neutral position (thumb upward) with the wrist extended slightly (10 to 20 degrees). Avoid wrist flexion. After properly positioning the wet plaster, fold back the ends of the stockinette and Webril and use a 3- or 4-inch elastic bandage to secure the splint in place. Fold the sides of the splint up around the forearm to create a gutter effect, and carefully mold the plaster to conform to the contours of the palm and wrist. Some clinicians prefer to extend the splint to the fingertips and then fold the wet plaster back toward the palm, which allows the fingers to “grasp” the rounded distal end when at rest. With either method, keep the thumb and fingers free to move unless they are injured and are being intentionally immobilized by the splint.

Sugar-Tong Splint

Indications. Use a sugar-tong splint (Fig. 50.12) for fractures of the distal end of the radius and ulna. The advantage of this splint over a volar splint is prevention of pronation and supination of the forearm. In addition, it immobilizes the elbow, which is desirable for the first few days after a distal forearm fracture.

Construction and Application. Construct and apply this splint in the same manner as the forearm portion of the double sugar-tong splint described earlier.

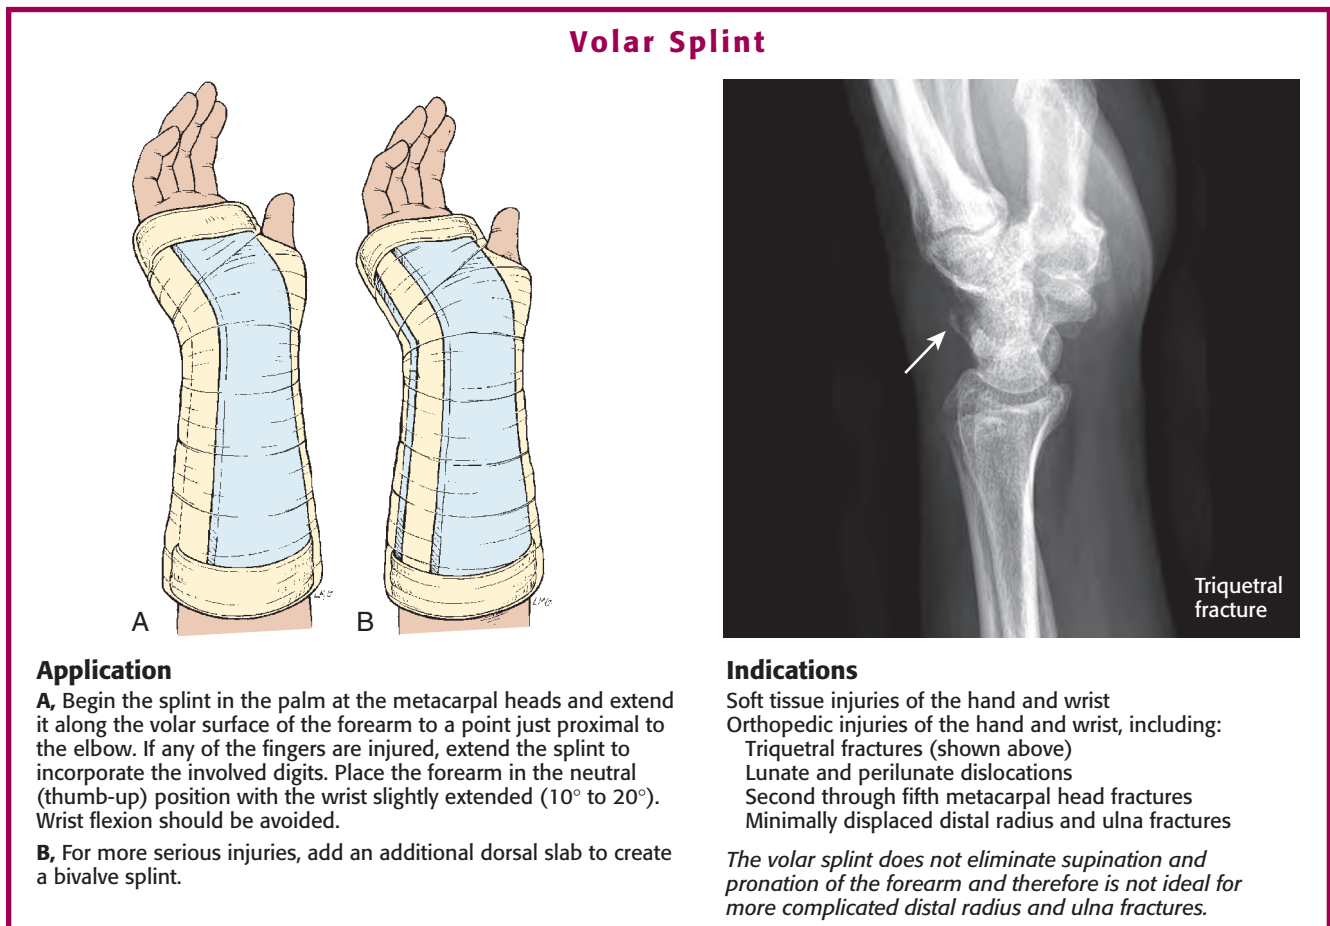

Figure 50.11 Volar splint. This splint does not eliminate pronation or supination of the forearm.

Forearm Sugar-Tong Splint

Application

Begin the splint at the metacarpal heads on the dorsum of the hand, extend it along the dorsal surface of the forearm, and then around the elbow. Continue along the volar surface of the forearm and stop at the level of the metacarpophalangeal joints.

Keep the elbow flexed at a 90° angle, the forearm in the neutral (thumb-up) position, and the wrist in a neutral position or slightly extended (10° to 20°).

Indications

Distal radius and ulna fractures (shown above)
Distal forearm fractures

The forearm sugar-tong splint, unlike the volar wrist splint, prevents supination and pronation of the forearm. Additionally, it immobilizes the elbow, which is desirable for the first few days after a distal forearm fracture.

Figure 50.12 Forearm sugar-tong splint. This splint will eliminate pronation and supination of the forearm.

Thumb Spica Splint

Indications. Use a thumb spica splint (Fig. 50.13) to immobilize injuries and fractures of the scaphoid, lunate, thumb, and first metacarpal. It is also used for the treatment of de Quervain's tenosynovitis. Traditionally, a thumb spica splint or cast was thought to be a requirement for properly immobilizing scaphoid fractures; however, there is no totally agreed standard. Clay and coworkers¹⁶ stated that the optimal method of casting scaphoid fractures has not been definitively established. They were unable to prove a difference in patient comfort, recovery of function, or incidence of nonunion between a Colles cast and a traditional scaphoid cast that included the thumb.

The incidence of nonunion of scaphoid fractures is approximately 10%, regardless of the type of immobilization in the ED, but it is greatest with unstable proximal pole fractures. Because some scaphoid fractures heal poorly under the best of circumstances, it seems prudent to provide thumb immobilization in the initial splinting. Failure to do so, such as when a "sprained wrist" is suspected, should not be construed as being beneath the accepted standard of care. Most volar splints will at least partly immobilize the base of the thumb, so the discussion may be moot.

Construction. Construct the splint with eight layers of 3-inch-wide plaster. Extend the splint from just distal to the interphalangeal joint of the thumb to the midforearm level.

Application. Place the forearm in the neutral position with the wrist extended 25 degrees and the thumb in the wineglass position (Fig. 50.14). Apply a stockinette and Webril from the base of the palm to the midforearm level. It is difficult to place a stockinette around the thumb. Instead, cut a hole in the stockinette to expose the thumb, and then pad the exposed thumb with small vertical strips of Webril or wrap it with 2-inch Webril. Place the dry plaster over the radial aspect of the forearm from just beyond the thumb interphalangeal joint to the midforearm level. Once in position, mark the location of the first MCP joint and make a small (1 to 2 cm) perpendicular cut 1 cm distal to the mark on each edge of the plaster (see Fig. 50.13 inset). This allows the splint to be molded around the thumb without creating a buckle in the plaster. If the plaster distal to the cut notches is too wide to mold around the thumb without overlapping, trim the edges to the desired width. Wet the plaster and secure it in place with a 2- or 3-inch elastic bandage. It is important to carefully mold the wet plaster around the thumb and palm and to maintain the thumb in the wineglass position while the plaster is drying.

Ulnar Collateral Ligament Injury (Gamekeeper's or Skier's Thumb)

Forced abduction with hyperextension of the thumb is the usual mechanism for injury to the ulnar collateral ligament. This is a rather disabling injury that requires early recognition because improper treatment can result in chronic pain, pinch

Thumb Spica Splint

Application

Extend the splint from just distal to the interphalangeal joint of the thumb to the midforearm level.

Place the forearm in the neutral position with the wrist extended 25° and the thumb in the wineglass position (see Fig. 50.12).

Inset: Make a small (1- to 2-cm) perpendicular cut 1 cm distal to the first metacarpophalangeal joint on each edge of the plaster to allow molding of the splint around the thumb without creating a buckle in the plaster.

Indications

Scaphoid fractures (shown above)
Lunate, thumb, and first metacarpal fractures
de Quervain tenosynovitis

Figure 50.13 Thumb spica splint.

weakness, and loss of stability of the thumb. Characterized by MCP joint pain, tenderness of the ulnar side, and laxity of this joint with valgus stressing, this is not a simple sprain. Although immobilization with a thumb spica splint or figure-of-eight thumb splint may suffice as definitive treatment (Fig. 50.15), surgery is often recommended for more advanced injuries. Splinting in the ED with referral to a consultant is prudent for all significant thumb soft tissue injuries consistent with an ulnar collateral ligament injury.

Ulnar Gutter Splint

Indications. Use an ulnar gutter splint (Fig. 50.16) to immobilize fractures and serious soft tissue injuries of the little and ring fingers and fractures of the neck, shaft, and base of the fourth and fifth metacarpals.

Construction. Make the splint with six to eight layers of 3- or 4-inch plaster. It incorporates both the little and the ring fingers. It runs along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the midforearm level.

Application. Apply a stockinette and Webril as usual. Place additional Webril or gauze between the little and ring fingers to prevent maceration of the skin. Position the forearm in the

neutral position with the wrist in slight extension (10 to 20 degrees), the MCP joints in 50 degrees of flexion, and the proximal and distal interphalangeal joints in slight flexion (10 to 15 degrees). When immobilizing a metacarpal neck fracture (i.e., boxer's fracture), flex the MCP joint to 90 degrees. Once in proper position, fold the sides of the splint up to form a gutter. Finally, fold the ends of the stockinette and Webril back to help hold the splint in place while it is secured to the extremity with a 2- or 3-inch elastic bandage.

Radial Gutter Splint

Indications. Use a radial gutter splint (Fig. 50.17) to immobilize fractures and serious soft tissue injuries of the index and long fingers and fractures of the neck, shaft, and base of the second and third metacarpals.

Construction. Make the splint with six to eight layers of 3- or 4-inch plaster. It runs along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the midforearm level.

Application. Apply a stockinette (with a hole cut to expose the thumb) and Webril as described previously. Insert an additional piece of Webril or gauze between the index and long fingers to prevent maceration of the skin. Place the hand

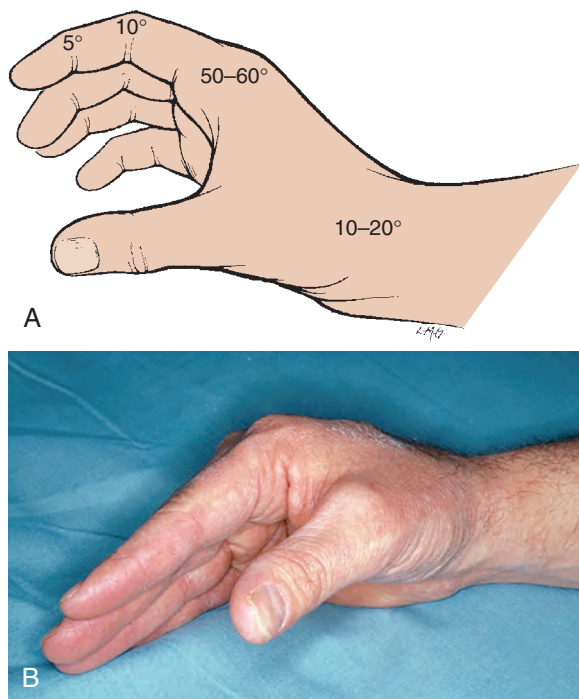

Figure 50.14 **A**, The wineglass position, also termed the position of function, is a safe splint position for the hand and fingers for short-term splinting (7 to 14 days). The wrist should allow alignment of the thumb with the forearm, the metacarpophalangeal (MCP) joint should be moderately flexed, and the interphalangeal joints should be only slightly flexed. The thumb should be abducted away from the palm. **B**, For longer splinting, the fingers should be extended to prevent flexion contractures. This is referred to as the intrinsic position. The MCP joint is flexed at 90 degrees. Either **A** or **B** is an acceptable position for initial short-term splinting in the emergency department.

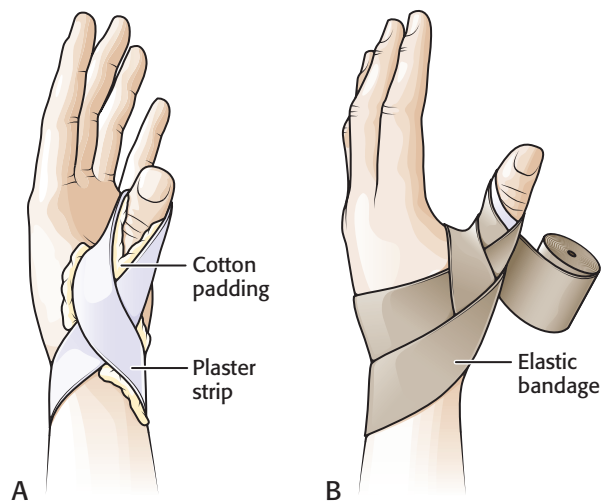

and fingers in the *position of function* or in the *intrinsic position* (see Fig. 50.14). Neither position has been proved to be superior for the first few weeks of splinting, which makes them both acceptable for initial immobilization in the ED. In the position of function, the forearm is in the neutral position with the wrist in slight extension (10 to 20 degrees), the MCP joints in 50 to 60 degrees of flexion, and the proximal and distal interphalangeal joints in slight flexion (5 to 10 degrees) (see Fig. 50.14A). When immobilizing a metacarpal neck fracture, the intrinsic position is often used, with the MCP joint flexed to 90 degrees and the fingers extended (see Fig. 50.14B).

Place the dry plaster over the extremity and mark the location of the thumb. Cut a hole in the dry plaster to expose the thumb. Dip the plaster and position the wet splint over the extremity. Fold back the ends of the stockinette and Webril to help hold the splint in place and secure it to the extremity with a 2- or 3-inch elastic bandage.

Finger Splints

Use finger splints for sprains, fractures, tendon repairs, or infections. Minor finger sprains can often be managed with dynamic splinting (e.g., buddy taping) (Fig. 50.18A) or a commercially available foam splint with aluminum backing (one-surface splint) (see Fig. 50.18B), but fractures, tendon repairs, and some soft tissue injuries benefit from formal

Figure-of-Eight Thumb Splint

Indications

Skier's/gamekeeper's thumb (ulnar collateral ligament injury)

Application

A, Cut a length of Webril and plaster approximately 14 to 16 inches long. Center the splint on the web space, cross over the dorsal aspect of the thumb in a figure-of-eight fashion, and overlap the cut edges around the styloid process of the ulna. **B**, Wrap with a small elastic bandage while overlapping in a figure-of-eight formation. Mold and position the splint after placement.

Figure 50.15 Figure-of-eight thumb splint.

splinting (e.g., thumb spica and ulnar and radial gutter splints). Specific conditions, such as mallet finger, require a specialized splint (plaster or Stack splint) (see Fig. 50.18C). When complete immobilization of a finger is required (e.g., unstable phalangeal fractures), an “outrigger” finger splint that incorporates the wrist may be used (see Fig. 50.18D). Both the position of function and the intrinsic position are acceptable for initial splinting.

Pitfalls of Hand Dressings and Splints

The two most common problems with hand dressings and splints are putting them on too tightly and leaving them on too long (Table 50.2). One must be especially careful to avoid wrapping elastic bandages too snugly. Before discharge from the ED, instruct patients to loosen an elastic bandage if it feels too tight, and be sure that they have access to emergency follow-up care. It is often advisable to start patients on a regimen of early protected motion. This means that the patient removes the splint for a specified period, performs a prescribed exercise, and then replaces the splint. A splint is not an all-or-none device, and the patient is generally weaned from it slowly before it is discarded entirely. A stiff hand is a nonfunctional one, and stiffness is often a consequence of prolonged immobilization. It is important for patients to be made aware of their responsibility for the injured hand.

Ulnar Gutter Splint

Application

The ulnar gutter splint incorporates both the little and the ring fingers. Therefore place Webbril or gauze between the digits to prevent maceration of the skin. Run the splint along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the midforearm level.

Maintain the forearm in the neutral position with the wrist in slight extension (10° to 20°), the metacarpophalangeal (MCP) joint in 50° of flexion, and the proximal and distal interphalangeal joints in slight flexion (10° to 15°). When immobilizing a metacarpal neck fracture, flex the MCP joint to 90° .

Indications

Injuries of the ulnar side of the hand, including:
 Fourth and fifth metacarpal fractures (shown above)
 Serious injuries of the ring and little fingers

Figure 50.16 Ulnar gutter splint.

Sling, Swathe and Sling, and Shoulder Immobilizer

Sling

Use a sling to maintain elevation and provide immobilization of the hand, forearm, and elbow (Fig. 50.19). It is most often used in conjunction with a plaster splint or cast. A number of commercial slings are available to choose from. Many of them are fairly economical and simple to use, whereas others are more expensive and do not allow the versatility of a simple, inexpensive triangular muslin bandage. When applying a sling, make it long enough to adequately support the wrist and hand. A sling that is too short will allow the wrist and hand to hang down (ulnar deviate) and can result in ulnar nerve injury.

Swathe and Sling

Use of a swathe and sling is the treatment of choice for most proximal humeral fractures and shoulder injuries, such as reduced dislocations. The sling supports the weight of the arm, and the swathe immobilizes the arm against the chest wall to minimize shoulder motion.

Shoulder Immobilizer

In most EDs the swathe and sling have been replaced by commercially available shoulder immobilizers. Its advantage

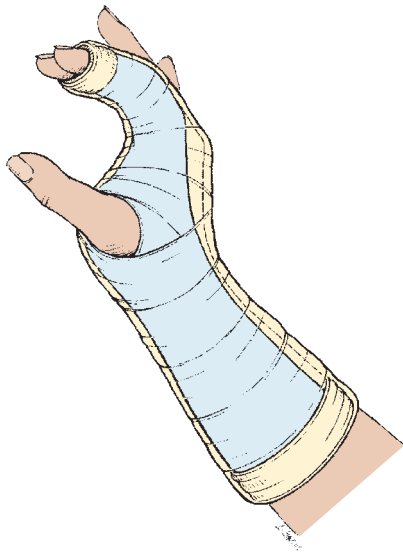

is that it may be removed for showering and range-of-motion exercises and is easily reapplied by the patient (a desirable option in the care of a shoulder dislocation). If the shoulder immobilizer is used for more than a few days, pad the axilla to absorb moisture and decrease skin chafing.

A Velpeau bandage is a sling and swathe device that positions the forearm diagonally rather than horizontally across the chest with the hand elevated to the level of the shoulder. It offers no particular advantage over a standard sling and swathe, is difficult to apply, cannot be removed easily, and is not well tolerated with prolonged immobilization.

Figure-of-Eight Clavicle Strap

In the past, clavicle fractures were often treated with an uncomfortable and complex figure-of-eight bandage. Despite its early popularity, this device never proved to be superior to a simple sling (in terms of cosmesis, functional outcome, or pain relief).^{17,18} Moreover, use of a figure-of-eight clavicle strap may actually promote nonunion or increase the deformity at the fracture site. When compared with a simple sling, a figure-of-eight clavicle strap is very uncomfortable, prohibits bathing, often causes chafing and discomfort in the axilla, and may predispose to axillary vein thrombosis.⁴ Thus, most emergency clinicians have abandoned the figure-of-eight dressing in favor

Radial Gutter Splint

Application

The radial gutter splint incorporates both the index and the long fingers. Therefore, Webril or gauze should be placed between the digits to prevent maceration of the skin. Run the splint along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the midforearm.

Maintain the forearm in the neutral position with the wrist in slight extension (10° – 20°), the MCP joint in 50° of flexion, and the proximal and distal interphalangeal joints in slight flexion (10° – 15°). When immobilizing a metacarpal neck fracture, flex the MCP joint to 90° .

Indications

Injuries on the radial side of the hand, including:
 Second and third metacarpal fractures (shown above)
 Serious injuries to the index and middle fingers

Figure 50.17 Radial gutter splint.

of a simple sling, which is sufficient to treat most clavicular fractures.

LOWER EXTREMITY SPLINTS

Knee Splints

Knee Immobilizer

Indications. A knee immobilizer (Fig. 50.20) is commonly used for mild to moderate ligamentous and soft tissue injuries involving the knee. It is removable and extremely easy to apply, which makes it popular among patients and clinicians alike. In most EDs it has replaced the bulkier plaster splint. Its use should be restricted to injuries that do not require immediate surgical intervention, traction, or casting. For these injuries, in which temporary but more complete immobilization is needed, use a plaster knee splint because it provides better stabilization and costs much less than a knee immobilizer. The exact scientific benefit of a knee immobilizer is poorly studied and difficult to document. However, it clearly helps relieve pain and, at least theoretically, hastens healing.

Application. Knee immobilizers are available in small, medium, large, and extra-large sizes. To choose the appropriate

size, place the knee immobilizer next to the injured leg so that the tapered end lies distal to the patient's knee; if present, the cutout patellar area on the anterior aspect of the splint lies adjacent to the knee joint. In this position, the splint should extend distally to within a few inches of the malleoli and proximally to just below the buttocks crease. To apply the knee immobilizer, slide the open splint under the injured leg, wrap it around the extremity, and secure it in place with the Velcro straps. A knee immobilizer can be applied directly over clothing, thus obviating the need to remove or cut the patient's pants.

Posterior Knee Splint

Indications. In many EDs the knee immobilizer has virtually replaced the plaster knee splint for mild to moderate injuries to the knee. However, a plaster knee splint can be particularly useful in patients whose extremities are too large for a knee immobilizer, in the treatment of angulated fractures, or for temporarily immobilizing injuries that require immediate operative intervention or orthopedic referral. The posterior (gutter) knee splint (Fig. 50.21A) is the type most commonly applied, but as alternatives, two parallel splints can be placed along each side of the leg and foreleg to create a bivalve effect (see Fig. 50.21B), or a long leg U-splint can be applied (see later). A bilateral knee splint is slightly more difficult to apply

Finger Splinting Techniques

A. Buddy Taping

Taping between the digital joints (toes or fingers) allows the normal adjacent finger to protect the collateral ligament of its injured neighbor. Place Webril between the digits to prevent maceration of the skin.

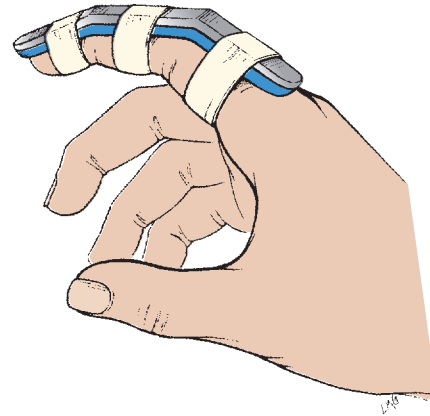

C. Mallet Finger Splints

Top: The dorsal splint immobilizes only the distal interphalangeal joint, which allows use of the finger. Hyperextension of this joint predisposes to skin sloughing and should be avoided. The patient should be advised to not flex the joint during splint changes.

Bottom: A Stack splint is designed especially to treat a mallet finger. Long-term immobilization (8 weeks) or surgical fixation is required for this injury.

B. Dorsal Aluminum Foam Splint

The bone is subcutaneous dorsally, and splints here afford better immobilization of the digit. The dorsal splint also allows preservation and use of tactile sense, which encourages function and better splint acceptance on the part of the patient.

D. "Outrigger" Finger Splint

Foam finger splint with aluminum backing

Finger splint sandwiched between layers of plaster

A padded aluminum splint is incorporated into the middle of a plaster splint to form an outrigger configuration. The plaster splint is applied to the dorsum of the hand and wrist with an elastic bandage; the finger is then taped to the aluminum splint. This provides complete immobilization of the finger.

Figure 50.18 Finger splinting techniques.

TABLE 50.2 Useful Estimates of Splint Times for Various Hand Problems

INJURY	SPLINT TYPE	IMMOBILIZATION TIME ^a
Mallet finger	FIN	8 wk
Boutonnière deformity	FIN	6 wk
Distal phalanx—soft tissue	FIN	1–2 wk
Extensor tendon	DHWF	3 wk
Sprain-strain ^b		
Interphalangeal joint	FIN	1–2 wk
Wrist	DHWF	1–2 wk
Hand burn	DHWF	5–7 wk
Infection		
Digit	DHWF	5–7 day
Hand	DHWF	5–7 day
Severe hand contusion	DHWF	5–7 day
Fracture		
Distal phalanx	FIN	2–3 wk
Middle phalanx	FIN	2–3 wk
Proximal phalanx	DHWF	2–3 wk
Metacarpal	DHWF	2–3 wk
Carpal tunnel	DHWF	Night only
de Quervain's disease	DHWF	2–3 wk
Trigger finger	FIN	Night only

^aThese are average times only. Every patient is treated as an individual when a splint is used. Clinical judgment is critical.

^bDiagnosis of a sprain should be made only after a thorough effort has been made to rule out a fracture or dislocation. This is particularly true in the wrist.

DHWF, Digit-hand-wrist-forearm; FIN, finger.

than a posterior knee splint, but it may provide better immobilization of the lateral and medial collateral ligaments and can be used for injuries to these structures.

Construction. Construct a posterior knee splint with 12 to 15 layers of 6-inch plaster. It should run from just below the buttocks crease to approximately 5 to 8 cm above the malleoli. The sides of the splint are folded upward to form a gutter configuration.

Application. Apply a stockinette in the usual manner, and wrap the leg with 4- or 6-inch Webril. Have an assistant elevate the leg and hold the splint in place while securing it to the extremity with 4- or 6-inch elastic bandages. If no aide is available, place the patient in the prone position and have him use his toes to elevate the lower part of the leg off the bed to allow sufficient room to wrap the Webril and elastic bandages around the injured extremity. Lay the splint along the posterior surface of the extremity, and secure it in place with 4- or 6-inch elastic bandages.

Jones Compression Dressing

Indications. A Jones compression dressing is commonly used for short-term immobilization of soft tissue injuries of the knee. It immobilizes and compresses the knee, thereby reducing both pain and swelling. However, because it does allow slight flexion and extension of the knee, it should not be used for injuries that require strict immobilization. In addition, it is difficult to maintain the splint for more than a few days.

Construction. A Jones dressing is fashioned from 6-inch Webril and elastic bandages.

Application. To apply a Jones dressing, place the patient supine on the stretcher. If available, ask an assistant to elevate the patient's leg to facilitate wrapping. If no help is available, place a pillow under the patient's heel to lift the extremity off the stretcher. Wrap Webril around the extremity from the groin to a few inches above the malleoli. Use two or three layers of Webril and overlap the previous turn by 25% to 50%. Complete the dressing by wrapping 6-inch elastic bandages (two are usually required) around the Webril. If more support is required, repeat the process with another two or three layers of Webril held in place by additional elastic bandages.

Ankle Splints

Posterior Splint

Indications. A posterior ankle splint (Fig. 50.22) is one of the most common splints applied in the ED. As noted in the introductory section, the entire concept of splinting an acutely sprained ankle has been questioned, with no firm evidence to support better outcomes with splinting or casting versus functional management (early mobilization with an external support). Nonetheless, an acutely sprained ankle is painful, and if nothing else, splinting for a few days helps alleviate the pain.

Use a posterior splint primarily to immobilize severe ankle sprains, fractures of the distal ends of the fibula and tibia, and reduce ankle dislocations. It can also be used for fractures of the tarsal and metatarsal bones or for other foot conditions that require immobilization. With particularly severe or unstable injuries, an additional anterior splint may be used to provide extra immobilization resembling that of a formal cast (Fig. 50.23). For severe lateral or bilateral ligamentous injuries, add a U-splint or stirrup splint (see later) to the posterior splint for increased immobilization. With minor soft tissue injuries, patients may have partial weight bearing on ankle splints after 24 hours. If the patient will be bearing weight, wearing a cast shoe over the splint makes it easier to walk and increases the longevity of the splint. Generally, though, walking on the splint is prohibited if immobilization for more than 2 or 3 days is desired.

Construction. Make the posterior splint with 4- or 6-inch-wide plaster strips. It should extend from the plantar surface of the great toe or metatarsal heads along the posterior surface of the foreleg to the level of the fibular head. If it hurts to move the toes, incorporate them into the splint (after padding is placed between the digits). It is a common mistake to apply a posterior splint that does not extend far enough to support the ball of the foot. Use 15 to 20 layers if partial weight bearing is allowed because this splint frequently breaks or cracks when walked on.¹⁹

Shoulder Slings

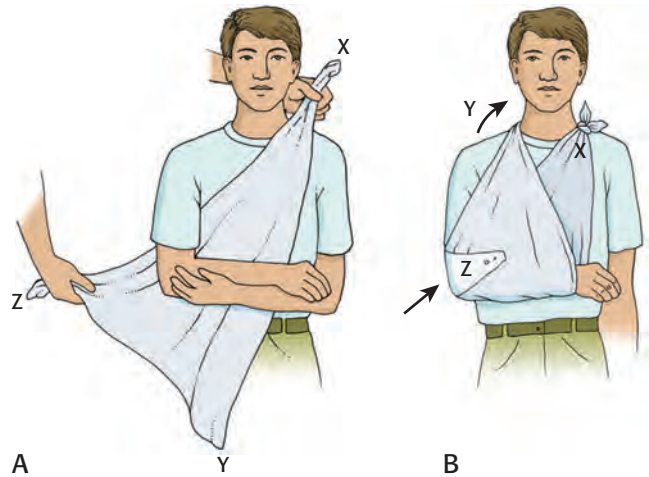

The shoulder immobilizer is used for most proximal humerus fractures and shoulder injuries. It may be removed for showering and range-of-motion exercises and is easily reapplied by the patient.

Proximal humerus fractures are common injuries in the elderly, especially after a fall. A shoulder sling is the immobilization device of choice.

An elastic bandage and sling provide similar shoulder immobilization. Note that the wrist is supported by the slings.

A, Stepwise application of a triangular muslin sling. (1) Place tip *X* over the uninjured shoulder. (2) Bring tip *Y* over the injured shoulder to enclose the arm. (3) Draw tip *Z* around the front and pin. **B**, Completed triangular muslin sling. (Note: When applying a sling it is important to have adequate support of the wrist and hand. A sling that is too short will allow the wrist and hand to hang down [ulnar deviate] and can result in hand edema and ulnar nerve injury.)

Figure 50.19 Shoulder slings.

Application. The easiest way to apply a posterior splint is to place the patient in the prone position with the knee and ankle flexed at a 90-degree angle. Failure to place the ankle in a 90-degree angle results in a plantar-flexed splint. A supine patient may help maintain the ankle in a 90-degree angle by

pulling up on the foot with a wide stockinette stirrup. Flexing the knee to a 90-degree angle relaxes the gastrocnemius muscle and facilitates ankle motion. With the knee and ankle in the proper position, apply a stockinette and pad the foot and leg with Webril as described earlier. Use extra padding over bony

Knee Immobilizer

Application

Choose the appropriate-size knee immobilizer for the patient. The tapered end should be distal to the knee. The splints simply wrap around the leg (and can be applied over clothing) and are secured with Velcro straps.

Indications

Ligamentous and soft tissue injuries of the knee.

Above, a *Segond fracture* is demonstrated. Note the small bony avulsion fracture on the lateral aspect of the tibial plateau. Although at first glance this appears to be a rather innocuous injury, a Segond fracture is highly associated with tears of the anterior cruciate ligament. This patient should be treated with a knee immobilizer until orthopedic follow-up can be arranged.

Figure 50.20 Knee immobilizer.

Posterior Knee Splint

Application

A, Extend the posterior knee splint from just below the buttocks crease to approximately 2 to 3 cm above the malleoli.

B, Alternatively, place two parallel splints along each side of the leg and foreleg to create a bivalve effect. Although this variation is more difficult to apply, it may provide better immobilization of the lateral and medial collateral ligaments.

Indications

Angulated fractures around the knee (shown above)
Temporary immobilization of injuries prior to operative repair
Knee injuries in patients with extremities too large for a knee immobilizer

The knee immobilizer has largely replaced the posterior knee splint in modern emergency department practice.

Figure 50.21 Posterior knee splint.

Posterior Ankle Splint

Application

Extend the splint from the plantar surface of the great toe (or metatarsal heads) along the posterior surface of the foreleg to the level of the fibular head. The ankle should be at a 90° angle.

Indications

Fractures of the distal ends of the fibula and tibia (shown above)
Severe ankle sprains
Reduced ankle dislocations

A, Apply the splint with the patient prone and the knee bent to 90°, thereby relaxing the calf muscles. Position the ankle at 90° so that the foot is flat for partial weight bearing. **B**, This is an unacceptable fiberglass splint. Note the very sharp frayed fiberglass edges (*arrows*) and the multiple internal ridges and folds that will produce soft tissue trauma when worn. **C**, Three things are wrong with this posterior ankle splint: (1) It does not extend distally enough to support the entire foot. (2) The ankle is not maintained at a 90° angle. (3) The edges and ankle area are not molded or protected. Overall, the splint is sloppy and ineffective.

Figure 50.22 Posterior ankle splint. Note unacceptable splints in **B** and **C**.

prominences, particularly the malleoli. To prevent skin maceration, place pieces of Webril or gauze between the toes if they are to be included in the splint. Lay the wet plaster over the plantar surface of the foot and secure it in place by folding back the ends of the stockinette and Webril and wrapping with one or two 4-inch-wide elastic bandages. Carefully mold the wet plaster around the malleoli and instep to ensure maximum comfort and immobilization. Leave the toes partially exposed for later examination of color and capillary refill.

Anterior-Posterior Splint

Indications. An anterior splint is never used by itself, but it can augment a posterior splint to create a bivalve effect (see [Fig. 50.23](#)). Use it for serious fractures and soft tissue injuries of the ankle.

Construction. Cut a piece of plaster several centimeters shorter than the one used for the posterior splint, but as this splint does not bear weight, only 8 to 10 layers are required.

Anterior-Posterior Ankle Splint

Application

Apply the posterior splint as described in Fig. 50.20.

For the anterior portion, begin on the dorsal surface of the foot at the level of the metatarsophalangeal joints. Extend the splint along the anterior portion of the foreleg, to the same height as the posterior splint. Maintain the ankle at a 90° angle.

Severely comminuted distal tibia and fibula fracture

Indications

Serious fractures and soft tissue injuries of the ankle.

The anterior portion of the splint is never used by itself; it is always used to augment the immobilization provided by the posterior ankle splint.

Figure 50.23 Anterior-posterior ankle splint.

Application. Position the patient and apply padding as described for a posterior splint. After the wet posterior splint has been applied, place the anterior splint over the anterior aspect of the ankle and foreleg parallel to the posterior splint. Hold the two in place with elastic bandages as described earlier for a posterior splint alone. An assistant is needed to apply an anterior-posterior splint because it is extremely difficult to hold both splints in place while wrapping the elastic bandages. Once secured, carefully mold both splints over the instep and ankle joint.

U-Splint (Stirrup Splint)

Indications. Use a U-splint or stirrup splint (Fig. 50.24) primarily for injuries to the ankle. It functions like a posterior splint, and either one provides satisfactory ankle immobilization. In one study that compared these splints in normal volunteers, the U-splint allowed less plantar flexion and broke less often with plantar flexion than did the posterior splint.¹⁹ In addition, because it actually covers the malleoli, a U-splint may protect the medial and lateral ligaments from further injury better than a posterior splint can.

Construction. Construct a U-splint of 4- or 6-inch-wide plaster strips. The splint passes under the plantar surface of the foot from the calcaneus to the metatarsal heads and extends up the medial and lateral sides of the foreleg to just below the level of the fibular head.

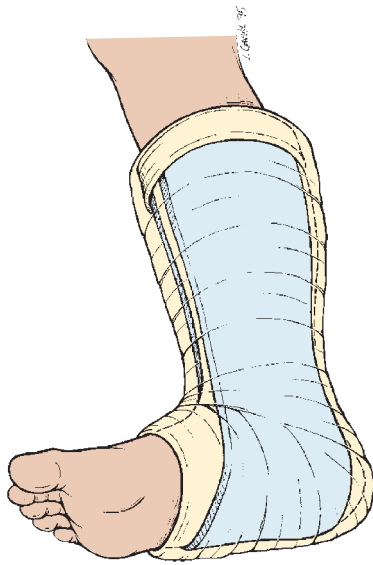

Application. Position the patient and pad the extremity as described for a posterior splint. Lay the wet plaster across the plantar surface of the foot between the calcaneus and the metatarsal heads with the sides extending up the lateral and medial aspects of the foreleg. Secure it in place with 4-inch elastic bandages. Wrap the elastic bandage around the extremity starting at the metatarsal heads and continuing around the ankle in a figure-of-eight configuration. Once the ankle has been wrapped, use another 4- or 6-inch elastic bandage to secure the remainder of the splint in place. Carefully mold the splint around the malleoli. The plaster may overlap on the anterior aspect of the ankle; this overlap does not interfere with the splint's ability to accommodate further swelling. Note that if a U-splint is combined with a posterior splint, apply the posterior splint first.

Walking Boots

Indications. Use a walking boot (e.g., CAM Walker Boot) for the treatment of moderate to severe soft tissue injuries of the ankle, including second- and third-degree sprains (Fig. 50.25A).²⁰ In addition, many orthopedic surgeons use it for isolated, nondisplaced lateral malleolar fractures.²¹ A walking boot provides a degree of immobilization similar to that of a U-splint but is easier to remove for bathing and dressing, and the Velcro straps allow adjustment for edema.

Refer patients in a walking boot for follow-up with an appropriate specialist. Advise them of the importance of partial

U-Splint (or Stirrup/Sugar-Tong Splint)

Application

Apply the splint under the plantar surface of the foot and extend it up the medial and lateral sides of the foreleg to just below the level of the fibular head. Keep the ankle at a 90° angle.

For immobilization of the knee, extend the sides of the splint proximally to the groin to create a long leg splint.

Indications

Injuries of the ankle, including:

- Fractures of the distal tibia and fibula
- Postreduction stabilization of ankle dislocations (above)

The U-splint can be combined with the posterior ankle splint to provide both anterior-posterior and medial-lateral stability.

Figure 50.24 U-splint (also referred to as a stirrup or sugar-tong splint).

Splints for Ankle Sprains

A walking boot can be used for the treatment of moderate to severe soft tissue injuries of the ankle, including second- and third-degree sprains and isolated, nondisplaced lateral malleolar fractures. A walking boot provides a similar degree of immobilization as a U-splint but is easier to remove for bathing and dressing, and the Velcro straps allow adjustment for edema.

Prefabricated semirigid orthoses such as the Aircast (pictured above) are often used for patients with minor ankle sprains. The Aircast can be worn inside the patient's shoe to provide early mobility along with increased ankle stability.

The Unna boot or an Ace wrap provides effective immobilization of an ankle soft tissue injury. The Unna boot is applied from a semisolid paste roll. The wrap is then covered with gauze or an elastic bandage. The entire dressing can be cut off by the patient at home. For similar short-term immobilization without plaster, a modified Jones dressing can be used. Copious Webril is wrapped around the ankle and foot and covered with an elastic bandage. A cast shoe can be used with this dressing.

Figure 50.25 Splints for ankle sprains.

or non-weight bearing as indicated by the type and degree of injury. When cleared by the follow-up physician, a walking boot allows easy transition to full weight bearing. Studies have shown that rapid mobilization after ankle injuries improves functional outcome and reduces disability time.⁷

Application. Walking boots come in a variety of sizes from extra small to extra large, depending on the manufacturer. The boot should fit comfortably with the patient's calcaneus snugly in the heel of the boot and the patient's toes close to but not extending over the front edge of the boot. Once the appropriate size has been determined, place the patient's bare foot and ankle into the boot, and adjust the Velcro straps for a secure, but comfortable fit.

Semirigid Orthosis

Indications. In patients with lateral ankle sprains associated with a stable joint, a functional brace with early mobilization is frequently more comfortable and results in earlier return to normal function than complete immobilization in a plaster splint or cast (see Fig. 50.25B).^{20–28} Consequently, functional bracing with early mobilization has become the treatment of choice in most EDs. However, it should be pointed out that there is no documented difference in long-term outcome between the two methods of treatment.

Application. Most functional ankle braces resemble a U-splint with air bladders (Aircast, Inc., Summit, NJ) or foam padding

(DeRoyal, Inc., Powell, TN) for cushioning the malleoli. The braces are secured about the ankle with Velcro straps. The device can be worn within the patient's shoe over a sock and helps eliminate ankle instability.

Hard Shoe (Cast or Reese Shoe)

Indications. Use a hard shoe to help reduce pain on ambulation in patients with fractures or soft tissue injuries of the foot. This device can also be used over a splint or cast to allow partial weight bearing. A hard shoe is commonly used for fractured toes that have been buddy-taped.

Application. If a cast shoe is going to be used for a patient with a fractured toe, first buddy-tape the injured digit to the adjacent toe (Fig. 50.26). After this is done, the patient can slip the hard shoe on like a sandal. Fasten the shoe with ties or Velcro straps.

Ankle Wraps and Bandages

There are no data supporting the routine use of ankle wraps for simple sprains, but some pain relief may be afforded by a proper wrap. Some type of temporary immobilization is commonly used in the ED and usually requested and expected by patients. For minor ankle injuries, a simple elastic (Ace) bandage can be applied in a figure-of-eight configuration. Apply the wrap to give only lateral support with minimal compression. It should not be tight enough to impair venous drainage, a common problem when patients apply their own elastic wraps (see Fig. 50.4).

Hard Shoe Splint

Indications

Reduction of ambulatory pain in patients with fractures or soft tissue injuries of the foot
Used over a splint to allow partial weight bearing

If the shoe is going to be used for a fractured toe, first buddy-tape the toe to the adjacent digit. Remember to place a piece of cotton or Webril between the toes to prevent skin maceration.

Figure 50.26 Hard shoe splint.

An Unna boot placed over Webril is an alternative to a simple elastic bandage (see Fig. 50.25C). The Unna boot is constructed from a semisolid paste roll that hardens as it dries. Apply an Unna boot in a figure-of-eight configuration, similar to a simple elastic bandage. Once in place, wrap the ankle with roller gauze or an elastic bandage. The entire dressing can be cut off by the patient at home.

Soft Cast

Indications. A soft cast is basically a modified Jones compression dressing for the ankle. Use it for minor ligamentous and soft tissue injuries of the foot and ankle that do not require prolonged or complete immobilization. A soft cast can help reduce the pain and swelling often associated with mild ankle sprains, and it gives support for early weight bearing.

Construction. Make the soft cast of 3- or 4-inch Webril and elastic bandages.

Application. Place the patient in a supine position with the foot and ankle extending off the end of the stretcher. Alternatively, ask an assistant to elevate the leg or place pillows under the knee and foreleg. Wrap the ankle and foot with five to seven layers of Webril starting at the metatarsal heads and continuing around the ankle in a figure-of-eight configuration. Extend the Webril 5 to 7 cm above the malleoli and overlap each turn by 25% to 50% of its width. After the Webril is in place, wrap an elastic bandage around the foot and ankle in a similar fashion. Additional layers of Webril and elastic bandages are seldom required. A cast shoe can be used with this dressing.

COMPLICATIONS OF SPLINTS

Ischemia

A compartment syndrome (see Chapter 54) leading to ischemic injury and ultimately to a Volkmann ischemic contracture is the most worrisome complication of cylindrical casts. Although the risk for ischemia is drastically reduced with splinting, Webril or elastic bandages can cause significant constriction. To reduce the likelihood of constriction occurring, do not pull the elastic bandage excessively tight. If the patient has a high-risk injury, cut the Webril lengthwise before the plaster is applied. Stress the importance of elevation, no weight bearing, and application of cold packs, and carefully review the signs and symptoms of vascular compromise with every patient. All patients whose injuries have the potential for significant swelling or loss of vascular integrity should receive follow-up care in the first 24 to 48 hours. *Never ignore complaints of increasing pain under a splint.* Patients with splint-related discomfort must be reevaluated clinically and should not be treated with a telephone prescription for opioid analgesics (Fig. 50.27).

Heat Injury

Fiberglass splints produce minimal heat when drying, but plaster generates considerable heat as it hardens. Many clinicians are unaware of the potential for drying plaster to produce second-degree burns.²⁹ Thermal injury can occur with both cylindrical casts and plaster splints. Some clinicians have reported a higher

Figure 50.27 If a patient complains of a cast being too tight, it probably is. The cast must be removed to inspect the area for infection or other problems. Complaints of pain under this cast were incorrectly met with a phone call to suggest elevation and a call-in prescription for narcotics.

incidence of burns with the use of plaster splints, although the reasons for this are unclear.^{29,30} Box 50.4 lists factors that can increase the amount of heat produced during plaster recrystallization. Their effects are additive, and this fact should be taken into account when applying a splint. For example, if 15 sheets of plaster are needed for strength in a particular splint, one should not increase the heat production further by using extra-fast-drying plaster or reusing warm dip water. To avoid plaster burns, use only 8 to 12 sheets of plaster when possible, use fresh dip water with a temperature near 24°C, and never wrap the extremity in a sheet or pillow during the setting process. Peak temperatures usually occur between 5 and 15 minutes after plaster wetting.

The patient should be warned that the hardening process produces warmth. The heat of drying may produce pain in patients with hemophilia-related hemarthroses. Splinting these patients may require that the plaster splint be placed only long enough to verify proper fit; the splint is then reapplied after setting (and cooling) of the plaster. If any patient complains of significant burning while the plaster is drying, *do not ignore this complaint!* Immediately remove the splint, and promptly cool the area with cold packs or cool water. Patients with vascular insufficiency or sensory deficits (e.g., diabetic neuropathy, stroke) are at high risk for plaster burns and require close observation during the drying process.

Pressure Sores

Pressure sores are an uncommon complication of short-term splinting (Fig. 50.28).³¹ They can result from stockinette wrinkles, irregular wadding of Webril, incorrectly padded or unpadded bony prominences, irregular splint ends, plaster ridges, or indentations produced from using the fingers rather than the palms to smooth and mold the wet plaster. Attention to detail during padding and splinting reduces the incidence of pressure sores. However, whenever a patient complains of a persistent pain or burning sensation under any part of a splint, remove the splint and inspect the symptomatic area closely. The padding incorporated in premade plaster and fiberglass splints is generally all that is needed for safe short-term splinting. However, the life of a splint applied in the ED may

Figure 50.28 The problem with this splint is that it was intended to be used for only a few days, but the patient wore it and walked on it for 3 weeks. Note the resultant full-thickness skin loss. No padding was used under the premade splint. Skin grafting was eventually required.

be longer than intended by the clinician; therefore it is prudent to err on the side of additional padding when placing splints on patients who may overuse the splint, such as those who will not use crutches, or for those who may not have ready access to follow-up.

Infection

Bacterial and fungal infections can occur under a splint.^{32,33} Infection is more common in the presence of an open wound but may occur with intact skin or in a skin lesion produced by prolonged splinting. The moist, warm, and dark environment created by the splint is an excellent nidus for infection. Toxic shock syndrome has been rarely reported from a staphylococcal skin infection that clandestinely developed under a splint or cast. In addition, it has been shown that bacteria can multiply in slowly drying plaster. To avoid infection, clean and débride all wounds before splint application, and use clean, fresh tap water for plaster wetting. If necessary, apply a removable splint that allows periodic wound inspection or local wound care.

Dermatitis

Occasionally, a rash develops under a plaster cast or splint.^{34–38} Allergy to plaster is exceedingly rare, but there are several reports of contact dermatitis when formaldehyde and melamine resins are added to the plaster.^{36,37} The rash is usually pruritic with weeping papular or vesicular lesions. Because these resins are unnecessary for ED splints, their use should be avoided whenever possible. Dermatitis has also been reported with the use of fiberglass splinting material.³⁹

Figure 50.29 This 9-year-old tried to scratch an itch under his splint with a pencil and the eraser fell off (arrow). This resulted in skin irritation and infection, requiring removal of the splint.

Figure 50.30 A, Never splint an injured wrist in flexion even though the patient prefers this position. B, When immobilizing an infected human bite, this splint was not held in position until hardened, and the patient reflexively flexed the wrist.

Pruritus

Itching under a cast can be problematic. Patients, especially children, use various objects such as pencils, coat hangers, or forks to get to the itch. This can cause skin maceration and possible infection, or a foreign body can be left under the cast (Fig. 50.29).

Joint Stiffness

Some degree of joint stiffness is an invariable consequence of immobilization (Fig. 50.30). It can range in severity from mild

TABLE 50.3 Suggested Length of Immobilization for Conditions That Frequently Require Splinting

TYPE OF CONDITION	IMMOBILIZATION (DAYS)
Contusions	1–3
Abrasions	1–3
Soft tissue lacerations	5–7
Tendon lacerations	Variable ^a
Tendinitis	5–7
Puncture wounds and bites	3–4
Deep space infections and cellulitis	3–5
Mild sprains	5–7
Fractures and severe sprains	Variable ^b

^aConsiderable controversy surrounds the length of immobilization for tendon lacerations, and duration is therefore best left to the consultant surgeon.

^bUsually requires prolonged immobilization, which is best determined by an orthopedic surgeon.

to incapacitating and can result in transient, prolonged, or in some cases, permanent loss of function. Stiffness appears to be worse with prolonged periods of immobilization, in elderly patients, and in patients with preexisting joint diseases such as rheumatoid arthritis or osteoarthritis. Thus, splints should be left on for only the time necessary for adequate healing. [Table 50.3](#) lists several injuries that commonly require splinting, along with some suggestions for length of immobilization. Fractures, dislocations, or other conditions that require prolonged immobilization (>7 days) should have orthopedic follow-up. Tell patients that a splint is only a short-term device and that prolonged immobilization can be detrimental. For minor injuries, suggest that patients use their own judgment about when to remove the splint, but a definite end point should be set.

Cast Pain

Cast-related pain is a common complaint that brings patients to the ED. Because of the potential for ischemia with circumferential casts, fully investigate all complaints, and rule out vascular compromise. If a patient states that a cast is too tight, it probably is (see [Fig. 50.27](#)). Do not prescribe narcotics for cast pain until a properly fitting (i.e., one that is not too tight) cast has been ensured.

Perform a detailed history and physical examination on all patients complaining of cast pain. The nature and onset of the pain are of particular importance. A dull, nonspecific pain that has worsened gradually since the time of injury may be the only clue to an early compartment syndrome (see [Chapter 54](#)). A sudden onset of throbbing pain associated with swelling and redness suggests a possible deep venous thrombosis. In both these cases, rapid intervention is the key to decreasing morbidity and mortality. During the physical examination, pay particular attention to areas of tenderness and

the effect of active and passive movement on the severity of the pain.

With a compartment syndrome, tenderness over the involved compartment is a common finding, and stretching or contracting ischemic muscle elicits significant pain. Evaluate for the presence and quality of distal pulses, the amount of edema fluid present, distal sensation, capillary refill, and color and temperature of the digits. The five Ps (pain, pallor, paresthesias, paralysis, and pulselessness) are pathognomonic for ischemia. Unfortunately, they seldom occur simultaneously, and their presence together is usually a late finding that carries a poor prognosis. Hence, the emergency clinician must maintain a high index of suspicion for possible ischemia and remove the cast if any possibility of vascular compromise exists. Almost any cast can be bivalved, with Webril and stockinette also cut, and the bivalved cast reapplied after inspection without significant loss of short-term immobilization.

To loosen a cast, use an oscillating cast saw to cut along the medial and lateral aspects of the cast ([Fig. 50.31](#)). This is called *bivalving the cast*, and it allows the halves to be spread and reapplied in a less constricting manner while still maintaining proper immobilization. To use an oscillating power saw, proceed in a series of downward cutting movements facilitated by wrist supination, and remove the blade between cuts to prevent it from getting hot enough to burn the skin. This is particularly important if synthetic material has been used in the cast. Additionally, do not allow the blade to slide along the skin, and never use the saw on unpadded plaster. In an apprehensive patient, demonstrate that the cast saw blade only vibrates (it does not turn) and that it does not cut the skin.

After the medial and lateral sides of the cast are completely cut through, separate the two halves with a cast spreader, and cut the padding lengthwise with scissors. Note that the padding may also contribute to the pressure, so once the plaster is bivalved, compression from padding must also be relieved. This may be sufficient to relieve early ischemia if the problem is simple postinjury swelling, but both the padding and the cast can be totally removed to inspect the injured area if necessary. If ischemia cannot be ruled out, measure compartment pressures (see [Chapter 54](#)) and obtain an orthopedic consultation.

If vascular integrity is established and no other problems are found, replace the bivalved cast. First, pad the extremity in the usual manner with fresh Webril. Line the cut ends of the bivalved cast with white adhesive tape, and replace the cast around the extremity. Finally, secure the cast in place with elastic bandages.

If plaster sores are causing the patient discomfort, consult the clinician who placed the cast. In some cases, additional padding is all that is needed, but in others, a window should be cut out over the problem area. Because pressure sores can lead to significant tissue necrosis, refer the patient for follow-up care within 24 hours.

If the patient's problem is plaster (or, more likely, resin) dermatitis, administer topical or oral steroids and antihistamines. Provide therapy in concert with an orthopedic surgeon because the patient may require admission for other forms of immobilization until the cast can be replaced. In mild cases, changing the cast or splint and using antihistamines for symptomatic relief may suffice. All patients should receive close follow-up, and if the condition does not improve, the cast must be removed.

Cast Removal

The cast saw vibrates; it does not rotate. It will not cut the patient. Note that the underlying Webril padding is cut to relieve pressure but is not removed.

The blade is controlled by placing the thumb (arrow) on the splint and lowering the saw blade to the plaster. The blade is raised and lowered for each cut; it is not drawn across the plaster like a knife.

This cast was too tight, and it was therefore bivalved from calf to forefoot with a cast saw. After separation of the edges of the cut cast, the anterior and posterior components were secured in place with an elastic bandage. A bivalved cast provides temporary immobilization equal to that of an intact cast. Extra padding can be used to protect the skin from the cut edges.

Figure 50.31 Cast removal.

CONCLUSION

Splinting is an important means of temporary fracture immobilization and provides protection and comfort for a variety of soft tissue injuries. The clinician should be aware of potential complications that can occur with improper splint application, including ischemia, thermal injury, and pressure sores. Use

proper technique to minimize the risk for these adverse outcomes. When ischemia is suspected, the emergency clinician should also be facile in the release of circumferential cast and splint material.

Podiatric Procedures

Douglas L. McGee

Normal daily activities cannot easily be accomplished without walking, so patients with painful or infectious conditions of the feet often seek medical attention. This chapter focuses on procedures performed for common maladies of the foot. Other procedures on the foot are described elsewhere in this text, including anesthesia of the foot and ankle (see [Chapters 29 and 31](#)), management of nail bed injuries (see [Chapters 35 and 37](#)), incision and drainage of paronychia (see [Chapter 37](#)), joint fluid analysis (see [Chapter 53](#)), management of common dislocations of the foot (see [Chapter 49](#)), and splinting (see [Chapter 50](#)).

COMMON NONTRAUMATIC CONDITIONS OF THE FOOT

Many painful conditions of the foot are chronic and do not usually require definitive treatment in the emergency department (ED); however, patients are often seen with common conditions that require evaluation and proper referral. To accomplish this, the clinician must be cognizant of basic podiatric conditions, including painful lesions over bony prominences, heel pain, foot infections, and pain on the plantar surface of the foot.

Footpad Use

Footpads redistribute pressure over an inflamed, tender area of the foot. The particular type of footpad and its placement depend on the condition being treated ([Fig. 51.1](#)). Commercially available aperture footpads are recommended for the temporary relief of warts, corns, hyperkeratoses, and bunions. Verruca virus introduced into the plantar surface of the foot may produce a painful hyperkeratotic lesion, commonly referred to as a *plantar wart*, on the sole of the foot. A simple callus may be painful and result in the formation of a “hard corn” when formed over the bony prominence of a digit. Once recognized, and after other conditions are ruled out, definitive care of these lesions is rarely indicated in the ED.

When tenderness is elicited over more than one metatarsal head, the diagnosis is metatarsalgia. Pain that is progressively worse while walking but relieved by rest, often beneath the second or third metatarsal head, is typical in this case. A pad placed under the first metatarsal head to raise the second and third metatarsals may provide some relief.

A bunion develops when unbalanced forces applied to the first metatarsal cause lateral displacement of the distal end of the hallux. Bunions typically form in women wearing heeled shoes with narrow toe boxes. The patient may complain of numbness over the distal, medial aspect of the first toe as a result of compression of the terminal branch of the medial dorsal cutaneous nerve. The mechanical forces that precipitate

bunion formation may also cause other painful conditions, including intermetatarsal neuromas, hammertoes, ingrown toenails, corns, and calluses. Bursitis may develop over the medial bony prominence of the first metatarsophalangeal (MTP) joint. Self-adherent bunion pads placed over the first MTP joint may provide temporary relief ([Fig. 51.2](#)). In the ED, treat patients suffering from these common disorders with analgesics and footpads, followed by referral for definitive care. Recommend that the patient avoid wearing the offending shoes. In men and postmenopausal women consider gout when evaluating pain over the first MTP joint, particularly in the presence of other signs of inflammation (e.g., redness, swelling, warmth).

Heel Pain Syndromes

Bony spurs on the plantar surface of the calcaneus, retrocalcaneal bursitis, calcaneal apophysitis, and other conditions may cause heel pain. Treat most of these conditions with rest, nonsteroidal antiinflammatory drugs (NSAIDs), modification of physical activities or shoe wear, footpads, and orthoses. Some clinicians also include injection of anesthetics or steroids for these conditions.

Heel spur pain can be quite bothersome and chronic or recurrent. This condition is not easily remedied in the ED, and after other conditions are ruled out, such as an unexpected foreign body (FB), minimal intervention with podiatric referral is often the best course of action. Patients typically have pain over the medial border of the plantar aspect of the calcaneus. The pain gradually worsens over a period of months. A bony prominence that begins as periostitis extends from the medial aspect of the calcaneal tuberosity into the central plantar fascia and may be seen on radiographs. Radiographs of the calcaneus that do not demonstrate a bony spur suggest plantar fasciitis (see the later section on [Painful Conditions of the Plantar Surface of the Foot](#)), even though many patients with plantar fasciitis have plantar calcaneal and Achilles spurs. Plantar calcaneal heel spurs are found in nearly 15% of the population, only 30% of whom have heel pain. Although many persons with heel spurs are asymptomatic, 75% of patients with heel pain have heel spurs.¹ However, radiographs have little value in evaluating nontraumatic heel pain because they rarely demonstrate radiographic abnormalities that prompt additional treatment.²

Shoe supports with a heel pad or cup, or a doughnut-shaped orthotic often help reduce the discomfort by redistributing weight. Few randomized controlled trials have evaluated steroid therapy; those that have do not provide substantial evidence supporting its long-term efficacy.^{3,4} Treatment for the painful site is 10 to 20 mg of methylprednisolone injected into the medial aspect of the foot while avoiding the sensitive plantar surface. Some evidence suggests that injecting 25 mg of prednisolone acetate into the medial aspect of the heel provides partial pain relief at 1 month in comparison to lidocaine only, but no advantage can be detected at 3 months.⁵ A short-leg walking cast may be effective in some patients with recalcitrant heel pain.⁶ There is little evidence to suggest that specific interventions aimed at reducing heel pain are superior to conservative, supportive treatment alone.

Retrocalcaneal Bursitis, Achilles Tendinopathy, and Calcaneal Apophysitis

Although retrocalcaneal bursitis and Achilles tendinopathy (formerly referred to as Achilles tendinitis) are anatomically

Figure 51.1 Use of aperture pads to redistribute pressure from painful areas to surrounding structures. The center hole is placed over the lesion and the surrounding pad absorbs the friction. (Courtesy Kenneth R. Walker, DPM.)

Figure 51.2 Use of an adhesive bunion pad. The hole in the pad is placed over the bunion and the surrounding pad absorbs the friction. (Courtesy Kenneth R. Walker, DPM.)

distinct, the clinical findings are similar. Pain at the insertion of the Achilles tendon is worsened with prolonged standing or walking and is aggravated by passive or active range of motion in both conditions. Directed palpation can distinguish one entity from the other, but both are treated similarly. Tenderness of the Achilles tendon suggests tendinopathy, whereas tenderness between the tendon and the calcaneus suggests retrocalcaneal bursitis. Importantly, Achilles tendinopathy has been noted to develop spontaneously after the use of quinolone antibiotics, occasionally with rupture. The condition may occur during quinolone use or a few weeks after therapy and prompts immediate discontinuation of use of the drug if recognized. Rest, elevation, ice, NSAIDs, heel pads, and an open-backed shoe provide relief in the majority of patients. A corticosteroid injection is not usually performed, but it may provide some relief, although its superiority over conservative measures is unproved. Repeated steroid injection is associated with Achilles tendon rupture.⁷ Injection of platelet-rich plasma (PRP) as treatment for Achilles tendinopathy has gained some support among sports medicine physicians, but

recently published studies (2016) have failed to demonstrate short- or long-term improvement in pain or function when PRP injection is compared with placebo.^{8,9} Osteochondrosis of the posterior calcaneal apophysis, often referred to as *Sever's disease*, may cause pain that is worsened by activity in children between 7 and 10 years of age. It is thought to represent an overuse syndrome in an athletically active child with tenderness in the posterior heel region.^{7,10} Treat this self-limited condition with rest, ice, and heel pads. Radiographs are not indicated unless other diagnoses are suspected.¹¹ Activity is resumed when the pain abates.

Painful Conditions of the Plantar Surface of the Foot

Plantar Fasciitis

Repeated microtrauma to the plantar aponeurosis causes pain on the plantar surface of the foot (Fig. 51.3A). Plantar fasciitis is typically unilateral and found in women who wear high-heeled shoes. The pain is maximally severe in the morning or after prolonged sitting and improves after walking, often referred to as *first-step pain*. Some patients with plantar fasciitis may also have a calcaneal heel spur, but the presence or absence of this radiographic finding is clinically irrelevant. Pain is elicited with palpation (see Fig. 51.3B), toe walking, or passive stretching of the plantar aponeurosis. Frequently, this annoying condition resolves spontaneously, but resolution is slow, with as long as 6 to 18 months needed. Conservative therapy, including rest, elevation, ice, and NSAIDs, results in a satisfactory outcome after 6 to 8 weeks in 90% of patients.¹² The pain improves over time in most patients, with or without NSAIDs, although the addition of NSAIDs appears to increase pain relief when compared with conservative treatments alone.¹³ The emergency clinician can do little to treat this chronic, distressing condition. Stretching exercises each morning and evening can be suggested (see Fig. 51.3D). Night splinting to keep the foot dorsiflexed and custom orthoses made from the patient's foot impression can be very helpful but usually require referral to podiatry for proper fitting (see Fig. 51.3C). Corticosteroid injection is used by some clinicians; however, its benefit remains unproved. A single injection may be warranted as supplemental therapy in resistant cases. Repeated injections of corticosteroids should be avoided and have been associated with rupture of the plantar fascia and fat pad atrophy.¹⁴ Some authors suggest the injection of autologous PRP when plantar fasciitis is chronic. The benefits of PRP remain unproved.¹⁵ In a 2010 study, 50 units of botulinum toxin type A injected into the plantar fascia decreased pain in comparison to placebo but did not cure the disease.¹⁶

Forefoot Neuroma

A forefoot neuroma, also known as *Morton's neuroma*, is a painful condition of the plantar surface of the foot. It most commonly affects women who wear high-heeled shoes. The neuroma forms after chronic irritation to the digital sensory nerve between the metatarsals. A neuroma frequently occurs in the third interspace but may be found in the second (Fig. 51.4A). Patients report the sensation of a lump or cord in the interspace and describe paresthesia or numbness in the third or fourth toes. Direct compression plus release of the forefoot causes pain and often a "click" (*Mulder's sign*) (see Fig. 51.4B). Rest, elevation, ice, and NSAIDs may result in some improvement, but surgical excision is often required.^{17,18} Few data support the use of corticosteroid injections. In one study, less than

Figure 51.3 Plantar fasciitis. **A**, The plantar fascia spans the plantar aspect of the foot. The origin is the medial tubercle of the calcaneus, which is the most common site of pain. A heel spur may be seen on radiographs, but inflammation of the plantar fascia, not the spur, is the source of the pain. **B**, Palpation of the tubercle of the calcaneus reproduces the pain of plantar fasciitis. **C**, A posterior lower leg splint may be created for patients in the emergency department, and it is intended to be worn at night to keep the foot in a position of dorsiflexion. Referral to podiatry for custom-fit orthoses may also be beneficial. **D**, Rolling the arch of the foot back and forth over a frozen water bottle will stretch the fascia and, over time, may lessen the pain of plantar fasciitis. A tennis ball can also be used.

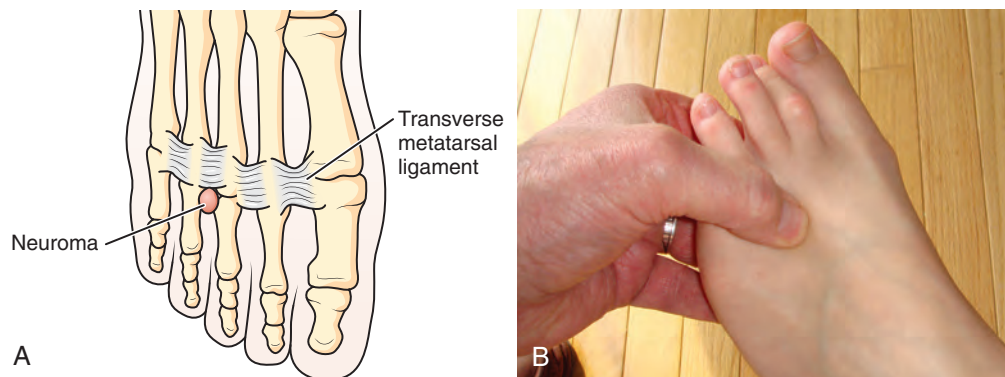

Figure 51.4 Morton's neuroma. **A**, Site of Morton's neuroma arising from a digital nerve. **B**, Palpation of the distal metatarsal area may reveal pain from Morton's neuroma. Squeezing and releasing this area (not shown) can elicit pain and a clicking sensation, termed Mulder's sign.

Figure 51.5 Ganglion cysts. A small amount of gel substance was aspirated with a needle, but a cyst of this size is best totally excised surgically.

50% of patients with a foot neuroma had any benefit from injected corticosteroids.¹⁷ Another study demonstrated complete or partial relief in 80% of patients injected with corticosteroids.¹⁹ Although this study demonstrated a trend toward improved outcome when injected corticosteroids were compared with footwear modifications, corticosteroid injection therapy alone was not statistically better than footwear modification at 1 year.¹⁹

Ganglion Cyst of the Foot

A ganglion cyst is histologically similar to the synovial sheath and contains synovial fluid. The diagnosis is easy to make when the cyst is located over a tendon on the dorsum of the foot (Fig. 51.5), but may be difficult when located among the compact structures of the plantar forefoot. A ganglion cyst usually causes edema along the involved tendon sheath. The mass should roll under the examiner's finger; a painless, immovable mass suggests a soft tissue neoplasm. Painful ganglion cysts are treated by aspiration, with or without injection of a corticosteroid (see Chapter 52). After local or regional anesthesia (see Chapters 29 and 31), insert a 20-gauge needle into the cyst and withdraw yellow, thick, synovial fluid. Manually express any remaining synovial fluid after the needle is withdrawn. Corticosteroid injection is often advocated for ganglion cysts, but recurrence is common after aspiration and corticosteroid injection, as high as 57% in one study.²⁰ Many studies have shown that recurrence, chronic pain, neuritis, stiffness, and infection are not uncommon, even after surgical excision.²¹ Other authors report improved functional outcome, a 9% occurrence of paresthesia, and only a 5.7% recurrence rate after excision.²²

TRAUMATIC CONDITIONS OF THE FOOT

Trauma to the feet and toes is common and covers a broad spectrum of injury. Lacerations, fractures, compartment syndromes, and nail bed injuries are described in other chapters of this text. Three specific injuries—toe fractures, sesamoid-bone fractures, and puncture wounds to the plantar surface of the foot—are discussed in detail here.

Figure 51.6 Proper treatment of oblique displaced fractures of the proximal phalanx of the great toe includes reduction, a non-weight-bearing splint that extends beyond the great toe, and referral to a foot and ankle surgeon because surgical intervention may be required

Toe Fractures and Fractures of the Sesamoid Bones

Emergency clinicians often treat toe fractures and can intervene to relieve the pain and encourage healing. As with any other fracture, pay attention to the possibility of disrupted joint cartilage, hypermobility of the fracture segments, and malposition or malunion of the fracture fragments. Fracture displacement greater than 2 mm is uncommon; reduction is rarely needed for most toe fractures.²³ However, aggressive reduction is indicated for fractures of the proximal phalanx of the great toe because it represents the main propulsive segment of the forefoot (Fig. 51.6). A plaster cast alone without anatomic reduction is insufficient treatment. Displacement suggests axial rotation or abnormal biomechanical interaction between the hallux and its own interphalangeal or MTP joint.

In the acute setting, a non-weight-bearing ankle splint that extends beyond the great toe provides protection until the patient with a complicated fracture of the great toe obtains follow-up with a foot and ankle surgeon. Open fractures require careful cleaning, usually antibiotic therapy, and close follow-up. Fractures of the lesser toes generally result from jamming the toe into a nightstand or bedpost when barefoot. Radiographs of the lesser phalanges confirm the suspected fracture and may occasionally reveal an unsuspected interphalangeal or MTP dislocation. However, radiographs are not typically required, and the injured digit is easily reduced.

Treat closed, lesser phalangeal fractures with immobilization for 6 weeks. After the fracture is reduced, splint the injured toe against an adjacent noninjured toe. Place a soft corn pad or other suitable material between the toes to prevent skin maceration, and hold the toes together with adhesive tape or a self-adherent wrap such as Coban (3M Company, St. Paul, MN) (Fig. 51.7). Demonstrate the procedure to the patient or family and dispense or prescribe enough material so that the splint can be changed every 2 to 3 days at home. Have the patient wear a less restrictive, stiff-soled shoe (Fig. 51.8). A postoperative shoe (or similar footwear) may be a comfortable alternative for the first several days.

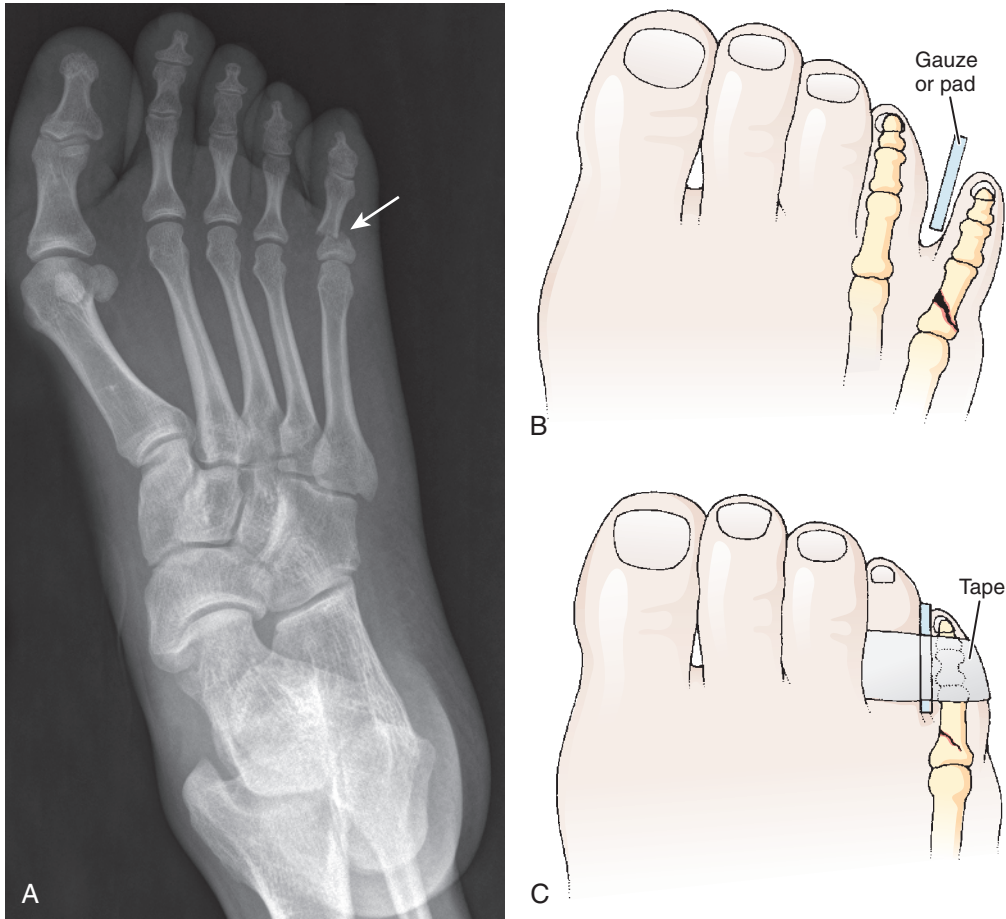

Figure 51.7 Buddy taping. **A**, Displaced fractures of the lesser toes (*arrow*) are often a result of jamming the foot into a bedpost or nightstand when barefoot and are easily reduced with in-line traction. **B**, A pad is placed between the injured toe and an adjacent toe. **C**, The toes are secured together with tape or a self-adherent wrap. After reduction of the misalignment by in-line traction, generally the only treatment required is a postoperative shoe and taping in place for 4 to 6 weeks. (**B** and **C**, Courtesy Kenneth R. Walker, DPM.)

Figure 51.8 A stiff-soled postoperative shoe prevents flexion of the foot and will provide comfort for patients suffering from toe and sesamoid fractures.

Jumping from a height can result in a fracture of the first MTP joint sesamoid bone (Fig. 51.9A). The great toe sesamoid bones lie in grooves on the bottom of the metatarsal head. Each bone lies within the tendon of its respective flexor hallucis brevis muscle belly. Localized pain on the plantar aspect of the first metatarsal head accompanies a sesamoid-bone fracture. Bipartite sesamoids (tibial more frequently than fibular) are common. Comparison radiographs clarify whether the radiographic abnormality represents a fracture.

For a tibial sesamoid injury, an aperture bunion-type pad, reinforced medially with 0.5- to 0.75-cm-thick felt, protects the sesamoid and transfers weight bearing to the surrounding structures (see Fig. 51.9B). A hard-soled shoe and NSAIDs are also helpful. Subsequent radiographs rarely show bony consolidation, but the fracture interface appears smoother.

Stress Fractures

A metatarsal stress fracture, commonly of the distal second and third metatarsals, can develop in runners, military recruits, or those with repetitive trauma to the foot (Fig. 51.10). Other risk factors are listed in Box 51.1.²⁴ There is pain on walking but minimal to no external findings. A bone scan or magnetic

Figure 51.9 Sesamoid fracture. **A**, Jumping from a height can result in a sesamoid fracture (*arrow*). **B**, Bunion shields can be used to redistribute pressure away from fractured sesamoid bones. The hole in the pad is placed over the fracture and the surrounding pad absorbs the pressure.

Figure 51.10 Metatarsal stress fractures. Repetitive foot trauma can lead to metatarsal stress fractures, most commonly the second and third metatarsals (*arrows*). These are usually subtle fractures that can be difficult to identify on conventional radiographs. **A**, Slight cortical disruptions or **B**, periosteal reactions indicative of healing may be seen, but often a bone scan or magnetic resonance imaging is needed to confirm the diagnosis. Treatment consists of rest and removing the precipitant causes.

resonance imaging (MRI) may detect the subtle fracture that often eludes a plain radiograph. Occasionally, an occult FB of the foot is the culprit and can mimic a stress fracture. Women are more prone to stress fractures than men. Treatment is usually rest and alleviation of the precipitant causes.

Plantar Puncture Wounds

Plantar puncture wounds present a diagnostic and therapeutic challenge for the clinician. Considerable controversy exists regarding the proper initial management of puncture wounds

BOX 51.1 Risk Factors for Stress Fractures

- Sports involving running and jumping, especially on angled, hard, or irregular surfaces
- Rapid increase in a physical training program
- Poor physical condition
- Female gender
- Hormonal or menstrual disturbances
- Osteoporosis or decreased bone density
- Nutritional deficiencies (including extreme dieting)
- Obesity and overweight
- Inappropriate footwear
- Poor flexibility

Adapted from Sanderlin BW, Raspa RF: Common stress fractures, Am Fam Physician 68:1527, 2003.

in the plantar surface of the foot, and no universally accepted standard of care exists. Treatment recommendations range from simple cleaning of the wound to aggressive débridement. No single approach has been demonstrated to be superior. The author supports close inspection for retained foreign material and an initially conservative approach, but an aggressive one is recommended if the patient returns, has an infection, or if the pain persists for more than a few days.

Although nails produce many such wounds, various other objects may cause them, including other metal objects, wood, and glass. Patient response to the injury depends on the penetrating material, location and circumstances of the wound, depth of penetration, footwear, time from injury until initial evaluation, and underlying health. As superficial puncture wounds generally do well, depth of penetration may be a primary determinant of outcome.²⁵ Because one's reflexes are not fast enough to pull back when stepping on a sharp object, the clinician should assume that the entire length of a protruding nail has entered the foot (minus the thickness of the footwear). Stepping on an unknown object in a field or while walking in

a stream requires a more cautious approach than a simple puncture from a known object, such as a protruding nail.

The vast majority of patients who step on a nail suffer nothing more than transient pain and never seek medical attention. Because most minor puncture wounds are not seen in the ED, the true risk for infection, including osteomyelitis, is unknown. Consequently, reported infection rates vastly overstate the actual incidence. Probably no more than 2% to 8% of puncture wounds become infected, and in only a small percentage of these wounds is surgical débridement needed or does osteomyelitis develop.²⁵⁻²⁷ A prospective series suggested that only the presence of symptoms (e.g., redness, tenderness, increased swelling) at 48 hours is associated with risk for infection or a potential retained FB.²⁸ Retained foreign material (e.g., a piece of sock or a portion of a tennis shoe sole) in the wound is an important factor in persistent infection. Because no single test detects all possible FBs, tailor the evaluation of a suspected FB to the suspected object.

Evaluation

The approach to the patient depends on several factors, including the time from injury to evaluation, suspicion of an FB, and the presence of infection. The extent to which an FB is pursued depends on the history and findings on physical examination. When the patient clearly states that a needle, pin, or nail was removed intact, radiographs or local wound exploration for a retained metallic FB is not needed. Stepping on an identified intact nail does not always require a radiograph, but if there is any debate regarding a retained metallic object, plain radiographs readily demonstrate their presence. Plain radiographs also demonstrate other radiopaque objects such as glass, gravel, bone, and teeth (Fig. 51.11). Rubber or pieces of a sock will not be visible on a radiograph. If the patient steps on an unknown object, a radiograph is usually indicated unless the entire depth of the wound can be ascertained and inspected. Ultrasonography is noninvasive and does not use radiation, thus making it potentially useful for radiolucent FBs, but soft tissue, air, or calcifications may suggest a retained FB when none is present. Bedside ultrasound has been used to localize radiolucent FBs for removal.^{29,30} Computed tomography (CT) can demonstrate radiopaque and radiolucent objects, but its expense and greater radiation exposure than with plain films make it unsuitable as an initial screening tool. Use CT scanning when other screening tools fail to demonstrate a suspected FB, when infection is present, or when joint penetration is suspected. Fluoroscopy may be used to help localize metallic or radiopaque FBs during exploration and removal. It may be particularly useful for long metallic objects such as needles and pins. MRI provides no additional benefit and cannot be used when metallic objects are retained. Diabetic patients with unexplained foot pain or infection warrant investigation for a retained FB; diabetic neuropathy may mask the initial puncture injury.

Treatment

As a general rule, the plantar surface of the foot should be examined under good lighting and in a bloodless field. This is best accomplished with the patient in a prone position, not in a chair (Fig. 51.12). Plantar puncture wounds explored for persistent infection often have foreign material in them. Because persistent infection does not develop in most patients, initial

Figure 51.11 Radiographic appearance of foreign bodies in the foot (arrows). Conventional radiographs will demonstrate a variety of foreign bodies. Shown here are **A**, glass, **B**, pencil graphite, and **C**, a metallic pin. Some objects, such as rubber or pieces of sock, will not be visible.

deep exploration in the absence of evidence or a strong suspicion of retained material cannot be advocated.²⁵ Routine initial deep wound exploration, including coring of the wound, is not supported by scientific research and is not recommended for simple, noninfected puncture wounds.²⁵ However, selected wounds may benefit from exploration to facilitate a search for FBs and to promote irrigation, cleansing, and drainage. When the wound is large and retained organic material is suspected, local wound exploration is warranted. Patients wearing rubber-soled shoes during plantar puncture wounds may retain a portion of the shoe in the wound. Exploration of the wound is most productive after local anesthesia or a regional anesthetic block and excision of the epidermal flap. An incision may be required to facilitate removal of the FB when known to be present, but it has not been proved that extensive removal of surrounding tissue increases successful removal of retained material.²⁵

Some clinicians favor a coring technique when an FB is found or suspected. Although this may be too aggressive for many wounds, it may be the best way to remove particulate matter as a block (Fig. 51.13). To accomplish coring, advance a No. 11 blade to the hilt and excise a 2- to 3-mm core. Use a hemostat to grab the cutout core or to open the tract to better visualize the wound. Alternatively, use a 2- to 3-mm punch biopsy instrument to core out the tract. The tract can be packed with gauze for a few days or left open. There is no

Foreign Body Removal

1 The best way to examine a puncture wound of the foot is to place the patient prone on a stretcher, have good lighting, and obtain a bloodless field (a blood pressure cuff was used here). First, remove the flap of skin at the puncture site. A local anesthetic injection (lidocaine 1%) is usually required but can be quite painful.

2 It is difficult to adequately try to examine the bottom of the foot with the patient in a hallway chair.

3 This piece of rubber (arrow) was introduced into a puncture when a nail went through a sneaker. It was not seen until the skin flap was removed and carefully examined.

4 After removing the foreign body, the wound can be left open or packed, as depicted here. Packing gauze can be dry or wet with saline or iodine solution.

Figure 51.12 Removal of a foreign body in the plantar surface of the foot.

evidence that coring a plantar puncture wound produces better outcomes than conservative or expectant treatment, and it should be reserved for selected cases. Occasionally, blunt probes may facilitate exploration of the wound. It is generally impossible and probably counterproductive to attempt to probe or visualize the entire length of the puncture tract. Patients initially seen within 24 hours and without signs of infection generally require only simple topical wound care. Although irrigation of all exposed dermal tissue is recommended, high-pressure irrigation of deep tissues with distention of soft tissues is unlikely to be helpful and is not recommended. Schwab and Powers described a case series of uncomplicated puncture wounds in healthy individuals who underwent conservative treatment with cleansing and crutches.²⁸ Radiographs were obtained at the discretion of the treating clinician and antibiotics were not given. At the 6-month follow-up, 88% of all patients healed without complication. In the remaining 12% complications developed, including wound infection from retained FBs. No findings on

initial evaluation predicted a subsequent infection. Initial antibiotic therapy remains controversial, but there is no evidence to suggest that prophylactic antibiotics reduce the already low rate of infection. In fact, some cases of *Pseudomonas* osteomyelitis develop despite initial treatment with anti-*Pseudomonas* antibiotics. The author does not suggest routine prophylactic antibiotics for uncomplicated puncture wounds, and such treatment may theoretically select out resistant organisms.

Symptomatic patients who delay presentation after injury (≥ 48 hours) may have an increased probability for a retained FB when inflammation or infection develops. Local wound exploration is warranted unless the patient does not have an infection or a clearly superficial cellulitis is expected to respond to simple oral antibiotics. Recurrent infection, deep soft tissue tenderness, and increasing soft tissue swelling suggest a retained FB or deep space infection, such as osteomyelitis. Such patients require prompt specialty referral or additional diagnostic studies in the ED.

Foreign Body Removal: Coring Technique

1 A foreign body is difficult to appreciate in this puncture wound of the big toe.

2 To core out a puncture, use a No. 11 blade and advance it to the hilt.

3 When the cored-out section was removed with a hemostat, a piece of rubber was found deep in the wound.

4 After coring out a puncture tract, the wound can be left open (as shown here) or packed (as shown in Fig 51.12).

Figure 51.13 Foreign body removal: coring technique.

Patients with obvious signs of infection within a few days of a puncture wound usually have a simple cellulitis (with or without an FB) with a gram-positive organism (Fig. 51.14). In a patient with persistent pain or swelling days to weeks after a puncture wound, the presence or absence of a deep soft tissue infection or low-grade osteomyelitis cannot be ruled in or ruled out by physical examination, plain radiographs, or laboratory tests (such as a sedimentation rate, complete blood count, or wound cultures). A high index of suspicion, coupled with additional investigation, is the prudent approach to patients with minimal findings on physical examination, normal laboratory test results, and continued pain or swelling after a seemingly simple puncture wound in the bottom of the foot. This usually entails CT, bone scan, or MRI. A study of 80 children with plantar puncture wounds and signs of infection at presentation found simple cellulitis in 59, retained FBs in 11, and osteomyelitis or septic arthritis in 10 children. Because a significant number of children in this study had retained FBs or bony infections, a cautious approach is warranted.³¹

Figure 51.14 This 5-day-old inflamed and infected puncture wound tract probably harbors a foreign body. Minor lymphangitis (arrow) spread up the ankle, but there were no systemic complaints, adenopathy, or leukocytosis. Excision of a core of the tract found scant pus and a few pieces of the patient's sock embedded in the wound. The wound was left open and did well with oral antibiotics and warm soaks.

Figure 51.15 A patient stepped on a nail while wearing this shoe. An initial evaluation in the emergency department 3 weeks earlier found no foreign body or infection. One week earlier the patient began taking antibiotics but did not improve. Findings on physical examination were quite benign, but the continued aching pain and minimal swelling suggested a deep infection. The complete blood count, sedimentation rate, and plain film were negative. Magnetic resonance imaging demonstrated osteomyelitis. *Pseudomonas* is often the offending organism in this scenario and often requires surgical débridement. Prophylactic antibiotics at the time of the puncture have not been shown to prevent this infection. The subsequent course is likely set at the time of injury and the key is to suspect this infection if pain is still present after the first week.

Plantar puncture wounds complicated by *Pseudomonas* osteomyelitis and osteochondritis are clinically clandestine and particularly devastating. They have been described for nearly 40 years. Some investigators have cultured *Pseudomonas* from the soles of tennis shoes, thus suggesting that puncture wounds made through athletic footwear may be inoculated with *Pseudomonas* (Fig. 51.15).³² No evidence suggests that prescribing prophylactic anti-*Pseudomonas* antibiotics on initial evaluation of an uncomplicated wound will prevent infection in patients with subsequent deep space or bone infections.³² Some argue that prophylactic antibiotics, at the time of puncture, may select out resistant organisms.³² Surgical débridement and prolonged intravenous antibiotics are often required for established infections.

INGROWN TOENAIL

An ingrown toenail is characterized by progressive curving or excessive widening of the lateral margin of the toenail and impingement of the nail into the periungual soft tissue (Fig. 51.16). The toenail normally grows distally in an unimpeded manner, thereby allowing the nail to pass beyond the lateral nail fold. Nail deformity, tight-fitting shoes, and rotational deformity of the toes increase the friction between the nail and the nail fold. Toenails that have been trimmed in a curve increase the likelihood that the lateral nail margin will impinge on the lateral nail fold (Fig. 51.17). The resulting soft tissue injury may lead to hyperkeratosis, edema, and erythema of the nail fold or frank infection (Fig. 51.18). Although an ingrown toenail can be found on any toe, the majority occur on the great toe.

Evaluation

The patient has pain, edema, and erythema of the lateral nail fold. Pressure over the nail margins increases the pain. Because

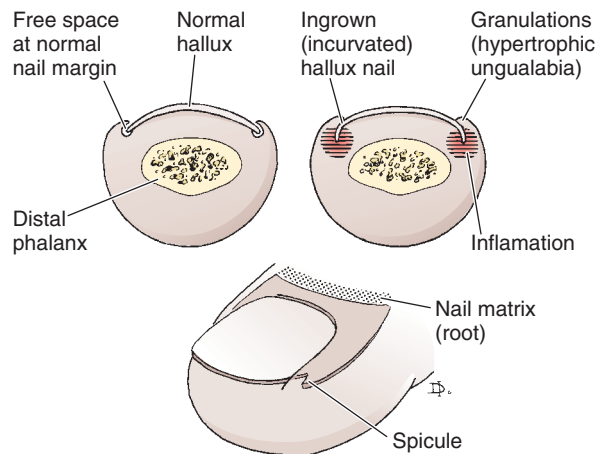

Figure 51.16 Pathology of an ingrown toenail. The normal free space at the nail margin is obliterated by inflammation and granulation tissue, which is caused by improper nail trimming, trauma to the matrix, and faulty footwear. (From Hill GL II, editor: *Outpatient surgery*, ed 3, Philadelphia, 1988, Saunders. Reproduced by permission.)

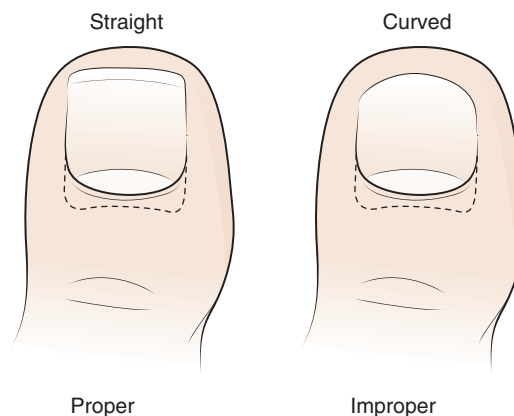

Figure 51.17 The proper way to trim a toenail that is prone to becoming ingrown is to cut the end of the nail straight across, not at an angle. This is counterintuitive to a patient who wants the nail to conform to the contour of the toe.

Figure 51.18 An ingrown toenail of this degree requires removal of a portion of the nail and débridement of inflamed tissue. Antibiotics effective against gram-positive organisms are often prescribed after surgical intervention.

intense pain often precipitates an early visit to the ED, most inflammatory or infectious responses are confined locally. Recurrent ingrown toenails or those in patients with circulatory dysfunction, neuropathy, or diabetes may have underlying osteomyelitis. Cleanse the toe gently to facilitate visualization of the periungual debris. When the free edge of the lateral part of the nail can easily be visualized as separate from the lateral nail fold, consider other painful conditions of the toe such as trauma, gout, paronychia, and cellulitis.

Treatment

Because the toe is exquisitely tender, additional treatment will usually require digital block anesthesia. The decision to treat and what course of action to take in the ED depend on the patient's degree of discomfort. Two general courses of action are often suggested: removal of the offending nail spicule or removal of the spicule and some portion of the nail. Any degree of nail removal is usually followed by ablation of the nail bed.³³ Nail-splinting techniques may also be effective and are less invasive than nail removal techniques.

Removal of the Nail Spicule and Débridement of Hyperkeratosis for Minor Ingrown Toenails

When the amount of inflammation and pain and the degree of nail deformity are both minimal, such as involvement of only the distal toenail area, simple removal of the impacted nail spicule is indicated and usually curative. If the condition is advanced, complete removal of a portion of the nail may be required. All procedures are best done with a tourniquet to produce a bloodless field. After a digital block and thorough cleansing, remove an oblique segment of the nail approximately one third to one half the way to the proximal nail fold (Fig. 51.19). The ideal instrument is an English anvil nail splitter, which is designed to cut the nail while minimizing trauma to the underlying nail matrix (Fig. 51.20). Sharp, pointed scissors may be substituted if care is taken to minimize injury to the nail bed by maintaining upward pressure while cutting the nail. Some clinicians use a disposable electric cautery device to cut the nail after softening it by soaking in warm soapy water.

After cutting the nail spicule free from the bulk of the nail, grasp the free edge of the nail with forceps or hemostats and

remove it to expose the irritated area. The nail fold typically contains impacted debris that must be removed after the nail fold has been gently retracted away from the nail. Remove debris until the epidermis or dermis is uncovered while taking care to avoid aggressive débridement that causes bleeding. A silver nitrate stick applied to the débrided area may be used to control bleeding. Dress the area with antibiotic ointment and a nonadherent dressing. Soaking the toe in warm water two or three times a day, with home redressing, is explained. Harsh chemicals are avoided in the soaking regimen. The wound should be reinspected for signs of infection at 48 to 72 hours. If the problem has resolved, no further therapy is necessary. If the problem is persistent or recurrent, referral for definitive podiatric care is reasonable. Instruct patients to wear less constricting shoes and to trim the nail straight across. Like most FB reactions, removal of the nail spicule resolves the inflammation and infection. Antibiotics given without removal of the nail spicule will not ensure a satisfactory result or add benefit after removal of the spicule.³⁴ Topical antibiotics (avoid those containing neomycin) are reasonable, but systemic antibiotics are not required. Diabetic patients and those with peripheral vascular disease require closer follow-up. When the ingrown toenail is caused by a nail deformity, a podiatrist or primary clinician can perform definitive removal during follow-up evaluation.

Toenail Removal for Complex or Extensive Ingrown Toenails

When irritation, infection, or both are more widespread or include the entire toe, removal of a portion of the nail and débridement of the inflamed tissue may be required (Figs. 51.21 and 51.22). Toenail removal (Videos 51.1 to 51.3) may be total or partial. Total nail removal is rarely needed but may be done when both lateral nail folds are infected, particularly if the condition has been present for more than a month. Consider partial removal of the toenail when ingrown toenails are associated with chronic inflammation, infection, or severe

Figure 51.20 English nail anvil used to divide the nail. (Courtesy Gill Podiatry Supply Company, Middleburg Heights, OH.)

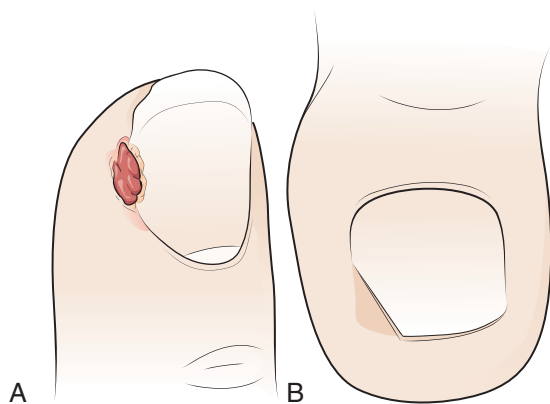

Figure 51.19 **A**, This minor ingrown toenail can be treated by removal of a portion of the distal end of the nail. **B**, An oblique wedge of nail is trimmed from the lateral margin of the nail to free it from the hyperkeratotic area. (**A** and **B**, Courtesy Kenneth R. Walker, DPM.)

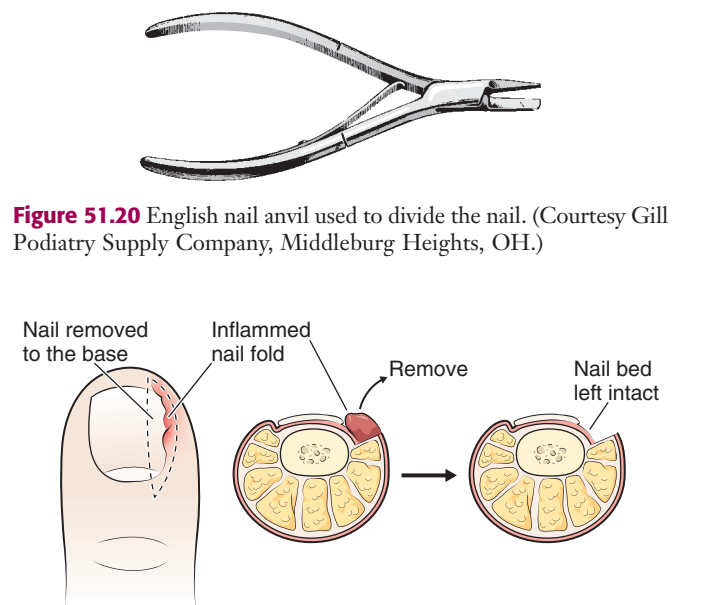

Figure 51.21 Resection of the entire length of a toenail plus removal of inflamed tissue is usually a curative intervention for a complex ingrown toenail. The nail bed is left intact.

Ingrown Toenail Removal

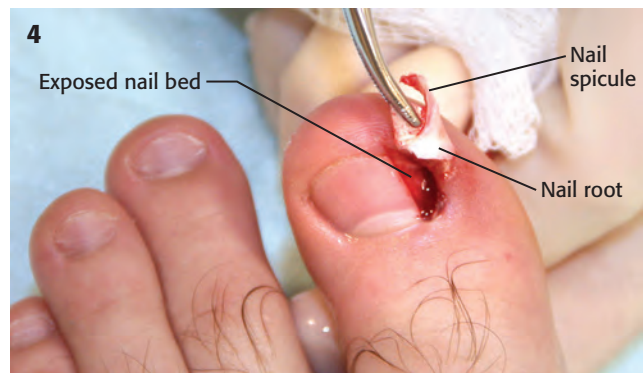

1 Cleanse the toe with antiseptic and then administer a digital block. Use of a tourniquet to provide a bloodless field is ideal but is not depicted here.

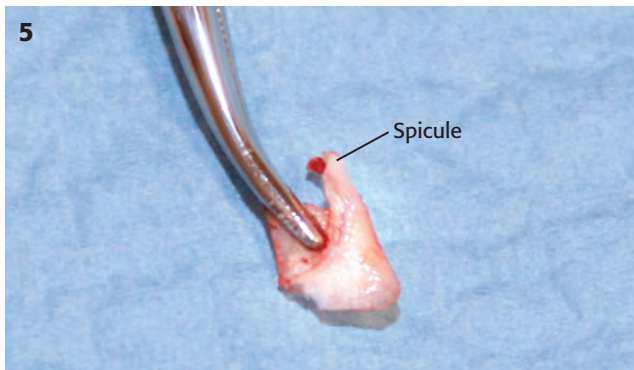

2 First separate the nail from the nail bed by advancing and separating scissors held parallel to the nail bed (see Fig. 51.23), and then split the nail lengthwise toward the cuticle as depicted above.

3 Grasp the end of the cut toenail with a hemostat and twist toward the remaining nail.

4 Use the twisting motion to remove the free piece of nail. Sharply remove any remaining skin and hyperkeratotic debris. Silver nitrate may be applied to the nail bed if desired.

5 Inspect the remnant to make sure that the entire piece of nail has been removed as desired. Note the prominent spicule present on this ingrown toenail.

6 Cover the wound with antibiotic ointment, a nonadherent dressing, and a dry sterile wrap.

Figure 51.22 Removal of an ingrown toenail. Antibiotics effective against gram-positive organisms are prescribed for significant associated infection but are likely not required for this localized process.

pain. Partial nail removal accomplishes two things: removal of the offending portion of nail and destruction of the underlying nail matrix to prevent regrowth of the nail. Phenol, the most commonly applied chemical, causes neurolysis of the nerve endings and necrosis of the nail matrix in a procedure called *matrixectomy*. Several studies have demonstrated that 10% sodium hydroxide solution is as effective as phenol and may be associated with less postprocedural pain and faster

recovery.³⁵⁻³⁷ As most EDs do not stock phenol or sodium hydroxide solution, nail bed ablation is usually not pursued on the initial visit.

After a digital block, exsanguinate the toe by squeezing or wrapping, and apply a tourniquet at the base of the toe. Stabilize the toe with the nondominant hand. Separate the lateral third of the nail from the nail bed by advancing and separating scissors held parallel to the nail bed (Fig. 51.23). Split the nail

Figure 51.23 Before cutting the nail lengthwise, separate the nail from the nail bed by advancing and spreading iris scissors held parallel to the nail bed. *Arrow* identifies the technique described in the figure regarding placing the phenol soaked applicator under the eponychium. Note the use of a tourniquet to provide a bloodless field.

lengthwise toward the cuticle. An English anvil nail splitter is desirable to begin the procedure, but sharp scissors or a No. 11 blade also work. Take care to perform a controlled division along the longitudinal lines of the nail for several millimeters past the proximal nail fold (cuticle). Grasp the end of the cut toenail with a hemostat or forceps. Remove the free piece of nail by twisting it toward the remaining nail. This will pull the nail root out from under the cuticle. Inspect the remnant to be certain that the entire piece of nail has been removed as desired. Sharply remove any remaining or swollen/heaped-up skin and all hyperkeratotic debris. After removal of the nail, most clinicians apply a silver nitrate stick to the nail bed and to granulation tissue for 2 to 3 minutes.³⁸ When finished, the nail bed is open and the heaped-up tissue is now flat.

As an option and if phenol or other ablating solutions are available, the following is suggested to permanently ablate the nail bed so that a new nail will not grow (Fig. 51.24). Apply a 10% sodium hydroxide solution to the nail bed with a cotton-tipped applicator for 1 to 2 minutes to provide effective ablation of the nail matrix.³⁵⁻³⁷ Alternatively, apply a 1% solution of aqueous phenol to the nail matrix beneath the involved area of the lateral nail groove and proximal nail fold with cotton-tipped applicators. A 1% phenol solution can be prepared by diluting a 70% to 90% aqueous phenol solution in an 80:1 ratio (e.g., 8 mL distilled water to 0.1 mL phenol). Remove some of the cotton if the applicator is too bulky to concentrate

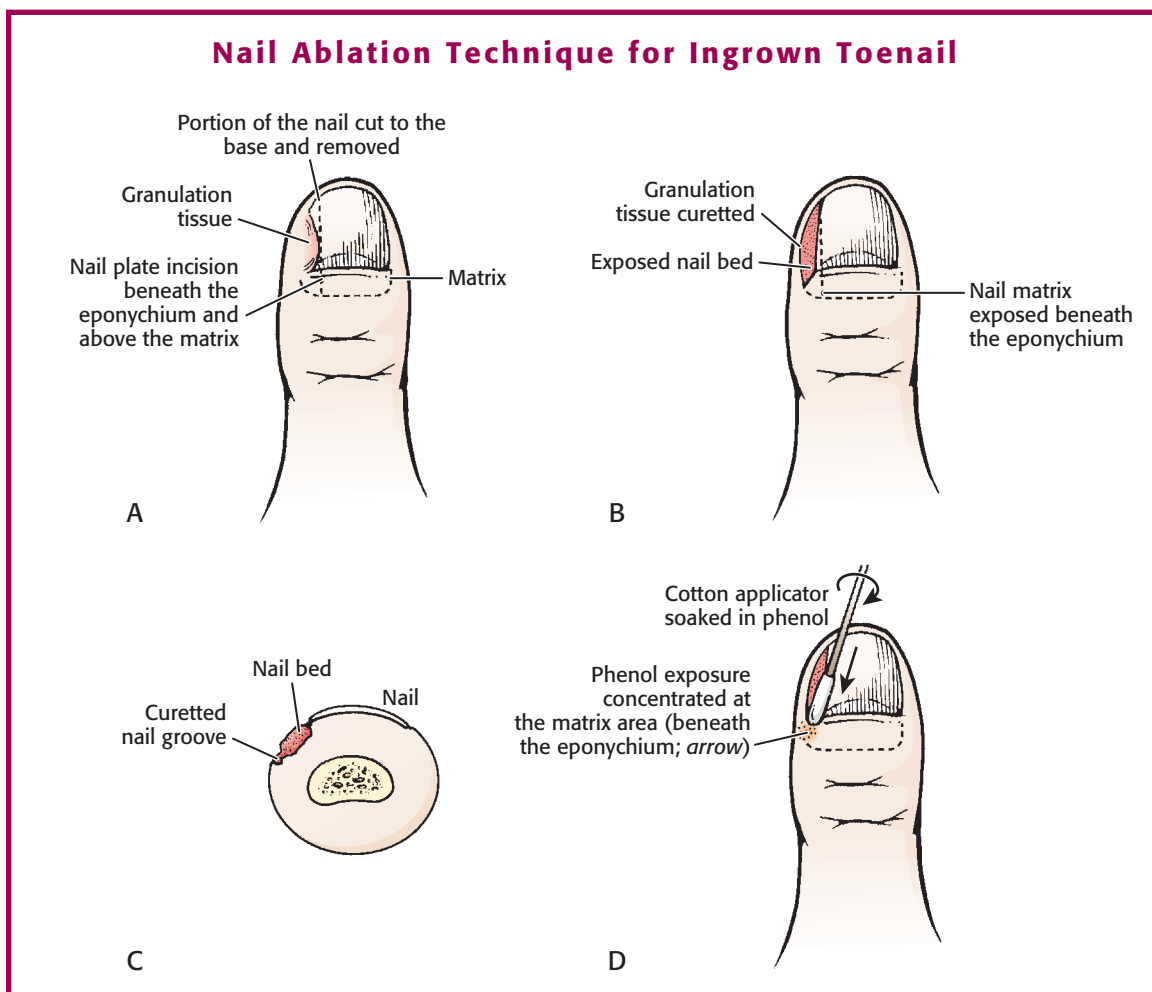

Figure 51.24 Nail ablation technique for the treatment of an ingrown toenail. The lateral portion of the nail is cut and removed (A) to expose the nail bed. Granulation tissue is curetted (B and C), and the nail matrix is cauterized with hydrogen peroxide or phenol (D) (see text).

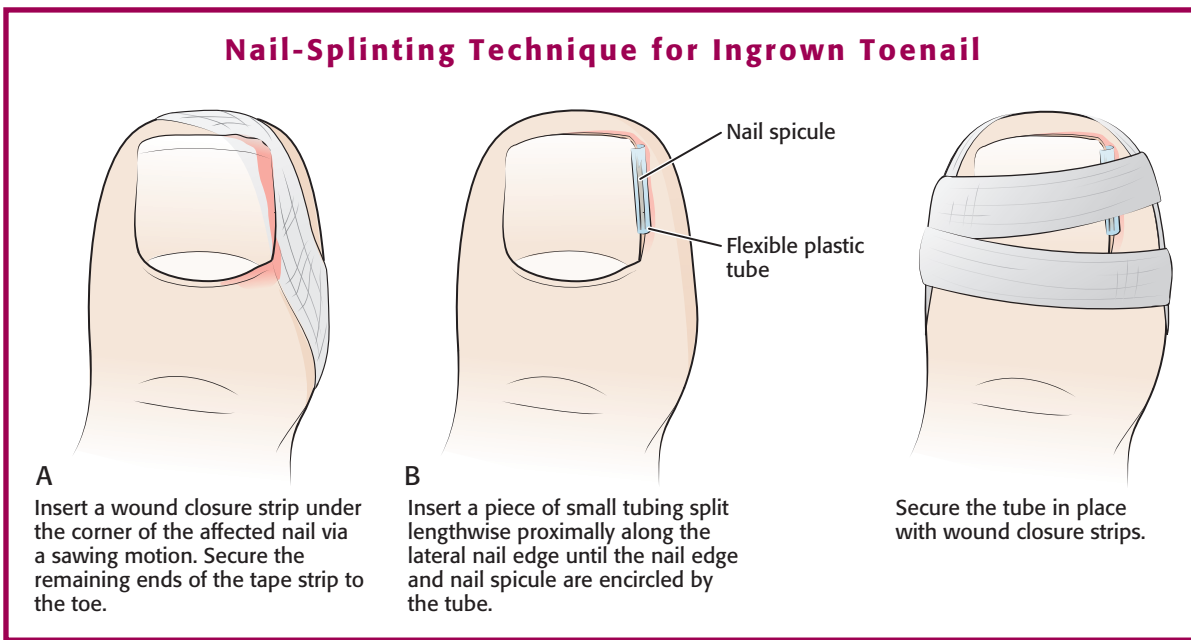

Figure 51.25 Splinting techniques for ingrown toenails.

the solution beneath the proximal nail fold and lateral nail groove. Apply thoroughly moistened (but not saturated) applicators for three 30-second applications. Avoid forcing phenol under the remaining nail by rolling the applicator so that it rolls over the matrix and over the nail surface rather than against the split edge of the nail. Although it is necessary to cover the lateral aspect of the nail bed and lateral nail fold, do not allow excess phenol to contact the exposed nail bed or surrounding healthy tissue. After the third application, the cauterized tissue appears brown-tinged or gray. Alternatively, a 1% phenol solution can be applied for 5 minutes. Thoroughly irrigate the cauterized nail bed with water and rub the area with a gloved finger to remove all traces of phenol. Snip away any remaining debris or dead skin with scissors.

Apply antibiotic ointment (not containing neomycin) and a nonadherent dressing to the wound, followed by a dry sterile wrap. Do not forget to remove the tourniquet after the dressing has been applied. Instruct the patient to wash the wound twice daily followed by dry dressing changes. Systemic antibiotics do not hasten wound healing and are not necessary in most cases.^{33,34} Soaking the open wound in warm water twice a day is soothing and allows the patient to view the healing process. The wound will heal in 2 to 4 weeks and may be accompanied by serous drainage for 2 weeks. The patient should be informed of this possibility. Complications include nail regrowth, infection, growth of an inclusion cyst, or delayed healing. If the condition returns, podiatric referral is recommended for more extensive ablation of the nail bed.

Nail-Splinting Technique

Splinting of the nail spicule at the lateral edge of the affected nail may allow the toenail to grow out without affecting the inflamed soft tissue. This technique provides time for the periungual tissue to heal while the nail continues to grow until it can be trimmed straight across. No portion of the nail is removed when the nail is initially splinted. When the degree

of inflammation is minimal, elevation of the nail spicule is easily accomplished with forceps or a hemostat. A cotton pledget inserted under the lateral edge to maintain elevation is often sufficient in minor cases. Alternatively, a wound closure strip can be used to elevate the corner of the offending nail.³⁹ After cleansing the edge of the nail and providing drainage if an abscess is present, insert a wound closure strip obliquely under the corner of the nail with a to-and-fro sawing motion until the corner is sufficiently elevated. Secure the tape closure around the toe (Fig. 51.25A). Instruct the patient to soak the toe in warm water daily, remove the tape closure, and reinsert a new tape strip. This procedure is repeated until the corner of the nail or the nail spicule has grown out and cleared the periungual soft tissue, at which time it can be cut straight across. When the degree of inflammation is moderate, nail splinting is accomplished by using the flexible tube procedure.^{40,41} Obtain a surgical drain (2 to 3 mm in diameter) used to perform percutaneous drainage procedures, or the small tubing in venipuncture kits. Split a 1-cm piece of the drainage tube lengthwise. Perform a digital block and elevate the lateral edge of the nail with forceps or a hemostat. Insert the split drainage tube along the lateral edge of the nail so that it completely encircles the nail spicule and push it proximally until as much of the lateral nail and nail spicule as possible are covered (see Fig. 51.25B). Some authors suggest that the tube be secured with 2-0 suture passed through the nail,⁴⁰ but securing the tube with wound closure strips is more easily accomplished (see Fig. 51.25B).⁴¹ Instruct the patient to wash the affected area daily and replace loosened tape strips when needed. When the inflammation and granulation tissue have subsided and the nail spicule has grown sufficiently to not impinge on the periungual soft tissue, the tube splint is removed by the patient and the nail is cut straight across.

Treatment of Bursitis, Tendinitis, and Trigger Points

Neeraj Gupta

Bursitis and tendinitis are terms frequently used to describe a variety of common and often ill-defined regional musculoskeletal conditions characterized chiefly by pain and disability at the involved site. They are either periarticular or contained within specific soft tissue structures. Myofascial pain syndromes are characterized by sensory, motor, and autonomic symptoms that are associated with a trigger point, a hyperirritable point in skeletal muscle that reproduces the patient's symptoms. These musculoskeletal conditions largely rely on a clinical diagnosis in that they often cannot be confirmed by objective data such as radiographs or laboratory studies. Use of injection therapy with local anesthetics and corticosteroids for bursitis and tendinitis can relieve pain, reduce inflammation, and improve mobility. Injection therapy may provide definitive treatment of a condition or serve as an adjunct to facilitate rehabilitation therapy. Several invasive and noninvasive techniques can be used for the treatment of trigger points and myofascial pain syndromes. Successful treatment of any these musculoskeletal conditions depends highly on an accurate diagnosis and the use of appropriate techniques.

GENERAL ANATOMIC CONSIDERATIONS

Bursae and Tendon Sheaths

Bursae are small fluid-filled sacs, subcutaneous and deep, which provide a cushion for bone and the surrounding soft tissue. They develop in relation to friction and facilitate the gliding motion of tendons and muscles. There are approximately 78 bursae on each side of the body as described by Monro and Spalteholz.^{1,2} Adventitious bursae may form in response to abnormal shearing stress at sites subjected to chronic pressure, such as a bunion over the metatarsal head of the great toe. Tendon sheaths are similar in composition to bursae but differ in overall shape. Tendon sheaths are long and tubular, whereas bursae are usually round and flat.

Inflammation of bursae, as in bursitis, can be seen microscopically as a thickening of the normal thin surface of synovial cells lining the bursal wall.³ This thickening coupled with increased production of synovial fluid leads to localized pain and swelling. Aside from simple overuse, bursitis may be caused by local trauma, infection, and crystal deposition. Underlying systemic and autoimmune disorders, such as lupus, rheumatoid arthritis, ankylosing spondylitis, psoriatic arthropathy, and gout, can also lead to bursitis.

Because of the adjacent location of bursae and tendons, an inflammatory process in one may also involve the other.⁴ *Tendinitis* and *tenosynovitis* are used to describe similar inflammatory reactions in tendons and tendon sheaths, respectively.

Some forms of tendinitis may be caused by factors other than overuse, inflammation, trauma, and degenerative disease. Gonococcemia, for example, is one cause of tenosynovitis that should be considered in the appropriate setting.⁵ Another rare cause is hemodialysis.⁶ In 2008 the U.S. Food and Drug Administration (FDA) added a black box warning to fluoroquinolone antibiotics, highlighting the potential for tendinopathy and tendon rupture. Clinicians should avoid tendon sheath injections in patients who are taking this class of drugs.⁷

Common sites of tendinitis and bursitis in the body are depicted in Fig. 52.1.

Trigger Points

Myofascial pain related to trigger points is probably omnipresent, but it is vague and ill-defined in the literature, the specific syndromes are unknown to many clinicians, and the disorders are difficult to clarify in many patients. Hence, myofascial pain originating from trigger points is often attributed to a plethora of other conditions. Consequently, the true incidence is unknown, and few clinicians practice trigger point injection therapy. Examples of misdiagnosis can include fibromyalgia, overuse syndromes, statin-induced myopathy, and malingering.

Trigger points are focal areas of hyperirritability usually found within a taut band of skeletal muscle or in the muscle fascia that are painful on compression and associated with a characteristic pattern of referred pain, motor dysfunction, and autonomic phenomena (Box 52.1).⁸ Trigger points can also be identified by the *local twitch response*, a brisk contraction of muscle fibers elicited by snapping palpation or rapid insertion of a needle into the trigger point itself.⁹

Trigger points probably develop in response to muscle fiber injury. The injury may be an acute traumatic event or more subtle repetitive microtrauma. The underlying pathophysiology has not been fully elucidated but probably involves chronic muscle stress, excessive release of acetylcholine, and dysfunctional motor end plates.¹⁰

Trigger points can occur in any muscle or muscle group; they are generally unilateral, but bilateral trigger points have been reported. As the stress associated with myofascial pain commonly affects both single muscles and whole muscle groups, trigger points tend to cluster. In the upper part of the trunk, a common trigger point cluster involves the muscles of the neck and shoulder area, including the trapezius, levator scapulae, and infraspinatus muscles (Fig. 52.2). In the lower part of the trunk, the quadratus lumborum, gluteus medius, and tensor fasciae latae are commonly affected. Trigger points often affect other muscles innervated by the same spinal segments, and subsequent treatment is usually directed at all muscles innervated by both the anterior and posterior branch of the same spinal nerve. Table 52.1 lists common trigger points and their associated myofascial pain syndromes.

RATIONALE FOR INJECTION THERAPY

Bursitis and Tendinopathies

Management of the pain resulting from bursitis and tendinitis may be greatly enhanced by the proper selection and administration of local injections. Successful application of local injection and intrasynovial (bursa and tendon sheath) therapy requires an understanding of the diagnosis, accurate localization of the

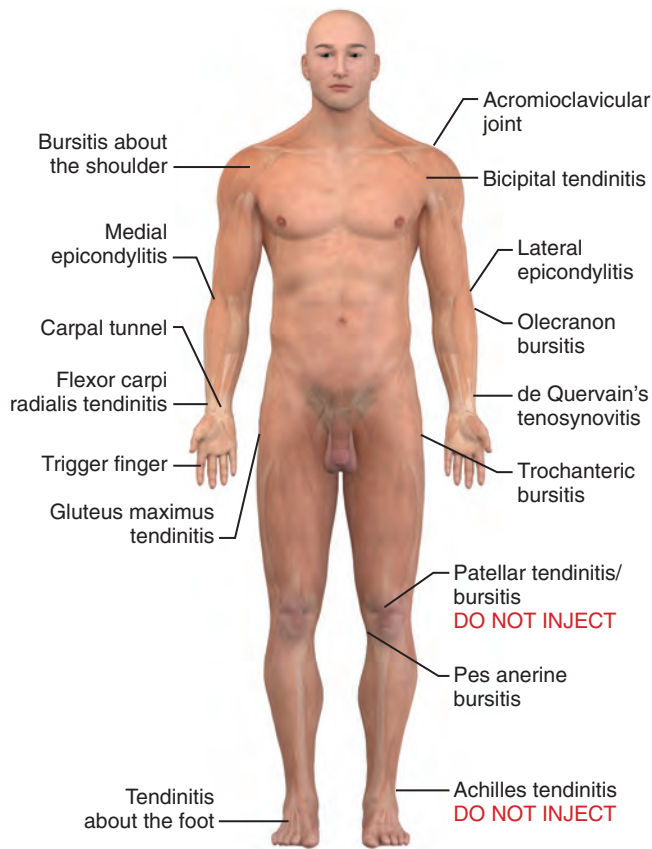

Figure 52.1 Common sites of tendinitis and bursitis. (Redrawn from Walker LG, Meals RM: Tendinitis: a practical approach to diagnosis and management, *J Musculoskel Med* 6:24, 1989.)

BOX 52.1 Clinical Characteristics of Myofascial Pain Syndromes

- Characteristic distribution pattern of the pain
- Restricted range of motion with increased sensitivity to stretching
- Weakened muscle because of pain with no muscular atrophy
- Compression causing pain similar to the patient's chief complaint
- A palpable taut band of muscle correlating with the patient's trigger point
- Local twitch response elicited by snapping palpation or rapid insertion of a needle
- Reproduction of the referred pain with mechanical stimulation of the trigger point
- Associated autonomic phenomena

pathologic condition, and appropriate injection techniques. Lidocaine and corticosteroid preparations may be injected separately or together as adjuncts for pain control. The goal of corticosteroid injection therapy is relief of pain so that the patient is able to regain function and participate in a physical rehabilitation program.⁵ In many cases a single injection may be all that is required to ameliorate a painful condition. However, injection therapy is best viewed as an adjunct in the management of painful tendinitis and bursitis syndromes. It

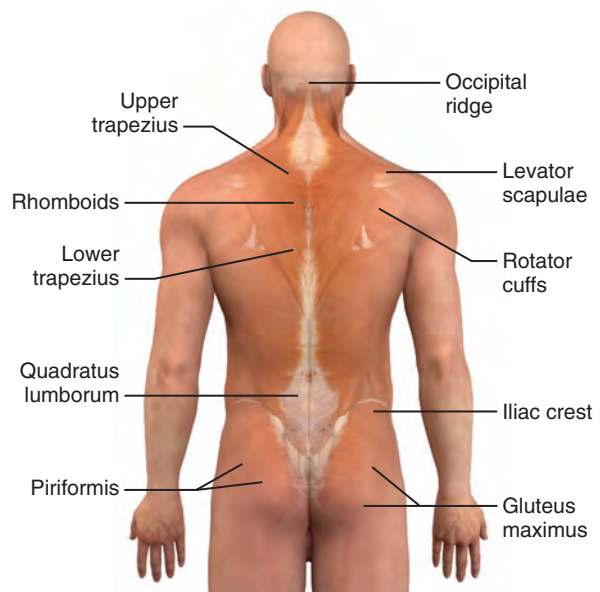

Figure 52.2 Common trigger point clusters on the back. In the upper part of the trunk, a common trigger point cluster involves the muscles of the neck and shoulder area including the trapezius, levator scapulae, and infraspinatus muscles. The quadratus lumborum, gluteus medius, and tensor fasciae latae are commonly affected lower trunk muscles.

should not be viewed as a single quick fix, but a method to facilitate other modalities.

The precise mechanisms for the lasting analgesia and beneficial therapeutic effects of local injection therapy have not been clarified. Few clinical trials have adequately measured the efficacy of corticosteroid therapy. Although steroids are known to reduce inflammation, it is unclear whether the antiinflammatory effect is responsible for the increased range of motion and relief of pain that the patient usually experiences. Histologic studies of chronic tenosynovitis lesions demonstrate degeneration, but not inflammation.⁵ It is therefore possible that the pain experienced with tendinitis and bursitis occurs as a result of mechanisms other than inflammation, such as mechanoreceptor stimulation by shearing, traction, or activation of nociceptive receptors by substance P and chondroitin sulfate.⁵

Though often performed in the emergency department (ED) and ubiquitous therapy by orthopedic surgeons, rheumatologists, and family practitioners, injection therapy may not be definitive care. Hence, follow-up and additional evaluations and interventions should be considered. In short, injection therapy should be considered an adjunct to a variety of treatment modalities including pain control, physical therapy, occupational therapy, relative rest, immobilization, and exercise. Additional pain control can be achieved with such options as nonsteroidal antiinflammatory drugs (NSAIDs), acupuncture, ultrasound, ice, heat, and electrical nerve stimulation.^{5,11,12} Besides pain relief, early participation in rehabilitative activities and exercises can be an important aspect of patient recovery. Patients receiving only analgesics may have worse outcomes than those who also incorporate exercise as part of their treatment.⁴ Any factors that provoke the initial injury should also be identified because failure to eliminate these provoking factors can contribute to the injury developing into a chronic condition.⁵

Although opinions in the literature differ, we recommend that corticosteroid injections not be repeated in the same site

TABLE 52.1 Myofascial Pain Syndromes

MUSCLE*	TRIGGER POINT LOCATION	AREA OF PAIN	COMMENTS
Levator scapulae	Superior medial aspect of the scapula along the flat muscle belly; insertion sites on the transverse processes of C1-C4	Posterior cervical region, posterior aspect of the scalp, periauricular area	May cause or contribute to headache syndromes in some patients
Splenius capitis and semispinalis capitis	May occur in any part of these muscles	Over the muscles themselves, head, face	Having the patient point to the area of maximal pain may help localize the trigger point or points; may also cause dizziness
Trapezius	Angle of the neck, occipital insertion sites	Trapezius muscle itself, occiput	Inject neck trigger points carefully to avoid iatrogenic pneumothorax
Sternocleidomastoid	Sternal and clavicular origins, occipital insertion site, upper two thirds of the muscle belly	Sternocleidomastoid muscle itself, periauricular area, frontal area, face	May also cause dizziness, ipsilateral ptosis, lacrimation, and conjunctival injection
Infraspinatus	Anywhere in the infraspinatus muscle	Arm, posterior and lateral aspects of the shoulder	May cause sympathetic hyperactivity; subject to early degeneration
Rectus abdominis	Most common in the upper 3 segments, less often in the lower muscle segments	Anterior abdominal wall (upper segment), back (lower segments)	Often flare after abdominal surgery
Pectoralis major and minor	Most common at the insertion site on the anterior medial aspect of the shoulder and in the inferior muscle belly, but may be found anywhere in the muscle	Over the trigger point, upper most part of the muscle, ipsilateral arm	Because trigger points may be found anywhere in the muscle, it is important to search the entire muscle
Intercostals	Intercostal spaces	Chest (increased during inspiration)	Often flare after chest surgery or trauma; inject carefully to avoid iatrogenic pneumothorax
Tensor fasciae latae	Muscle belly	Lateral thigh pain to the knee	Tensor fasciae latae trigger points are generally easy to locate
Anterior tibialis	Upper third of muscle	Anterior aspect of the foreleg and ankle, dorsal surface of the ankle	
Gastrocnemius and soleus	Medial and lateral muscle margins, along the midline of the muscle	Posterior of the knee, Achilles tendon near the heel	Often flare with vascular insufficiency of the lower extremities
Quadratus lumborum	Along the 12th rib, around the iliac crest, lateral border of the muscle	Area of the 12th rib (especially during deep inspiration), anterior abdominal wall	May accentuate postoperative pain or pain associated with abdominal wall scars
Gluteus medius	Along the iliac shelf; in severe cases, the entire gluteal ridge may be involved (including the gluteus minimus and maximus from the sacroiliac joint to the anterior superior iliac spine)	Most often cause hip, leg, and lower back pain; may cause remote pain in the cervical region and head	Often associated with sympathetic hyperactivity; common in late-stage pregnancy and in patients with unequal leg lengths

*See also Fig. 52.30 for diagrams of trigger points for specific muscles.

unless at least a partial clinical response has occurred. In addition, an injection should not be repeated in the same site more than once every 3 months.^{5,11–14} Some limit corticosteroid injections at any given site to two or three injections before alternative therapy is pursued. Despite few data on the outcome of repeated injections, these recommendations are generally accepted and may limit the risk for adverse effects.

Though universally practiced and generally considered safe and effective for short-term therapy, there are sparse scientific data defining a true benefit of corticosteroid injections for musculotendinous conditions. Inflammation is not always the cause of tendinopathy. Although true inflammatory tendinitis may respond quite well to corticosteroid injections, conditions such as posttraumatic shoulder impingement and rotator cuff tears may not benefit from local injection any more than from treatment consisting of rest, time, physical therapy, and NSAIDs.^{13,14} Despite appearing to initially be effective for conditions such as olecranon bursitis, lateral epicondylitis, and de Quervain's tenosynovitis, long-term relief of other conditions is often superior with other modalities. In addition, oral corticosteroids can be as effective as local injection and can be an alternative for emergency clinicians reluctant to perform an injection.

Trigger Points

Injection therapy is the most widely accepted and scientifically supported modality for treating trigger point pain.¹⁵ However, because it may place patients at risk for becoming dependent on injection for pain relief, some authors reserve injection therapy for patients who have failed other measures (Box 52.2).¹⁶

Various substances have been used for trigger point injections, including local anesthetics, botulinum toxin, sterile water, and sterile saline.¹⁶ Dry needling, a technique that involves multiple advances of a needle into the muscle at the region of the trigger point, provides as much pain relief as an injection of lidocaine.¹⁷ In fact, in a 2001 systematic review on needling therapies for trigger points, Cummings and White¹⁸ concluded that, based on current medical evidence, "the nature of the injected substance makes no difference to the outcome and wet needling is not therapeutically superior to dry needling." In support of these findings, it has been proposed that the needle (not the injected substance) reduces trigger point pain by mechanically disrupting dysfunctional activity at the motor

BOX 52.2 Modalities for Treating Trigger Point Pain

end plate.¹⁶ Nevertheless, the addition of a local anesthetic is recommended to reduce the degree of postinjection soreness.¹⁷

The use of steroids for trigger point injection is controversial and without a clear rationale because there is little evidence to support an inflammatory pathophysiology for trigger point pain.¹⁶ Hence, the use of steroids for trigger point injection is not recommended.

INDICATIONS AND CONTRAINDICATIONS

Bursae and Tendon Sheaths

The indications for steroid injection are twofold: therapy and diagnosis. Injection therapy offers not only relief of pain, particularly when a local anesthetic is used concurrently, but also a medium to deliver therapeutic agents. In addition to relieving pain, injection therapy may aid in diagnosis. When injecting a bursa, for example, bursal fluid is sometimes collected for laboratory analysis. In addition, relief of pain helps differentiate a localized site of injury from referred or visceral pain.¹²

Absolute contraindications to local injection therapy are limited and include specific infections such as bacteremia, infectious arthritis, periarticular cellulitis or ulceration, and adjacent osteomyelitis (Box 52.3). The procedure is also contraindicated in patients with bleeding disorders. A history of hypersensitivity, either to the corticosteroid or to the vehicle by which it is delivered, is an absolute contraindication. Finally, corticosteroid injections should not be performed in a patient who has a documented osteochondral fracture. Relative contraindications depend on both the clinician's experience and the indication for the injection. Violation of the integrity of the skin or chronic foci of infection, either locally or in the vicinity of the site of involvement, is a relative contraindication. The procedure is also relatively contraindicated in patients taking anticoagulants, in patients with poorly controlled diabetes, and in those with internal joint derangements or

BOX 52.3 Contraindications to Local Injection Therapy

ABSOLUTE

Infection (bacteremia, infectious arthritis, periarticular cellulitis or ulceration, adjacent osteomyelitis)
 Uncontrolled bleeding disorder
 Hypersensitivity/allergy to corticosteroid or vehicle
 Osteochondral fracture

RELATIVE

Anticoagulant therapy
 Joint instability
 Poorly controlled diabetes (steroids raise blood glucose levels)
 Hemarthrosis
 Decubitus ulcers
 Joint prosthesis
 Adjacent abraded skin
 Chronic foci of infection
 Internal joint derangement
 Partial tendon rupture

hemarthrosis. Patients with a preexisting tendon injury may be subject to tendon rupture if the corticosteroid injection relieves the pain and full activity is then resumed. Therefore partial tendon rupture is a relative contraindication.

Trigger Points

Consider trigger point injection once a myofascial pain syndrome has been identified (see [Box 52.1](#) and [Table 52.1](#)). As mentioned previously, some authors reserve injection for patients who fail noninvasive modalities (see [Box 52.2](#)). There are few contraindications to trigger point injection. Overlying infection is an absolute contraindication. Relative contraindications include proximity to sensitive structures, bleeding disorders, anticoagulation, an uncooperative patient, and lack of clinician experience. Dry needling is as effective as injection therapy, so in those with allergy to local anesthetics, the clinician may perform dry needling to avoid the problem.

HAZARDS AND COMPLICATIONS

All injection therapies can be expected to cause local effects such as pain at the site, bruising, and hematoma formation. These can be ameliorated with proper technique. Local anesthetics should be mixed with a corticosteroid preparation to increase volume, decrease postinjection pain, and assess the accuracy of bursae and tendon sheath injections. However, some clinicians prefer to inject local anesthetics alone before injecting the corticosteroid. Subcutaneous bleeding may occur occasionally at the site of injection if a venule, an arteriole, or a capillary is penetrated. Warn patients that this may occur and reassure them that the discoloration or hematoma will disappear spontaneously. Advise patients to apply ice packs or cold compresses to the involved area for the first 24 hours. Be aware of the local anatomy and aspirate after injecting every 1 to 2 mL of solution to help prevent inadvertent vascular injection. Penetration into or striking a nerve may cause sharp pain or paresthesia, and the patient should be warned of this possibility in advance.

Anesthetic Injections. Injection of a local anesthetic causes discomfort secondary to tissue irritation related to its acidity and from tissue distension caused by infiltration. Mixing the anesthetic solution with sodium bicarbonate 8.4% (9 mL of anesthetic to 1 mL of sodium bicarbonate) can reduce this pain by creating a more physiologic pH. Warming and slowly injecting the anesthetic may also be helpful.^{19,20} Other minor reactions occasionally seen after injection of amide preparations include light-headedness or dizziness, pallor, weakness, sweating, nausea, fainting (rare), and tachycardia. These symptoms usually disappear within a few minutes after the injection and rarely require any treatment except reassurance and application of a cold compress to the patient's forehead. Frequently, it is difficult to determine whether the symptoms are the result of sensitivity to the drug or a fright (vasovagal) reaction to needles and injections. Always place the patient in a supine, prone, or reclining position during the injection to minimize the effect of a potential vasovagal reaction.

The major hazards with injection of local anesthetics are hypersensitivity reactions and accidental intravenous or intraarterial injection (see [Chapter 29](#)). Serious or fatal hypersensitivity to procaine and other regional anesthetic agents is

encountered very rarely. This possibility is usually suggested by a previous history of reactions to these compounds. Ester solutions (e.g., procaine, tetracaine) that produce the metabolite para-aminobenzoic acid (PABA) account for the majority of these reactions. Amide solutions (e.g., lidocaine, bupivacaine) are rarely involved, and usually the preservative methylparaben, which is structurally similar to PABA, is responsible. When a definite history of sensitivity is present, use of any agent from that class of anesthetic agents is absolutely contraindicated.

Corticosteroid Injections. Corticosteroid injections have been found to be safe procedures with few complications ([Box 52.4](#)).²¹ Although there is evidence of allergic reactions from corticosteroids given orally and parentally, the possibility of an allergic reaction caused by corticosteroid injection is highly unlikely, and such cases occur infrequently.²² Nevertheless, the clinician should be aware that anaphylaxis after injection of methylprednisolone acetate has been reported.²³ In addition, an unusual rash after an intraarticular methylprednisolone injection, which appears to be consistent with a delayed type of hypersensitivity, has also been documented.²⁴ Introducing infection is one of the most serious potential complications, but infections occurring as an aftermath of intrasynovial injections are extremely rare. In a study at the Mayo Clinic involving 3000 injections given in 1 year, no infections were reported.²⁴ Others have found the risk for infection to be 4.6 per 100,000 intraarticular injections.²⁵ Although the problem of infection is usually avoided with meticulous attention to aseptic technique, caution the patient to watch for the development of any significant pain, redness, or swelling after local injections. We do not recommend routine prophylactic antibiotic administration after corticosteroid injections.

BOX 52.4 Potential Side Effects of Corticosteroid and Local Anesthetic

INJECTION THERAPY

Systemic Side Effects

- Cushing's syndrome
- Facial flushing
- Nausea
- Impaired diabetic control
- Menstrual irregularity/uterine bleeding
- Hypothalamic-pituitary axis suppression
- Fall in the erythrocyte sedimentation rate and C-reactive protein level
- Anaphylaxis
- Dysphoria
- Pancreatitis
- Cataracts

Local Side Effects

- Postinjection flare of pain
- Skin depigmentation, fat atrophy
- Bleeding, bruising
- Steroid "chalk" calcification
- Steroid arthropathy
- Nerve injury
- Tendon rupture and atrophy
- Joint and soft tissue infection

Local undesirable reactions are usually minor and reversible. After steroid injection, approximately 2% of patients may experience an acute synovitis otherwise known as *postinjection flare*.^{10,16} This may be slightly more common with methylprednisolone acetate (Depo-Medrol, Pfizer Inc., New York, NY) and less common with triamcinolone acetonide (Kenalog, Bristol-Myers Squibb Company, Princeton, NJ). Characterized by an increase in pain and joint swelling, symptoms usually begin a few hours after steroid injection and can last as long as 3 days. These reactions can be stressful to the patient who has expected relief, rather than exacerbation, from an injection. These reactions may be quite symptomatic but should not be misinterpreted as faulty technique or an infection secondary to the injection. Histologically, steroid crystals have been seen within polymorphonuclear leukocytes, making it a true synovitis.^{13,22} This reaction may be difficult to differentiate from an infection, and infection must be ruled out if the symptoms last longer than 48 hours or are associated with fever, warmth, or other suspicious signs. Postinjection flare appears to be more likely to develop with the more soluble (shorter-acting) steroid solutions and may be related to the carrier in which the steroid is manufactured.^{13,24} Limiting activity of the involved area for 2 days after the injection might help reduce the incidence of postinjection flare.²² When it does occur, the reaction is usually mild and can be controlled adequately with the application of ice or cold compresses and analgesics as needed.

Rarely, *afterpains* may occur and last for several hours after an injection. Although the cause is obscure, this phenomenon may result from the trauma of needle insertion, penetration of inflamed tissue, or pressure on adjacent nerves from local swelling or bleeding. Afterpains can usually be relieved by the application of moist or dry heat and analgesics until the pain abates, but it is best prevented by mixing a long-acting anesthetic, such as bupivacaine, with the steroid preparation.

Another relatively minor complication is localized subcutaneous or cutaneous atrophy at the site of the injection.¹³ This problem is chiefly of cosmetic concern and is recognized as a small depression in the skin frequently associated with depigmentation, transparency, and the occasional formation of telangiectases. These changes in the skin occur when injections are made near the surface and some of the injected steroid leaks back along the needle track. The skin depression usually recedes and the skin returns to normal when the crystals of the steroid have been completely absorbed. These changes are usually evident 6 weeks to 3 months after the initial injection and generally resolve within 6 months, although they can be permanent.^{11,13} In the *two-syringe technique* the anesthetic is injected first, the needle is advanced into the bursa/peritendon area, and the syringe is then exchanged for another to inject the steroid. This technique helps prevent injection site atrophy by avoiding any leakage of the steroid suspension close to the skin's surface.²⁶ Use a small amount of lidocaine or normal saline to flush the suspension from the needle before removing it. The *Z-tract technique* is a method of creating an indirect route from the skin puncture to the ultimate site of the steroid injection.²⁶ To perform this technique, insert the needle 0.5 to 1.0 cm from the actual target site. When the needle is halfway through the fat tissue, redirect it to the target site and inject both the anesthetic and the corticosteroid. Injection site atrophy is more likely to occur with preparations that are less soluble and thus longer acting.¹¹

Minor skin depigmentation, especially in dark-skinned individuals (e.g., African Americans), occurs in 1.3% to 4%

of patients undergoing local corticosteroid injections.²⁷ It usually occurs within a few months after the initial injection and resolves several months later.²⁸ Causes include leakage of the steroid preparation back along the needle track and poor injection technique. The exact etiology is unclear but may be secondary to reducing the number and activity of melanocytes.²⁸ This complication can be limited by applying pressure to the site during withdrawal of the needle. Hydrocortisone would be the preferable agent for superficial injections to minimize depigmentation.

One of the most serious complications after local steroid injection is tendon rupture. In general, the risk is very low (<1%) and appears to be related to the dose used.^{11,13} Some believe that injecting steroids directly into the tendon leads to a decrease in the tendon's tensile strength.^{13,22,29,30} Gray and Gottlieb,¹³ however, noted no cases of tendon rupture after more than 300 tendon sheath injections. We still advise that one be diligent and careful about injecting into the surrounding area of the tendon sheath and not into the tendon substance. Moreover, by using one size of needle and syringe, the operator is more likely to appreciate the increase in resistance when injecting directly into the tendon. We also suggest limiting the frequency of injections to no more than once every 3 months in the same site.^{5,11-13} Tendon rupture is more likely to occur in major stress-bearing tendons in athletes, such as the Achilles tendon and the patellar tendons. For this reason, injection of corticosteroids in these areas should be avoided in the ED.²³

There have been reports of accidental nerve injury after corticosteroid injection, particularly of the ulnar nerve (for treating medial epicondylitis) and the median nerve (for treating carpal tunnel syndrome).³¹ In addition, pericapsular calcifications develop in up to 42% of patients undergoing local steroid therapy, although they are generally asymptomatic.^{13,26} Finally, within minutes to hours after injection, approximately 1% of patients may experience facial and neck flushing. This reaction may last a few days, but it is usually a benign and self-limited reaction. Facial flushing seems to be more common with triamcinolone preparations.^{11,13,22}

Systemic absorption of local corticosteroid injections does occur, although at a slower rate than with oral steroids.¹² As a result patients are at low risk for systemic complications, but they do occur. Specifically, intrasynovial injections of steroids have been shown to suppress the hypothalamic-pituitary-adrenal axis for 2 to 7 days.¹¹ This complication is more likely to occur in patients who receive repeated injections in a short period or multiple injections in different sites at one time.²² Corticosteroids can also exacerbate hyperglycemia in diabetics.^{12,26} Abnormal uterine bleeding has also been reported.^{11,12,23}

Other potential complications of corticosteroid and local anesthetic injections are outlined in [Box 52.4](#).

CORTICOSTEROID PREPARATIONS

Commonly used corticosteroid repository preparations for the injection of bursae and tendon sheaths are described in [Table 52.2](#). Local anesthetics such as lidocaine or bupivacaine can be mixed with the corticosteroid preparation in the same syringe. All corticosteroid suspensions, with the exception of cortisone and prednisone, can produce a significant and rapid antiinflammatory effect (in the synovial spaces). Corticosteroids should not be used for trigger point injections.

TABLE 52.2 Injectable Corticosteroids

INTRASYNOVIAL PREPARATIONS	POTENCY ^a	RANGE OF USUAL DOSAGE (mg)	SOLUBILITY
Short Acting			
Hydrocortisone acetate	1	12.5–75	High
Cortisone	0.8	15–25	High
Intermediate Acting			
Prednisone	3.5	2.5–5	Medium
Prednisolone acetate	4	5–30	NA
Methylprednisolone acetate ^b	5	5–40	Medium
Long Acting^c			
Triamcinolone acetonide ^c	5	5–40	Low
Triamcinolone diacetate	5	4–40	Low
Triamcinolone hexacetonide	5	4–25	Low
Betamethasone acetate and disodium phosphate	25	1.5–6	Low
Dexamethasone acetate	25	0.8–6	Low

^aHydrocortisone equivalents (per milligram).

^bPreferred for emergency department use.

^cBest used for intraarticular injection.

Corticosteroid preparations are categorized by their solubility and relative potency. Solutions that are more soluble have a shorter duration of action, primarily because they are absorbed and dispersed more rapidly. The addition of tertiary butyl acetate to the solution causes decreased solubility and therefore a longer duration of action. For example, triamcinolone hexacetonide, the least soluble preparation has the longest duration of action.¹³ Because the long duration of action increases its potential for subcutaneous atrophy, some authors use this preparation only for intraarticular injections.^{12,13}

There is little consensus in the literature regarding which corticosteroid to use and what dosage is most appropriate for a given site.^{5,24,26} Centeno and Moore³² noted that the choice of injection agent is most dependent on the institution where the clinician trained. In 1995 a survey of 172 rheumatologists found that opinions differ regarding almost every facet of soft tissue and intraarticular injection, including patient preparation, choice of corticosteroid, and postinjection advice.³³ Some clinicians advocate mixing both shorter- and longer-acting corticosteroids in the same syringe with little consideration for the location or type of condition.^{12,13} We do not recommend using longer-acting corticosteroids for soft tissue injections, particularly because of the increased risk for associated atrophy,^{5,12} including atrophy of surrounding structures such as ligaments and fascia.³⁴ In general, use a short- or intermediate-

acting agent for an acute or subacute condition such as bursitis or tendinitis; reserve longer-acting agents such as triamcinolone for chronic and prolonged conditions, including arthritis.^{11,13} Triamcinolone acetonide and methylprednisolone acetate are reasonable first choices for most ED procedures.

DOSAGE AND ADMINISTRATION

Bursae and Tendon Sheaths

The dose of any corticosteroid suspension used for intrasynovial injection may be selected arbitrarily. Factors that influence the dosage and expected response include the size of the affected area, the presence or absence of synovial fluid or edema, the severity and extent of any synovitis, and the steroid preparation selected (Table 52.3; also see Table 52.2). Dosages may need to be reduced in the elderly.³⁵

A useful guideline for estimating dosage is as follows: for relatively large spaces such as the subacromial, olecranon, and trochanteric bursae, use 40 to 60 mg of methylprednisolone acetate or its equivalent. For medium- or intermediate-sized bursae and ganglia at the wrists, knees, and heels, use 10 to 20 mg. For tendon sheaths, such as flexor tenosynovitis of the digits and the abductor tendon of the thumb (de Quervain's disease), use 5 to 15 mg. Sometimes it may be necessary to give larger doses for an optimal response. Intrabursal treatment of the elbow (olecranon) or the knee (prepatellar) bursae, which contain a considerable amount of fluid, may require 30- to 40-mg doses.

Unlike intraarticular injections for synovitis in patients with chronic joint disease, repeated infiltration for soft tissue conditions such as bursitis and tendinitis is not generally recommended or required. However, if only a partial response occurs or if recurrence develops, a single injection can be repeated as long as one waits at least 12 weeks between injections.^{5,11–13,23}

Trigger Points

In contrast to injection of bursae and tendon sheaths, use small volumes of local anesthetic, botulinum toxin, sterile water, or sterile saline for trigger point injection.¹⁵ In most cases 1 to 2 mL of the chosen agent is sufficient.

PREPARATION OF THE SITE

Preparation of the site before injection requires meticulous adherence to aseptic technique. Anatomic landmarks may be outlined with a skin pencil. It is important that the injection site and needle tip remain sterile with use of the no-touch technique, although sterile drapes are not generally considered necessary.^{5,21} For operator protection, universal precautions should be followed.¹²

TECHNIQUES

General Considerations

Before beginning the injection inform the patient of the specific indication or indications for treatment. Describe the procedure, including the risks and complications, and obtain informed

TABLE 52.3 A Guide for Needle Size and Dosage for Injection of Common Regional Disorders

DISORDER OR INJECTION SITE	NEEDLE SIZE	USUAL DOSAGE OF METHYLPREDNISOLONE ACETATE (mg) ^a
Bicipital tendinitis	1.5–2 inches, 22–25 gauge	20–40
Calcaneous tendinitis Subacromial bursitis	1.5–2 inches, 22–25 gauge	20–60
Radiohumeral bursitis Epicondylitis	1.5 inches, 22–25 gauge	20–40
Olecranon bursitis	1–1.5 inches, 20 gauge ^b	15–30
Ganglia on the wrist	1 inch, 22–25 gauge	10–15
de Quervain's disease	$\frac{7}{8}$ inch, 22–25 gauge	10–20
Carpal tunnel syndrome	1–1.5 inches, 22–25 gauge	20–40
Digital flexor tenosynovitis	$\frac{7}{8}$ inch, 22–25 gauge	5–10
Trochanteric bursitis	1.5–2 inches, 22–25 gauge	20–40
Prepatellar bursitis	1–1.5 inches, 22–25 gauge	15–20
Anserine bursitis	1–1.5 inches, 22–25 gauge	20–40
Bunion bursitis	1 inch, 22–25 gauge	5–10
Calcaneal bursitis	1 inch, 22–25 gauge	10–20
Superficial trigger point	1.5 inch, 22 gauge	N/A
Deep trigger point	2.0–2.5 inch, 21 gauge	N/A

^aEmpirical dose. A larger or smaller dose may be used, depending on the clinical scenario.

^bAllows bursa aspiration and steroid injection without removing the needle.

N/A, Not applicable.

consent. Subsequently, document the details of the procedure in the medical record. A written consent form is not standard and its use is best based on institutional or departmental policy.

The material required for local injection procedures includes antiseptic solution, needles, syringes, a hemostat, culture and laboratory tubes, bandages, and sterile gauze (Fig. 52.3). Special trays may be stocked for this purpose. The usual sizes of needles for injection sites and corticosteroid doses are listed in Table 52.3.

Bursae and Tendon Sheaths

Local skin anesthesia is an option before injection but not universally practiced. For bursae and tendon sheaths, local anesthetics can be injected alone or with corticosteroids mixed together in the same syringe. Use the Z-tract technique to limit the risk for a fistulous tract in the soft tissue. Because the steroid may theoretically precipitate or layer in the barrel of the syringe during the injection, agitate the syringe immediately before using it to optimize its distribution. In addition to minimizing the pain associated with the injection, mixing an anesthetic with the corticosteroid also produces a larger volume for delivery.⁵

The duration of action of lidocaine is approximately 1 hour, whereas bupivacaine may last 6 to 8 hours. Caution the patient that the local anesthetic effect may wear off within a couple of hours and that the beneficial effects of the corticosteroid may be delayed.

Figure 52.3 Typical equipment required for injection therapy. Needle sizes and choice of corticosteroid and anesthetic can vary. Typical corticosteroid doses are listed in Table 52.3.

The optimum technique for joint and soft tissue injections has not been firmly established. However, one important aspect of a successful technique is accurate positioning of the needle. Injecting an inflamed synovial space, such as a bursa containing fluid, may be as simple as puncturing a balloon. Aspiration of fluid confirms that the needle has correctly entered the sac. Conversely, direct injection into a painful soft tissue lesion

requires additional skill that can be acquired only with experience. Sometimes it is advisable to reaspirate and reinject several times within the barrel of the syringe, a procedure called *barbotage*, to obtain heterogeneous mixing and maximal dispersion of the steroid throughout the synovial cavity. Although it is desirable to inject the solution directly into the bursa, direct injection into the tendon itself is best avoided. If the injection requires the application of significant pressure, the needle may be in the tendon and should be withdrawn or advanced a few millimeters. The patient may commonly feel some myofascial radiating pain during the injection, but true paresthesia should not be elicited. Electric shocks felt with an injection may signal that the needle is in a nerve and should be repositioned.

Although an accurate injection is desirable, using a generous volume of anesthetic (3 to 6 mL) to dilute and hence disperse the steroid can compensate for less than perfect injections. Asking the patient to use one finger to localize the area of maximum pain and tenderness is the best way to ensure the most accurate positioning of the needle. In general, if the patient cannot localize a specific area of tenderness, the diagnosis should be reconsidered or the expectations of success lowered. Diffuse pain, such as throughout the entire shoulder or knee, is probably not tendinitis or bursitis and is not likely to be relieved with a local injection.

Trigger Points

Successful treatment of a myofascial pain syndrome requires accurate diagnosis (see [Box 52.1](#) and [Table 52.1](#)) and precise identification of the trigger point (a taut band of muscle fibers). There are three generally accepted methods for identification of trigger points: flat palpation, pincer palpation, and deep palpation.¹⁵

To perform flat palpation, slide a fingertip across the muscle fibers of the affected muscle group, and at the same time use the opposite hand to retract the skin to either side until the taut band is identified ([Fig. 52.4, 1–3](#)). Snap the band like a violin string to precisely identify the trigger point. Pincer palpation involves firmly grasping and rolling the muscle fibers between the thumb and forefinger until the taut band is found (see [Fig. 52.4, 4–6](#)). Use deep palpation when the taut band is obscured by superficial tissue. Place a fingertip over the muscle attachment of the area suspected of housing the trigger point and apply pressure in different directions. Reproduction of the patient's symptoms identifies the trigger point. It may be helpful to mark the trigger point with a skin marker for easy identification before treatment.

Once the trigger point has been found, therapy can be divided into invasive and noninvasive techniques (see [Box 52.2](#)). Noninvasive techniques used in the ED include spray and stretch, massage therapy, and ischemic compression therapy.¹⁵ Physical therapy, transcutaneous electrical stimulation, and ultrasound treatments are adjuncts that may be arranged by the patient's primary care physician. Invasive techniques involve injecting the trigger point with a local anesthetic, botulinum toxin, or dry needling.

Noninvasive Techniques

Spray and Stretch

The technique of spray and stretch was once advocated by some as the single most effective treatment of trigger point pain.⁸ Place the patient in a comfortable position; ensure that

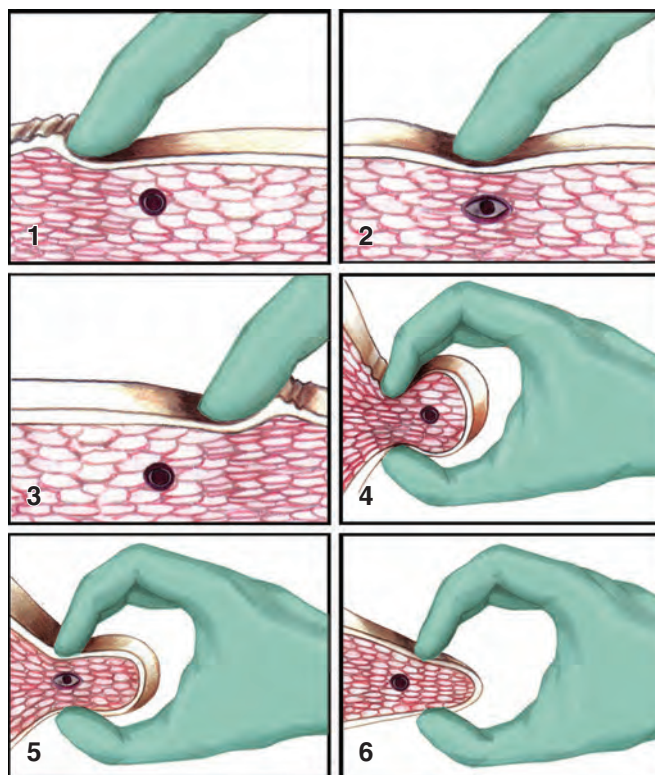

Figure 52.4 Identification of trigger points. 1, Push the skin to one side to begin palpation. 2, Slide the fingertip across the muscle fibers to feel the cordlike texture of the taut band rolling beneath it. 3, Push the skin to the other side at completion of the movement (this same movement performed vigorously is snapping palpation). 4, Surround the muscle fibers with the thumb and fingers in a pincer grip. 5, Feel the hardness of the taut band while rolling it between the digits. 6, Sharply define the palpable edge of the taut band as it escapes from between the fingertips, often with a local twitch response. (Modified from Sola AE: Myofascial trigger point therapy, *Res Staff Physician* 27[8]:44, 1981.)

the target muscle is well supported and under minimal tension, and that one end of the trigger point is securely anchored. Anesthetize the skin overlying the trigger point with vapocoolant spray (ethyl chloride, dichlorodifluoromethane, or trichloro-monofluoromethane) over the entire length of the muscle. Apply the spray at a 30-degree angle to the skin. After the first pass of spray, apply immediate pressure on the other end of the muscle to create a passive stretch. Perform multiple slow spray passes over the entire width of the muscle while maintaining passive stretch until the muscle achieves a full range of motion. Do not perform more than three repetitions before rewarming the area with moist warm heat, and do not allow each spray to last more than 6 seconds. Educate patients to not overstretch muscles after each therapy session.

Massage Therapy

This technique, as described by Simons and colleagues, uses deep stroking or stripping massage to allow the affected muscle group to be lengthened and relaxed as much as possible.³⁶

Ischemic Compression Therapy

The principle behind ischemic compression therapy is to use pressure to induce ischemia for ablation of the trigger point.

To perform this technique, apply and maintain pressure on the trigger point with increasing resistance until tension in the muscle is relieved. The patient might perceive mild discomfort but not profound pain. Repeat the process for each trigger point encountered.

Invasive Techniques Injection Therapy

Almost any trigger point is suitable for injection therapy. Those that fail to respond to noninvasive treatments should be strongly considered for injection. Historically, various substances have been used, including local anesthetics, botulinum toxin, sterile water, and sterile saline. Despite the different compositions, durations of action, and mechanisms of action of these substances, a common finding is that the duration of pain relief following the procedure outlasts the duration of action of the injected substance.¹⁵ As noted earlier, the authors of a 2001 systematic review concluded that based on current medical evidence, the nature of the injected substance makes no difference on the outcome and that wet needling is not therapeutically superior to dry needling.¹⁸ Nevertheless, the addition of a local anesthetic has been shown to reduce the degree of postinjection soreness and is recommended by most authors.¹⁷

The technique most often recommended for trigger point injection has been referred to as the *universal technique*. Position the patient in a recumbent position to assist in relaxation of the affected muscles, overall comfort, and prevention of syncope. Re-identify the previously marked trigger point of interest, and scrub the overlying skin with a topical antiseptic solution. For superficial trigger points, use a 22-gauge, 1.5-inch needle. Deeper muscles may require a 21-gauge, 2- or 2.5-inch needle (see Table 52.3). Grasp the skin overlying the trigger point between the thumb and index or middle finger of the non-dominant hand. Insert the needle approximately 1 to 1.5 cm from the trigger point and advance it into the trigger point at a 30-degree angle. Aspirate to confirm that a blood vessel has not been entered, and inject a small amount of the agent. Withdraw the needle to the skin, redirect it to another area of the trigger point, and inject again. Use a fast-in, fast-out approach to elicit a local twitch response, which has been shown to increase the effectiveness of the trigger point injection and allows the entire trigger point area to be treated.^{37,38} Severe cramping or paresthesia suggest inadvertent nerve entry and mandates withdrawal and redirection of the needle. For best results it is critical to elicit a local twitch response with every injection. Following the procedure, the muscle group that was injected should undergo a full active stretch.¹⁵

Specific Regions and Clinical Entities

Bursitis and Tendinitis Shoulder Region

Shoulder pain continues to be a common complaint in both the emergency and primary care settings. The pain can be associated with significant disability and may result from pathology that is intraarticular or extraarticular including bicipital tendinitis, calcareous tendinitis, and subacromial bursitis (Fig. 52.5). Because injection (Videos 52.1 and 52.2) is easy and safe to perform, these areas are frequently injected, especially in patients who have failed more conservative therapy such as ice, rest, and oral antiinflammatory medications. Injections may also offer a diagnostic advantage when evaluating a patient with subacromial pain or a rotator cuff syndrome in

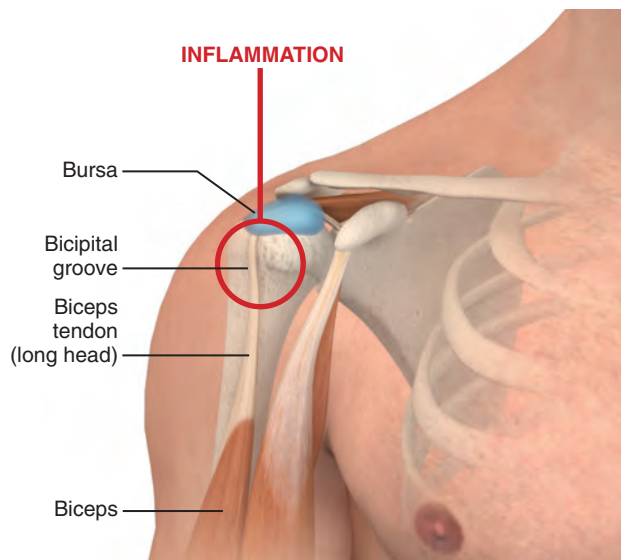

Figure 52.5 Bicipital tendinitis and subacromial bursitis. Pain in the shoulder may be caused by biceps tendinitis or subacromial bursitis, but this is difficult to clinically differentiate from other shoulder conditions. Sudden pain and a distinct soft tissue bulge in this area can indicate rupture of the long head of the biceps.

differentiating shoulder weakness caused by impingement (shoulder strength improves after injection) and a true rotator cuff tear (no change in strength following injection). A potential long-term complication of untreated persistent inflammation is the development of a *frozen shoulder* (adhesive capsulitis).³⁹

Bicipital Tendinitis (Tenosynovitis) (Fig. 52.6). The biceps tendon is a common extraarticular cause of shoulder pain and injuries to the tendon can range from inflammation to complete rupture. Bicipital tendinitis and tenosynovitis represent non-specific low-grade inflammation of the biceps tendon and/or its sheath that is more common in those who repeatedly flex the elbow against resistance, such as weight lifters and swimmers.^{4,40} The elderly are more likely to develop degenerative tendinosis and rupture, whereas isolated tendinitis is more common in younger patients.⁴¹

The bicipital tendon courses through the joint and along the bicipital (intertubercular) groove (see Fig. 52.5), which can be appreciated when the elbow is held at 90 degrees of flexion and the arm is internally and externally rotated.⁴⁰ Patients typically complain of pain over the biceps muscle extending into the anterior shoulder. They may have restricted or normal range of motion and normal strength; however, they usually complain of tenderness on palpation over the bicipital groove.⁴ Efforts to elevate the shoulder, reach the hip pocket, or pull a back zipper all aggravate the symptoms. Tenderness over the bicipital groove does not confirm the diagnosis, however, because the supraspinatus tendon is in close proximity to the insertion of the bicipital tendon.⁴⁰ Other diagnostic clues include the Lippman test, in which rolling the bicipital tendon produces localized tenderness; the Yergason test, which elicits pain along the bicipital groove when the patient attempts supination of the forearm against resistance while holding the elbow flexed at a 90-degree angle against the side of the body; and the Speed test, in which pain is reproduced when the patient resists forward elevation of the humerus against an extended elbow

Bicipital Tendinitis

Yergason's test. Yergason's test helps determine the stability of the long head of the biceps tendon in the bicipital groove. This test, which involves resisted supination of the forearm with the elbow flexed to 90 degrees, may accurately reproduce symptoms of bicipital tendinitis.

Speed's test. While the elbow is maintained in extension and the forearm in supination, perform forward flexion of the shoulder against resistance. Patients with bicipital tendinitis may have pain or tenderness in the bicipital groove with this maneuver.

Insert the needle along the side of the biceps tendon (long head) at a 30 degree angle, aimed at one border of the bicipital groove.

Make a peritendinous infiltration by injecting around the biceps tendon in a fan-wise distribution. Avoid intratendinous injection. Use a 10- to 20-mg equivalent of Kenalog 40 (triamcinolone acetonide).

Figure 52.6 Bicipital tendinitis.

(see Fig. 52.6). Although helpful, these tests are only moderately specific for bicipital tendinitis.⁴² Radiographic findings are normal and they are not required if the clinical diagnosis is supported.

APPROACH. Place the patient in a seated position with both hands resting comfortably in their lap. Locate the point of maximal tenderness along the bicipital tendon. Make entry with a 22- or 25-gauge, 3.9- to 5.0-cm needle through an optional lidocaine skin wheal. Avoid an intratendinous injection, which may cause weakening of the tendon and predispose the patient to tendon rupture. Advance the needle along the side of the tendon at a 30-degree angle and aim at one border of the bicipital groove to perform a *peritendinous infiltration* (see Fig. 52.6). Administer one-third of the injection at this point. Withdraw the needle slightly but keep it subcutaneous and redirect it upward approximately 2.5 cm for injection of another third of the drug. Withdraw it again and redirect it downward

so that it touches the bicipital border gently. Deposit the remainder of the drug at this point. With any of these injections, resistance to injection suggests intratendinous needle placement, which should be avoided.⁴³ If the two-syringe technique is used, instill 1 to 1.5 mL of an intermediate-acting corticosteroid suspension, such as prednisolone tebutate, at the point of maximum tenderness. Inject the anesthetic (2 to 4 mL of 1% lidocaine, or 0.25% bupivacaine) along the upper and lower borders of the tendon. Ultrasound may aid in locating and injecting the tendon sheath.⁴⁴

Calcaneous Tendinitis, Supraspinatus Tendinitis, and Subacromial Bursitis. These inflammations are so clinically similar that their symptoms and signs are difficult to differentiate. The musculotendinous rotator cuff is composed of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles, which insert as the conjoined tendon into the greater tuberosity of the humerus. The subacromial bursa lies just

superior and lateral to the supraspinatus tendon (Fig. 52.7). Both the tendon and the bursa are located in the space between the acromion process and the head of the humerus, and are particularly prone to impingement in this “critical zone.” Impingement can occur when the shoulder moves forward and compresses the cuff and bursa under the anterior third of the coracoacromial arch. Injections into either the bursa or the tendon sheath area are commonly performed to relieve inflammation and overuse.

In *calcareous* (or calcific) tendinitis of the shoulder, a calcific deposit (hydroxyapatite) is located within the substance of one

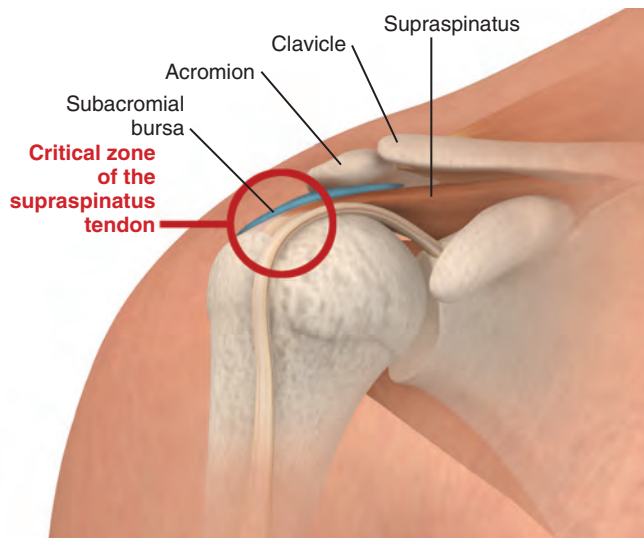

Figure 52.7 The “critical zone.” Note the close relationship of the supraspinatus tendon and subacromial bursa to the humeral head and acromion, which make an exact clinical diagnosis very difficult.

or more of the rotator cuff tendons (commonly the supraspinatus).⁴⁵ These calcium crystals can occasionally rupture into the adjacent subacromial bursa and cause acute pain and tenderness in the deltoid area (Fig. 52.8). The bursae in relation to the greater tuberosity and the subdeltoid (subacromial) bursa are the most common sites of calcific deposits.

During the acute or hyperacute stage the patient holds the arm in a protective fashion against the chest wall. The pain may be incapacitating, and all ranges of motion are disturbed, with internal rotation especially limited. Tenderness is often diffuse over the perihumeral region. The patient may also complain of pain at night when lying on the affected side and with abduction of the arm. Supraspinatus tendon impingement is most apparent when the humerus is abducted and internally rotated. The Hawkins test elicits pain with forcible internal rotation while the patient’s arm is passively flexed forward at 90 degrees, and the Neer test elicits pain with full forward flexion between 70 and 120 degrees (Fig. 52.9). Both tests are fairly sensitive but not specific for supraspinatus tendon impingement.⁴⁶ Constitutional symptoms are rare, but swelling may sometimes be apparent with the hyperacute form, and a fever and elevated sedimentation rate may even develop in some patients. When shoulder radiographs demonstrate a calcific deposit, the shadow appears “hazy” with lightening of the periphery caused by the pressure of inflammatory edema (see Fig. 52.8). Night pain may be intolerable and often requires opioids for control.

ANTERIOR APPROACH. In calcific tendinitis, or supraspinatus tendinitis without calcification, use the anterior (subcoracoid) approach. With the extremity resting on the patient’s lap, externally rotate the arm approximately 15 degrees. The point of insertion is over the depression that is palpable inferior and lateral to the coracoid process and medial to the head of the humerus (see Fig. 52.9).

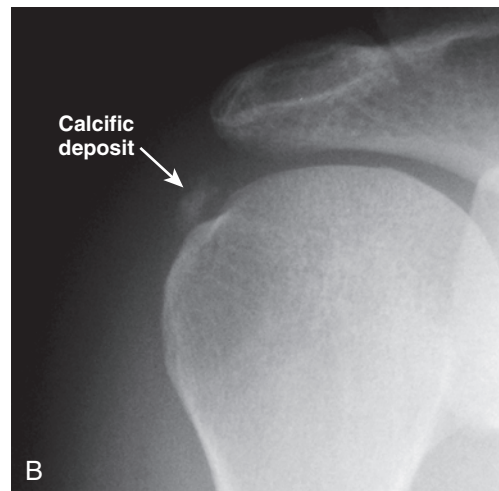

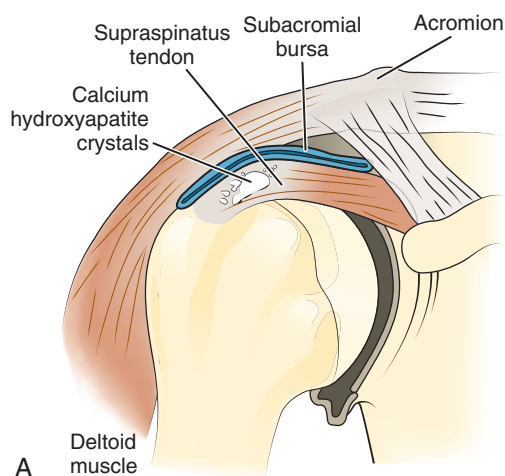

Figure 52.8 Calcareous tendinitis. **A**, In calcareous tendinitis of the shoulder, calcium hydroxyapatite crystals are deposited in the tendons of the rotator cuff and occasionally rupture into the adjacent bursa. **B**, Abnormal calcific deposits in calcareous tendinitis of the shoulder are usually demonstrated roentgenographically in the suprahumeral region or adjacent to the greater tuberosity. When the bursal calcifications appear to be dense (as on this x-ray film), they are frequently asymptomatic, whereas lightening at the margins of the calcium deposit is compatible with the presence of inflammatory edema in the rotator cuff, which produces pain and tenderness in the shoulder region. The location of the calcific deposit on the radiograph may be a useful guide for the point of entry for aspiration and injection. Direct the needle to the calcareous deposit, aspirate, and deposit a portion of the steroid medication there. The calcium may subsequently disappear. Not infrequently, it does so spontaneously.

Calcaneous Tendinitis, Supraspinatus Tendinitis, and Subacromial Bursitis

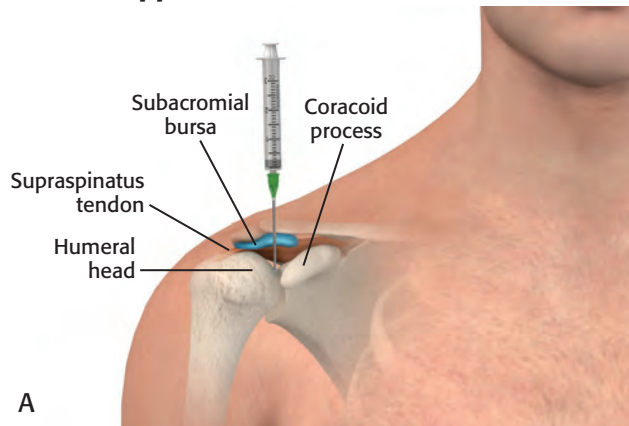

Hawk's test. With the patient's arm and elbow flexed to 90 degrees, the examiner rotates the forearm internally (i.e., thumb pointed down so that the palm of the hand is directed as far posteriorly as possible). Pain is reproduced if there is impingement of the coracoacromial ligament.

Neer's test. With one hand placed on the patient's scapula, the forearm is slowly flexed forward. The arm should be internally rotated such that the thumb is pointing downward. This test causes pain as the greater tuberosity of the humerus impinges on the acromion. Pain may be reproduced between 70 degrees and 120 degrees of forward flexion.

Anterior Approach

A

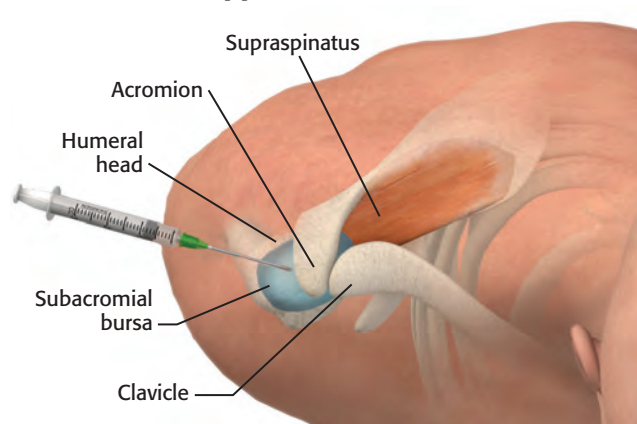

Externally rotate the arm to 15 degrees. Insert the needle over the depression that is palpable inferior and lateral to the coracoid process and medial to the head of the humerus.

B

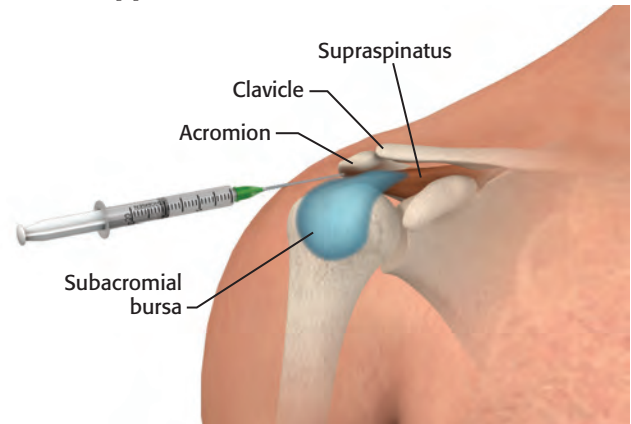

The bursa lies mainly under the acromion, but this is variable. Supraspinatus tendinopathy often occurs with subacromial bursitis.

Posterolateral Approach

Insert the needle in the depression just inferior to the posterolateral tip of the acromion and superior to the head of the humerus.

Lateral Approach

For the lateral approach, insert the needle over the superior aspect of the humeral head and under the lateral margin of the acromion.

Figure 52.9 Calcaneous tendinitis, supraspinatus tendinitis, and subacromial bursitis. Subacromial bursitis pain is quite common and responds well to injection. Recurrent pain can be due to a rotator cuff tear, which requires evaluation with magnetic resonance imaging. Pain is felt in the deltoid area and can radiate down the arm. The bursa lies mainly under the acromion, but this is variable. Supraspinatus tendinopathy often occurs together with subacromial bursitis.

POSTEROLATERAL APPROACH. With the patient sitting and the lower part of the extremity resting on the lap, make a lidocaine skin wheal at the depression approximately 1 cm inferior to the posterolateral tip of the acromion, located between the head of the humerus and the acromion. Direct a 3.9- to 5.0-cm, 22- or 25-gauge needle toward the center of the head of the humerus and upward at an angle of approximately 10 degrees. Because the bursa does not extend posteriorly beyond the middle of the acromion, it is important that the needle be positioned sufficiently anterior and inferior to the acromion (see Fig. 52.9).⁴⁷ After the site has been penetrated 2 to 3 cm, aspirate for any fluid or calcific material. Remove the syringe but leave the needle in position. Attach another syringe containing 20 to 40 mg of methylprednisolone suspension or an equivalent intermediate-acting steroid, and inject the medication. Little resistance should be encountered when injecting the steroid. If resistance is appreciated, reposition the needle because it may be in the tendon substance of the rotator cuff. Follow this injection with 4 to 6 mL of 1% lidocaine (or a similar volume of 0.25% bupivacaine). Alternatively, combine the local anesthetic and steroid in the same syringe. Be generous with the volume of local anesthetic injected to ensure adequate dispersion of the steroid. A single treatment relieves the majority of acute disorders. An injection into the peritendinous space is similar to that described previously except that the needle is advanced deeper than with a subacromial bursal injection.⁴⁸

If calcific tendinitis is suspected, some recommend attempting to aspirate the calcium deposits. After the bursa has been anesthetized, use an 18-gauge needle to penetrate the calcium, which often creates a gritty sensation.⁴⁰ Barbotage can facilitate cleavage of the calcium deposits and obtain greater dissemination of the injection. Use this method as described previously by aspirating and reinjecting the steroid or anesthetic-steroid combination repeatedly.⁴⁵ Needling followed by aspiration and lavage of the subacromial space has also been proven to be effective.^{49,50}

Sometimes a painful reaction develops after the analgesic has worn off. Warn the patient about this possibility and give appropriate analgesia. A sling may provide additional relief. Short-term use of opioids is also appropriate. Although some authors claim that patients who do not also undergo physical therapy after corticosteroid injection have satisfactory results, some evidence supports the importance of close patient follow-up, range-of-motion exercises, and physical therapy for total recovery.⁴⁰

Acromioclavicular Joint Inflammation. Pain arising in the acromioclavicular (AC) joint can be the result of an acute injury, such as falling on an outstretched hand or from repetitive strain injuries and degeneration. With this injury, all ranges of motion of the shoulder cause pain, and the joint is tender but rarely swollen. Tenderness over the AC joint is sensitive but not specific for AC joint pathology. Be aware that an obvious deformity or mechanism of injury may suggest AC separation or dislocation. With AC joint inflammation, crepitus is not uncommon.⁴⁰ Adduction of the arm across the body with forward elevation to 90 degrees (the cross-arm test) may exacerbate the pain because the AC joint is compressed with this motion.⁴⁰ In a study by Jacob and Sallay,⁵¹ injection of corticosteroids provided short-term relief of symptoms but did not alter the long-term course of patients with AC joint arthropathy. However, a 2008 prospective study found that improvements in pain and function after injection of the AC joint can last up to 12 months.⁵² Nevertheless, because many patients obtain relatively short-term pain relief from injection therapy, some clinicians believe that AC joint injection should be performed only in patients with persistent pain despite a trial of rest, oral antiinflammatory medications, and modification of activity.⁴³

APPROACH. Make an entry through an optional cutaneous lidocaine wheal over the interosseous groove at the point of greatest tenderness (Fig. 52.10). This is usually at the AC joint, which is palpated as a small V-shaped depression posteriorly

Acromioclavicular Joint

Insert the needle in the interosseous groove at the point of greatest tenderness. This is usually at the AC joint, which is a small V-shaped depression at the most lateral aspect of the clavicle.

The joint is relatively superficial, and the needle will need to be advanced only about 5 mm. It is not necessary to advance the needle beyond the proximal margin of the joint surface.

Figure 52.10 Acromioclavicular (AC) joint inflammation.

at the most lateral aspect of the clavicle.⁴⁰ In this area the joint line is relatively superficial. Advance a 2.2- to 2.5-cm, 22- or 25-gauge needle approximately 5 mm and inject 1 to 2 mL of lidocaine and 5 to 10 mg of a prednisolone suspension. It is not necessary to advance the needle beyond the proximal margin of the joint surface.

Elbow Region

The elbow is subject to characteristic extraarticular disorders, including radiohumeral bursitis, lateral and medial epicondylitis (*tennis elbow* and *golfer's elbow*), and olecranon bursitis (*barfly's elbow*).

Radiohumeral Bursitis, Lateral Epicondylitis, and Medial Epicondylitis. Radiohumeral bursitis occurs at the juncture of the radial head and the lateral epicondyle of the elbow. This condition is commonly found in combination with lateral epicondylitis, which is thought to result from repetitive microtrauma at the insertion of the *extensor carpi radialis longus* and *extensor digitorum longus* muscles. The symptoms of the two adjacent problems are indistinguishable, but tenderness overlies the radiohumeral groove with bursitis, whereas tenderness occurs chiefly at the lateral epicondyle with tennis elbow (Fig. 52.11). Although the term *epicondylitis* suggests an inflammatory cause of the pain, some evidence indicates that the injury in lateral epicondylitis results from a degenerative process causing a “tendinosis.”⁵³ Regardless of the exact pathophysiology, there is often a history of repetitive motion of the wrist (flexion, extension, supination, pronation, or any combination thereof) such as while playing tennis, gardening, or using tools.⁴ A clinical sign supporting the diagnosis of tennis elbow is provocation of pain when the patient attempts extension of the middle finger against resistance with the wrist and elbow held in

Figure 52.11 Lateral epicondylitis. Commonly known as *tennis elbow*, this condition is common and quite painful and the result of microscopic rupture and incomplete tendinous repair of the extensor carpi radialis brevis origin on the lateral epicondyle of the humerus. Pain usually occurs over the lateral humeral epicondyle during work or recreation. Although this condition often responds well to an injection, recurrences are common. Physical therapy is indicated for recurring pain.

extension. Alternatively, pain is reproduced at the elbow when the patient is asked to extend the wrist against resistance.

Medial epicondylitis (*golfer's elbow*) is a similar condition, although it occurs on the side opposite that of lateral epicondylitis and is much less common (Fig. 52.12).⁴ This condition involves the origin of the *pronator teres* and *flexor carpi radialis* muscles. On physical examination the patient usually complains of pain when the wrist is *flexed* against resistance or when the forearm is pronated. Palpation of the medial epicondyle also elicits tenderness.

There is evidence supporting the short-term efficacy of corticosteroid injection for both lateral and medial epicondylitis.⁵⁴⁻⁶² Successful injection of lateral epicondylitis produces a predictable short-term (usually less than 6 weeks) improvement in pain that is superior to that with nonsteroidal drug therapy and physical therapy.^{55-59,62} However, after 6 weeks, physical therapy reduces symptoms more than corticosteroid injection does.⁶¹ Nevertheless, some clinicians still feel corticosteroid injection should be a first-line treatment for lateral epicondylitis.⁶³ A similar effect was noted with medial epicondylitis; at 6 weeks patients injected with corticosteroids also reported significantly less pain than those receiving physical therapy alone.⁵⁷ However, at 3 months and 1 year there were no significant differences in pain between groups receiving corticosteroids and physical therapy and physical therapy alone.⁵⁷

APPROACH. For lateral epicondylitis, pronate the patient's forearm and flex the elbow to 90 degrees (Fig. 52.13). Palpate the radial head as a bony protrusion just distal to the epicondyle (confirm identification of the radial head by rotating the patient's forearm). The entry site is at the point of maximal tenderness, which is usually found at a location slightly distal to the lateral epicondyle. Using a 3.9-cm, 22-gauge needle, deposit 20 to 30 mg of methylprednisolone or equivalent intermediate-acting steroid mixed with anesthetic through a lidocaine skin wheal. Alternatively, follow the steroid with 1 to 3 mL of local anesthetic. Inject the solution in a fanlike pattern while avoiding direct tendon injection. For radiohumeral bursitis, instill part of the repository preparation into the radiohumeral bursa and

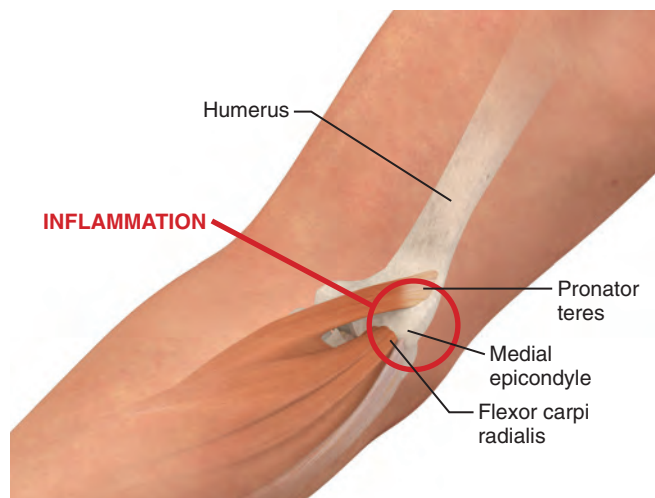

Figure 52.12 Medial epicondylitis. Also known as *golfer's elbow*, medial epicondylitis is a flexor tendinitis with pain in the medial aspect of the elbow that is elicited by flexing the wrist. This condition is much less common than the lateral variety.

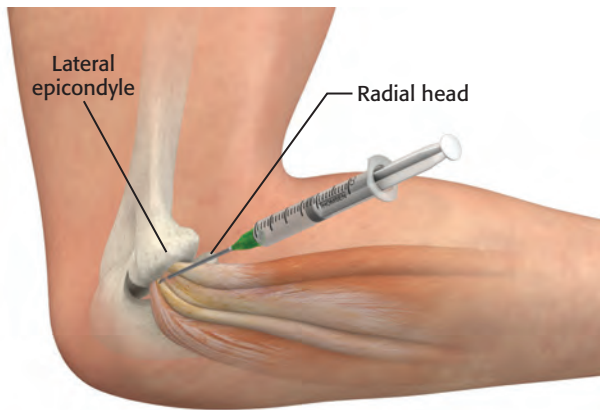

Lateral Epicondylitis

Patients often localize the pain with one finger.

Because this is an extensor tendinitis, extending the wrist against resistance or taking a book off a shelf elicits pain with lateral epicondylitis.

Insert the needle at the point of maximum tenderness, which is usually at a point slightly distal to the lateral epicondyle.

Infiltrate the injection in a fanlike distribution while avoiding direct injection of the tendon.

Figure 52.13 Lateral epicondylitis

part at the lateral epicondyle (see Fig. 52.11). With medial epicondylitis (golfer's elbow) use a similar technique, but take care to avoid the ulnar nerve, which lies in the ulnar groove behind the medial epicondyle (Fig. 52.14). Damage to this nerve during steroid injection has been reported.⁶⁴ Subcutaneous injections should also be avoided because they can result in skin depigmentation, atrophy, or both.⁵⁸

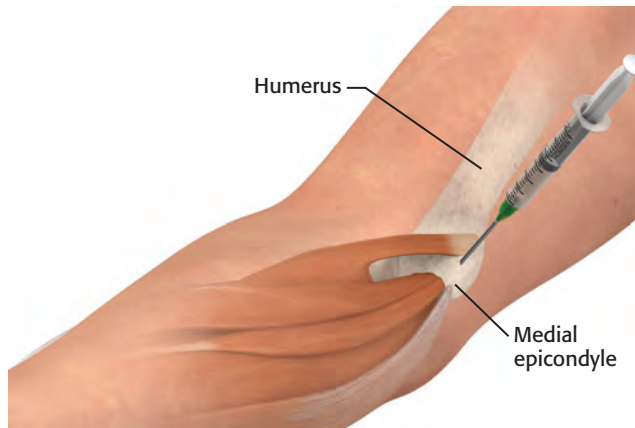

Olecranon Bursitis (Aseptic). Olecranon bursitis is an inflammation of the olecranon bursa of the elbow, located between the skin and the olecranon process (Fig. 52.15). Swelling of the bursa is easy to detect given its superficial location and can be differentiated from an elbow joint effusion by preserved elbow extension and flexion. The most common cause of olecranon bursitis is minor trauma,⁶⁵ or activities that involve chronic leaning or repetitive elbow motion. As a result of the latter, olecranon bursitis is also known as *barfly elbow* or *student's elbow*. It may also be seen after an AstroTurf rug burn of the elbow during sporting activities. Other patients at risk for olecranon bursitis include gardeners, auto mechanics, carpet layers, gymnasts, and wrestlers.⁶⁶ More significant trauma, such as a direct blow to the elbow, can also cause olecranon bursitis. In this case, hemorrhage into the bursa results in acute hemorrhagic bursitis. Less common causes of olecranon

bursitis include hemodialysis⁶⁷ and systemic diseases such as rheumatoid arthritis, lupus, uremia, and gout.⁶⁸

Although most cases of olecranon bursitis are sterile, the olecranon bursa is the most frequent site of septic bursitis.⁶⁹ Therefore, it is important to accurately differentiate between the two entities. Steroid injections are absolutely contraindicated in cases of confirmed or suspected septic bursitis. Frequently the diagnosis will be suggested by the history and physical examination, but it may be necessary to aspirate and analyze the fluid if septic bursitis is suspected.

In aseptic olecranon bursitis, findings on radiographs are usually normal, but soft tissue swelling may be evident. Bony spurs or amorphous calcific deposits may also be seen, especially in older patients.⁶⁵ Occasionally with rheumatoid arthritis and gout, nodules, or tophi, may be palpated within the bursal sac. The bursa and surrounding structures are not typically tender, and there is full and painless range of motion of the involved elbow. Signs of infection such as warmth and erythema of the overlying skin are usually absent. It should be noted, however, that pain, warmth, tenderness, and erythema might be present in both septic and aseptic olecranon bursitis. If there is any suspicion of septic olecranon bursitis, aspiration should be performed and corticosteroid injection deferred until an infectious cause has been ruled out.⁶⁵

Medial Epicondylitis

Enter the skin at the point of maximum tenderness, over the medial epicondyle.

During injection, avoid the ulnar nerve, which lies in the ulnar groove behind the medial epicondyle.

Figure 52.14 Medial epicondylitis.

Aseptic olecranon bursitis may be cosmetically bothersome to the patient but does not usually cause discomfort and may resolve spontaneously. In cases of bursal swelling that is neither tender nor tense, treatment is symptomatic and includes NSAIDs, compression, and avoidance of further injury.⁶⁵ In cases of acute hemorrhagic bursitis, aspiration of the bursa followed by application of a compression dressing and ice will decrease the incidence of chronic bursitis.⁶⁵ In patients with aseptic olecranon bursitis who have large, tense, and inflamed bursae, aspiration with steroid injection (after infection has been excluded) has been shown to hasten the resolution of symptoms. Smith and colleagues⁷⁰ demonstrated the superiority of intrabursal methylprednisolone acetate over oral naproxen or placebo at 6 months, and noted faster resolution and less reaccumulation of fluid with the steroid injection. The addition of a course of an oral NSAID after steroid injection did not affect the outcome.⁷⁰ Aspiration of the olecranon bursa, followed by injection of corticosteroids into the elbow joint, is an alternate approach that has been associated with good success and fewer complications.⁷¹ Following aspiration and steroid injection, application of a compression dressing and a brief period of relative immobilization may be helpful.⁶⁵ Repetitive steroid injections for aseptic olecranon bursitis have been associated with triceps rupture and should be avoided.⁷²

Olecranon Bursitis (Septic). Because of its superficial location, the olecranon bursa is a common location for septic bursitis along with the pre- and infrapatellar bursa.⁷³ Infection of the other bursa is much less common. The infection is most likely caused by direct percutaneous inoculation of common skin organisms into the bursa as a result of trauma or contiguous spread from an overlying cellulitis.^{65,73,74} Septic bursitis secondary to hematogenous spread is rare.^{65,73,74} Most cases of septic bursitis are caused by *Staphylococcus aureus* (80%), followed by streptococcal organisms.⁷⁵ Other less common organisms include coagulase-negative staphylococci, enterococci, and gram-negative organisms such as *Escherichia coli* and *Pseudomonas aeruginosa*.⁷³ Isolated cases of bursitis caused by fungi (*Aspergillus*

terreus, *Candida lusitanae*), *Brucella*, and *Mycobacterium tuberculosis* have also been reported.⁶⁵ Such unusual organisms should be considered in cases of septic bursitis that are subacute or chronic, and those discovered in an immunocompromised host.⁶⁵

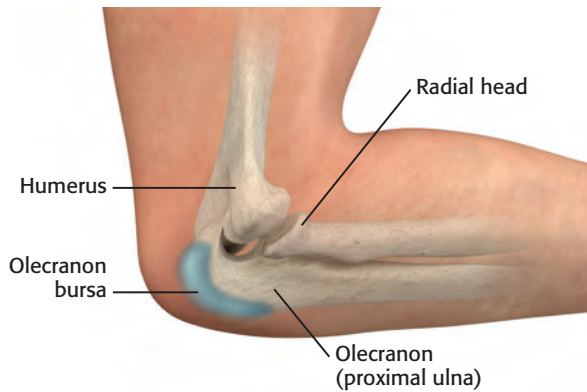

The most common cause of olecranon septic bursitis is trauma. It has been estimated that as many as 70% of cases of septic bursitis are related to trauma, either chronic and caused by repetitive injury, or acute and often associated with occupational or recreational activities.⁷³ Other risk factors for the development of septic bursitis include chronic illnesses (e.g., diabetes mellitus, alcoholism), and previous inflammation of the bursa, which occurs with gout, rheumatoid arthritis, and uremia.⁷³ Infection may follow an injection of corticosteroids into the bursa in up to 10% of cases.⁷⁶

At times the diagnosis of septic bursitis can be challenging. Acute gouty olecranon bursitis may have a very similar clinical picture, and often can only be accurately differentiated from septic arthritis by fluid analysis (Fig. 52.16). Other conditions that may mimic bacterial septic olecranon bursitis include acute rheumatoid bursitis, aseptic bursitis secondary to oxalosis induced by dialysis, or infectious bursitis caused by unusual organisms such as *Mycobacterium*, *Serratia marcescens*, or fungi. Approximately one third of all cases of olecranon bursitis are septic.⁶⁵

In some cases the diagnosis of septic bursitis is obvious (see Fig. 52.16A). The onset of pain and swelling may be quite rapid (over a period of 8 to 24 hours), as opposed to the more gradual onset of aseptic bursitis. The bursa is erythematous, tense, swollen, warm, and very painful. Flexion of the elbow is limited by pain; however, some joint mobility may be present because the bursa does not usually extend into the joint.⁷³ The patient may report a history of trauma to the area, which may be evident on physical examination. Some patients will also have a fever. Smith and associates found that the infected bursa was generally 2.2°C or warmer than the unaffected elbow.⁷⁷

Aspiration of infected bursal fluid with culture of bacteria from the aspirate confirms the diagnosis of septic bursitis. Fluid is usually easily obtained from the tense bursa and (in

Olecranon Bursitis

The olecranon bursa is found on the posterior aspect of the elbow and is directly superficial to the olecranon process of the ulna. Trauma is the leading cause of olecranon bursitis, but it may also be related to rheumatoid arthritis, lupus, uremia, and gout. Most cases are sterile, although septic bursitis is a clinical possibility and should be considered.

Aspiration and injection are not usually difficult because the bursa is often quite distended with fluid. Insert the needle into the most dependent aspect of the bursal sac. Minimize the risk for persistent drainage and skin contamination by inserting the needle through the skin 2 to 3 cm away from the bursa.

Aspiration and Injection of Olecranon Bursitis

1 Painless swelling over the posterior aspect of the elbow is characteristic of nonseptic olecranon bursitis. The mass is soft, movable, and fluctuant.

2 Using sterile preparation, advance a 20-gauge needle on a 10-mL syringe parallel to the forearm.

3 Aspirate the bursal fluid completely. Compress the bursa during aspiration. Typically, slightly blood-tinged serous fluid is obtained.

4 Change the aspirating syringe while the needle remains in the bursal sac.

5 Inject a long-acting steroid preparation (such as 40 mg of methylprednisolone). Use an elastic bandage to compress the site for 12 hours.

Figure 52.15 Olecranon bursitis.

the case of established infection) may be cloudy or grossly purulent. The white blood cell count of the fluid in septic bursitis is usually 5000 to 100,000 cells/mm³ or greater, and the proportion of polymorphonuclear cells usually exceeds 90%. Neither fever nor systemic leukocytosis is considered

sensitive or specific for the disease. However, in immunocompromised patients (e.g., those with diabetes mellitus, or alcoholism), the white blood cell count in the bursal fluid tends to be higher.⁷⁸ Because of some overlap in the leukocyte count of bursal fluid in septic versus aseptic bursitis, it is important

Figure 52.16 **A**, Fully developed septic bursitis is usually distinguished from nonseptic bursitis by clinical parameters. In the septic variety, there is diffuse swelling (as opposed to a discrete mass), and the area is red, warm, and quite tender. In addition, bursal fluid leukocytosis is present. **B**, Acute gout can cause painful olecranon bursitis resembling septic bursitis. **C**, Aspiration can yield urate paste. **D**, Tophi in a patient with advanced gout.

to remember that a low bursal white blood cell count does not exclude a septic cause. Moreover, the sensitivity of Gram stain may be 50% or less.⁷⁹ In a study of 200 patients with olecranon bursitis, cell count and Gram stain were not always helpful in the acute evaluation and treatment of new cases of septic bursitis.⁸⁰ Therefore if clinical suspicion for septic olecranon bursitis is high, even in the presence of a normal or equivocal fluid cell count or Gram stain, steroid injection should be delayed and empirical antibiotic therapy started until the results of culture are available.⁶⁵

Treatment of septic bursitis includes the use of antibiotics directed against penicillinase-producing *Staphylococcus*, splinting, warm soaks, and drainage of the bursa. Drainage may be performed by daily needle aspiration until the fluid is sterile.⁷⁴ However, open incision and drainage might be required, particularly if the infection is recurrent or refractory.⁸¹ In addition to daily drainage of the bursa as necessary, administer antibiotics for at least 2 weeks.⁷⁴ Consider additional antibiotic coverage against methicillin-resistant *S. aureus* based on the patient's risk factors and epidemiology.⁷³ Outpatient therapy with oral antibiotics is generally acceptable, although this approach has been challenged for immunocompromised patients.⁷⁸ This decision is generally guided by the clinical appearance of the bursa, in addition to associated comorbid conditions, compliance, and other factors regarding patient care. Response to antibiotic therapy might be slow. Thus it is important to initiate antimicrobial treatment as soon as clinical suspicion of septic bursitis exists. Additional treatment with oral NSAIDs may help reduce the pain. Standard gout medications will generally resolve acute gouty bursitis.

APPROACH. Insert a 2.5- to 3.9-cm, 20-gauge needle through a lidocaine skin wheal at a dependent aspect of the bursal sac

(see Fig. 52.15, steps 1–5). To minimize the risk for persistent drainage after aspiration and for contamination of the overlying skin, penetrate the skin 2 to 3 cm from the bursa.^{54,55} If infected or inspissated fluid is anticipated, use a 16- to 18-gauge needle to aspirate the viscous contents. Aspirate as much fluid as possible. With aseptic bursitis, the aspirated fluid may be yellow and clear, but it is often mildly serosanguinous in appearance. The leukocyte count of the aspirated fluid of aseptic bursitis should be less than 1000/mm³. Counts of approximately 2000 to 10,000/mm³ are associated with a higher incidence of infection or acute gout. After aspiration and injection, wrap the elbow in an elastic compression bandage for 5 to 7 days. If septic olecranon bursitis is suspected, do not perform corticosteroid injections.

Wrist and Hand Region

Ganglion Cysts of the Wrist or Hand. These cystic swellings occur frequently on the hands, especially on the dorsal aspect of the wrist (Fig. 52.17). They are easily discovered on physical examination and are usually firm and round, and have a rubbery consistency. When physical examination alone is not diagnostic, transillumination or ultrasound can help differentiate cysts from solid tumors. Ganglion cysts are common and make up approximately 60% of all soft tissue tumors affecting the wrist and hand. They usually develop spontaneously in adults between 20 and 50 years of age, with a female-to-male ratio of 3:1. Ganglion cysts may also be seen on the foot and ankle, generally on the extensor surface.

The etiology of ganglia remains obscure; there is usually no history of trauma.⁸² The word *ganglion* is derived from the Greek word meaning “cystic tumor.” The mesothelium- or synovium-lined cystic structures are attached to or may arise from tendon sheaths or near the joint capsule and do not

Figure 52.17 Typical dorsal ganglion cyst of A, the wrist and B, dorsum of the foot.

extend into the joint itself.⁸³ Attachment is often by a pedicle. The wall of a ganglion is smooth, fibrous, and of variable thickness. The cyst is filled with a clear, gelatinous, sticky, or mucoid fluid of great density. The viscous fluid in the cyst may sometimes represent almost pure hyaluronic acid.

The types of ganglia vary with their location. The most common ganglia are located on the dorsal surface of the wrist and arise from the scapholunate joint. These constitute approximately 70% of ganglia. Volar wrist ganglia, which arise over the distal aspect of the radius, constitute another 20% to 25% of ganglia and are often adherent to the radial artery.⁸⁴ Flexor tendon sheath ganglia make up the remaining 10% to 15% and are found on the hand and wrist.

Close to 60% of ganglia spontaneously regress and do not require treatment.⁸⁵ However, they can sometimes cause pain, loss of function, or weakness (from soft tissue or nerve compression or bone erosion), prompting intervention. In addition, some patients request treatment because of cosmetic concerns. Treatment options include aspiration and surgical excision. Simple aspiration is usually an effective approach, but up to three aspirations may be required for complete resolution. In

one study, 69% of 116 patients required only a single aspiration for successful treatment.⁸⁶ Two or three aspirations were required in 19%, and only 12% of patients ultimately needed surgical excision.⁸⁶ It should be noted, however, that ganglia often recur after aspiration or surgery. In fact, over half of all ganglion cysts that undergo aspiration will recur within one year,⁸⁵ and most of those within the first 3 months.⁸⁷ Following aspiration there is no apparent benefit to the instillation of steroids,⁸⁸ although there may be some value in injecting a combination of a steroid and hyaluronidase.⁸⁹ Because aspiration is associated with considerable cost savings and shorter recovery times than surgery, and because there is no difference in recurrence rates, aspiration appears to be the initial treatment of choice.⁹⁰ In the event that nonsurgical treatment fails, surgical excision may be indicated. The old treatment of attempting to rupture the ganglion with a heavy book is not advised because of the potential for local injury. Aspiration of volar wrist ganglia should also be undertaken with caution because the radial artery often adheres to the cyst and may be at risk for injury.⁸⁴

APPROACH. Following the instillation of 1% lidocaine for local anesthesia, insert a 2.5-cm, relatively large-bore needle (17 to 18 gauge) into the center of the ganglion and aspirate the contents (see Fig. 52.17A). Usually 1 to 2 mL of mucinous fluid can be aspirated. Milk the contents of the cyst toward the aspiration needle to maximize the volume removed, taking care not to stick yourself with the needle.⁹¹ After the cyst is localized by aspiration, if desired (although there is no supporting evidence for this practice) use another smaller needle to administer 10 to 15 mg of methylprednisolone or a combination of methylprednisolone and hyaluronidase (which has been shown to be beneficial).^{89,92} Following aspiration a splint is not usually required, and activity need not be restricted. There is no proven role for routine NSAIDs or oral steroid therapy.

de Quervain's Disease and Intersection Syndrome. de Quervain's disease, a relatively common disorder, is a stenosing tenovaginitis of the extensor pollicis brevis (EPB) and abductor pollicis longus (APL) tendons of the thumb (Fig. 52.18). Though commonly referred to as a *tenosynovitis*, which denotes inflammation of the synovial sheaths, this condition is more accurately described as a *tenovaginitis*, which refers to thickening of the fibrous sheath of the first extensor compartment. In 1912, de Quervain described "thickening of the dense fibrous connective tissues without any fresh sign of inflammation, neither round cell inflammation nor increase in numbers of cells."⁹³ Histologically the thickening is caused by the accumulation of mucopolysaccharide within the tendon sheath.^{94,95}

It is commonly thought that the disorder occurs more often after repetitive use of the wrists, especially with a wringing motion. Hence, the syndrome has been called *washerwoman's sprain* and often no specific cause is apparent. However, a study by Kay⁹³ challenged the association between repetitive motion and de Quervain's disease. In a retrospective study of 100 cases, no strong correlation was found with occupation or history of repetitive activities in patients in whom de Quervain's disease was diagnosed.⁹³ Thus it may be possible that repetitive activities exacerbate the pain associated with a condition for which the cause is unclear. Women during pregnancy or within 12 months of childbirth are also frequently affected.⁶⁸

Tenderness, enlargement, and occasionally palpable crepitation are elicited just distal to the radial styloid process, where both tendons come together in an osseofibrous tunnel. Patients

Figure 52.18 de Quervain's disease and intersection syndrome. de Quervain's tenosynovitis occurs in the first dorsal compartment of the wrist secondary to tenosynovitis of the abductor pollicis longus and extensor pollicis brevis tendons. Symptoms, which include pain over the radial styloid, are generally caused by overuse. Intersection syndrome, often confused with de Quervain's disease, produces symptoms 4 to 8 cm more proximally.

Figure 52.19 This 25-year-old woman had signs and symptoms of tenosynovitis of the wrist that was initially thought to be de Quervain's disease. A single hemorrhagic papule (arrow) demonstrating a septic embolus was found on the forearm and is a subtle but classic lesion of gonococcal bacteremia. One aspect of this sexually transmitted disease is tenosynovitis. Cervical cultures were positive for *Neisseria gonorrhoeae* despite the absence of vaginal symptoms.

usually have radial wrist pain that is exacerbated with certain thumb and wrist movements. The condition may be confused with first carpometacarpal arthrosis (osteoarthritis of the thumb) and intersection syndrome. Radiographs will have normal findings in de Quervain's disease, but it might be appropriate to rule out other pathologic abnormalities. Ultrasound may demonstrate thickening and edema of the synovial sheath, but has not yet been routinely used to make or confirm the diagnosis.⁹⁶ Rarely, gonococcal tenosynovitis might simulate this inflammatory condition (Fig. 52.19).

A useful clinical maneuver that indicates de Quervain's disease is the Finkelstein test (Fig. 52.20). With the patient's thumb grasped in his or her palm, apply ulnar deviation at the wrist. Severe pain at the site of the affected tendon sheaths indicates a positive test. When performing the Finkelstein test, also palpate the tender area for crepitus. If axial traction

or compression (the carpometacarpal grind test) and rotation of the thumb produce pain, the condition is most likely caused by degenerative changes in the carpometacarpal joint of the thumb rather than de Quervain's disease. It should be noted that gonococcal tenosynovitis of the wrist may mimic de Quervain's disease, and one should inquire about other symptoms (e.g., sore throat, penile or vaginal discharge, or fever) and carefully look for the characteristic rash of this sexually transmitted disease (see Fig. 52.19).

Patients with mild symptoms may be managed with splinting and NSAIDs, but more severe cases typically require local corticosteroid injection.^{97,98} In one study comparing steroid injection with immobilization and oral NSAID therapy alone, the latter was effective only in a small group of patients with minimal symptoms.⁹⁷ In another retrospective study, 84% of 58 patients were effectively managed either with a single injection (60%) or with repeat injections (24%), with only 12% requiring surgical treatment.⁹⁹ These data support a meta-analysis of 495 subjects treated for de Quervain's tenovaginitis in which an 83% cure rate was found with injection alone versus 61% for injection and splinting, 14% for splinting alone, and 0% for rest or NSAIDs.¹⁰⁰ The strikingly favorable response to local injection therapy suggests that surgery to release the tendon sheaths is seldom needed. Interestingly, some evidence suggests that failure of steroid injections may be the result of an anatomic variant in which the EPB is located in a separate synovial compartment.^{100,101} This is supported by a study in which steroids selectively injected into the EPB tenosynovium resulted in the resolution of symptoms in all 50 patients.¹⁰² Clinical suspicion for this anatomic variant should be raised when previous steroid injections have failed and patients have pain with firm resistance to thumb metacarpophalangeal joint extension (the EPB entrapment test).¹⁰¹ Consider selective injection into the EPB tenosynovium in these patients.

Accurate injection of the corticosteroid has been found to be an important aspect of the patient's response to treatment.¹⁰³

Using radiographic dye to verify correct corticosteroid placement, researchers have found that when the corticosteroid and anesthetic injection did not successfully reach either the EPB or the APL compartment, the patient did not experience relief of pain. Conversely, when the medication was injected accurately, most patients reported an improvement in symptoms. If available, ultrasound may help guide the injection.^{104,105} Studies from 2012 comparing ultrasound-guided injections with standard blind technique demonstrated higher success rates with the use of ultrasound.^{106,107}

Intersection syndrome is a condition that may easily be confused with de Quervain's disease. Because the treatment approach and the clinical course of intersection syndrome differ from that of de Quervain's tenovaginitis, it is important that the clinician also be familiar with this entity. First described in 1841 by Velpea, intersection syndrome describes a clinical entity approximately 4 to 8 cm proximal to the location of de Quervain's disease (see Fig. 52.18).¹⁰⁸ Although the cause is not yet clear, intersection syndrome is thought to result from inflammation of the second dorsal compartment of the wrist, which houses the extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB) tendons.¹⁰⁹ Other possible causes include inflammation of a bursa that develops between the APL and the ECRB tendons,⁸² and inflammation of the ECRL and ECRB tenosynovium where they cross the muscle bellies of the APL and EPB.¹¹⁰

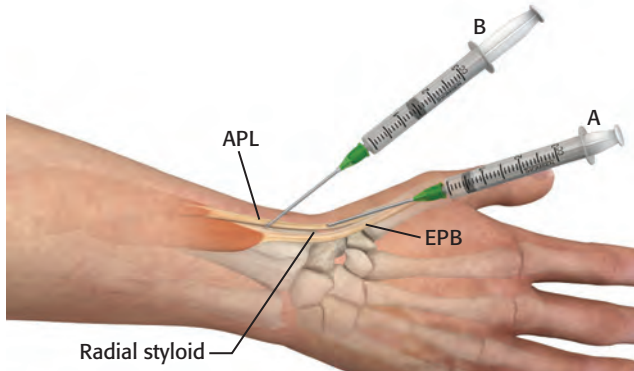

De Quervain's Disease And Intersection Syndrome

Finkelstein's test. The Finkelstein test is positive when pain is reproduced by ulnar deviation of the wrist while the patient grasps the thumb with the fingers.

Occasionally, crepitus may be palpated over the involved area. To elicit this sign, the examiner's fingers are placed over the painful area and the patient's wrist is placed in ulnar deviation, which produces the characteristic sensation.

A, For de Quervain's disease, insert the needle through the most tender point, usually about 1 cm distal to the radial styloid. **B,** For intersection syndrome, the target site is again the site of maximal tenderness, which is usually 4 to 8 cm proximal to the radial styloid. (APL, Abductor pollicis longus; EPB, extensor pollicis brevis.)

Injection for de Quervain's tenosynovitis usually produces a good result.

Figure 52.20 de Quervain's disease and intersection syndrome.

Intersection syndrome is characterized by pain, tenderness, edema, and occasional crepitus 4 to 8 cm proximal to the radial styloid and may be mistaken for de Quervain's disease. This condition is seen in athletes who play sports that require forceful repetitive wrist flexion and extension, such as rowing, weight lifting, gymnastics, and tennis.⁸² Treatment includes rest, NSAIDs, and immobilization with a thumb spica splint in 15 degrees of wrist extension. After a 2- to 3-week trial of splinting, corticosteroid injection therapy is recommended for patients with persistent symptoms. Most patients with intersection syndrome respond well to nonoperative treatment, and surgery is generally reserved for refractory cases.¹¹⁰

APPROACH. For injection of de Quervain's tenosynovitis position the patient's hand so that the ulnar side of the wrist is on the table and the radial side is facing upward (see Fig. 52.20). Introduce a 2.2-cm, 25-gauge needle at the most tender point (approximately 1 cm distal to the radial styloid) through a lidocaine skin wheal, and inject 10 to 20 mg of prednisolone or an equivalent intermediate-acting steroid suspension mixed

with 4 to 5 mL of 1% lidocaine adjacent and parallel to the tendon sheath (peritendinous infiltration). The injection should be under the edge of the first dorsal compartment retinaculum within the first extensor compartment. If firm resistance is met or if needle movement is noted when the patient abducts and extends the thumb, the needle may be in the tendon and should be redirected to prevent intratendinous injection.¹¹¹ Because many superficial vessels are present in this area, aspirate before injecting to verify that the needle is not in a blood vessel.¹⁰³ Be generous with the injection volume because a common reason for failure is the inability to get medication into both tendon sheaths. Frequently, edema is visible at the radial aspect of the first metacarpal base and at the thumb metacarpophalangeal joint dorsally after successful injection.¹⁰³ A lightweight thumb or wrist splint for support and protection may be used at night for several weeks after the injection, but routine splinting after injection is not required.¹⁰⁸ Oral NSAIDs may be prescribed for analgesia but will probably not effect a cure by themselves. There is no proven role for oral corticosteroids.

Carpal Tunnel Syndrome

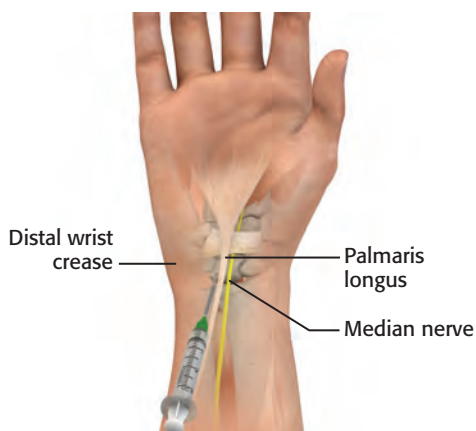

Tinel test. Tap over the median nerve at the volar wrist crease with a reflex hammer; reproduction of tingling and paresthesias supports the diagnosis.

Phalen test. Instruct the patient to hold the wrists together in a flexed position for several minutes; observe for symptoms in a median nerve distribution.

Prior to needle insertion, identify the palmaris longus tendon (*arrow*) by instructing the patient to oppose the thumb and pinky finger while flexing the wrist.

Insert the needle on the ulnar side of the palmaris longus tendon about 1 cm proximal to the distal wrist crease.

Hold the needle at a 45-degree angle, aimed toward the tip of the middle finger. Advance the needle about 1 to 2 cm. If the patient experiences paresthesias, reposition the needle tip because direct nerve injection should be avoided.

Figure 52.21 Carpal tunnel syndrome. Recurrent pain may require surgery.

Injection for intersection syndrome is similar to that for Quervain's disease except that the target site is at the point of maximal tenderness, which is usually 4 to 8 cm proximal to the radial styloid (see Fig. 52.20).

Carpal Tunnel Syndrome. Carpal tunnel syndrome (CTS) is the most common nerve entrapment neuropathy of the wrist.¹¹² Caused by median nerve compression in the fibro-osseous tunnel of the wrist, carpal tunnel syndrome is characterized by pain at the wrist that is associated with pain and paresthesia along the median nerve territory. This includes the medial aspect of the thumb, palmar side of the index and middle fingers, and radial half of the ring finger. Typically, the patient wakes during the night with burning or aching pain, numbness, and tingling. Occasionally the discomfort is extremely severe and causes the patient to seek emergency care. Clinical signs that support this diagnosis include a positive Tinel sign, which is elicited by reproducing the tingling and paresthesia by tapping (with a reflex hammer) over the median nerve at the volar crease of the wrist (Fig. 52.21).¹¹³ In addition, one can perform the Phalen test, described as holding the dorsal sides of the flexed wrists at a 90-degree angle against each

other for several minutes to provoke symptoms in the median nerve distribution (Fig. 52.21).¹¹³ The Phalen test is more sensitive than Tinel sign and is more specific for CTS.¹¹² Severe muscle atrophy of the thenar eminence may develop in advanced or neglected cases. In many patients the disturbance is idiopathic, without a recognizable underlying cause. However, people who participate in repetitive activities of the wrist, such as typing, driving, assembly line work, and racquet sports are at risk for the development of carpal tunnel syndrome.⁶⁸ Other conditions associated with CTS include rheumatoid arthritis (sometimes as the initial manifestation), pregnancy, hypothyroidism, diabetes, and acromegaly. CTS is a clinical diagnosis, but nerve conduction studies can help support the diagnosis. Radiography is not indicated.

Initial therapy for carpal tunnel syndrome consists of modification of activity and splinting; the latter is particularly helpful at night.⁶⁸ Of the medications sometimes used to treat carpal tunnel syndrome, diuretics, NSAIDs, and pyridoxine have been shown to offer little to no relief.¹¹⁴ In contrast, the benefits, at least in the short term (e.g., 4 to 6 weeks), of local steroid injections for carpal tunnel syndrome have been well proven.^{115,116} In a 2007 Cochrane review of randomized trials

by Marshall and colleagues, local steroid injection provided greater clinical improvement 1 month after injection than did placebo and up to 3 months after injection than oral steroid treatment. However, symptoms after local corticosteroid injection were no different from the symptoms after either NSAIDs or splinting at 8 weeks.¹¹⁶ The benefits of initial steroid injection versus surgical intervention for carpal tunnel syndrome are controversial because there is little scientifically valid information from which to draw any conclusions. In one small study, Hui and associates¹¹⁷ found that surgery resulted in a better symptomatic outcome (but not grip strength) than did local steroid injection over a 20-week period. It appears that local steroid injection for carpal tunnel syndrome offers improvement in symptoms, but this improvement may not be permanent or long term. Current recommendations include a trial of conservative treatment (including possible steroid injection) for patients who have mild to moderate symptoms and lack thenar wasting.¹¹⁸ Surgery is indicated for patients with persistent symptoms after conservative treatment and for those with severe weakness of the thumb abductors.¹¹² Nerve compression should be confirmed by nerve conduction studies before surgery.¹¹⁵

APPROACH. Insert the needle through a lidocaine skin wheal just ulnar to the palmaris longus tendon and approximately 1 cm proximal to the distal crease at the wrist. The palmaris longus tendon can be appreciated by having the patient pinch all the fingertips together while holding the wrist in a neutral position (see Fig. 52.21).¹¹⁹ Injecting medial (ulnar) to the palmaris longus is preferred because it avoids accidental injection of the median nerve and superficial veins. Direct a 2.5- to 3.9-cm, 25-gauge needle at a 45-degree angle to the skin surface toward the tip of the middle finger. Advance the needle 1 to 2 cm and inject 20 to 40 mg of methylprednisolone (or another intermediate-acting steroid equivalent) with or without lidocaine along the track and into the tissue space. If the patient complains of paresthesia, or the needle meets resistance during injection, redirect the needle to avoid injecting directly into a nerve or tendon, respectively.¹¹⁹ Up to 2 weeks may be required for the paresthesia to abate significantly, although it usually takes only a few days for improvement of nocturnal pain.¹²⁰ A lightweight wrist splint may hasten recovery. Repeated injections may be given, but if a response is not elicited or permanent after two or three injections decompressive surgery should be considered.

Trigger Finger (Stenosing Flexor Tenosynovitis). A *trigger* or *snapping* finger is one of the most common problems of the hand, affecting roughly 2% of the general population. It is characterized by a stenosed tendon sheath at the level of the first annular pulley (A1), which is located on the palmar surface over the base of the metacarpal head (Fig. 52.22).¹²¹ In this condition the A1 pulley becomes inflamed, and a nodule develops on the tendon as it gets “pinched” under the constricted sheath.¹²¹ Locking occurs when the involved digit is in flexion and is especially troublesome when the patient awakens in the morning. This can occur in any finger but is seen most frequently in the ring and middle fingers.

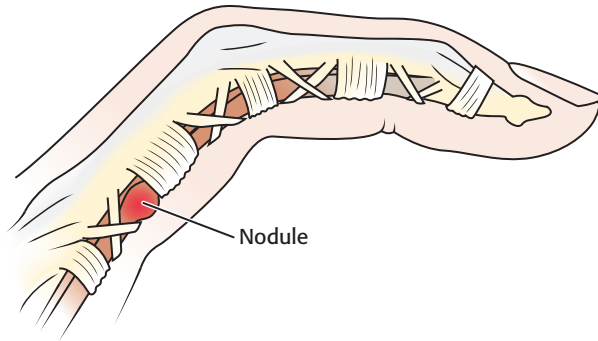

Besides thickening and stenosing of the tendon sheath, a trigger finger may also be characterized by flexor tendon synovitis. The tendon sheaths are long and tubular, and the walls are lined with a thin layer of synovial cells. Symptoms develop when the tendon becomes trapped and is unable to glide within the tendon sheath. A nodule or fibrinous deposit

may form at a site in the tendon sheath, usually over or just distal to the metacarpal head of the trigger finger. When the digit is flexed, the nodule moves with the tendon proximally, and on extension it gets “stuck” on the pulley thereby leading to intermittent catching of the tendon.¹²¹ The nodule may be palpable on physical examination, but this is not necessary for diagnosis.⁶⁸ Carpal tunnel syndrome commonly coexists with a trigger finger and may be caused by tenosynovitis. Common causes of tenosynovitis include trauma, diabetes mellitus, and rheumatoid arthritis, although it may also be a primary and idiopathic disorder.¹⁰⁹

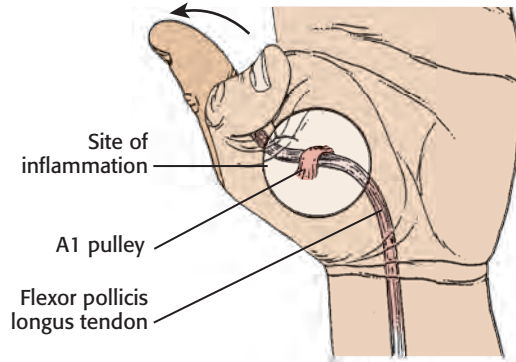

Conservative treatment including local rest or splinting, application of moist heat, and NSAID therapy is a common initial approach aimed at alleviating pain and allowing for smoother movements of the finger. Splinting involves immobilization of the metacarpophalangeal (MCP) joint with slight flexion for up to 6 weeks and has been shown to be an effective option for those who want to avoid corticosteroid injections.¹²² However, if these measures fail to control the symptoms, or if the symptoms are severe, corticosteroid injection is indicated. One double-blind, placebo-controlled, randomized study of trigger finger demonstrated that steroid injections were significantly more effective than placebo.¹²³ At follow-up 3 weeks after treatment, 9 of the 14 patients receiving a combination of lidocaine and steroid injections were asymptomatic versus 2 of the 10 patients receiving lidocaine injections alone. Similar results were noted in a 2009 Cochrane review, which found that corticosteroid injection with lidocaine was more effective than lidocaine alone at 4 months.¹²⁴ Steroid injections are more successful when performed in patients with a palpable nodule or symptoms for less than 6 months.¹²⁵ Younger age, insulin-dependent diabetes, involvement of multiple digits, and a history of other tendinopathies is associated with treatment failure.¹²⁵ There is also evidence to suggest that the efficacy of steroid injections for trigger fingers diminishes with each subsequent injection at the same site.¹²⁶ As a general guideline, if treatment fails after three injections (separated by several weeks or months), consider surgery for treatment of the condition.⁶⁸ In addition, patients with insulin dependent diabetes mellitus require surgical release for trigger finger more often than do noninsulin-dependent diabetics.¹²¹ Division of the first annular pulley, digital nerve injury, scarring, and recurrence are well-known complications of surgical release.¹²⁶

APPROACH. Preparation of the site before injection requires meticulous adherence to aseptic technique. Rest the patient's hand on a table with the palm facing upward. The injection point is at the base of the finger's flexion crease between the A1 and the A2 tendon pulleys. Using a 2.2-cm, 25-gauge needle, enter the skin at a 30-degree angle and insert the needle into the tendon sheath parallel to the tendon fibers. Inject 0.25 to 0.35 mL of an intermediate-acting corticosteroid suspension mixed with 1.5 to 3 mL of anesthetic (see Fig. 52.22). If resistance is felt on insertion of the needle, an intratendinous location is suggested. Withdraw the needle slightly before injection. Similar injections can be administered in the base of the thumb metacarpal for a snapping thumb. Although injection into the tendon sheath is the goal, Taras and coworkers¹²⁷ showed that injection of steroid into the subcutaneous tissue surrounding the tendon sheath provided similar improvement as intrasheath injections. If relapses are frequent or the clinical response is not satisfactory, surgical release is indicated.

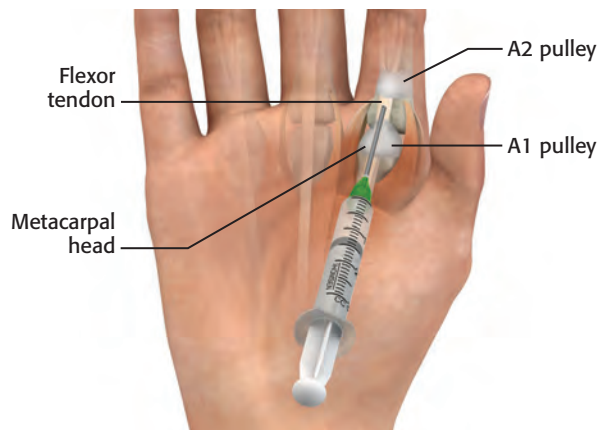

Digital Flexor Tenosynovitis (“Trigger Finger”)

Trigger finger (stenosing tenosynovitis) can affect any digit, including the thumb, but it is most common in the ring and middle fingers. Palpation of the flexor tendon sheath over the metacarpophalangeal joint often reproduces the symptoms. Injection is often very effective, but the nodule may persist.

In advanced cases, inflammation at the proximal (A1) pulley of the flexor tendon sheath overlying the metacarpophalangeal joint may hold the digit in either a flexed or an extended position. Generally, the tendon becomes thickened either proximal or distal to the pulley, which causes a snapping or a locking phenomenon with finger flexion or extension.

Locate the tendon point at the base of the finger flexion crease, which is located between the A1 and A2 pulleys.

Angle the needle 30 degrees into the involved tendon sheath, parallel to the tendon fibers.

Figure 52.22 Digital flexor tenosynovitis (“trigger finger”). (Top right, from Walker LG, Meals RA: Tendinitis: a practical approach to diagnosis and management, *J Musculoskel Med* 6:41, 1989. Reproduced with permission.)

CARPAL/METACARPAL INFLAMMATION. Overuse and aging can lead to pain at the base of the thumb and fingers. This is especially common in elderly women and can be quite painful. The first metacarpal articulates with the trapezium, a common site for this condition. Injection therapy is usually quite successful (Fig. 52.23).

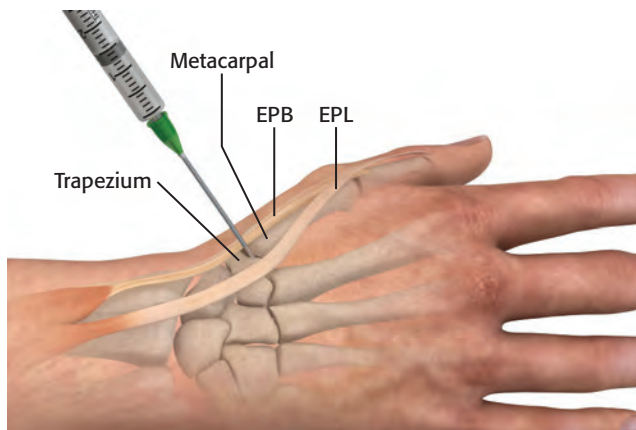

Hip Region

Greater Trochanteric Pain Syndrome (Formerly Trochanteric Bursitis). Greater trochanteric pain syndrome (GTPS) is the second leading cause of lateral hip pain after osteoarthritis.¹²⁸ Formerly referred to as *trochanteric bursitis*, recent imaging and histopathological studies have shown that the actual bursa is rarely involved. GTPS can be confused with other conditions at or near the hip such as sacrolumbar disease, hip or femur pathology, and metastases.^{129–131} The hallmark, though, is the demonstration of discrete tenderness on deep palpation at or adjacent to the greater trochanter.¹²⁹

GTPS is primarily caused by tendinopathy of the gluteus medius or minimus. The principal bursae, when involved, are the subgluteus maximus bursa, the subgluteus minimus bursa, and the gluteus minimus bursa, although other bursae of the hip may be affected (Fig. 52.24). The pain may be acute, but is more often subacute or chronic; frequently, patients have already tried NSAIDs without success and have been assigned a number of incorrect diagnoses. Risk factors include female gender, obesity, and those with underlying lower gait disturbances and scoliosis. The chief locus of the pathologic condition is in the abductor mechanism of the hip. Pain occurs near the greater trochanter and may radiate down the lateral or posterolateral aspect of the thigh and, rarely, into the knee.¹³² The pain is described as *deep, dull, and aching*, and often interferes with sleep. Lying on the affected hip, stepping from curbs, and descending steps frequently provoke the pain.

On examination, with the patient lying on the unaffected side, tenderness may be elicited over and adjacent to the greater

Carpal/Metacarpal Inflammation

Painful and limited motion of the thumb is often caused by inflammation at the trapezium-metacarpal joint. Inject at the apex of the snuffbox while avoiding the radial artery. (EPB, Extensor pollicis brevis; EPL, extensor pollicis longus. The anatomical snuffbox is outlined by these two tendons.)

Injection therapy is usually quite successful for this very painful condition, which is common in older women.

Figure 52.23 Carpal/metacarpal inflammation.

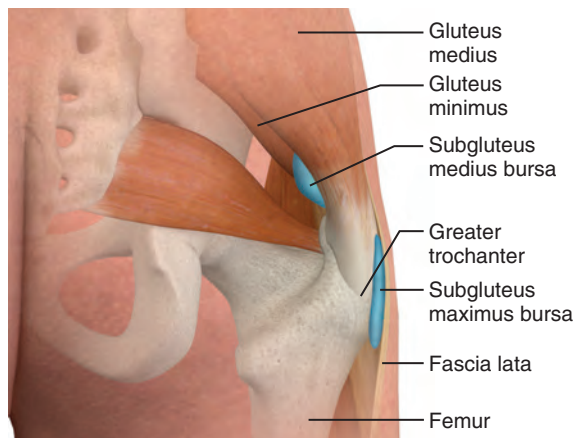

Figure 52.24 Greater trochanteric pain syndrome. The principal bursa lies between the gluteus maximus and the greater trochanter, although other bursae may also be involved.

trochanter. In contrast to true hip joint involvement, the Patrick FABERE sign (*flexion, abduction, external rotation, and extension*) may be negative, and complete passive range of motion is relatively painless. Active abduction when the patient lies on the opposite side typically intensifies the discomfort, and sharp external rotation may accentuate the symptoms. Internal rotation does not usually affect the level of pain.¹²⁹ Hip radiographs may demonstrate a calcific deposit adjacent to the trochanter; however, the incidence of this finding is low.¹²⁹

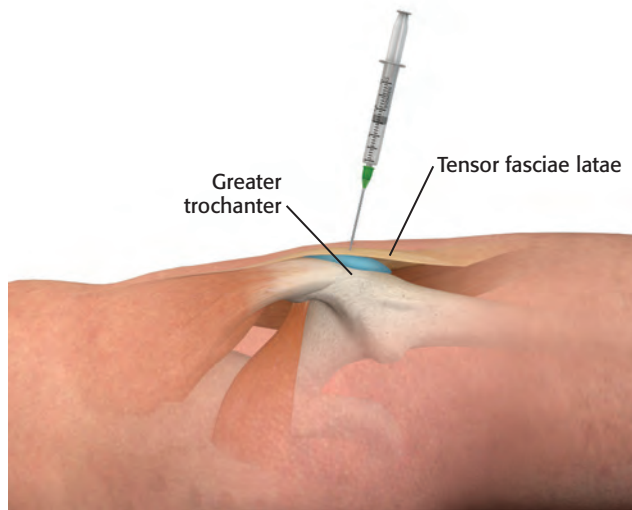

GTPS is a self-limited condition that can improve with conservative measures such as rest, ice, oral acetaminophen and NSAIDs, weight reduction, and correction of length discrepancy. In patients with persistent pain, corticosteroid injection for GTPS can be an effective therapy.¹³⁰ In one study, 77% of patients reported improvement of their pain after an

injection of betamethasone mixed with lidocaine; 61% of the patients had sustained improvement at 26 weeks.¹³³ However, in a 2011 randomized controlled trial, the benefits of steroid injection were not seen at 12-month follow-up.¹³⁴ Failure of corticosteroid therapy should prompt the clinician to seek alternative diagnoses, such as true hip joint disease, which can easily be confused with GTPS.¹³⁵ In addition, although rare, there have been case reports of septic trochanteric bursitis caused by tuberculosis.¹³⁶

APPROACH. Place the patient in a supine or lateral recumbent position and identify the site of maximum tenderness for needle entry. Advance a 3.9- to 5.0-cm, 20- or 21-gauge needle perpendicular to the skin until the tip of the needle reaches the trochanter (Fig. 52.25). Withdraw the needle slightly and widely infiltrate the site with 3 to 10 mL of lidocaine and 20 to 40 mg of methylprednisolone or an equivalent steroid.

Ischiogluteal Bursitis. *Weaver's bottom* is a painful disorder characterized by pain over the center of the buttocks with radiation down the back of the leg.¹³⁰ This condition is rarely diagnosed initially and is often mistaken for lumbosacral strain, a herniated disk, or a spinal cord tumor. The ischial or ischiogluteal bursa is adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Patients are usually asymptomatic when standing; however when going to a seated position, the gluteus maximus muscle slides away from the bursa allowing for direct contact between the bursa and subcutaneous tissue. The condition is often associated with a sedentary lifestyle, which is where it gets its nickname. Sitting on hard surfaces, bending forward, and standing on tiptoes may all provoke the pain. Maximal tenderness is present over the ischial tuberosity. At times a soft tissue mass may also be felt in this area.¹³⁷ When it is recognized, a skillful intrabursal injection, coupled with a few days rest, usually relieves the extreme pain.

Greater Trochanteric Pain Syndrome

Place the patient in the lateral recumbent or supine position. Insert the needle at the area of maximum tenderness, and advance perpendicular to the skin until the needle tip reaches the greater trochanter.

After the trochanter is reached, withdraw the needle slightly, and infiltrate the site widely with 3 to 10 mL of lidocaine and 20 to 40 mg of methylprednisolone (or the equivalent).

Figure 52.25 Greater trochanteric pain syndrome.

APPROACH. Place the patient in a prone position and insert a 5.0-cm, 20- to 22-gauge needle through a lidocaine skin wheal. Advance the needle cautiously to avoid the sciatic nerve, which lies at a depth of approximately 6.5 to 7.5 cm. If paresthesias occur (indicating contact with a nerve), withdraw and redirect the needle. Inject 5 to 10 mL of lidocaine and 20 to 40 mg of methylprednisolone into the bursa. Because of the close proximity of the bursa to the sciatic nerve, some experts advise against the use of injection therapy in this area, especially as the addition of steroids can cause soft tissue atrophy making sitting uncomfortable.

Knee Region

Prepatellar Bursitis. *Housemaid's knee* or *nun's knee* is characterized by swelling with effusion of the superficial bursa anterior to the patella (Fig. 52.26). In contrast to intraarticular pathology, passive motion of the knee is fully preserved and the pain is generally mild, except during extreme knee flexion or direct pressure. Although the disorder is usually caused by pressure from repetitive kneeling on a firm surface, it can also develop after direct trauma, and occasionally it is a manifestation of rheumatoid arthritis or gout.¹³⁸ Although uncommon, the prepatellar bursa is one of the most frequent sites of septic bursitis.⁴ In fact approximately one third of all cases are septic in nature.¹³⁹ Moreover, patients with septic prepatellar bursitis may not have the classic signs of infection such as erythema, warmth, or fever, making it difficult to differentiate from aseptic bursitis.¹⁴⁰ The bursal aspirate should therefore always be sent for laboratory analysis.

Acute bursitis is more likely to be septic with the most common bacteria being skin flora; however, gout and direct trauma are also known causes. Chronic bursitis is more likely to be secondary to trauma and less likely infection. Symptoms of septic bursitis include localized redness, swelling, and tender-

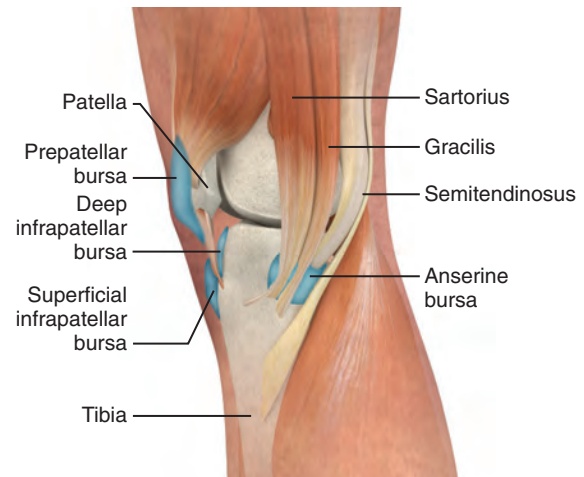

Figure 52.26 Bursae of the knee (medial view). The prepatellar bursa lies superior to the patella, and the pes anserine bursa lies deep to the insertion of the sartorius, gracilis, and semitendinosus tendons. Prepatellar bursitis is common in carpet layers, and pes anserine bursitis is seen in dancers and runners. Infrapatellar bursitis is common in long-distance runners and can be mistaken for patellar tendinitis. Pain is felt below the patella at the midpoint of the patellar tendon and is elicited by knee extension. Note that there are two infrapatellar bursae. Osgood-Schlatter disease is similar in adolescents, a condition that should not be injected.

ness over the patella. Fever may be present in 30% of patients. Examination may reveal subtle evidence of trauma including abrasions or puncture wounds. Patients with aseptic bursitis may experience the same swelling; however, warmth and tenderness are mild or absent in most patients.

APPROACH. Place the patient supine with the affected leg extended (Fig. 52.27). The bursa is located superficially, between the skin and the patella, and can often be “milked” during the procedure to facilitate aspiration. Use a 2.5-cm, 20- to 21-gauge needle to enter the bursa and aspirate as much fluid as possible. Aspiration often yields a surprisingly scant amount of clear, serous fluid because the prepatellar bursa is multilocular rather than the usual single cavity. Once aspiration is complete, instill 1 to 2 mL of lidocaine with 15 to 20 mg of a prednisolone (or an equivalent steroid) suspension. In some cases the procedure may need to be repeated more than once (in 6- to 8-week intervals) to obtain a lasting result. Following the procedure, instruct the patient to discontinue the provocative activity and avoid direct pressure to the knees. A compressive dressing should be worn for a few days.

Suprapatellar Bursitis. Suprapatellar bursitis is usually associated with synovitis of the knees. On occasion the bursa is largely separated from the synovial cavity with only a very minor communication, and the swelling and effusion are chiefly confined to the suprapatellar area. This may be traumatic in origin or a manifestation of an inflammatory arthropathy.

APPROACH. The procedure for aspiration and injection of the suprapatellar area is similar to that for the knee.

Pes Anserinus Pain Syndrome (Formerly Anserine Bursitis). Historically referred to as *anserine bursitis*, Pes anserinus pain syndrome (PAPS) is used to characterize pain along the medial aspect of the leg from the upper tibia down to the knee. Imaging studies in PAPS patients seldom demonstrate an associated anserine bursitis,^{141,142} hence the change in terminology. In the past, the syndrome was associated with horseback riding (and the disease was referred to as *Cavalryman's disease*); however, it now mainly occurs in heavy women with disproportionately large thighs in association with osteoarthritis of the knee, although it may also be seen in athletes involved in running, baseball, and racquet sports.¹³⁰ In rare cases there may be true bursitis of the anserine bursa, which is relatively large at 7 cm and located on the anteromedial side of the knee, inferior to the joint line at the site of insertion of the conjoined tendons of the sartorius, semitendinosus, and gracilis muscles, and superficial to the medial collateral ligament. The entity is characterized by a relatively abrupt onset of knee pain along with localized tenderness and a sense of fullness in the vicinity of the anserine bursa approximately 4 to 5 cm below the anteromedial aspect of the tibial plateau. Pain is exacerbated by flexion of the knee. Corticosteroid injection for PAPS has been shown in clinical trials to be an effective treatment.¹⁴³

APPROACH. Position the patient with the knee flexed 90 degrees. Using an anterior or medial approach with a 2.5- to 3.9-cm, 22-gauge needle, identify the point of greatest tenderness and gently advance the needle until the tibia is reached. Withdraw the needle 2 to 3 mm and inject 2 to 4 mL of lidocaine along with or followed by approximately 20 to 40 mg of a corticosteroid suspension (Fig. 52.28). Prompt symptomatic relief is frequently obtained, but the duration of benefit is variable and probably correlates with the patient's weight-bearing activities. It is important to avoid direct injection of the corticosteroid suspension into the nearby tendons.

Medial Collateral Ligament Bursa. This bursa is located anterior to the tibia and posterior to the medial collateral ligament. Injury to this bursa often occurs when the patient undergoes a twisting motion with concurrent external rotation of the tibia. Tenderness may be appreciated along the anteroinferior aspect of the medial collateral ligament, and the pain is exacerbated with extension of the knee. This condition may sometimes be confused with a medial meniscus tear, and magnetic resonance imaging might be necessary to differentiate the two conditions. Treatment is usually successful with conservative measures, including relative rest, compression, and NSAIDs.¹³⁰

Popliteal Cyst. Baker cysts are herniated fluid-filled sacs of the articular synovial membrane that extend into the popliteal fossa, sometimes through the natural communication between the bursa in the posterior of the knee and the joint itself. These cysts may also be caused by swelling of the medial gastrocnemius or semimembranosus bursae alone. Baker cysts are common with prevalence in the general population of 4.7%.¹⁴⁴ They may occur secondary to trauma and are seen in patients with rheumatoid arthritis, gout, and osteoarthritis.¹³⁰ Patients will often complain of *popliteal fossa* tenderness and swelling that may extend into the calf. Activities that involve active flexion of the knee, such as walking or jumping, exacerbate the symptoms.

The clinical manifestation of Baker cysts can mimic that of deep venous thrombosis (DVT). For this reason, symptomatic Baker cysts are also known as *pseudothrombophlebitis syndrome*, and it is important to take great care in differentiating the two.¹⁴⁵ In most studies, 2% to 6% of patients suspected of having DVT actually have a popliteal cyst as the cause of their knee or calf pain. Ultrasound is an important tool in this diagnosis. Many cases of Baker cyst resolve spontaneously over a few weeks. However, treatment may require surgery to correct any articular injury or to remove the cyst.

Smith and colleagues reported safe and effective treatment of symptomatic popliteal cysts with ultrasound-guided aspiration of fluid through a spinal needle, fenestration of the cyst walls and septations, and injection of 1 mL triamcinolone and 2 mL 0.5% bupivacaine into the decompressed remnant.¹⁴⁶ Another approach involves arthrocentesis followed by injection of glucocorticoids directly into the knee joint.^{147,148} In a study of thirty patients with knee osteoarthritis complicated with a symptomatic Baker cyst, a single intraarticular injection of 40 mg triamcinolone acetonide resulted in an improvement in knee pain, swelling, and range of motion, in addition to a reduction in Baker cyst size.¹⁴⁹ Steroid injections should be done with care because of the risk for neurovascular injury.

Ankle, Foot, and Heel Region

Ankle Tendinitis. This is a relatively uncommon condition that may result from unusual repetitive activity, or rarely from acute trauma. The disorder is differentiated from ankle joint involvement by the lack of pain or restricted motion during passive flexion and extension of the ankle. Active flexion and extension of the toes produces pain and there is tenderness along the involved tendons. Initial treatment consists of rest, NSAIDs, and immobilization, sometimes for several weeks. Some patients may eventually need operative intervention for prolonged symptoms.¹⁵⁰ Local steroid injections have been used successfully in patients who do not respond to conservative measures; however, the risk for tendon rupture is well documented. As a result, tendon sheath injections should be

Prepatellar Bursitis Aspiration

1 This patient has had anterior knee swelling for 6 weeks after falling directly onto his knee. This collection is confined to the prepatellar space, and passive range of motion of the knee is preserved.

2 After careful antiseptic preparation, infiltrate the entry site and the anticipated trajectory of the needle with lidocaine.

3 Keep the knee extended during the procedure. Insert the needle into the fluctuant area in the space between the skin and the patella; either a medial or a lateral approach may be used.

4 Once in the bursa, aspirate the fluid. Occasionally, a substantial volume of fluid may be obtained, so use a large syringe.

5 "Milk" the bursa during aspiration to facilitate fluid removal. The needle may be repositioned if needed because the prepatellar bursa is a multiloculated structure (as opposed to a single cavity).

6 Note that this patient's aspirate was grossly hemorrhagic, consistent with his history of knee trauma.

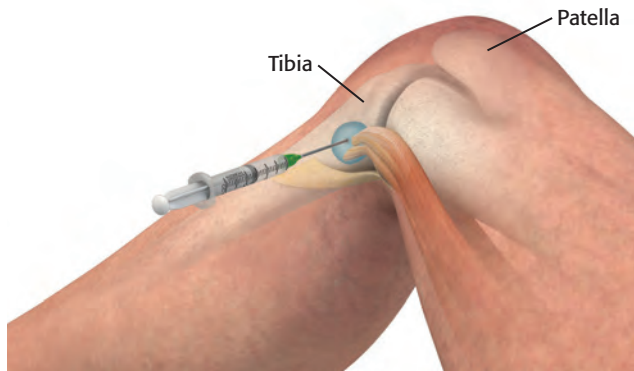

7 Remove as much fluid as possible. This patient's knee regained a normal appearance after the procedure.

8 At the end of the procedure, apply a compressive dressing to reduce recurrence.

Figure 52.27 Prepatellar bursitis aspiration.

Pes Anserine Pain Syndrome

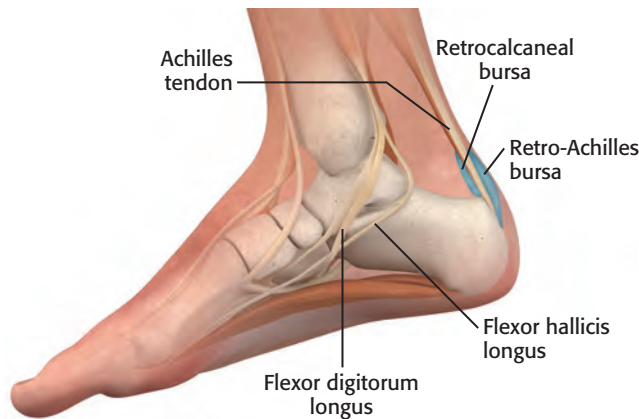

Insert the needle at the point of maximum tenderness. This will be inferior to the patella and medial to the tibial tuberosity.

Advance the needle until the tibia is reached, and then slightly withdraw the needle and inject the steroid. Avoid direct injection into the nearby tendons.

Figure 52.28 Pes anserine pain syndrome.

Heel Pain

Heel pain. Talalgia may involve the tendons, bursae, or fasciae around the heel. Do not inject Achilles tendinitis since tendon rupture may occur. Fluoroquinolones can cause significant Achilles tendinopathy (see Box 52.1).

Injection of calcaneal bursitis with a heel spur. A lateral injection is preferred (see Chapter 51).

Figure 52.29 Heel pain.

reserved for patients with persistent symptoms despite an adequate trial of conservative therapy, and should be done in consultation with a foot and ankle specialist.

APPROACH. Enter the tendon sheath tangentially with a 2.5- to 3.9-cm, 22- or 25-gauge needle and inject approximately 2 to 4 mL of a mixture of corticosteroid (20 to 40 mg of methylprednisolone) and lidocaine.

Bunion Bursitis. Hallux valgus deformity of the big toe is more commonly referred to as a *bunion*. This common medical condition is found in up to 23% of all adults, especially patients over 65 and in women.¹⁵¹ On rare occasions inflammation develops in the medial bursa of the first metatarsophalangeal joint of the great toe. Initial treatment is conservative and

includes shoe modification, stretching, and ice; however, on occasion tense swelling occurs and decompression is required. In these cases, aspiration with culture of the fluid should be performed.

APPROACH. If no infection is present, the bursa is injected with 5 to 10 mg of methylprednisolone via a 2.5-cm, 20-gauge needle. Special shoes or an orthopedic correction will be needed if the swelling recurs.

Heel Pain. *Talalgia* may be caused by many different conditions including Achilles tendinitis, retrocalcaneal bursitis, and plantar fasciitis (Fig. 52.29). Additional discussion may be found in Chapter 51. The bursae of clinical significance around the heel include the retroachilles bursa (located in the space between

the skin and the Achilles tendon), the retrocalcaneal bursa (located between the Achilles tendon and the calcaneus), and the subcalcaneal bursa. Achilles tendinitis or bursitis may be traumatic in origin but is more apt to be part of a systemic disease such as rheumatoid or gouty arthritis. Although a normal Achilles tendon is thick and strong, when affected by an inflammatory arthropathy it is predisposed to degeneration, and because the Achilles tendon is not invested by a full synovial sheath, it is more vulnerable to intratendon instillation. Because of the potential hazard of tendon rupture after local steroid injection, avoid infiltration of steroids into this area. Rather, treat Achilles tendinitis with rest, splinting, and oral NSAIDs.

Retrocalcaneal bursitis is often seen in association with Haglund deformity, a bony ridge on the posterosuperior aspect of the calcaneus. The bursa lies anterior to the Achilles tendon and posterior to the calcaneus. Local swelling and tenderness at the posterior aspect of the heel, proximal (and sometimes lateral) to the insertion of the Achilles tendon, characterize this bursitis. Treatment is focused on minimizing pressure on the bony ridge, which includes the use of open-heeled shoes (clogs), bare feet, sandals, or a heel lift. Conservative measures such as ice, oral NSAIDs, and rest are other common treatment modalities. Corticosteroid injections are not recommended because of the risk for Achilles tendon rupture.^{152,153}

The condition in this region that is most amenable to injection therapy is plantar fasciitis, which is also the most common cause of heel pain in adults.¹⁵⁴ The plantar fascia is located deep to the fat layer of the foot and extends from the calcaneus to the base of the digits. It is responsible for support of the medial longitudinal arch of the foot.¹⁵⁵ Signs of this condition include pain on the plantar medial aspect of the heel, which is often worse in the morning after long periods of rest, and with passive dorsiflexion of the toes.¹⁵⁴ The pain may be relieved with activity. Although patients may have a heel spur, many symptomatic patients do not, and the presence of a heel spur should not be considered pathognomonic for the condition. Although still debated, the pathology is generally thought to originate from microtears in the fascia, often as a result of overuse.^{152,153} Obesity may also increase the risk for plantar fasciitis because of the excessive load on the fascia.¹⁵⁴

Most cases of plantar fasciitis eventually resolve with nonsurgical management.¹⁵⁶ Treatment begins with elimination of any precipitating activity, relative rest, strength and stretching exercises, arch supports, and night splints. If these conservative measures are not effective, injection of the painful heel will usually provide short-term improvement. In a Cochrane review, steroid injections for plantar fasciitis resulted in significant improvement at 1 month, but not at 3 or 6 months when compared with control groups.¹⁵⁷ Ultrasound guidance may improve the accuracy and success rates for injection, but data thus far are conflicting.^{158–160} It should also be remembered that there is a risk for rupture of the plantar fascia and fat pad atrophy with corticosteroid injections.¹⁵² One study reported a rupture rate of close to 10%.¹⁶¹ Therefore caution should be exercised when injecting steroids into a painful heel. In addition, because this condition tends to be chronic or recurring, referral to an appropriate specialist is recommended.

APPROACH. Insert a 2.5-cm, 22- to 24-gauge needle at the spot of maximal tenderness on the medial aspect of the heel (see Fig. 52.29). Enter the plantar surface at 90 degrees by sliding into the space at the midpoint of the calcaneus. The tip of the needle should lie in the aponeurosis of the attachment

to the os calcis. Inject 1 mL of lidocaine and 10 to 20 mg of methylprednisolone. Injection through the more superficial aspect of the base of the foot should be avoided because it may result in dispersion of medications into the fat pad and produce fat pad atrophy.¹⁵⁵

Trigger Points

The technique for trigger point injection (universal technique) is the same regardless of location and is described in detail earlier in the chapter (see section on **Invasive Techniques**).

Myofascial Headache Syndromes

Trigger points commonly contribute to the muscle component of many headache syndromes, so it is important to carefully examine the muscles of the entire head, neck, shoulder, and back region for hypersensitive areas when evaluating patients with headaches. Trigger points are often found in the sternocleidomastoid, levator scapulae, and trapezius muscles, and less frequently in the scalp and facial muscles. The posterior strap muscles, including the splenius and semispinalis muscles, are also commonly involved. Trigger points along the muscles of mastication can lead to unilateral headaches, and also ear, tooth, and temporomandibular joint pain.¹⁶² Trigger points in the thoracic paraspinal muscles are frequently associated with both migraine and tension headaches, whereas trigger points in the quadratus lumborum and gluteus medius have been associated with unilateral headaches.

Torticollis. Myofascial causes of torticollis usually involve the trapezius, sternocleidomastoid, and levator scapulae muscles, either alone or in a synergistic manner. The splenius and semispinalis muscles may also be involved. Carefully inject trigger points in the trapezius muscle to avoid puncture of a high-rising apical pleura.

Levator Scapulae Muscle Syndrome. Painful sensitive foci may occur at the origin of the levator scapulae muscle on the superior medial aspect of the scapula, along the flat muscle belly, or at the insertion of the transverse processes of the first four cervical vertebrae (Fig. 52.30A). Pain is usually referred to the posterior cervical region, the posterior aspect of the scalp, and the periauricular area.

Splenius Capitis and Semispinalis Capitis Muscle Syndrome. Pain resulting from the trigger points in the splenius capitis and semispinalis capitis muscles may be located over the muscles themselves or be perceived in the head and face and give rise to headaches and dizziness (see Fig. 52.30B). Trigger points in the splenius capitis and semispinalis capitis muscles may be difficult to pinpoint, so having the patient point to the area of maximal tenderness is extremely helpful.

Trapezius Muscle Syndrome. The trapezius muscle is a frequent source of muscle pain and headache, especially at the angle of the neck or at the occipital insertion where trigger points are most commonly located (see Fig. 52.30C). When injecting trigger points at the angle of the neck be careful not to puncture the apical pleura.

Sternocleidomastoid Muscle Syndrome. The sternocleidomastoid muscle is also a frequent source of neck pain and headache. Trigger points are most often found at its sternal and clavicular origins and occipital insertions, in addition to

the upper two thirds of the muscle belly (see Fig. 52.30C). Dizziness, ipsilateral ptosis, lacrimation, and conjunctival injection may accompany trigger points located in the sternocleidomastoid muscle.¹⁶³ Pain may involve the muscle itself or be referred to the periauricular, facial, or frontal areas.

Cervical Myofascial Pain Syndrome. This syndrome represents a chronic cause of neck pain, sometimes mistaken for radiculopathy. Trigger points can be present in the head, neck, or shoulder area causing referred pain through the cervical area. A nonfocal neurologic exam and sometimes imaging is paramount to exclude more serious causes.

Myofascial Shoulder Disorders

Myofascial shoulder pain is frequently misdiagnosed as bursitis. It is important to remember that a painful shoulder may be caused by trigger points, which are most often located in the posterior scapular muscles. Other common sites include the supraspinatus, infraspinatus, and pectoralis major muscles. The teres, deltoid, and triceps muscles are rarely involved. Occasionally, trigger points located in the splenius, semispinalis, and gluteal muscles contribute to shoulder pain syndromes and should be treated if found.

Scapula Muscles. When injecting trigger points in the lateral scapular and periscapular muscles, place the patient prone with a pillow under the chest to round the shoulders and facilitate injection. Note the anatomy and boundaries of the shoulder before injection, and warn the patient to not move the shoulder. Stabilize the scapula with the nondominant thumb and fingers to prevent movement of the lower portion of the scapula, which could result in inadvertent puncture of the pleura.

Myofascial pain is also commonly associated with a number of muscle beds at the medial border of the scapula including the rhomboids, the serratus anterior, the subscapular muscles, and the levator scapulae. To inject trigger points in these medially situated muscles, have the patient place the ipsilateral hand behind the back. This will cause winging of the scapula and a safer approach. Direct the needle tangentially for easy access to the serratus anterior and subscapularis muscles. As with the lower portion of the scapula, care should be taken to inject the levator scapulae at an oblique angle that is nearly parallel to the thorax to help reduce the chance of accidentally inducing pneumothorax.

Infraspinatus Muscle Syndrome. Because of its multiple functions, this muscle is subject to earlier degeneration than other muscles of the rotator cuff and is more susceptible to trigger points (see Fig. 52.30D). Trigger points in the infraspinatus muscle invariably cause sympathetic hyperactivity and often contribute to dystrophy-like syndromes of the upper extremity. To identify trigger points in the infraspinatus muscle it is important to palpate along the entire length of the muscle bundles, and also across the grain of the muscle (see Fig. 52.4).

Somatic Visceral Reflex Phenomenon

Skeletal muscle trigger points may contribute to visceral pain by either induction or continuation of the spinal reflex arc.^{164–169} Visceral sympathetic afferent nerves converge on the same dorsal horn neuron as somatic nociceptive afferent nerves do. Reflex sympathetic efferent nerve activity may result in spasm of the visceral sphincters and cutaneous nociceptors (leading in part to referred cutaneous pain). The rectus abdominis

muscle is particularly prone to trigger point development in conjunction with visceral pain. For example, right upper quadrant trigger points are associated with gallbladder disease, left upper quadrant trigger points with esophageal and ulcer disease, right lower quadrant trigger points with dysmenorrhea, and left lower quadrant trigger points with intestinal disorders.

Treatment of abdominal wall trigger points can provide significant relief of somatic and visceral pain in appropriate patients. Consider injecting these trigger points when palpating the trigger point or placing the affected muscle under tension (e.g., performing a sit-up) produces the characteristic visceral discomfort. It should also be noted that abdominal wall trigger points are often accompanied by trigger points in the corresponding posterior paraspinal muscle segment. For example, esophageal spasm is frequently associated with trigger points on the left posterior aspect of the thorax at spinal nerve levels T3 through T6. To provide more effective pain control, treat these trigger points also.

Rectus Abdominis Muscle Syndrome. These muscles are frequent sites of anterior abdominal wall pain. They often flare up after abdominal surgery and may be a major cause of postoperative pain in some patients. Abdominal wall trigger points are most commonly found in the upper three segments of the rectus muscle and can be located more easily by placing the patient in a supine position with the head and neck flexed so that the rectus muscles are under tension (see Fig. 52.30E). Pain and tenderness are usually localized directly over the trigger point. Trigger points in the lower rectus segments may be a cause of low back pain. Lower segment trigger points may be associated with trigger points in the corresponding posterior lumbar spinal segments (i.e., L4, L5, S1).

Pectoralis Major/Pectoralis Minor Muscle Syndrome. The pectoralis major muscle is a frequent site of myofascial pain, particularly at its insertion on the anterior medial portion of the shoulder (see Fig. 52.30E). The inferior belly of the muscle is also a common area for trigger points, so be sure to carefully search the entire muscle to avoid missing a treatable area. Pain is usually located at the trigger point, but patients with trigger points in the clavicular portion of the muscle may have referred pain in the uppermost part of the muscle, whereas others may experience referred pain in the arm.

Intercostal Muscle Syndrome. In patients with musculoskeletal chest pain, palpate the intercostal muscles for areas of tenderness. Pain emanating from the exterior intercostal muscles is usually localized near the site of the trigger point and is emphasized during inspiration (see Fig. 52.30F). Intercostal muscle trigger points often flare after chest surgery or trauma. Exercise extreme care when injecting an intercostal muscle trigger point to avoid entry into the pleural space.

Knee Region

Tensor Fasciae Latae Muscle Syndrome. Because the tensor fasciae latae muscle is easy to examine, trigger points located here are easy to identify (see Fig. 52.30G). Patients usually complain of pain along the lateral aspect of the thigh as far down as the knee.

Ankle, Foot, and Heel Region

Anterior Tibialis Muscle Syndrome. Trigger points located in the anterior tibialis muscle usually cause pain along the

anterior aspect of the ankle, but the entire ankle may be involved in severe cases. Trigger points are most commonly found in the upper third of the muscle and typically cause pain in the anterior portion of the leg and dorsal portion of the ankle (see Fig. 52.30H).

Gastrocnemius/Soleus Muscle Syndrome. Myofascial pain related to trigger points in the gastrocnemius and soleus muscles is usually located behind the knee and along the Achilles tendon near the heel (see Fig. 52.30I). These trigger points are generally found along the lateral and medial margins of the muscle group or along the midline (or in both areas) and often flare in patients experiencing vascular insufficiency of the lower extremities. One author suggests locating and injecting these trigger points for relief of the pain associated with intermittent claudication.¹⁶⁹

Myofascial Back Pain

Patients with myofascial back pain syndromes can have presenting symptoms of chronic aching muscle pain, spasms, stiffness, and sometimes weakness. Direct palpation of the back muscles may reveal the presence of trigger points as the true cause, especially in unilateral back pain. The most common trigger points are found in the levator scapulae, quadratus lumborum, and gluteus medius muscles. Syndromes involving the quadratus lumborum and gluteus medius should be considered in all patients presenting with low back pain.

The lumbosacral muscles are also commonly involved in low back pain. Trigger points may occur secondary to nerve root or vertebral spondylolysis and cause neuropathic pain. In these cases, patients may experience only minimal or temporary relief from trigger point injections. Hence, if the patient is no better after a reasonable trial of trigger point injections, referral should be made to further evaluate for more invasive treatment.

Quadratus Lumborum Muscle Syndrome. The quadratus lumborum is considered a hip hiker and lateral flexor of the spine. It also assists respiratory function by anchoring the 12th rib for the pull of the diaphragm. Trigger points may be found

along the 12th rib, around the iliac crest, and along the lateral border of the muscle (see Fig. 52.30J) and are often associated with distress on deep inspiration and 12th rib pain. Pain can be local or referred to the anterior abdominal wall. In addition, these trigger points may accentuate postoperative pain or painful abdominal scars over the lower quadrant.

Gluteus Pain Syndromes. The gluteal region is composed of several muscles that allow for extension, rotation, and abduction of the hip joint.¹⁷⁰ Trigger points located in the gluteus medius may be the most critical trigger points in the lower extremities (see Fig. 52.30J). They are most commonly found along the iliac shelf, and with extensive involvement along the entire gluteal ridge, including the gluteus minimus and maximus muscles from the sacroiliac joint to the anterior superior iliac spine. Trigger points in the gluteus medius may cause hip pain that mimics greater trochanteric pain syndrome (common during the latter stages of pregnancy), whereas trigger points in the gluteus minimus can cause pain radiating down the lateral and posterior aspect of the leg imitating sciatica.¹⁷¹

Similar to the infraspinatus muscle syndrome, trigger points in the gluteus medius muscle are frequently associated with sympathetic hyperactivity. In addition, when these trigger points flare, they often recruit trigger points in the quadratus lumborum, tensor fasciae latae, and other gluteal muscles, where they induce diffuse low back pain, or in the cervical muscles causing neck pain and headaches. Though less common, isolated gluteus medius pain may also occur and usually projects along the iliac crest into the posterior of the hip, thigh, and calf.

Arthrocentesis

Stewart O. Sanford

BACKGROUND

Arthrocentesis, the puncture and aspiration of a joint, is an acknowledged, useful procedure that is easily performed in the emergency department (ED).¹ It has been established as both a diagnostic and therapeutic tool for various clinical situations. When performed properly, the procedure offers a wealth of clinical information and is associated with few complications. In the ED it is difficult to make an accurate assessment of an acutely painful, hot, and swollen joint without performing arthrocentesis.

INDICATIONS AND CONTRAINDICATIONS

The indications for arthrocentesis are listed in [Review Box 53.1](#).

Infection in the tissues overlying the site to be punctured is generally considered an absolute contraindication to arthrocentesis. However, inflammation with warmth, swelling, and tenderness may overlie an acutely arthritic joint, and this condition may mimic a soft tissue infection. Once convinced that cellulitis does not exist, the clinician should not hesitate to obtain the necessary diagnostic joint fluid. Known bacteremia

is a theoretical relative contraindication because infection can spread to the joint; however, this complication should be weighed against the useful information and culture results gained by fluid analysis. Bleeding diatheses are rarely a relative contraindication, and arthrocentesis to relieve a tense hemothrosis in bleeding disorders such as hemophilia is an accepted practice after infusion of the appropriate clotting factors. There are few data regarding the safety or dangers of arthrocentesis in patients taking anticoagulants or platelet inhibitors. Studies have demonstrated that the risk for iatrogenic hemothrosis in patients treated with oral anticoagulants is extremely low, even in those who have international normalized ratios (INRs) as high as 4.5.² One prospective trial of 32 patients taking warfarin found no complications after arthrocentesis.³ Hence, when necessary, arthrocentesis should be performed in patients taking anticoagulants. The value of reversing a coagulopathy with blood components before the procedure is not proved, and clinical judgment should prevail. Prosthetic joints are at high risk for infection, and arthrocentesis should be avoided whenever possible in this situation. However, if an infected prosthesis is suspected, arthrocentesis should be performed.

Articular Versus Periarticular Disease

Periarticular conditions such as trauma, tendinitis, bursitis, contusion, cellulitis, or phlebitis may mimic articular disease and suggest the need for arthrocentesis. Therefore evaluation of acute joint disease requires that the clinician first determine whether the patient's constellation of signs and symptoms derives from the joint itself or from some other musculoskeletal or periarticular structure. Such a distinction, however, may be difficult, if not impossible to make without analysis of synovial fluid. No specific test or physical finding has high specificity for solving this dilemma; however, some physical findings may prove helpful. A common periarticular structure that can be associated with a joint effusion is a Baker cyst (popliteal cyst).

Arthrocentesis

Indications

- Diagnosis of septic or crystal-induced arthritis
- Diagnosis of traumatic bony or ligamentous injury
- Instillation of medications for acute or chronic arthritis
- Relief of the pain of acute hemothrosis
- Determination of communication between the laceration and joint space

Contraindications

Absolute:

- Overlying cellulitis

Relative:

- Bleeding diathesis

Complications

- Introduction of infection
- Bleeding
- Allergy to local anesthetic
- Pain

Equipment

Review Box 53.1 Arthrocentesis: indications, contraindications, complications, and equipment.

Figure 53.1 Periarticular problems may mimic an intraarticular process. This patient developed anterior soft tissue swelling and fluctuance after a trauma to the knee, representing a hematoma of the prepatellar bursa, not a hemarthrosis. Pressure applied to the edge of the swelling aids in the aspiration of all blood from the bursa (arrow).

If the swelling is secondary to joint effusion or inflammation, the entire articular capsule will be inflamed and distended and fluid can often be palpated within the joint. In the knee, this condition must be differentiated from effusion into the prepatellar bursa, where swelling distends the bursa that lies mainly over the lower portion of the patella, between it and the skin. Effusion into the joint occurs posterior to the patella, whereas bursal swelling occurs anterior to it (Fig. 53.1). When considerable articular effusion of the knee is present, the capsule of the joint is distended and an inverted U-shaped swelling of the joint develops. This characteristic shape occurs because the dense patellar ligament prevents distention of the capsule along its inferior border. In addition, with the knee extended a large effusion causes the patella to “float” or lift away from the femoral condyles. Complete extension and flexion are often impossible because of the joint tension produced by the effusion.

Joint effusion causes limited movement of the joint in all directions, with active and passive motion producing pain. The pain arising from a pathologic condition involving a joint may be diffuse or clearly localized to the joint, or it may radiate. Hip pain, for example, frequently radiates into the groin or down the front of the thigh into the knee. Shoulder joint pain commonly radiates into the elbow or the neck. Therefore complete examination of contiguous structures is essential for adequate diagnosis.

In contrast, pain from a periarticular process is often more localized, and tenderness can be elicited only with certain specific movements or at specific points around the joint. In periarticular inflammation, one can often passively lead a joint through a range of motion with minimal discomfort, yet pain is significant when the patient attempts active motion. *Crepitus* may be elicited with tendinitis, or the pain may be traced along the course of a specific tendon.

Septic Arthritis

Acute monoarticular arthritis is a common problem in emergency medicine. Although acute monoarticular arthritis has many causes, septic arthritis is the one requiring most urgent

diagnosis and treatment. Infectious arthritis is still relatively frequent, and suspicion of a septic process in the joint is the first step in appropriate management; confirmation requires arthrocentesis and culture of synovial fluid. In the ED, synovial fluid analysis is the diagnostic test most heavily relied on in making the diagnosis of an acute intraarticular infection. Culture remains the most definitive study, although it is not 100% sensitive.⁴ Gram stain may be helpful, but a negative Gram stain does not exclude the presence of a joint infection because not all infected joints have a positive Gram stain. Therapeutic arthrocentesis might need to be repeated when treating a septic joint. Such therapy is usually performed on an inpatient basis.⁵

Infection of a joint occurs by one of several mechanisms: hematogenous spread (bacteremia, infective endocarditis, intravenous drug use) from a contiguous source of infection, direct implantation, postoperative contamination, or trauma.⁴ Septic arthritis is typically monoarticular with a swollen, erythematous, and painful joint. The noninfectious differential diagnosis includes crystal-induced arthritis, fracture, hemarthrosis, foreign body, osteoarthritis, ischemic necrosis, and monoarticular rheumatoid arthritis. In addition, osteomyelitis may mimic septic arthritis because of the close proximity of the infected metaphysis to the joint space.⁶ In many instances an acutely inflamed joint from gout or other arthritides simply cannot be distinguished from infection clinically. Nonetheless, early diagnosis is essential to prevent complications such as impairment of growth, articular destruction with ankylosis, osteomyelitis, and soft tissue extension.⁷

Because an acutely swollen joint may be indicative of a number of disease entities, a thorough history and physical examination are the cornerstones of evaluation, followed by arthrocentesis (Fig. 53.2). Laboratory findings can be useful in making a diagnosis, as can response to therapy (e.g., the response to empirical antibiotics in gonococcal arthritis is often the only criterion for diagnosis because the organism is difficult to culture from joint fluid). Blood cultures may be positive because joint infections may be due to hematogenous spread. Patients with malignancy (especially leukemia) or those who are immunosuppressed or otherwise debilitated are at particular risk for a septic cause. Infectious arthritis should be considered primarily in these patients, as well as in those with preexisting joint diseases such as rheumatoid arthritis. In general, a swollen joint is not usually injected with corticosteroids until the possibility of infection has been eliminated.⁸

Neisseria gonorrhoeae, *Staphylococcus* (including methicillin resistant), and *Streptococcus* are the most frequently identified etiologic agents. *N. gonorrhoeae* is the most common organism causing septic arthritis in adolescents and young adults. Patients older than 40 years and those with other medical illnesses are more likely to have *Staphylococcus* joint infections. In children, *Staphylococcus*, *Streptococcus*, and *Escherichia coli* predominate. *Haemophilus influenzae* was a common cause of pediatric septic arthritis in the past, but widespread use of the conjugate vaccine has reduced *H. influenzae* infection rates to nearly zero.^{9,10} In neonates, staphylococci, Enterobacteriaceae, group B streptococci, and *N. gonorrhoeae* are the most likely organisms. Staphylococcal or pseudomonal infections commonly develop in injection drug abusers. *Salmonella* arthritis is more prevalent in patients with sickle cell disease than in the general population; however, more common organisms still predominate. Prosthetic joints or postoperative infections have high rates of *Staphylococcus aureus*, *Streptococcus epidermidis*, Enterobacteriaceae, and *Pseudomonas* infection.¹¹

Figure 53.2 A and B, Tophaceous gout. These nodules are painless and full of uric acid crystals. C, The acutely swollen and painful wrist joint in this patient is most likely due to acute gouty arthritis, which can produce fever and leukocytosis. In some cases, joint fluid analysis is the only way to differentiate gout from a septic joint. D, Aspiration of a tophus yields a precipitated, waxy, soft uric acid conglomeration.

The prevalence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) mandates special attention. Epidemiologic data on the incidence of CA-MRSA septic arthritis are sparse; however, one 2009 study noted that 50% of synovial fluid cultures in suspected septic arthritis ultimately grew MRSA.¹² It would be prudent to consider empirical therapy for MRSA in those suspected of having septic arthritis until the results of culture become available. MRSA-infected joints can be multiple, progress rapidly, and be very destructive of joint tissue and adjacent bone.

Although precise incidence data for nongonococcal septic arthritis have not been established, predisposing factors have been described and include age 80 years or older, diabetes mellitus, rheumatoid arthritis, hip or knee prosthesis, joint surgery, and skin infection.¹³ The simultaneous occurrence of gout and septic arthritis is possible, and one should not allow the establishment of a diagnosis of crystal-induced disease to stop a thorough search for infection.¹⁴

Because *N. gonorrhoeae* is the most common organism causing septic arthritis, gonococcal arthritis deserves special mention. Disseminated gonococcal infection occurs in 0.5% to 3% of cases of mucosal infection. Gonococcal septic arthritis is more common in women, especially during pregnancy or after menstruation, because women with sexually transmitted gonorrhea infections are more likely to be asymptomatic. The time needed for local infection to disseminate can vary from several days to weeks. Patients will often experience systemic symptoms, including fevers, chills, and malaise, as well as migratory polyarthralgia. Gonococcal tenosynovitis without joint involvement occurs in two thirds of patients. Dermatitis is also present in two thirds-of patients (Fig. 53.3). The most common rash

consists of scattered painless, nonpruritic 0.5- to 0.75-cm macules or papules with necrotic or pustular centers, distributed on the extremities and trunk. Eventually, the infection settles into one or two large joints to yield a purulent arthritis.^{9,15} Overt urethritis and vaginitis may be absent or overlooked because of concentration solely on the obvious joint pathology. Hence, it is important to realize that disseminated gonococcal infections can be associated with surprisingly minimal or even absent signs and symptoms of a genital infection source. Some joints may become inoculated through hematogenous spread from anal and oral sites of infection. Even though *N. gonorrhoeae*-infected joint fluid is usually “septic” in character, the yield of positive synovial fluid cultures has ranged from 25% to 50%. Blood cultures appear to be less helpful as they are positive in only 20% to 30% of cases. Because blood and joint fluid culture has a low yield, it would be prudent to culture all possible sites of gonococcal infection, including anal and pharyngeal sites. The organism can often be identified in asymptomatic genitourinary sites,⁹ with cultures from the primary mucosal site being positive in up to 80% of infected patients.¹⁵

A positive Gram stain is immediately diagnostic of septic arthritis. However, Gram stains are positive in only 71% of gram-positive infections, 40% to 50% of gram-negative infections, and 25% of gonococcal infections.^{16,17} An elevated synovial white blood cell (WBC) count and a reduction in synovial fluid glucose may give confirmatory data. However, the synovial fluid WBC count in gonococcal arthritis is often between 10,000 and 20,000 cells/mm.⁴ Although mild leukocytosis and an elevated erythrocyte sedimentation rate may occur, normal laboratory values do not exclude infection.^{16,18}

Figure 53.3 **A**, Often mistaken for insect or spider bites, these multiple embolic skin lesions (ranging from single or multiple petechiae to pustules) may be seen in patients with acutely swollen joints infected with *Neisseria gonorrhoeae*. Skin lesions are usually found on the extremities, especially the feet and hands, and may be present before a large joint effusion accumulates or with gonococcal tenosynovitis. **B**, A genital manifestation of urethritis (penile discharge) or vaginitis may be seen but can be rather clinically silent. **C**, Maculopapular rash associated with *N. gonorrhoeae*.

Hemarthrosis

Isolated nontraumatic hemarthrosis may occasionally be seen by the emergency clinician. An inflammatory reaction may follow intracapsular bleeding, and the proliferative reaction and the hyperplastic synovium formed might predispose patients to recurrent hemorrhage in that joint, especially those with bleeding diatheses. The knee is the most commonly affected joint, followed by the ankle, elbow, shoulder, and hip.¹

The most common cause of intraarticular hemorrhage in the setting of no or minor trauma is a hereditary clotting factor deficiency such as hemophilia. Hemarthrosis is an infrequent complication of oral anticoagulant therapy but might occur even with prothrombin times within the normal range.¹⁹ Cessation of anticoagulant therapy in these patients must be weighed against the risk for adverse clot formation (e.g., acute cerebrovascular accident). Chronic arthritis does not appear to be a long-term complication in patients with intraarticular bleeding from oral anticoagulant therapy. Hemarthrosis may also be a complication of sickle cell anemia, pseudogout, amyloidosis, pigmented villonodular synovitis, synovial hemangioma, rheumatoid arthritis, and infection.^{18,20}

Management of acute hemarthrosis depends on the cause. Hemarthrosis associated with oral anticoagulant therapy improves only after use of the oral anticoagulant is discontinued and the prothrombin time returns to normal. Hemarthrosis after trauma is a frequent occurrence. It is most common in the knee and often denotes significant internal damage. A massively swollen knee after trauma is frequently seen with knee dislocation (occasionally with spontaneous relocation) and a tear of the anterior cruciate ligament. Intraarticular fractures can cause a significant hemarthrosis.

Distension of the joint by effusion or hemorrhage causes considerable pain and disability. If the fluid is not removed it is partially absorbed, but part of it may undergo organization and result in the formation of adhesions or bands in the joint. This is one argument for drainage of the joint.² Some believe that in an otherwise healthy joint that is subjected to a single traumatic event, even a relatively large hemarthrosis will be spontaneously reabsorbed without significant sequelae and therefore presents no pressing need for drainage. Unfortunately, no literature exists to guide the best approach; hence, there is no universal standard of care regarding the need or lack thereof of draining blood from a traumatic joint.

Nonetheless, a large, tense, traumatic effusion is quite painful and its presence precludes proper evaluation of an injured joint. Therapeutic arthrocentesis to drain a symptomatic traumatic effusion is a common and well-accepted practice.^{2,19,21,22} The source of blood after trauma is frequently a tear in a ligamentous structure, capsule, synovium, or fracture. Cruciate (especially anterior) ligament injury is the most common cause of significant hemarthrosis after trauma to the knee.²⁰ A joint effusion that develops 1 to 5 days after trauma may be secondary to a slow hemorrhage or reinjury, but the swelling is often caused by a nonhemorrhagic irritative synovial effusion.

Occasionally, one will diagnose an occult fracture by the presence of lipohemarthrosis, or fat globules in the arthrocentesis specimen (Fig. 53.4). This may be appreciated when the bloody effusion is placed in a clear container (e.g., emesis basin) and held to a light. If the history of trauma is vague, arthrocentesis may be required to differentiate hemorrhage from other causes of joint effusion. An occult tibial plateau fracture is an example in which evaluating for lipohemarthrosis

Figure 53.4 Blood aspirated from a traumatized joint is placed in an emesis basin and put under a bright light to search for lipohemarthrosis, which is clinical evidence of an intraarticular fracture. Note the characteristic greasy sheen of floating fat. Do not throw away this blood before assessing for lipohemarthrosis.

TABLE 53.1 Intrasynovial Corticosteroid Preparations^a

PREPARATION	LARGE-JOINT DOSE (mg)	SMALL-JOINT DOSE (mg) ^b
Triamcinolone hexacetonide	20	2–6
Triamcinolone acetonide	20	2–6
Methylprednisolone acetate	40	3.5–10.5
Triamcinolone diacetate	20	2–6
Dexamethasone acetate	5	0.5–1.5

^aListed in approximate descending order of duration of action.

^bThe dose will depend on joint size, capsular distensibility, and degree of inflammation.

From Gray RG, Gottlieb NL: Corticosteroid injections in RA: appraisal of a neglected therapy. *J Musculoskelet Med* 7:53, 1990. Reproduced by permission.

may be of particular value. Following therapeutic arthrocentesis for a hemarthrosis, it may be desirable to inject 2 to 15 mL, depending on joint size, of a long-acting local anesthetic (see [Chapter 29](#)) into the joint to facilitate examination or provide temporary relief of the symptoms.

Intraarticular Corticosteroid Injections

In 1951 Hollander and coworkers²³ first demonstrated that intraarticular corticosteroid injections are useful for relief of symptoms in patients with severe rheumatoid arthritis. The use of steroids has proved to be a dependable method for providing rapid relief of pain and swelling of inflamed joints, although it is strictly local, usually temporary, and rarely curative.^{2,24,25} It is easily performed in the emergency setting. Acute gout responds well to joint injection, and this may be preferable in patients who cannot tolerate indomethacin or colchicine.

Corticosteroid injections are most helpful when only a small number of joints are actively inflamed. The most frequently used corticosteroids for intraarticular injection are shown in [Table 53.1](#).² Diminution of joint pain, swelling, effusion, and warmth is usually evident within 6 to 12 hours after injection.

Though very rare, the most serious complication of this practice is intraarticular infection.² Therefore steroids should not be injected into a joint if a joint space infection is suspected. Repeated injections into one joint pose a risk for necrosis of juxtaarticular bone with subsequent joint destruction, instability, and suppression of the hypothalamic-pituitary axis from systemic absorption. Other complications include local soft tissue atrophy and calcification, tendon rupture, intraarticular bleeding, and transient nerve palsy.^{2,25} Transient elevations in blood glucose, as well as erythema, warmth, and diaphoresis of the face and torso, may also occur after intraarticular steroid injections. Acute pain, redness, and swelling 12 to 24 hours after steroid injection can mimic infection, but with this timing it is most likely an inflammatory reaction (steroid flare) to crystal-containing steroid preparation (often methylprednisolone). Deposition of steroid crystals on the synovium might give rise to a transient, self-limited flare-up of synovitis.^{2,26}

It is always important to determine whether local corticosteroid therapy has been used previously, not only to consider the array of clinical conditions associated with steroid use but also because crystalline corticosteroid material can hinder proper interpretation of crystals found in synovial fluid.²⁶

EQUIPMENT

The materials needed for arthrocentesis include skin preparation solutions (e.g., chlorhexidine); sterile gloves and drapes (optional in some cases); local anesthetic; syringes for injecting local anesthetic and aspirating joint fluid; a three-way stopcock for draining large amounts of fluid; lavender-, red-, and green-topped blood tubes; and various sizes of needles and intravenous catheters (see [Review Box 53.1](#)).

Depending on the size of the effusion to be drained, a 10-, 20-, or 30-mL Luer-Lok syringe can be used. If a large effusion is suspected, a three-way stopcock between the needle and the syringe allows complete drainage with a single joint penetration. Fluid for cell count should be collected in a lavender-topped tube; however, viscosity, protein, and glucose determinations do not require anticoagulants, and fluid should be placed in a red-topped tube. Though still common practice in many institutions, recent evidence suggests that synovial fluid protein and glucose levels are poor differentiators of noninflammatory and inflammatory effusions and are no longer recommended (see section on [Synovial Fluid Interpretation](#) later).^{2,27–29} Immediately examine fresh synovial fluid in its unadulterated form for crystals. Calcium oxalate and lithium heparin anticoagulants have been reported to introduce artifactual crystals into the fluid. Joint fluid to be analyzed for crystals should be collected in a green-topped tube containing sodium heparin. If culturing for *N. gonorrhoeae*, the fluid should be immediately placed on proper medium and stored in a low-oxygen environment in the ED.

GENERAL ARTHROCENTESIS TECHNIQUE

Joint fluid may be obtained even when there is little clinical evidence of an effusion. Although one may aspirate successfully at the point where the joint bulges maximally, certain landmarks are important. The most crucial part of arthrocentesis is defining the joint anatomy by palpating the bony landmarks as a guide.

Text continued on p. 1114

ULTRASOUND BOX 53.1: Arthrocentesis

by Christine Butts, MD

Ultrasound offers a significant advantage when evaluating a patient with a complaint of joint pain. In patients with obesity or significant pain, limited physical examination makes the diagnosis of joint effusion difficult. Attempting blind aspiration in these patients may cause significant pain for the patient and frustration for the clinician. Ultrasound allows the physician to thoroughly evaluate the joint space for the presence of effusion and to plan the best approach for aspiration. The initial evaluation of the major joints is discussed hereafter, followed by a general approach to aspiration.

Knee

Although effusions of the knee are frequently diagnosed on physical examination alone and aspirated blindly, ultrasound allows the clinician to distinguish effusion from other conditions that may cause generalized swelling (such as bursitis).

A high-frequency transducer (7.5 to 10 MHz) should be used to allow the greatest resolution. Begin with the indicator pointing toward the patient's head (in longitudinal orientation) over the anterior aspect of the knee and attempt to locate the patella (Fig. 53.US1). The patella can be seen as a brightly echogenic (white) object with posterior shadowing (Fig. 53.US2). Locating the patella is key to distinguishing prepatellar bursitis, which will appear as a dark, fluid-filled collection superficial to the patella, and a joint effusion, which will appear as a dark, fluid-filled collection deep to the patella. Once the patella has been identified, move the transducer medially or laterally to "look under" the patella into the joint space (Fig. 53.US3). Fluid will appear as a dark gray or black collection between the articular surface of the femur and fibula or tibia (Fig. 53.US4). Once this area has been evaluated, move the transducer superiorly to evaluate the suprapatellar bursa, which lies superior to the patella and deep to the quadriceps tendon. The suprapatellar bursa communicates with the joint space and frequently houses a large amount of fluid (Fig. 53.US5).

Shoulder

Either an anterior or posterior approach can be used to evaluate the shoulder. In the anterior approach, place the patient first in a seated position with the elbow adducted and the palm facing up. Then, place the high-frequency transducer in a transverse orientation over the approximate location of the biceps tendon (Fig. 53.US6). The biceps tendon is an extracapsular extension of the joint and will be seen to

Figure 53.US1 Placement of the ultrasound transducer in a longitudinal orientation over the patella. Such placement enables localization of the patella and serves to orient the sonographer.

Figure 53.US2 Ultrasound image of a normal patella. The patella is seen as a brightly echogenic (*white*) arcing line just beneath the surface (*arrow*). Prepatellar fluid collections, such as bursitis, will be seen superficial to this area.

Figure 53.US3 Placement of the ultrasound transducer to "look under" the patella into the joint space.

Figure 53.US4 Ultrasound image of the junction of the femur (at the left of the image) and the tibia (at the right of the image) (*arrow*). When an effusion is suspected, the suprapatellar recess should be evaluated in addition to this space because fluid frequently collects in the potential space superior to this junction.

ULTRASOUND BOX 53.1: Arthrocentesis—cont'd

Figure 53.US5 Ultrasound image of a joint effusion within the suprapatellar recess of the knee joint. The recess is distended with anechoic (*black*) fluid and the femur can be seen as the hyperechoic (*white*) line at the bottom of the image.

Figure 53.US6 Placement of the ultrasound transducer over the anterior aspect of the shoulder to evaluate the biceps tendon. To obtain the best view, the patient's arm should be flexed at the elbow, supinated, and slightly abducted.

distend with fluid when a joint effusion is present. A normal tendon can be seen to lie within the biceps groove of the humerus (Fig. 53.US7). When surrounded by fluid, the tendon will be seen to “float” within an anechoic (black) area (Fig. 53.US8).

To evaluate the joint from the posterior approach, place the patient in a seated position with the affected hand on the opposite shoulder to open the joint space. Then, place the transducer at the approximate location of the articulation of the humeral head with the glenoid (Fig. 53.US9). In a normal joint, the humerus can be seen to articulate with the glenoid without any intervening fluid (Fig. 53.US10). When an effusion is present, a dark gray or black collection can be seen medial to the glenoid (Fig. 53.US11).

Ankle

The ankle joint is best evaluated in the longitudinal axis with the transducer placed over the space between the posterior edge of the tibia and the talus (Fig. 53.US12). Slightly plantar-flexing the foot will enable the transducer to “fit” in this space. In a normal joint, the distal edge of the tibia can be seen to articulate with the talus without any intervening fluid (Fig. 53.US13). When an effusion is present, it is seen as a triangular, dark gray or black pocket between the tibia and talus (Fig. 53.US14). Ultrasound can also be used to identify the location of the dorsalis pedis artery before aspiration.

Figure 53.US7 Ultrasound image of a normal-appearing biceps tendon. The tendon will appear as a hyperechoic (*white*) bundle within the groove of the humerus as indicated by the *arrow*.

Figure 53.US8 The biceps tendon is surrounded by anechoic (*black*) fluid. (Courtesy Verena Valley, MD.)

Figure 53.US9 Placement of the ultrasound transducer over the posterior aspect of the shoulder to evaluate the glenohumeral joint. This joint line can typically be palpated to approximate the best initial position.

ULTRASOUND BOX 53.1: Arthrocentesis—cont'd

Figure 53.US10 Ultrasound of a normal-appearing shoulder joint. Deep to the overlying musculature, the glenoid can be seen at the left of the image (*arrowhead*). The humeral head is seen to the right of the glenoid (*arrow*).

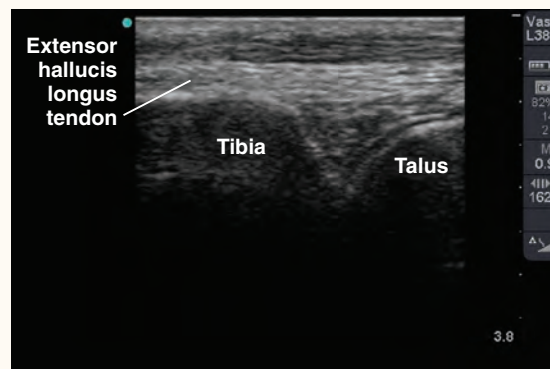

Figure 53.US13 Ultrasound image of a normal ankle joint. At the left of the image is the tibia, with the talus seen at the right. The intervening area is free of fluid and the extensor hallucis longus can be seen superficial to this area.

Figure 53.US11 Shoulder effusion as viewed from a posterior approach. Free fluid will appear as an anechoic collection medial to the glenoid rim. (Courtesy Verena Valley, MD.)

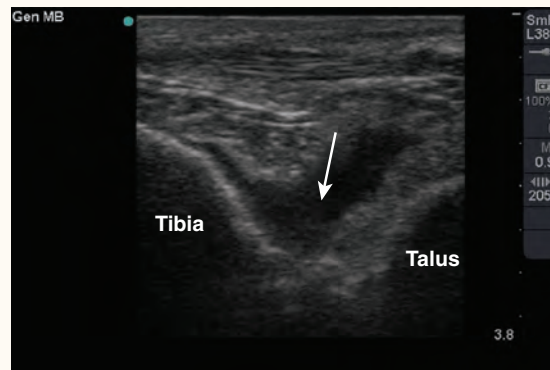

Figure 53.US14 Ultrasound image of an ankle effusion. As with the normal image, the tibia and talus can be seen on either side of the image. However, in the intervening area, an anechoic (*black*) fluid collection can be seen (*white arrow*).

Figure 53.US12 Placement of the ultrasound transducer over the anterior aspect of the ankle to evaluate for an ankle effusion.

Elbow

The elbow is easily evaluated from the posterior approach. With this approach, place the transducer over the olecranon fossa with the elbow flexed and the lower part of the arm supported (Fig. 53.US15). In a normal elbow the olecranon fossa can be seen as a slight “divot” between the olecranon of the ulna and the humerus (Fig. 53.US16). When an effusion is present, dark gray or black fluid can be seen to distend this space (Fig. 53.US17).

Hip

The hip joint is unique in that physical examination may suggest the presence of an effusion, but direct confirmation is difficult with traditional examination techniques. Ultrasound will easily confirm the presence of an effusion. To evaluate the hip joint, select a low-frequency transducer (3 to 5 mHz) initially because of the depth of the joint. In very thin patients, the distance from the skin to the joint may be small enough to allow the use of a high-frequency transducer. Align the transducer in a slightly oblique axis (mimicking the orientation of the femoral neck) along the inguinal area. It may be helpful to aim toward the umbilicus. Look for the femoral neck and head. They will appear as brightly echogenic outlines in the expected

ULTRASOUND BOX 53.1: Arthrocentesis—cont'd

Figure 53.US15 Placement of the transducer in the transverse plane over the area of the olecranon fossa. For best resolution, a high-frequency transducer should be used.

Figure 53.US16 Ultrasound image of a normal elbow joint. The olecranon fossa can be identified as the echogenic (*white*) crescent at the bottom of the image (*arrow*). The area just above the fossa should be evaluated for the presence of fluid indicative of an effusion.

Figure 53.US17 Elbow joint distended by anechoic fluid (*arrow*) superficial to the olecranon fossa. (From Allan PL, Baxter GM, Weston MJ, editors: *Clinical ultrasound*, ed 3, Philadelphia, 2011, Elsevier.)

shape of the bones (Fig. 53.US18). Once the femur has been identified, look for the joint capsule. It will appear as an arcing, hyperechoic line superficial to the bones (Fig. 53.US19). In a normal hip there will be very little tissue between these two structures. There may be a small amount of anechoic or hypoechoic fluid present in this space in a normal hip, and correlation with the unaffected side will aid in evaluation. In the presence of a significant effusion, a large anechoic or hypoechoic fluid collection will be seen between the femoral neck and the capsule (Fig. 53.US20).

Figure 53.US18 Normal ultrasound of the hip. The femoral head can be seen as the hyperechoic (*white*) line highlighted by the *arrow*. The area immediately superficial to the femur is devoid of any significant fluid collection.

Figure 53.US19 Ultrasound image of the hip with demonstration of the joint capsule. The joint capsule can be seen as the hyperechoic (*white*) arcing structure marked by the *arrow*.

Figure 53.US20 Ultrasound image of a hip effusion. As in a normal hip, the femur can be seen at the bottom of the image. Immediately superficial to the femur, an anechoic (*black*) fluid collection is highlighted by the *arrow*.

ULTRASOUND BOX 53.1: Arthrocentesis—cont'd

Aspiration

Once the joint in question has been evaluated, the optimal site for aspiration can be planned. In contrast to the traditional, blind aspiration technique, the use of ultrasound may suggest an alternative approach. Ultrasound will enable the clinician to map the best approach to the effusion. Once this approach has been clarified, one of two techniques

can be applied. The site can be marked and the aspiration can then proceed blindly under sterile conditions. In other cases it may be preferable to perform the tap under direct ultrasound guidance. In these circumstances the needle is inserted either from the transverse or from the long-axis approach and guided directly into the joint space.

First, select a puncture site and an approach to the joint. Avoid tendons, major vessels, and major nerve branches. In most instances the approach is via the extensor surfaces of joints because most major vessels and nerves are found beneath the flexor surfaces. In addition, the synovial pouch is usually more superficial on the extensor side of a joint. Ultrasound may be particularly helpful in locating small effusions.

Use aseptic technique, including the use of sterile gloves and instruments, to avoid infection. Do not attempt arthrocentesis if there is a definite or suspected infection overlying the joint. Allow antiseptic preparation solution to dry for several minutes because the bactericidal effects of iodine are both concentration and time dependent. Remove the iodine solution with an alcohol sponge to prevent transference of iodine into the joint space, which can lead to an inflammatory process. Although the utility of draping is unproved and it may obscure the site, a sterile perforated drape may be placed over the joint.

With appropriate local anesthesia, arthrocentesis should be a relatively painless procedure; without anesthesia, it may be quite painful and distressing to the patient. The synovial membrane itself has pain fibers associated with blood vessels, and the articular capsule and periosteum are richly supplied with nerve fibers so both are very sensitive. The articular cartilage has no intrinsic pain fibers. It is important to have the patient relax during the procedure. Tense muscles narrow the joint space and make the procedure more difficult, often necessitating repeated attempts or resulting in inadequate drainage. Distraction of the joint may enhance the target area, especially in areas such as the wrist and finger joints. Traction not only increases the chance of entering the joint but also lessens the chance of scoring the articular cartilage with the needle.

To best accomplish anesthesia, infiltrate the skin down to the area of the joint capsule along the entire route of needle penetration. Use a local anesthetic agent such as 1% or 2% lidocaine (Xylocaine [AstraZeneca, Cambridge, United Kingdom]) via a 25- to 27-gauge needle. For extremely painful joints, a regional nerve block is appropriate.

Use the landmarks described in “[Specific Arthrocentesis Techniques](#)” later in this chapter. Take care not to bounce the needle off bony structures as a means of finding the joint space because this may cause unnecessary pain. However, in contrast to earlier beliefs, striking bone with the arthrocentesis needle is unlikely to damage articular cartilage.² Attach an 18- to 22-gauge needle or intravenous catheter and needle set of suitable length to an appropriately sized syringe. Insert the needle at the desired anatomic point through the skin and subcutaneous tissue into the joint space. Use the largest needle that is practical to avoid obstructing the lumen with debris or clot. Large joints, such as the knee, can accommodate large effusions, so it is suggested that one use a 30- to 60-mL syringe

because it may be difficult to change a syringe when the needle is within the joint cavity (Fig. 53.5). A three-way stopcock placed between the needle and the syringe is an option for draining large effusions (Fig. 53.6). If the syringe must be changed during the procedure, grasp the hub of the needle with a hemostat and hold it tightly while the syringe is removed. The authors prefer to use only a rigid needle and not a flexible catheter to perform arthrocentesis; however, a sturdy catheter is used by some clinicians. If an intravenous catheter and needle set is used, remove the needle while leaving the outer atraumatic plastic catheter in the joint space. Then attach the syringe to the catheter for aspiration. Manipulation of the joint or catheter can now occur with little threat of tissue injury.

Aspiration of synovial fluid and easy injection and return of fluid indicate intraarticular placement of the needle tip. As a general rule, try to remove as much fluid or blood as possible. If the fluid stops flowing, it indicates that the joint has been drained completely, the tip of the needle has become dislodged, or debris or clot is obstructing the needle. In this case, slightly advance or retract the tip of the needle, rotate the bevel, or lessen the force of aspiration. Never reintroduce a needle through a plastic catheter that has been left in the joint. Occasionally, reinjecting a small amount of fluid into the joint space confirms placement of the needle and may clear the needle. If fluid flows freely back into the joint and is easily reaspirated, one has probably removed all the fluid. If resistance is met, the needle has probably been jarred from the joint space and is lodged in soft tissue. In some instances, minor changes in position produced by flexion or extension of the joint may allow the fluid to flow more freely. Scraping or shearing the articular cartilage with the needle should be avoided. One should enter the joint in a straight line and avoid unnecessary side-to-side motion of the needle.

Send synovial fluid for studies as indicated by the clinical situation. Studies usually obtained include cell count with differential, crystal analysis, Gram staining, and bacterial culture and sensitivity analysis. Synovial protein, glucose, and lactate dehydrogenase determinations have been shown to be unreliable in distinguishing noninflammatory from inflammatory and infectious causes and are no longer recommended.^{2,29-33} Less frequently obtained studies include rheumatoid factor analysis, lupus erythematosus cell preparation, viscosity analysis, mucin clot, fibrin clot, fungal and acid-fast stains, Lyme titer, fungal and tuberculous culture, and synovial fluid complement analysis. If the arthrocentesis is performed for the relief of hemarthrosis, the fluid need not be sent for analysis. One should be selective in ordering tests. There is no need to order a large battery of tests routinely on all fluids. If the volume of fluid collected is low, Gram stain, culture, and examination of the “wet preparation” under regular and polarizing microscopy have the highest priority. Prompt examination of specimens should be performed

General Arthrocentesis Technique

1 Position the patient and identify all landmarks.

2 Cleanse the skin with antiseptic; use of a sterile drape is optional.

3 Raise a wheal with local anesthetic.

4 Inject anesthetic along the entire track of the aspiration needle.

5 Aspirate as the needle is advanced; always use a large syringe if there is a potential for a large effusion.

6 "Milk" the effusion if necessary; always remove as much fluid as possible.

7 Grasp the needle hub with a hemostat (to maintain correct position) if a syringe change is needed.

8 Place fluid into appropriate tubes and submit to the laboratory.

Figure 53.5 General arthrocentesis technique.

to avoid misdiagnosing borderline inflammatory fluids, missing crystals that dissolve with time, or overinterpreting the findings because of new artifactual crystals that appear over a prolonged time.³⁴

Complications

Significant complications are rare with arthrocentesis but include the following:

1. Infection. Skin bacteria may be introduced into the joint space during needle puncture. Nevertheless, infection occurs

rarely because the bacteria are either quickly cleared or not viable.² One can further limit this complication by maintaining rigorous sterile technique and avoiding insertion of the needle through obviously (or possibly) infected skin or subcutaneous tissue. Various studies report the incidence of infection after routine arthrocentesis to be in the range of 1 in 10,000.³⁴ However, in immunocompromised patients, particularly those with rheumatoid arthritis, the incidence is higher (1 in 2000 to 10,000 aspirations).^{35,36} Joint aspiration in the presence of bacteremia was discussed previously. Acute pain, redness, and swelling 12 to 24 hours after steroid

Figure 53.6 Use of a stopcock will negate the need to change the syringe during arthrocentesis. Turn the stopcock (*arrow*) to collect and then expel fluid, or inject lidocaine or steroid without moving the needle.

injection can mimic infection but is most likely an inflammatory reaction (steroid flare) to the steroid preparation (often methylprednisolone).

2. **Bleeding.** Bleeding with subsequent hemothrosis is rarely a complication, except in patients with a bleeding diathesis. In those with a bleeding diathesis such as hemophilia, arthrocentesis should be delayed until clotting competence has been enhanced by infusing specific clotting factors. In general, spontaneous bleeding into a hemophiliac patient's joint is an indication for replacement of clotting factors. Occasionally, a small quantity of blood may be aspirated along with synovial fluid. This happens most often when the joint is nearly emptied. A small amount of blood-tinged fluid is generally the result of nicking a small synovial blood vessel and is usually inconsequential.
3. **Arthrocentesis and joint injections in patients receiving chronic warfarin therapy,** with a therapeutic INR, were shown to be safe by Ahmed and Gertner,³⁷ without an increased risk of bleeding complications. In this study of 456 procedures in patients on chronic warfarin therapy, there was no statistically significant difference in the overall complication rate between patients with an INR of 2.0 or greater and patients with an INR less than 2.0. Of note, 103 of 456 procedures (22.5%) were safely performed in patients with an INR greater than 3, with the highest INR being 7.8.
4. **Allergic reaction.** Hypersensitivity to the local anesthetic can usually be prevented by thorough history taking. Facial and torso flushing associated with corticosteroid injection may represent an idiosyncratic reaction to preservatives in the steroid preparation.² Fainting during the procedure is not uncommon and most often the result of vasovagal influences. To help prevent this, perform the procedure with the patient lying down whenever possible.
5. **Corticosteroid-induced complications.** See earlier section on [Intraarticular Corticosteroid Injections](#).

SPECIFIC ARTHROCENTESIS TECHNIQUES

Arthrocentesis of the hip is generally performed by an orthopedic surgeon under fluoroscopic, ultrasound, or magnetic resonance imaging, or computed tomography guidance and is not discussed here. If available, fluoroscopy or ultrasound can also be used to guide aspiration of other joints, but these imaging

Figure 53.7 Landmarks for arthrocentesis of the first carpometacarpal joint. All small joints pose a difficult aspiration. When aspirating small joints, apply continuous suction to the syringe, and walk the tip of the needle along the bones until the joint is entered or fluid is obtained. Apply longitudinal traction to facilitate entry into a small joint. *MCP*, Metacarpophalangeal.

adjuncts are not generally required. For small joints, application of traction is often very helpful in obtaining fluid. While applying continuous suction to the aspirating syringe, walk the needle over palpated bone until the joint is entered or fluid is obtained. However, it may be quite difficult to obtain fluid from small joints in the hand and foot, so the clinician must often treat empirically. If only one drop of fluid is obtained from small joints, it is best to send it for culture.

First Carpometacarpal Joint (Fig. 53.7)

Landmarks. The radial aspect of the proximal end of the first metacarpal is the arthrocentesis landmark for this joint. Locate the abductor pollicis longus (APL) tendon by active extension of the tendon.

Position. Oppose the thumb against the little finger so that the proximal end of the first metacarpal is palpable. Apply traction to the thumb to widen the joint space between the first metacarpal and the greater multangular (trapezium) bone.

Needle Insertion. Insert a 22- to 23-gauge needle at a point proximal to the prominence at the base of the first metacarpal on the palmar side of the APL tendon.

Comments. Degenerative joint disease commonly affects this joint. Arthrocentesis is moderately difficult. The anatomic “snuffbox” (located more proximally and on the dorsal side of the APL tendon) should be avoided because it contains the radial artery and superficial radial nerve. A more dorsal approach may also be used.

Interphalangeal and Metacarpophalangeal Joints (Fig. 53.8)

Landmarks. The landmarks are located on the dorsal surface. For the metacarpophalangeal joints, palpate for the prominence at the proximal end of the proximal phalanx. For the interphalangeal joints, palpate for the prominence at the proximal

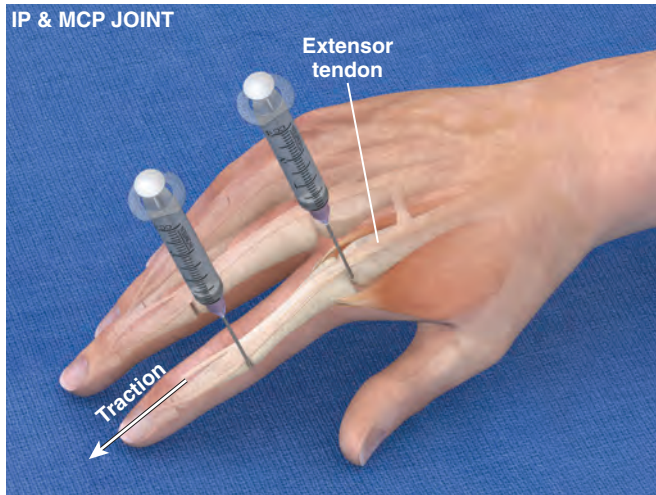

Figure 53.8 Landmarks for arthrocentesis of the interphalangeal and metacarpophalangeal joints. *IP*, Interphalangeal; *MCP*, metacarpophalangeal.

end of the middle or distal phalanx. The extensor tendon runs down the midline.

Position. Flex the fingers to approximately 15 to 20 degrees and apply traction.

Needle Insertion. Insert a 22- to 25-gauge needle into the joint space dorsally, just medial or lateral to the central slip of the extensor tendon.

Comments. Synovitis causes these joints to bulge dorsally. Normally, it is unusual to obtain fluid in the absence of a significant pathologic condition.

▶ Radiocarpal Joint (Wrist) (Fig. 53.9; Videos 53.1 and 53.2)

Landmarks. The dorsal radial tubercle (Lister's tubercle) is an elevation found in the center of the dorsal aspect of the distal end of the radius. The extensor pollicis longus tendon runs in a groove on the radial side of the tubercle. The tendon can be palpated by active extension of the wrist and thumb.

Position. Position the wrist in approximately 20 to 30 degrees of flexion with accompanying ulnar deviation. Apply traction to the hand.

Needle Insertion. Insert a 22-gauge needle dorsally, just distal to the dorsal tubercle on the ulnar side of the extensor pollicis longus tendon. Avoid the anatomic snuffbox, located more radially, to prevent injury to the radial artery or superficial radial nerve.

▶ Radiohumeral Joint (Elbow) (Fig. 53.10; Videos 53.3 and 53.4)

Landmarks. The lateral epicondyle of the humerus and the head of the radius are the arthrocentesis landmarks for the radiohumeral joint. With the elbow extended, palpate the depression between the radial head and the lateral epicondyle of the humerus.

Figure 53.9 **A**, Landmarks for arthrocentesis of the radiocarpal (wrist) joint. This is a difficult joint to aspirate. **B**, Acute joint effusion of the right wrist. *EPL*, Extensor pollicis longus.

Position. With the palpating finger still touching the radial head, flex the elbow to 90 degrees. Pronate the forearm, and place the palm flat on a table.

Needle Insertion. Insert a 20-gauge needle from the lateral aspect, just distal to the lateral epicondyle and directed medially.

Comments. Elevation of the anterior fat pad or the presence of a posterior fat pad on a lateral soft tissue elbow radiograph signifies blood, pus, or fluid in the elbow joint (see Fig. 53.10B). Effusions in the elbow joint may bulge and be readily palpated (see Fig. 53.10C). Frequently, the effusion appears inferior to the lateral epicondyle. The bulge can then be aspirated from a posterior approach on the lateral side (see Fig. 53.10D). A medial approach is not recommended because the ulnar nerve and superior ulnar collateral artery may be damaged. Gout and septic arthritis commonly affect this joint. The most common cause of elbow hemarthrosis after trauma with no obvious fracture is a nondisplaced radial head fracture. A small hemarthrosis need not be aspirated, but removal of blood from a tense elbow joint will significantly hasten recovery and facilitate range of motion in patients with a radial head fracture.

Figure 53.10 **A**, Landmarks for arthrocentesis of the radiohumeral (elbow) joint. **B**, On a lateral elbow radiograph, displacement of the anterior fat pad (*arrows*) or the presence of a posterior fat pad (*arrows*) indicates blood, pus, or fluid in the joint. **C**, An effusion in the elbow joint can usually be readily palpated. A palpating finger is placed over the lateral epicondyle (*asterisk*) and slid posteriorly and inferiorly toward the olecranon (*arrow*). Usually, a depression is felt as the finger leaves the epicondyle, but a bulge is appreciated if a joint effusion is present. **D**, Removal of only a few milliliters of blood will reduce pain and hasten recovery of range of motion. The most common pathology after trauma with a radiograph negative for fracture but positive for hemarthrosis is a nondisplaced radial head fracture.

▶ Glenohumeral Joint (Shoulder), Anterior Approach (Fig. 53.11; Video 53.5)

Landmarks. Anteriorly palpate the coracoid process medially and the proximal end of the humerus laterally.

Position. The patient should sit upright with the arm at the side and hand in the lap.

Needle Insertion. Insert a 20-gauge needle at a point inferior and lateral to the coracoid process and direct it posteriorly toward the glenoid rim.

Comments. Arthrocentesis of this joint is moderately difficult. Other approaches have been suggested but are less well accepted.

▶ Knee Joint, Anteromedial Approach (Fig. 53.12; Videos 53.6 and 53.7)

Landmarks. The medial surface of the patella at the middle or superior portion of the patella is the landmark for the knee joint.

Position. It is usually recommended that the knee be extended as far as possible. Alternatively, some practitioners prefer to flex the knee 15 to 20 degrees by placing a towel under the popliteal region to open the joint space up. Relaxation of the quadriceps muscle greatly facilitates needle placement. Keep the foot perpendicular to the floor.

Needle Insertion. Insert an 18-gauge needle or catheter and needle set at the midpoint or superior portion of the patella

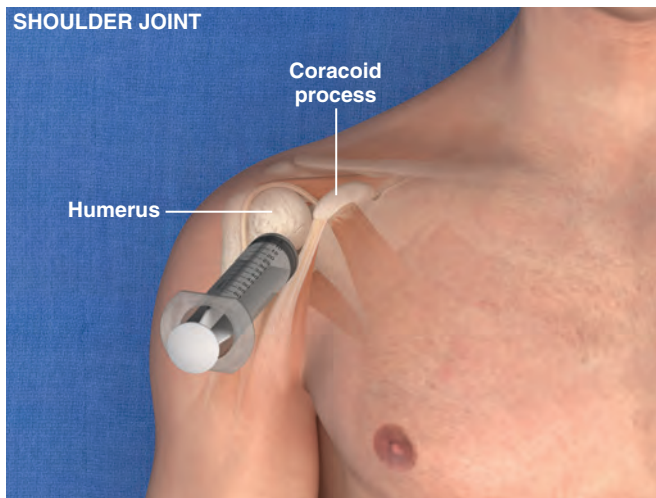

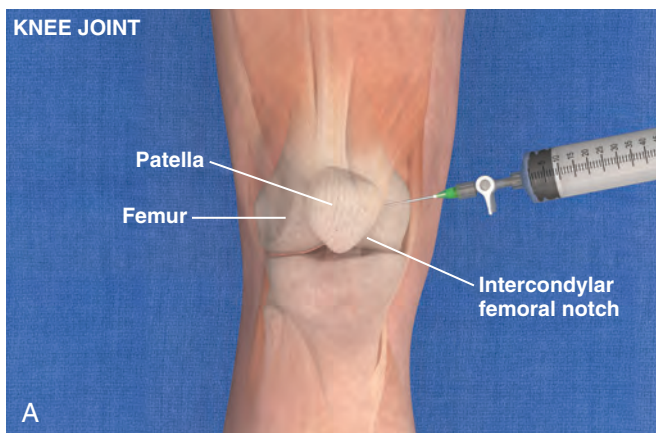

Figure 53.11 Landmarks for arthrocentesis of the glenohumeral (shoulder) joint.

A

B

Figure 53.12 A, Landmarks for arthrocentesis of the knee joint. B, Note the use of a stopcock on the syringe to allow complete drainage without repositioning the needle. Note that the syringe is held parallel to the table. Compression of the suprapatellar region by the operator or an assistant will facilitate complete aspiration. For the knee, a 60-mL syringe and an 18-gauge needle should be used to drain large effusions. Note that the red streaks of blood denote a traumatic tap rather than hemarthrosis. The blood streaks started after clear fluid had been withdrawn.

approximately 1 cm medial to the anteromedial patellar edge. Direct the needle between the posterior surface of the patella and the intercondylar femoral notch. The patella may be grasped with the hand and elevated to aid entry of the needle into the joint. Keeping the needle/syringe parallel to the bed limits internal injury.

Comments. If the patient is tense, contraction of the quadriceps will greatly hinder entering the joint. However, the knee is probably the easiest joint to enter, and removal of a tense hemarthrosis will relieve pain and facilitate examination for ligamentous injury. If fluid stops flowing, squeeze the soft tissue area of the suprapatellar region to “milk” the suprapatellar pouch of fluid. Alternatively, wrap the patient’s thigh with a 6-inch elastic bandage from the groin to the suprapatellar area before beginning the procedure. The knee can easily accommodate 50 to 70 mL of fluid, so use a large syringe. Hold or secure the hub of the needle with a hemostat to remove the syringe without changing the position of the intraarticular needle. Alternatively, a stopcock on the needle will allow complete removal of fluid without changing the position of the needle (see Fig. 53.12B). The knee is a common site for septic arthritis (especially gonococcal) and various inflammatory or degenerative diseases. An anterolateral approach can be accomplished in a similar manner.

Tibiotalar Joint (Ankle) (Fig. 53.13; Video 53.8)

Landmarks. The medial malleolar sulcus is bordered medially by the medial malleolus and laterally by the anterior tibial tendon. The tendon can easily be identified with active dorsiflexion of the foot.

Position. With the patient lying supine, plantar-flex the foot.

Needle Insertion. Insert a 20- to 22-gauge needle at a point just medial to the anterior tibial tendon and directed into the hollow at the anterior edge of the medial malleolus. The needle must be inserted 2 to 3 cm to penetrate the joint space.

Comments. If the joint bulges medially, one may use an approach that is more medial than anterior and enter at a point just anterior to the medial malleolus. The needle may have to be advanced 2 to 4 cm with this approach.

Metatarsophalangeal and Interphalangeal Joints (Fig. 53.14; Videos 53.9 and 53.10)

Landmarks. For the first digit, landmarks are the distal metatarsal head and the proximal base of the first phalanx. For the other toes, the landmarks are the prominences at the proximal interphalangeal and distal interphalangeal joints. The extensor tendon of the great toe can be located by active extension of the toe.

Position. With the patient supine, flex the toes 15 to 20 degrees. Then apply traction.

NEEDLE INSERTION. Insert a 22-gauge needle on the dorsal surface at a point just medial or lateral to the central slip of the extensor tendon.

Figure 53.13 **A**, Landmarks for arthrocentesis of the tibiotalar joint. This is a difficult joint to aspirate. **B**, Acute gout of the ankle is common but can mimic an infected joint, an uncommon condition. Arthrocentesis was unsuccessful, but a previous history of gout and the clinical features allowed empirical treatment of gout.

SYNOVIAL FLUID INTERPRETATION

Synovial fluid examination is essential for the diagnosis of septic arthritis, gout, and pseudogout.^{38–40} Inflammatory joint disease of previously unknown etiology can often be diagnosed precisely by synovial fluid analysis. Joint fluid is a dialysate of plasma that contains protein and hyaluronic acid. Normal fluid is clear enough to read newsprint through and will not clot. It is straw colored, flows freely, and has the consistency of machine oil. Normal fluid produces a good mucin clot and yields a positive “string sign” (see the next section). The uric acid level of joint fluid approaches that of serum, and the glucose concentration is normally at least 80% of that in serum. The clarity of the fluid reflects the leukocyte count. High leukocyte counts result in opacity, the degree of which generally correlates with the degree of elevated synovial fluid leukocytes. However, the degree of opacity cannot be used to reliably determine the synovial fluid leukocyte count and should not be used as a surrogate for laboratory cell count measurements.

String Sign

Viscosity correlates with the concentration of hyaluronate in synovial fluid. Any inflammation degrades hyaluronate, which

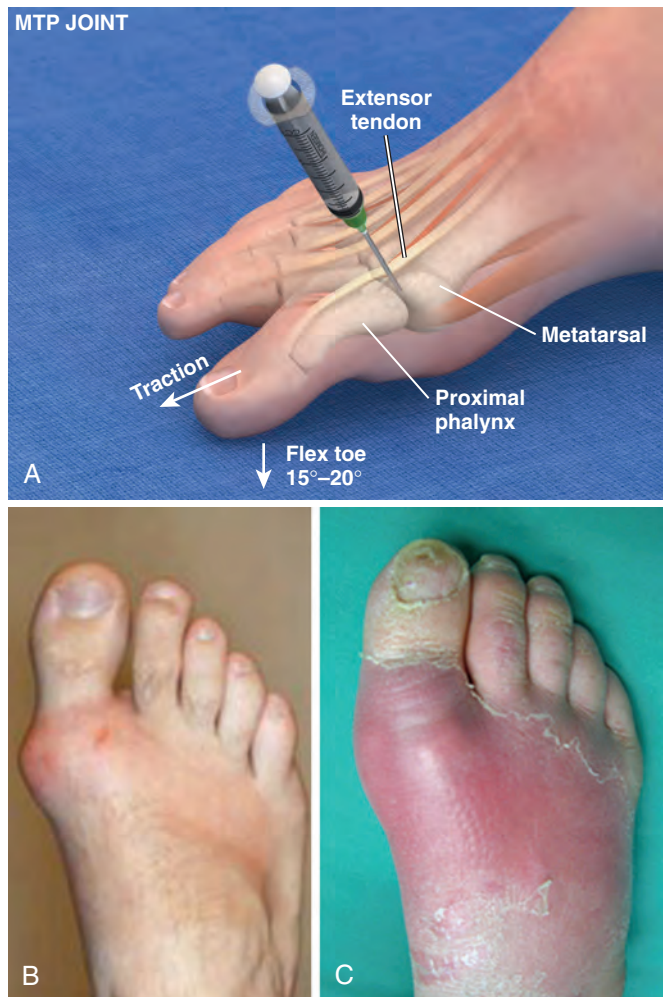

Figure 53.14 **A**, Landmarks for arthrocentesis of the first metatarsophalangeal joint. This is a difficult joint to aspirate. **B**, Acute gout can be mistaken for cellulitis, but this is classic podagra. Aspiration of small joints may be difficult. One can treat gout empirically with close follow-up to be certain that infection or coinfection is not present. **C**, The red, warm, swollen, and painful condition of the dorsum of the foot is a common finding with gout but may suggest cellulitis. Clinical acumen may diagnose gout (e.g., woke up with sudden acute pain, diuretic use, previous gout, elevated uric acid level), but arthrocentesis is often helpful, especially if this is the first manifestation of gout. *MTP*, Metatarsophalangeal.

characteristically results in low-viscosity synovial fluid. The string sign is a simple test for assessing viscosity. The practitioner measures the length of the “string” formed by a falling drop of synovial fluid extruded from a syringe or stretched between the thumb and the index finger of a gloved hand. Normal joint fluid produces a string 5 to 10 cm long (Fig. 53.15). If viscosity is reduced, as with inflammatory conditions, synovial fluid forms a shorter string or falls in drops.

Mucin Clot Test

The mucin clot test also corresponds to viscosity and inflammation. The greater the inflammatory response, the poorer the mucin clot and the lower the viscosity. This test may be useful to define the degree of polymerization of hyaluronate.

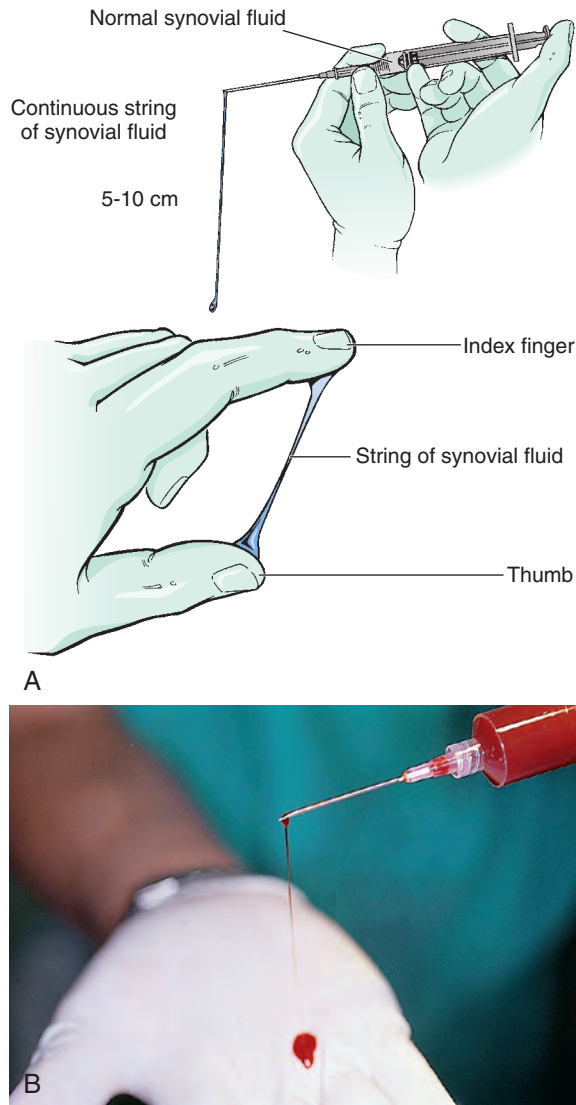

Figure 53.15 A, Ability of normal synovial fluid to form a long tenacious string. Inflammatory fluid will not produce this finding. B, Bloody joint fluid from recent trauma forms a normal string sign.

Mucin clots are produced by mixing one part joint fluid with four parts 2% acetic acid. A good clot indicates a high degree of polymerization and correlates with normal high viscosity. In inflammatory synovial fluid, such as that seen with osteoarthritis- and rheumatoid arthritis-related effusions, the mucin clot is poor. This test is rarely performed.

Cell Count

A leukocytosis consisting predominantly of neutrophils is usually seen with inflammatory arthritides; a WBC count greater than $50,000/\text{mm}^3$ (i.e., $>50,000/\mu\text{L}$) is highly suggestive of a septic joint. Shmerling and colleagues³⁸ found a WBC count of greater than $2000/\text{mm}^3$ to be 84% sensitive and 84% specific for all inflammatory arthritides. Of their septic arthritis patients, 37% had a synovial WBC count lower than $50,000/\text{mm}^3$. However, 89% of their patients with a synovial WBC count greater than $50,000/\text{mm}^3$ had a septic joint.³⁸

Glucose and Protein

Current literature suggests that synovial protein and glucose are highly inaccurate markers of inflammation.^{2,28} In one study of 100 consecutive patients undergoing diagnostic arthrocentesis, the sensitivity of synovial protein and glucose was found to be 0.52 and 0.20, respectively.³⁶ The authors of this study recommended that ordering chemistry studies on synovial fluid should be discouraged because such studies are likely to provide misleading or redundant information.

Serology

Though available, most serologic tests are not likely to be useful in the emergency setting. Polymerase chain reaction (PCR) is an effective means of identifying septic arthritis, even in the setting of a negative fluid culture or when antibiotics have been administered previously. PCR can also help isolate slowly growing microorganisms. Gas-liquid chromatography, a rapid and sensitive method for detection of short-chain fatty acids, may complement the currently available methods used to diagnose septic arthritis.³⁹

Counterimmunoelectrophoresis and latex agglutination are also useful and available in some centers on an emergency basis. Other immunologic markers such as complement, rheumatoid factor, and antinuclear antibodies have little diagnostic value in the acute setting but may be useful to the clinician providing follow-up care when compared with serum levels.

Fluid Processing

Proper collection of joint fluid is essential for examination and testing. Tests for viscosity, serology, and chemistries are done on fluid collected in a red-topped (clot) tube, whereas cytology samples are collected in tubes with an anticoagulant (purple top). One should always transfer the fluid for crystal examination into a tube with liquid heparin (green top) because undissolved heparin crystals from powdered anticoagulant tubes can be seen on microscopy. Early transfer of synovial fluid to this green-topped tube is essential to prevent clotting. Culture requirements for transport and processing should be accessed before the procedure to ensure appropriate processing or plating of specimens.

Polarizing Microscope

No synovial fluid analysis is complete until the fluid has been examined for crystals under a polarizing light microscope. The polarizing microscope used for crystal identification differs from the ordinary light microscope in that it contains two identical polarizing prisms or filters. One filter, called the *polarizer*, is positioned below the condenser. The other filter is called the *analyzer* and is inserted at some point above the objective. Examination for crystals is performed by most hospital laboratories.

Polarization Physics

The polarizer allows passage of light in only one specific orientation. The analyzer acts as a crossed filter by removing all light in the light path unless the material being examined rotates the beam from the polarizer into the plane of the analyzer. The compensator functions by imparting color of a certain wavelength (red at approximately 550 nm). Birefringent

materials change the wavelength to blue or yellow, depending on the direction (negative or positive) of refringence.

Microscopic Analysis

When examining crystals under polarized microscopy, the technician orients crystals on a stage according to two axes, referred to as x and z. If the long axis of the crystals is blue when parallel to the z-axis and yellow when perpendicular to it, it is calcium pyrophosphate and termed *positively birefringent*. If the long axis of the crystal is yellow when parallel to the z-axis and blue when perpendicular to it, it is monosodium urate and termed *negatively birefringent*. Urate crystals are 2 to 10 μm and usually needle shaped (Fig. 53.16). Calcium

Figure 53.16 Monosodium urate crystals under a polarizing light microscope. The crystals are positively birefringent and usually needle shaped. (From Hochberg MC, Silman AJ, Smolen JS, editors: *Rheumatology*. ed 5, St Louis, 2011, Elsevier.)

pyrophosphate crystals range from 10 μm down to tiny crystals that have to be examined with the oil objective; they appear as rods, rhomboids, plates, or needle-like forms and are weakly birefringent (Fig. 53.17). Cholesterol crystals are sometimes seen and are large, very bright square or rectangular plates with broken corners.^{40,41}

Items found in synovial fluid that can be confused with sodium urate or calcium pyrophosphate crystals include collagen fibrils, cartilage fragments, cholesterol crystals, metallic fragments from prosthetic arthroplasty, and corticosteroid esters.⁴⁰ One may also identify fat globules (Fig. 53.18). Note that rare cases of uric acid spherulites in gouty synovia have been reported.⁴⁰ The spherulites are birefringent and do not take up fat stains.

Table 53.2 summarizes synovial fluid features for the joint diseases commonly encountered and studies commonly performed in the ED.

Figure 53.17 Calcium pyrophosphate dihydrate crystals under a polarizing light microscope. These crystals are negatively birefringent and rhomboid shaped. (From Hochberg MC, Silman AJ, Smolen JS, editors: *Rheumatology*. ed 5, St Louis, 2011, Elsevier.)

TABLE 53.2 Characteristics of Synovial Fluid

	APPEARANCE	VISCOSITY	CELLS PER mm^3	PMN (%)	CRYSTALS
Normal	Transparent	High	<180	<10	Negative
Osteoarthritis	Transparent	High	200–2000	<10	Occasional calcium pyrophosphate and hydroxyapatite crystals
Rheumatoid arthritis	Translucent	Low	2000–50,000	Variable	Negative
Psoriatic arthritis	Translucent	Low	2000–50,000	Variable	Negative
Reactive arthritis	Translucent	Low	2000–50,000	Variable	Negative
Spondyloarthropathy	Translucent	Low	2000–50,000	Variable	Negative
Gout	Translucent to cloudy	Low	200 to >50,000	>90	Needle-shaped, positive birefringent monosodium urate monohydrate crystals
Pseudogout	Translucent to cloudy	Low	200–50,000	>90	Rhomboid, negative birefringent calcium pyrophosphate crystals
Bacterial arthritis	Cloudy	Variable	2000 to >50,000	>90	Negative
PVNS	Hemorrhagic or brown	Low			Negative
Hemarthrosis	Hemorrhagic	Low			Negative

Figure 53.18 **A**, Blood aspirated from a traumatized joint is placed in an emesis basin and put under a bright light to search for lipohearthrosis, which is clinical evidence of an intraarticular fracture. Note the characteristic greasy sheen of floating fat. Do not throw away this blood before assessing for lipohearthrosis. **B**, A fibular head fracture (*arrow*) was initially thought to be responsible for a large knee hemarthrosis, but anatomically it is extraarticular. A tibial plateau fracture is not appreciated on this radiograph. Such injuries are often occult. **C**, On this view one might appreciate the radiolucent lines suggestive of a lateral tibial plateau fracture (*arrows*), but such subtle findings are easily missed, as was the case with this patient. Therapeutic arthrocentesis was performed to alleviate pain, and an obvious lipohearthrosis was noted. **D**, Magnetic resonance imaging demonstrates an obvious lateral tibial plateau fracture (*arrows*), which was searched for only after lipohearthrosis was noted. Computed tomography could also be used.

JOINT ARTHROGRAPHY

Background

Wounds near joints raise concern regarding joint penetration. Treatment and interventions may be altered significantly if a joint space has been traumatically violated. Plain radiographs may demonstrate air in the joint, which clinches the diagnosis, but in questionable cases the diagnostic approach includes injection arthrograms. Historically, these were performed by injecting methylene blue into the joint in question and assessing leakage from the joint. However, the dye can interfere with arthroscopic evaluation and produce an inflammatory reaction, so saline arthrography (SA) is now preferred. SA, or a “saline load test,” was first described in 1975 but became more popular in the 1990s.^{42,43}

Indications and Contraindications

SA should be performed in patients with penetrating injuries near a joint in which violation of the joint itself is unclear (**Fig. 53.19**). Smaller joints such as those in the hand are inspected visually. However, for larger joints, SA is the preferred test.

Figure 53.19 This periarticular laceration raises the question of knee joint penetration. A plain radiograph may demonstrate air in the joint space, but a saline arthrogram may also be used. Methylene blue alone is not generally required and it can cause an inflammatory reaction and obscure arthroscopy. A small amount of methylene blue may be added to color the saline.

Figure 53.20 Saline arthrography. Using a stopcock and an 18-gauge needle, enter the joint in a manner identical to that for arthrocentesis. Note that a bag of intravenous saline (or additional vials of saline) introduced into the syringe may be required to provide enough saline to distend the joint properly. Unless the joint is markedly distended, a false-negative test may result. When completed, drain the injected saline via the original needle. A positive test is egress of saline into the original wound or slow loss of saline from the joint. A small amount of methylene blue may be added to the saline.

Contraindications to performing SA are essentially the same as for performing arthrocentesis. When indicated, underlying fracture of the joint should first be ruled out. An obvious open fracture would preclude the need to perform SA.

Equipment and Procedure

Aseptic technique is essential, but the equipment and procedure are essentially the same as for performing arthrocentesis, with minor differences. First, a source of sterile saline is required (e.g., a small bag of intravenous fluid). Second, larger joints require more saline infusion, and this is most easily performed if a stopcock is used to allow refill of the syringe (Fig. 53.20).

Because saline is not as viscous as joint fluid, a 20-gauge needle is sufficient. Once the joint space has been reliably entered, a variable amount of saline to “load” that joint is slowly injected. The amount of saline injected varies with the size of the joint. In general, inject a sufficient volume to visibly distend the joint or create resistance to injection which may

cause the patient discomfort. The sensitivity of the test in detecting small traumatic joint injuries is proportional to the volume injected. Specifically, for knee injuries, injecting 50 mL of saline was 46% sensitive and injecting 100 mL, 75% sensitive; to achieve 95% sensitivity required an average of 194 mL of saline.⁴³ The following is the recommended volume of injection per joint:

- Knee: 100 to 200 mL
- Elbow: 20 to 30 mL
- Ankle: 20 to 30 mL
- Wrist: 5 mL
- Shoulder: 40 to 60 mL

Once the injection is complete, do not remove the needle but close the stopcock to avoid backflow. Examine the joint for evidence of leakage of fluid from the wound. This is performed in a static position but, if negative, also with some gentle passive movement of the joint. Visible leakage of fluid into the laceration confirms the diagnosis of joint space violation. A negative test is defined as absence of evidence of leakage after an appropriate amount of saline has been injected. A slow loss of fluid may indicate a small insult to the joint, and saline can be left in the joint for a few minutes to observe for this. After completion, the fluid should be evacuated for patient comfort. This is generally performed by leaving the original needle in place with a closed stopcock attached, which is then used to aspirate the saline in the joint.

Complications

Complications associated with performing SA are essentially the same as those for performing arthrocentesis. In addition, some temporary patient discomfort because of joint distention should be assumed.

Conclusion

Small traumatic joint penetration can be difficult to diagnose clinically. SA can help confirm the diagnosis. To be a sensitive test, it must be performed with an adequate amount of saline infusion to truly “load” the joint. If the test is positive, orthopedic consultation is indicated.

Compartment Syndrome Evaluation

Chaiya Laoteppitaks

Open fractures, dislocations, and exposed joints are true orthopedic emergencies that must be managed aggressively to prevent morbidity and mortality. Even when managed appropriately, these injuries may be further complicated by a compartment syndrome, a condition of increased pressure within a limited space that results in compromised tissue perfusion leading to tissue ischemia, and ultimately dysfunction of the neural and muscular structures contained within that space.¹ Compartment syndrome is most often associated with significant trauma, particularly long bone fractures (e.g., tibia, radius, ulna). However, it may also occur following less severe trauma that does not cause fractures, such as crush injuries, severe thermal burns, penetrating trauma, injury to vascular structures in the extremities and, in some cases, even minor injuries. Patients on anticoagulants, those with a bleeding diathesis, and those who continue to use an injured limb are at increased risk. Nontraumatic causes of compartment syndrome occur less often, and include ischemia-reperfusion injury,

excessive muscular exertion, thrombosis, bleeding disorders and coagulopathies, vascular disease, nephrotic syndrome, certain animal envenomations and bites, extravasation of intravenous (IV) fluids, injection of recreational drugs, and prolonged external pressure (e.g., from a tight circumferential bandage or cast, or from lying on an extremity for a prolonged period secondary to drug or alcohol intoxication).

Numerous drugs and toxins have been reported to cause rhabdomyolysis, possibly because of a direct effect or secondary to agitation and exertion, with the *theoretical potential* for the development of compartment syndrome (Fig. 54.1). This list is exhaustive but includes heroin, various hydrocarbons, cocaine, amphetamines, antidepressants, antipsychotics, salicylates, propoxyphene, nonsteroidal antiinflammatory drugs, succinylcholine, human immunodeficiency virus (HIV) medications, antimetabolite and cancer drugs, antimalarials, diphenhydramine, baclofen, ecstasy, ethanol, anticoagulants and thrombolytics, strychnine, statins, and phenothiazines.²

Causes of compartment syndrome are categorized into those that decrease compartment volume capacity, those that increase the contents of a compartment, and those that create externally applied pressure (Box 54.1).¹

Subtleties in the early signs and symptoms of compartment syndrome or other clinical priorities render some cases simply impossible to recognize and treat early enough to thwart the ultimate disability. In fact, approximately 10% of cases of acute compartment syndrome secondary to fractures and 20% of non-fracture-associated cases will have muscle necrosis requiring débridement at the time of surgery.³ These statistics indicate that even with diligent clinical care, it is often difficult to identify all cases before injury to muscles occurs. This is

Compartment Syndrome Evaluation

Indications

Suspected compartment syndrome with clinical findings that are equivocal or difficult to interpret:

- Unresponsive patients
- Uncooperative patients
- Children
- Patients with multiple or distracting injuries
- Patients with peripheral nerve deficits attributable to other causes (fracture-associated nerve injury, diabetic peripheral neuropathy)

Contraindications

Absolute

None

Relative

- Coagulation disorders
- Overlying infection, cellulitis, or burns

Complications

- Pain from needle insertion, fluid injection, or bleeding
- Inaccurate readings due to poor technique, improper needle position, injected fluid or anesthetic, or external compression
- Injury to underlying tissue, nerves, or blood vessels
- Local or systemic infection

Equipment

Equipment shown is for the Stryker method. The side-port needle, prefilled syringe, and diaphragm chamber are packaged together in the Stryker 295-2 Quick Pressure Monitor Set (Stryker, Kalamazoo, MI).

Figure 54.1 The diagnosis of compartment syndrome is not always straightforward. **A**, This man was initially seen while in a coma from a heroin overdose and had been lying on his arm for a number of hours. He was hypotensive, in renal failure, comatose, and on a ventilator. The entire arm was swollen and rhabdomyolysis was correctly suspected. **B**, Clear urine, a strongly positive dipstick for blood (*arrow*), and no red blood cells by microscopy equate to myoglobinuria. Because of the coma, he was unable to voice any complaint of pain. **C**, When he awakened 20 hours later, the pain was severe, and compartment pressures indicated the need for fasciotomy. Heroin can cause rhabdomyolysis, and hypotension/reperfusion and certainly prolonged pressure on the muscles may have exacerbated the condition. **D**, The classic wringer washer injury predisposes to compartment syndrome, but industrial rollers are now usually the culprit.

BOX 54.1 Causes of Compartment Syndrome**DECREASED COMPARTMENTAL VOLUME**

Closure of fascial defects
 Application of excessive traction to fractured limbs
 Compressive devices (casts, splints, circumferential dressings)

INCREASED COMPARTMENTAL CONTENTS

Bleeding
 Major vascular injury
 Coagulation disorders
 Bleeding disorder
 Anticoagulation therapy
 Thrombolytic therapy
 After placement of an arterial line

INCREASED CAPILLARY FILTRATION

Reperfusion after ischemia
 Arterial bypass grafting
 Embolectomy
 Ergotamine ingestion
 Cardiac catheterization
 Lying on the limb
 Trauma
 Fracture
 Contusion
 Intensive use of muscles
 Exercise or severe exertion
 Seizures
 Eclampsia
 Tetany
 Burns
 Thermal
 Electric

Intraarterial drug injection
 Cold
 Orthopedic surgery
 Tibial osteotomy
 Hauser's procedure
 Reduction and internal fixation of fractures
 Snakebite

INCREASED CAPILLARY PRESSURE

Intensive use of muscles
 Venous obstruction
 Phlegmasia cerulea dolens
 Ill-fitting leg brace
 Venous ligation
 • Diminished serum osmolarity, nephrotic syndrome

OTHER CAUSES OF INCREASED COMPARTMENTAL CONTENTS

Infiltrated infusion
 Pressure transfusion
 Leaky dialysis cannula
 Muscle hypertrophy
 Popliteal cyst
 Carbon monoxide poisoning

EXTERNALLY APPLIED PRESSURE

Tight casts, dressings, or air splints
 Lying on the limb
 Pneumatic antishock garment
 Congenital bands

particularly true in uncooperative, unconscious, or critically injured patients who are unable to report symptoms. Unfortunately, the vagaries of the clinical scenario that result in failure to recognize the early signs and symptoms of compartment syndrome may have severe and irreversible limb- or life-threatening consequences.

Although compartment syndrome is essentially a clinical diagnosis, objective measurement of compartment tissue pressure may assist in confirming the diagnosis and determining if operative management is required. This chapter discusses the indications, complications, and interpretation of compartment pressure monitoring, as well as the equipment and techniques required to measure and monitor compartment pressure.

BACKGROUND

Though recognized as a clinical syndrome in the mid-19th century, the pathophysiology of ischemia in extremities was not fully described until more than a century later. Postischemic myoneural dysfunction and its associated contractures were first described in the 1870s by the German surgeon Richard von Volkmann, who recognized the effects of increased pressure causing vascular compromise of the limb.⁴

Over the past 40 years or so, various needles and equipment have been developed to measure compartment pressure (Fig. 54.2).⁵⁻¹¹ The *wick catheter*, originally developed to measure subcutaneous and brain tissue pressure, was modified during the mid-1970s to provide continuous compartment pressure measurements. This catheter is rarely used today because of the fear of catheter breakdown leading to errors in measurement and retained foreign bodies. The *slit catheter* was introduced in 1980.^{10,11} As its name implies, this catheter has slits at its distal end that prevent clogging. The proximal end of the catheter is connected to a transducer and infusion system, which permits continuous pressure monitoring. Both the wick and slit catheters have been shown to offer similar accuracy and reproducibility as long as patency of the catheter is ensured.¹¹⁻¹³

The Stryker Intracompartmental Compartment Pressure Monitoring System (Kalamazoo, MI) has become the most commonly used commercially available device to measure compartment pressure in the emergency department (ED) (see Review Box 54.1). This device uses a fluid-filled pressure measurement catheter, a pressure monitor, and a fluid infusion mechanism that maintains catheter patency and ensures accurate measurement. In contrast to earlier devices in which relatively large volumes of fluid were injected into the compartment to measure pressure, the Stryker system uses a minimal amount of saline (< 0.3 mL). This helps ensure accurate measurements

Figure 54.2 A, An 18-gauge straight needle. B, An 18-gauge side-port needle. C, A slit catheter. (A–C, from Boody AR, Wongworawat MD: Accuracy in the measurement of compartment pressures: a comparison of three commonly used devices, *J Bone Joint Surg Am* 87:2415, 2005.)

▶ (Videos 54.1 and 54.2) while reducing the chance of further increases in compartment pressure. The Stryker system also has the ability to record a single measurement or provide continuous compartment pressure recordings when required.

Noninfusion systems such as the transducer-tipped fiberoptic system offer a distinct advantage over conventional fluid-filled systems in that they do not produce hydrostatic pressure artifacts or require the injection of fluid for long-term or continuous measurements. However, the fiberoptic transducer is relatively large, must be attached to a sheath approximately 2.0 mm in diameter, and is likely to cause pain during measurements.¹⁴ A newer approach to predicting the onset of compartment syndrome involves measuring compartment pH as a marker of compromised circulation and decreased tissue perfusion.¹⁵ A rise in lactic acid from ischemic tissue lowers the pH of the compartment and has promise as an early predictor of compartment syndrome.

In recent years, noninvasive, less painful methods of measuring compartment pressure have been studied in patients with both acute and chronic exertional compartment syndromes. Investigations using magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT), myotonometry, electromyography, ultrasound, near-infrared spectroscopy, and microwave tomography have provided encouraging results in the evaluation of compartment syndrome.^{16–33} In addition, externally applied devices that measure muscle tissue “hardness” are under investigation as an economic alternative to these modalities, although support for their use has been mixed.^{34–36} Though promising, these evolving noninvasive methods have not yet replaced needle-driven techniques as the standard for measuring intracompartmental pressure.

The remainder of this chapter describes the most commonly used devices and techniques for measuring compartment pressures in the acute setting. Each method provides rapid measurements with reasonable accuracy. The method chosen will depend on the availability of the supplies and equipment necessary for a particular procedure and the experience of the operator.

PATHOPHYSIOLOGY

Several theories have been proposed to account for the tissue ischemia associated with compartment syndrome. They include the “arteriovenous (AV) gradient” theory, which suggests that reduced AV pressure-perfusion gradients prevent adequate blood supply³⁷; the “critical closure” theory, in which blood flow is arrested well before the AV perfusion gradient declines to zero^{38,39}; and the “venous occlusion” theory,⁴⁰ which states that externally applied pressure, thrombotic events, and reperfusion contribute to the increased compartment pressure and, ultimately, tissue ischemia. Although the exact mechanism has not been agreed on, inherent in each of these theories is a decrease in blood flow to levels below those required to meet the metabolic demands of the tissue. Hence, the final common pathway is cellular hypoxia and muscle necrosis.

Adequate blood flow to tissues is a function of AV gradients across capillary beds. Once blood flow falls below a critical level, delivery of oxygen to these structures is impaired and aerobic cellular metabolism is no longer possible. Anaerobic metabolism then ensues until energy stores become depleted. Muscles then become ischemic, and a reduction in venous and lymphatic drainage creates increased pressure within this confined space. It is important to note that ischemia and necrosis of the musculature can occur despite an arterial pressure high enough to produce pulses, therefore merely assessing distal pulses is insufficient.⁴¹

A drop in blood pressure, an increase in compartment pressure, or a combination of the two can reduce AV gradients and lead to insufficient blood flow. Hypotension can occur in a variety of settings, including hypovolemia, acute blood loss, cardiac disease states (e.g., ischemia), and sepsis. An increase in the contents of a compartment, a decrease in its volume capacity, and external constriction of a compartment can all lead to increases in compartment pressure. Thus, the relationship between intracompartmental pressure and the circulatory status of the extremity is an important factor in the development of compartment syndrome.⁴²

At rest, normal adult compartment pressures are typically below 10 mm Hg. However, deviations of 2 to 6 mm Hg have been reported.^{1,8–10,12} Data suggest that normal compartment pressures in the lower extremity at rest are higher in children.⁴³ The *perfusion pressure* of a compartment is defined as the difference between diastolic blood pressure and intracompartmental pressure.⁴⁴ A model using legs of volunteers has shown that a progression of neuromuscular deficits occurs when the perfusion pressure drops below 35 to 40 mm Hg.⁴⁵ Below this level, tissue perfusion is interrupted. Studies of neuromuscular tissue ischemia have demonstrated that inflammatory necrosis can occur at intracompartmental pressures between 40 and 60 mm Hg.^{46,47}

Whitesides and colleagues demonstrated that when tissue pressure within a closed compartment rises to within 10 to 30 mm Hg of the patient’s diastolic blood pressure, inadequate perfusion ensues and results in relative ischemia of the involved limb.⁶ Heppenstall and associates further clarified this relationship by demonstrating that the difference (ΔP) between mean arterial pressure (MAP) and the measured compartment pressure is directly related to blood flow to the tissue.⁴⁸ They noted that as compartment pressure approaches MAP, ΔP decreases. Once ΔP falls below 30 mm Hg, tissue ischemia becomes more likely. In normal musculature, a ΔP of less than 30 mm Hg results in loss of normal aerobic cellular metabolism.⁴⁸ In

traumatized muscle, a ΔP of less than 40 mm Hg is associated with abnormal cellular function, thus highlighting the importance of maintaining adequate systemic blood pressure in the setting of neuromuscular injury.⁴⁸

For years, conventional wisdom maintained that immediate reperfusion of traumatized tissue would provide improved motor and neurologic function after injury. In the last decade, research suggests that muscle tissue may remain viable even after prolonged periods of ischemia and that a substantial proportion of the injury is generated during reperfusion.^{49,50} Tissue acidosis, intracellular and extracellular edema, free radical-mediated injury, loss of adenine nucleotide precursors, and interruption of mitochondrial oxidative phosphorylation by increased intracellular calcium have been implicated in the development of reperfusion-associated compartment syndrome.⁴⁹⁻⁵⁴ A 2010 study has identified the potential role of *N*-acetylcysteine in the attenuation of tissue injury in compartment syndrome.⁵⁵ Even in the absence of local trauma, ischemia followed by reperfusion has been shown to increase compartment pressure in canine models of hypovolemic shock.⁵⁶

Evidence also suggests that elevated compartment pressure itself (in addition to causing ischemia) plays a role in the cellular deterioration seen with compartment syndrome.⁵⁷ In a study by Heppenstall and associates,⁵⁷ muscle ischemia caused by placement of a tourniquet was compared with an experimentally derived high-pressure compartment syndrome. The authors found no difference in the degree to which phosphocreatine levels fell between groups. However, levels of adenosine triphosphate (ATP) diminished rapidly in the compartment syndrome group in comparison to the tourniquet group. Moreover, phosphocreatine levels, ATP, and tissue pH normalized within 15 minutes of releasing the tourniquet. In the group with compartment syndrome, these levels remained low even after fasciotomy. These results suggest that elevated tissue pressure plays a synergistic role with ischemia in cellular deterioration.

CLINICAL FEATURES

Any compartment limited by fascial planes is potentially at risk for compartment syndrome. However, because of their propensity for injury and the presence of several low-volume compartments, the lower extremities are most commonly affected. In the leg, the anterior compartment is involved most often,⁵⁸ whereas the posterior compartment is most often associated with a delayed diagnosis. The hands, feet, forearms, upper part of the arms, thighs, thorax, abdomen, gluteal musculature, and back are other locations where compartment syndrome is known to occur.¹

Risk factors for the development of compartment syndrome include recent trauma to an extremity (including acupuncture, venipuncture, IV infusions, or IV drug use), vascular injury, bleeding within a compartment, a restrictive cast or splint, a crush or compression injury, a prolonged lithotomy position, prolonged external pressure on an extremity, placement of a tourniquet during an operative procedure, and circumferential burns.⁵⁹⁻⁶³

Long-bone fractures account for approximately 75% of traumatic compartment syndromes, and the absence of a fracture in a traumatized extremity is a factor in delayed diagnosis. The tibia is most often involved, followed by bones of the forearm. Supracondylar fractures in children are at risk for compartment syndrome. Comminuted fractures increase the

risk. Closed fractures are of greatest concern, but open fractures do not necessarily decompress elevated compartment pressures. Treatment of fractures, by both open and closed reduction, can increase compartment pressures. Compartment pressures may peak *immediately after reduction*. In addition, some evidence suggests that compartment syndrome may occur in the setting of chronic exertion and muscle overuse.^{64,65} Although the exact etiology remains elusive, studies have demonstrated elevated lactate and water levels in the tibialis anterior muscle after exercise with a reduction in these levels after fasciotomy.^{66,67} Increases in muscle mass (related to a rise in blood volume during exertion) and hypertrophy of muscle and fascia with chronic use and exertion have also been reported.⁶⁸⁻⁷²

The signs and symptoms of acute compartment syndrome generally appear in a stepwise fashion, with rapid progression over a few hours. This underscores the need for serial examinations, particularly in those with equivocal or subtle findings. The classic findings associated with arterial insufficiency, the “five P’s” (pain, pallor, pulselessness, paresthesias, paralysis), are often described as signs of acute compartment syndrome, but these are seldom all seen together and do not need to be present to suspect the diagnosis. When this constellation of signs and symptoms are present, it is generally late in the course of the disease when tissue death and permanent dysfunction are likely.

Early signs of compartment syndrome include a burning sensation over the involved compartment, nonspecific sensory deficits, or poorly localized deep muscular pain. Common features include pain that seems out of proportion to the apparent injury and clinical examination and pain that intensifies when the musculature is passively stretched. Pallor, a pulse deficit with respect to the opposite limb, paresthesias, paresis, or paralysis are variably seen and lack diagnostic sensitivity. Neurologic complaints such as weakness and paresthesias can be confusing because peripheral nerve injury may also result from the inciting trauma. In addition, these findings are not discernable in young children^{73,74} and patients with altered mental status. When present, sensory deficits typically precede motor deficits and manifest distal to the involved compartment. Paralysis is always a late finding.

The period between the injury and the onset of symptoms can be as short as 2 hours and as long as 6 days.⁷⁵ The peak interval appears to be 15 to 30 hours. Frequently, the first symptom described by patients is pain greater than expected given the clinical scenario. Although pain out of proportion to the visible injury may raise the question of drug-seeking behavior, a focused evaluation for the possibility of limb-threatening disorders must precede this diagnosis of exclusion.

Physical examination may reveal a tense compartment with a firm, “woody” feel, muscles that are weak, and hypoesthesia in the distribution of the involved nerves. Sensory deficits, including loss of two-point discrimination and decreased vibratory sensation, may be present.⁷⁶⁻⁷⁸ The presence or absence of a palpable arterial pulse is not an accurate indicator of relative tissue pressure or the risk for compartment syndrome. Pulses may be present in a severely compromised extremity.⁷⁹ [Table 54.1](#) lists the signs and symptoms of compartment syndrome specific to each compartment.

DIAGNOSIS

Even experienced clinicians may find it difficult to diagnose a compartment syndrome, and no specific standard of care

TABLE 54.1 Compartment Syndromes and Associated Physical Signs

COMPARTMENT	SENSORY LOSS	MUSCLES WEAKENED	PAINFUL PASSIVE MOTION	LOCATION OF TENSENESS
Foot	Digital nerves	Foot intrinsics	Toe flexion, extension	Dorsal or plantar surface of the foot
Lumbar	—	Erector spinae	Lumbar flexion	Paraspinous
Forearm				
Dorsal	—	Digital extensors	Digital flexion	Dorsal surface of the forearm
Volar	Ulnar, median nerves	Digital flexors	Digital extension	Volar surface of the forearm
Hand				
Interosseus	—	Interosseus	Abduction/adduction (metacarpophalangeal joints)	Dorsum of the hand between the metacarpals
Leg				
Anterior	Deep peroneal nerve	Toe extensors Tibialis anterior	Toe flexion	Anterior aspect of the leg
Superficial posterior	—	Soleus and gastrocnemius	Foot dorsiflexion	Calf
Deep posterior	Posterior tibial nerve	Toe flexors Tibialis posterior	Toe extension	Distal medial part of the leg between the Achilles tendon and tibia
Gluteal	(Rarely sciatic)	Gluteals, piriformis, or tensor fasciae latae	Hip flexion	Buttock
Upper Part of Arm				
Flexor	Ulnar and median nerves	Biceps and distal flexors	Elbow extension	Anterior aspect of the upper part of the arm
Extensor	Radial nerves	Triceps and forearm extensors	Elbow flexion	Posterior aspect of the upper part of the arm

exists with regard to a time interval from injury to definitive treatment. In an unconscious patient or in those with other life-threatening conditions that mandate other priorities, the clinical scenario simply does not allow a diagnosis to be made in a timely fashion. In cases without trauma or in patients who are unable to voice pain or cooperate with an examination, compartment syndrome is often not considered and the diagnosis is delayed. Regional nerve blocks or epidural anesthesia may also obscure the signs and symptoms of increased compartment pressure and cause further delays in diagnosis.

The difficulty in diagnosing acute compartment syndrome was highlighted in a report by Vaillancourt and coworkers.⁸⁰ In a retrospective review of 76 patients who underwent fasciotomy at major university trauma centers or teaching hospitals, the interval from initial patient assessment to diagnosis of compartment syndrome was up to 8 hours. A delay in diagnosis was most common in nontraumatic cases. The interval from the precipitating event to definitive surgery was up to 35 hours, thus reflecting the difficulty in recognizing the presence of a compartment syndrome and instituting definitive therapy in clinical practice. Such statistics describe actual care, which may be less than ideal when compared with theoretical benchmarks.

Notwithstanding the difficulties just described, the diagnosis of compartment syndrome is primarily a clinical one that may be supplemented by direct measurement of compartment pressure. In a study evaluating the utility of clinical findings in making the diagnosis of compartment syndrome, Ulmer noted that the sensitivity and positive predictive value of clinical findings are low, whereas the specificity and negative predictive value of these findings are high.⁸¹ Nonetheless, the study found that although the sensitivity of an individual clinical finding may be low, the probability of compartment syndrome rises considerably when more than one clinical hallmark is present.⁸¹ Other studies have suggested that the absence of clinical evidence is more useful in excluding compartment syndrome than its presence is in confirming the diagnosis.⁸²⁻⁸⁴ All things considered, compartment syndrome remains largely a clinical diagnosis, and a high index of suspicion is paramount.

The differential diagnosis of compartment syndrome is extensive and includes primary vascular, nerve, and muscle injuries that produce similar findings. Acute arterial occlusion, cellulitis, osteomyelitis, neuropraxia, reflex sympathetic dystrophy, synovitis, tenosynovitis, stress fractures, envenomations, necrotizing fasciitis, deep vein thrombosis, and thrombophlebitis are additional diseases that should be considered. Differentiating

BOX 54.2 Ancillary Studies That May Be Helpful in Identifying Other Diagnoses, Associated Conditions, and Complications in Patients Suspected of Having Compartment Syndrome

LABORATORY STUDIES

- Complete metabolic profile (including electrolytes and renal function testing)
- Complete blood count with differential
- Serum and urine myoglobin
- Creatine phosphokinase
- Urinalysis to evaluate for concurrent rhabdomyolysis
- Coagulation studies

IMAGING STUDIES

- Radiography of the affected limb to evaluate for a fracture or foreign body
- Ultrasonography to rule out deep vein thrombosis or Doppler ultrasonography to evaluate blood flow to the extremity

compartment syndrome from these and other orthopedic disorders requires a detailed history and thorough physical examination, often supplemented by measurement of compartment pressures (Table 54.2).

ANCILLARY STUDIES

In general, laboratory and radiographic studies are not helpful in confirming the diagnosis of compartment syndrome. However, they might be useful in identifying other diagnoses, associated conditions, and complications. Box 54.2 lists useful studies for patients in whom compartment syndrome is suspected. A 2013 retrospective study of 97 patients by Valdez and colleagues attempted to determine if a threshold serum creatinine kinase (CK) level was associated with the development of compartment syndrome.⁸⁵ They found that a CK level greater than 4000 U/L was associated with compartment syndrome and when serial measurements were obtained, the combination of a maximum CK greater than 4000 U/L, a maximal chloride level greater than 104 mg/dL, and a minimal blood urea nitrogen (BUN) level less than 10 mg/dL had a 100% association with compartment syndrome.

INVASIVE COMPARTMENT PRESSURE MONITORING

Indications and Contraindications

The earliest objective manifestation of acute compartment syndrome is an elevation in the tissue pressure of one or more compartments. However, signs and symptoms do not generally develop until tissue pressure has reached a critical level (see earlier section on Pathophysiology). In some patients the diagnosis of compartment syndrome is clinically obvious, and one can proceed directly to fasciotomy. When the clinical findings are equivocal or difficult to interpret, measurement of tissue pressure may help guide treatment. However, it must be remembered that the interpretation of such measurements always requires clinical judgment.

There are several groups of patients in whom clinical findings are difficult to obtain or interpret and who would benefit from measurement of compartment pressure. These groups include unresponsive patients, uncooperative patients, children, patients with multiple or distracting injuries, those with peripheral nerve deficits attributable to other causes (e.g., fracture-associated nerve injury, diabetic peripheral neuropathy), and those whose clinical findings are equivocal.

There are no absolute contraindications to measurement or continuous monitoring of compartment pressure. Caution should be taken when performing these procedures on patients with platelet dysfunction or other coagulation disorders. If possible, avoid inserting needles through overlying areas of infection, cellulitis, or burns.

Patient Preparation and Positioning

Explain the procedure to the patient or surrogate. Written informed consent is not a universal standard, but may be an institutional requirement. Positioning the patient and extremity for measurement of the compartment pressure depends on the extremity and the compartment being studied, coexisting injuries, and the clinical status of the patient. In general, patients should be in the supine position.^{86–88} The exceptions to supine positioning are discussed in subsequent sections related to the specific compartment of interest.

For most patients, measurement of compartment pressure is a painful procedure that requires adequate local anesthesia (see Chapter 29), systemic analgesia, or procedural sedation (see Chapter 33). Some patients may require more than one method of pain control. Anesthetize the skin with a small amount of local anesthetic while avoiding the underlying muscle

and fascia. Inadvertent injection into the underlying structures may falsely elevate compartment pressure. Patient movement (as a result of inadequate analgesia or improper positioning) may also falsely elevate compartment pressure, particularly if the patient requires limb restraint. To minimize the discomfort of multiple attempts at localizing the correct compartment, some have advocated the use of ultrasound guidance to improve the accuracy of needle insertion.⁸⁹ However, there is currently no consensus regarding the use of ultrasound guidance in this setting.^{90,91} In general, place the extremity being studied at the level of the heart and in a position that permits insertion of the needle perpendicular to the compartment being measured. This may require that an assistant hold the extremity above the stretcher. Remove any obstruction to needle entry and all objects that may constrict or exert pressure on the compartment.

Perform compartment pressure measurements with sterile technique, including standard skin preparation and draping at the planned insertion site (see [Chapter 34](#)). Avoid placing the needle through areas of overlying burn or infection. If a circumferential cast is present, bivalve the cast or, if necessary, create a window overlying the desired area with a cast saw.

Equipment

Needles commonly used for measurement of compartment pressure include a simple 18-gauge needle, an 18-gauge spinal needle (for deep compartments), and a side-port needle (Stryker Instruments, Kalamazoo, MI). The side-port needle may be more accurate than simple 18-gauge needles.⁴² Nevertheless, simple 18-gauge needles are more readily available and more commonly used. The wick catheter and slit catheter described previously generally require specialized, cumbersome equipment not often available in most EDs and are therefore not described.

In an effort to reduce the pain associated with insertion of larger-gauge needles, Mars and colleagues evaluated the accuracy and reliability of measuring compartment pressures with smaller-gauge needles.⁹² The authors compared compartment pressures measured with 18- to 25-gauge needles and found that smaller-gauged needles provided results similar to or better than the more traditional 18-gauge needles did. Furthermore, the addition of a side port did not improve accuracy.⁹² Unfortunately, no additional studies have been done to corroborate these findings. As a result, most clinicians continue to use 18-gauge needles.

Pressure Measurement Systems

Stryker Intra-Compartmental Pressure Measurement (Fig. 54.3)

Equipment

- Stryker Quick Pressure Monitor System
- Stryker handheld pressure monitoring unit (included)
- One side-port 18-gauge needle (included)
- One diaphragm chamber (included)
- One syringe prefilled with 3 mL of saline (included)

Setup and Procedure (see Fig. 54.3)

1. Position the patient. Prepare and anesthetize the needle insertion site according to the guidelines described earlier.
2. Open the Quick Pressure Monitor Set and remove the contents while maintaining sterile conditions.
3. Place the needle firmly on the tapered chamber stem.

4. Remove the cap on the prefilled syringe and screw the syringe onto the remaining chamber stem. Take care to avoid contaminating the fluid pathway.
5. Open the monitor cover and inspect the device for damage or contamination. Place the chamber into the device well (black surface down) and push gently until it seats.
6. Snap the cover closed, but **DO NOT FORCE IT**. The latch must have “snapped” in place.
7. Hold the needle at approximately 45 degrees from the horizontal plane and slowly force fluid through the disposable system to purge it of air. *Caution:* **DO NOT** allow saline to roll down the needle into the transducer well.
8. Turn on the unit; it should read between 0 and 9 mm Hg.
9. Hold the device at the intended angle of insertion and press the “ZERO” button to calibrate it. After a few seconds, the display should read “00.” Failure to calibrate the device while in the intended angle of insertion may result in inaccurate readings. *Note:* The display must read “00” before continuing. If it does not, follow the troubleshooting instructions provided by the manufacturer before proceeding.
10. Now insert the needle into the compartment being measured (see later section on [Needle Placement Techniques](#)). Slowly inject no more than 0.3 mL of saline into the compartment to equilibrate with the interstitial fluid.
11. Wait for the display to reach equilibrium and record the resulting pressure.
12. *For additional measurements*, turn the unit off and repeat steps 8 through 11. Recalibrate the unit to zero before each measurement.
13. For continuous monitoring with an indwelling slit catheter, refer to the instructions accompanying the system.

Mercury Manometer System (Fig. 54.4)

Equipment

- Two 18-gauge simple or spinal needles
- Two plastic extension tubes
- One 20-mL syringe
- One three-way stopcock
- One vial of sterile normal saline
- One mercury manometer

Setup and Procedure

1. Position the patient. Prepare and anesthetize the needle insertion site according to the guidelines described earlier.
2. Assemble the syringe, tubing, extension tubing, and needle as shown in [Fig. 54.4A](#).
3. Insert the needle into a vented vial of sterile saline. Aspirate a column of saline into the tubing halfway to the stopcock; care should be taken to avoid the formation of bubbles. Close the three-way stopcock to the tube to prevent the loss of saline during insertion of the needle, and remove the needle from the vial of sterile saline.
4. Insert the needle into the muscle of the compartment being measured (see later section on [Needle Placement Techniques](#)).
5. Attach the second extension tubing to the monitor and to the third port of the three-way stopcock. Turn the stopcock so that the syringe is open to both extension tubes (see [Fig. 54.4B](#)). This closed system has equal pressure in both extension tubes.
6. Increase the pressure in the system gradually by *slowly* depressing the syringe plunger while simultaneously watching

Compartment Pressure Evaluation: Stryker Method

1 Place the 18-gauge needle with a side port on the tapered stem of the diaphragm chamber.

2 Screw syringe prefilled with 3 mL of saline onto the back of the diaphragm chamber.

3 Place the diaphragm chamber assembly into the pressure monitor, black side down. Gently push the chamber until it is well seated in the device.

4 Snap the cover closed-- *do not force it!* Listen for the latch to snap into place.

5 Hold the needle at a 45° angle up from horizontal and depress the plunger to force fluid through system and purge it of air.

6 Turn the pressure monitor on. It should read between 0 and 9 mm Hg.

7 Hold the pressure monitor at the intended angle of insertion and press the "ZERO" button to calibrate the unit. The device display should read "00."

8 Insert the device into the compartment being measured (after skin cleansing and administration of anesthetic). Slowly inject no more than 0.3 mL into the compartment and wait for the device to record and display the pressure.

Figure 54.3 Measuring compartment pressure with the Stryker 295-2 pressure monitor. Normal tissue compartment pressure is between 0 and 8 mm Hg. The diagnosis of compartment syndrome is not based only on compartment pressures. The clinical evaluation must be correlated with measured pressures.

Figure 54.4 A and B, Mercury monitor technique for monitoring compartmental pressure. This system is not usually applicable to use in the emergency department. *IV*, intravenous. (A and B, From Whitesides TE, Haney TC, Morimoto K, et al: Tissue pressure measurements as a determinant for the need of fasciotomy, *Clin Orthop* 113:43, 1975.)

the column of saline. The mercury manometer will rise as pressure in the system increases. When the pressure in the system exceeds that in the tissue, injection of saline into the compartment will occur, which causes the saline column to move. Read the manometer at the moment that the saline is noted to move. This reading corresponds to the tissue pressure in millimeters of mercury.

- To obtain a second reading, completely remove the needle and repeat steps 4 through 6. A third measurement might be necessary to achieve two readings in agreement. Check the needle for tissue plugs and blood clots between readings.

Procedural Caveats

The most common error with this system is depressing the syringe plunger too quickly. Only when saline is injected slowly into the compartment will the mercury column (which has greater inertia) accurately reflect compartment pressure. Another source of error is obstruction of the needle with a plug of tissue (or blood clot) if the plunger of the syringe is pulled back. Finally, aneroid manometers are prone to inaccuracy, are not well calibrated at lower pressure ranges, and should not be substituted for the more accurate mercury manometers for this procedure.

NEEDLE PLACEMENT TECHNIQUES FOR SPECIFIC COMPARTMENTS

General Principles

Accurate pressure measurements depend on careful needle insertion and confirmation of correct placement. Proper needle insertion requires (1) reliable placement in the compartment being measured, (2) avoidance of important neurovascular structures, (3) simplicity and reproducibility, and (4) minimal patient discomfort.⁹³ Most compartments are superficial and easily accessible. Only the deep posterior compartment in the

leg and the gluteal compartment may require a spinal needle to reach the required depth. Most approaches require that the needle enters the tissue perpendicular to the skin.

Lower Extremity

Because of its high vulnerability to injury and limited fascial compliance, the lower part of the leg is predisposed to compartment syndrome. The foreleg traditionally has four compartments: anterior, lateral, deep posterior, and superficial posterior (Fig. 54.5).¹ The anterior compartment is the most frequent site of compartment syndrome.⁴⁵ In some patients the tibialis posterior muscle may occupy its own compartment, separate from the rest of the deep posterior compartment.⁹⁴⁻⁹⁶ Keep this possibility in mind when measuring compartment pressure in this area.

The easiest cross-sectional level for placement of the needle in any foreleg compartment is approximately 3 cm on either side of a transverse line drawn at the junction of the proximal and middle thirds of the lower part of the leg (see Fig. 54.5). When measuring compartment pressure in the foreleg, place the patient in the supine position with the leg at the level of the heart. An exception occurs when measuring the superficial posterior compartment. In this case, place the patient in the prone position. Prepare and anesthetize the needle insertion site as described previously in this chapter.

Anterior Compartment (Fig. 54.6A)

With the patient supine, palpate the anterior border of the tibia at the junction of the proximal and middle thirds of the lower part of the leg. Insert the needle perpendicular to the skin 1 cm *lateral* to the anterior border of the tibia to a depth of approximately 1 to 3 cm. A several fold rise in pressure during (1) external compression of the anterior compartment just proximal or distal to the needle insertion site, (2) plantar flexion of the foot, or (3) dorsiflexion of the foot confirms proper needle depth.

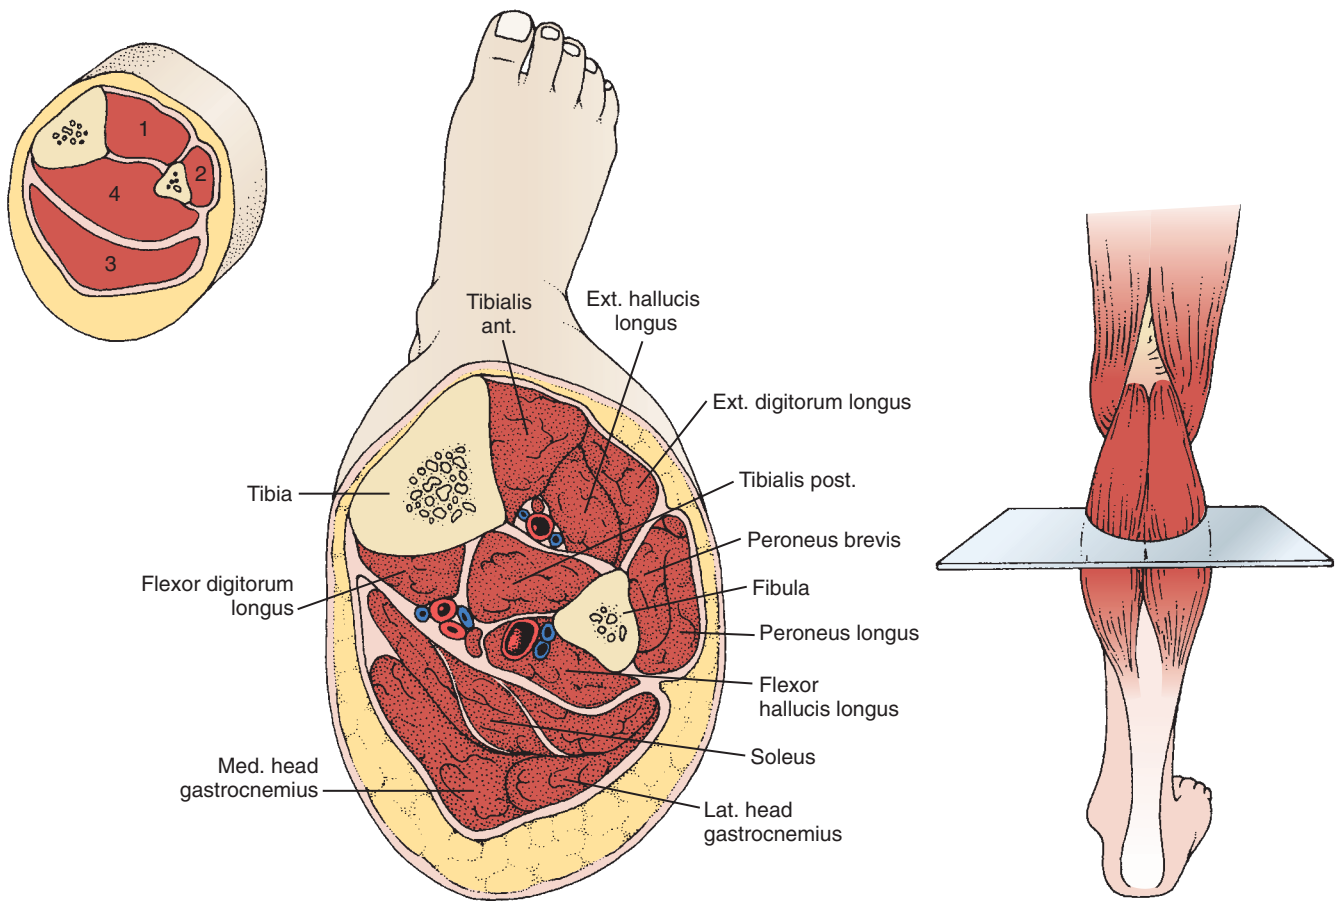

Figure 54.5 Fascial compartments of the lower part of the leg with enclosed muscle groups (*insert, upper left*): 1, anterior; 2, lateral; 3, superficial posterior; and 4, deep posterior compartments.

Deep Posterior Compartment (see Fig. 54.6B)

With the patient supine, have an assistant elevate the leg slightly off the stretcher (if the clinical situation permits). Palpate the medial border of the tibia at the junction of the proximal and middle thirds of the lower part of the leg while simultaneously palpating the posterior border of the fibula on the lateral aspect of the leg at the same level. Insert the needle perpendicular to the skin just posterior to the medial border of the tibia and direct it toward the palpated posterior border of the fibula to a depth of 2 to 4 cm (the final depth depends on the amount of subcutaneous adipose tissue). Confirm proper needle depth by observing a rise in pressure during (1) toe extension or (2) ankle eversion.

Lateral Compartment (see Fig. 54.6C)

With the patient supine and the leg at heart level, have an assistant elevate the leg slightly off the stretcher (if the clinical situation permits). Palpate the posterior border of the fibula at the junction of the proximal and middle thirds of the lower part of the leg. Insert the needle into the skin just anterior to the posterior border of the fibula and direct it toward the fibula to a depth of 1 to 1.5 cm. If the needle contacts bone, withdraw it approximately 0.5 cm. Confirm proper needle depth by observing a rise in pressure during (1) external compression of the lateral compartment just inferior or superior to the needle's entrance or (2) inversion of the foot and ankle.

Superficial Posterior Compartment (see Fig. 54.6D)

With the patient in the prone position and the leg at heart level, identify an imaginary transverse line (or draw one with a marking pen) between the proximal and middle thirds of the lower part of the leg. Insert the needle perpendicular to the skin at this level, 3 to 5 cm on either side of a vertical line drawn down the middle of the calf. Direct the needle toward the center of the leg to a depth of 2 to 4 cm. Confirm proper needle depth by observing a rise in pressure during (1) digital external compression of the posterior compartment just inferior or superior to the needle insertion point or (2) dorsiflexion of the foot.

Forearm

Traditionally, the forearm has been considered a two-compartment limb.¹ However, some authors place the extensor carpi radialis brevis, the extensor carpi radialis longus, and the brachioradialis muscles in a third compartment called the “mobile wad.”^{97–99} The forearm compartments (particularly the volar compartment) are predisposed to compartment syndrome because of their use during vigorous exercise, accessibility for drug use, IV infiltration of fluid or medication, and vulnerability to injury and burns.^{1,100–103}

The junction of the proximal and middle thirds of the forearm is the cross-sectional level for insertion of the needle.⁹⁷

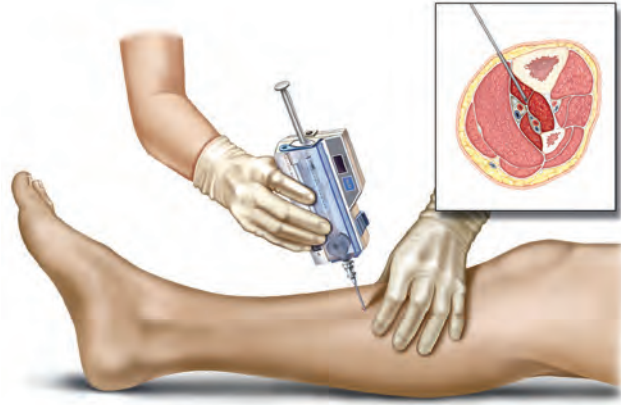

Lower Extremity Compartments

A. Anterior

Place the patient in the supine position. Insert the needle at the junction of the proximal and middle thirds of the lower part of the leg, 1 cm *lateral* to anterior border of the tibia. Direct the needle perpendicular to the skin to a depth of 1 to 3 cm.

B. Deep Posterior

Place patient in the supine position with the leg slightly elevated. Insert the needle at the junction of the proximal and middle thirds of the lower part of the leg, just posterior to the medial border of the tibia. Direct the needle perpendicular to the skin and toward the posterior border of the fibula to a depth of 2 to 4 cm.

C. Lateral

Place patient in the supine position with leg slightly elevated off the stretcher. Insert the needle at the junction of the proximal and middle thirds of the lower part of the leg, just anterior to the posterior border of the fibula to a depth of 1 to 1.5 cm.

D. Superficial Posterior

Place the patient in the prone position. Insert the needle at the junction of the proximal and middle thirds of the lower part of the leg, 3 to 5 cm on either side of the anatomic midline. Direct the needle perpendicular to the skin toward the center of the leg to a depth of 2 to 4 cm.

Figure 54.6 Lower extremity needle placement techniques. (From Custalow CB: *Color atlas of emergency department procedures*. Philadelphia, 2005, Saunders.)

When measuring forearm compartment pressure, place the patient in the supine position with the arm at the level of the heart. Prepare and anesthetize the needle insertion site as previously described.

Volar Compartment (Fig. 54.7A)

Hold the forearm in supination. Identify the palmaris longus tendon by having the patient oppose the thumb and small finger with the wrist flexed against resistance. Follow the tendon to the junction of the proximal and middle thirds of the forearm. Palpate the posterior border of the ulna and insert the needle perpendicular to the skin just medial (ulnar) to the palmaris

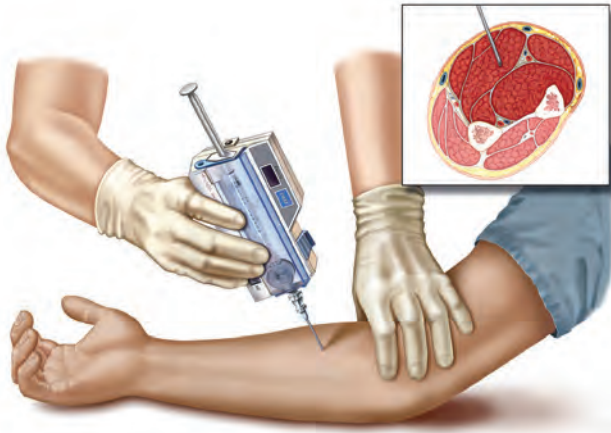

longus tendon. Direct the needle toward the palpated posterior border of the ulna to a depth of 1 to 2 cm. Confirm proper needle depth by observing a rise in pressure during (1) external compression of the volar compartment just proximal or distal to the needle insertion point or (2) extension of the fingers or wrist.

Dorsal Compartment (see Fig. 54.7B)

Hold the forearm in pronation with the elbow flexed and the dorsum of the forearm facing upward. Palpate the posterior aspect of the ulna at the junction of the proximal and middle thirds of the forearm. Insert the needle perpendicular to the

Upper Extremity Compartments

A. Volar

Hold the forearm in supination. Insert the needle at the junction of the proximal and middle thirds of the forearm, just medial to the palmaris longus tendon. Direct the needle perpendicular to the skin, toward the posterior border of the ulna, to a depth of 1 to 2 cm.

B. Dorsal

Hold the forearm in pronation with the elbow flexed and the dorsum of the forearm facing up. Insert the needle at the junction of the proximal and middle thirds of the forearm, 1 to 2 cm lateral to the posterior aspect of the ulna. Direct the needle perpendicular to the skin to a depth of 1 to 2 cm.

C. Mobile Wad

Hold the forearm in supination. Insert the needle at the junction of the proximal and middle thirds of the forearm, at the most lateral (radial) portion of the forearm. Direct the needle perpendicular to the skin to a depth of 1 to 1.5 cm.

Figure 54.7 Upper extremity needle placement techniques. (From Custalow CB: *Color atlas of emergency department procedures*. Philadelphia, 2005, Saunders.)

skin 1 to 2 cm lateral (radial) to the posterior aspect of the ulna to a depth of 1 to 2 cm. Confirm proper needle placement by observing a rise in pressure during (1) digital external compression of the dorsal compartment just proximal or distal to the needle insertion point or (2) flexion of the wrist or fingers.

Mobile Wad (see Fig. 54.7C)

Hold the forearm in supination. Identify the most lateral (radial) portion of the forearm at the junction of its proximal and middle thirds. Insert the needle into the muscle tissue lateral to the radius and perpendicular to the skin to a depth of 1 to

1.5 cm. Confirm proper needle placement by observing a rise in pressure during (1) digital external compression of the mobile wad just proximal or distal to the needle entry point or (2) deviation of the wrist.

Gluteal Musculature

A two-layer fascia encases the muscle bellies of the tensor fasciae latae anteriorly and the gluteus maximus posteriorly. This fascia divides the musculature into three distinct compartments: maximus, tensor, and medius/minimus (Fig. 54.8A and B). The sciatic nerve is deep to the fascia but lies between the

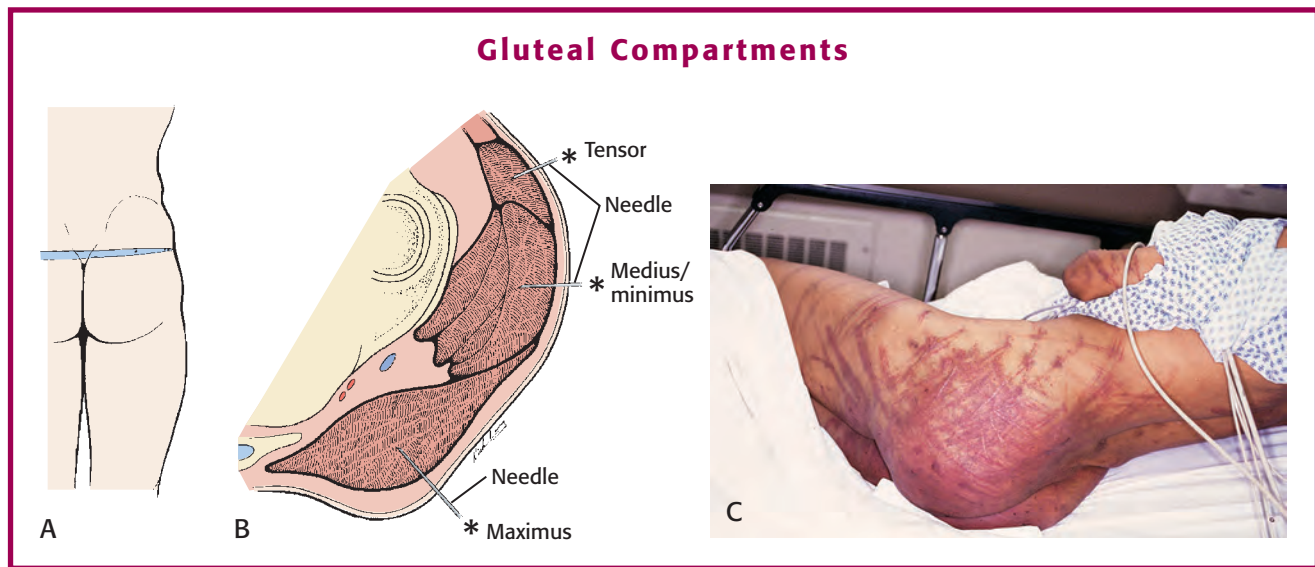

Figure 54.8 Gluteal compartment syndrome. **A**, Suggested entry points are indicated along the blue line. The needle should be inserted to a depth of 4 to 8 cm, depending on which compartment is being measured. **B**, Needle tips (asterisks) are shown entering the muscle compartments. **C**, This patient suffered extensive soft tissue trauma to the buttocks as a result of repeated blows from a stick (domestic abuse) and is at risk for rhabdomyolysis and gluteal compartment syndrome. (A and B, Modified with permission from Owen CA, Moody PR, Mubarak SJ, et al: Gluteal compartment syndromes, *Clin Orthop* 132:57, 1978.)

pelvis–external rotator complex and the gluteus maximus, which makes it vulnerable to injury when compartment syndrome occurs here. Gluteal compartment syndrome is very rare and unknown to many clinicians. Most reported cases of gluteal compartment syndrome result from prolonged immobilization and local compression in association with drug or alcohol intoxication.^{104–108} Prolonged pressure from a toilet seat or significant soft tissue contusions (whipping, paddling) may predispose to this condition. Patients typically have gluteal tenderness that is often attributed to contusion or hematoma. This, combined with the rarity of a compartment syndrome in this area, frequently results in a delayed or missed diagnosis. Rhabdomyolysis should be considered in patients with gluteal compartment syndrome given the large muscle mass involved.

Gluteal Compartments

To measure gluteal compartment pressure, place the patient in the prone position with the gluteal structures at the level of the heart. Prepare and anesthetize the needle insertion site as described previously. Cutaneous landmarks for the three compartments are not consistent from patient to patient. Therefore in cases of suspected gluteal compartment syndrome, insertion of the needle at the point of maximal tenderness is considered sufficient to provide adequate pressure measurements.¹⁰⁴ Insert an 18-gauge spinal needle perpendicular to the skin and direct it toward the point of maximal tenderness to a depth of 4 to 8 cm (see Fig. 54.8B). Confirm proper needle placement by observing a rise in pressure during external compression of the gluteal musculature.

Foot

Crush injuries account for the majority of reported cases of compartment syndrome in the foot,^{109–111} but it may also be

seen after vascular injuries, fractures, and other high-energy injuries. Although compartment syndrome of the foot is rare, it is being reported with increasing frequency as clinicians become more aware of this entity. Despite a lack of universal agreement on the number or exact location of the anatomic compartments in the foot,^{112–116} it is generally accepted that there are at least nine compartments separated into four groups: the central/calcaneal, intrinsic/interosseous, medial, and lateral (Fig. 54.9A).

For measurement of pressure in any of the foot compartments, place the patient in the supine position with the foot at the level of the heart and prepare and anesthetize the needle insertion site as described previously. Note that pedal edema has been shown to increase resting tissue pressure in the foot.^{117,118}

Medial Compartment (see Fig. 54.9B)

The medial compartment contains the abductor hallucis and flexor hallucis brevis muscles. The compartment is bounded medially and inferiorly by an extension of the plantar aponeurosis, laterally by an intramuscular septum, and dorsally by the first metatarsal. To measure pressure in this compartment, insert the needle perpendicular to the skin at the medial aspect of the foot just inferior to the base of the first metatarsal into the abductor hallucis muscle, which is approximately 1 to 1.5 cm deep.¹¹⁹ Confirm proper needle depth by observing a rise in pressure during external compression of the medial compartment of the foot.

Central (Calcaneal) Compartment (see Fig. 54.9B)

The central compartment contains the flexor digitorum brevis, the quadratus plantae, the lumbricals, and the abductor hallucis muscles. Its boundaries are the plantar aponeurosis inferiorly, the osteofascial tarsometatarsal structures dorsally, and the

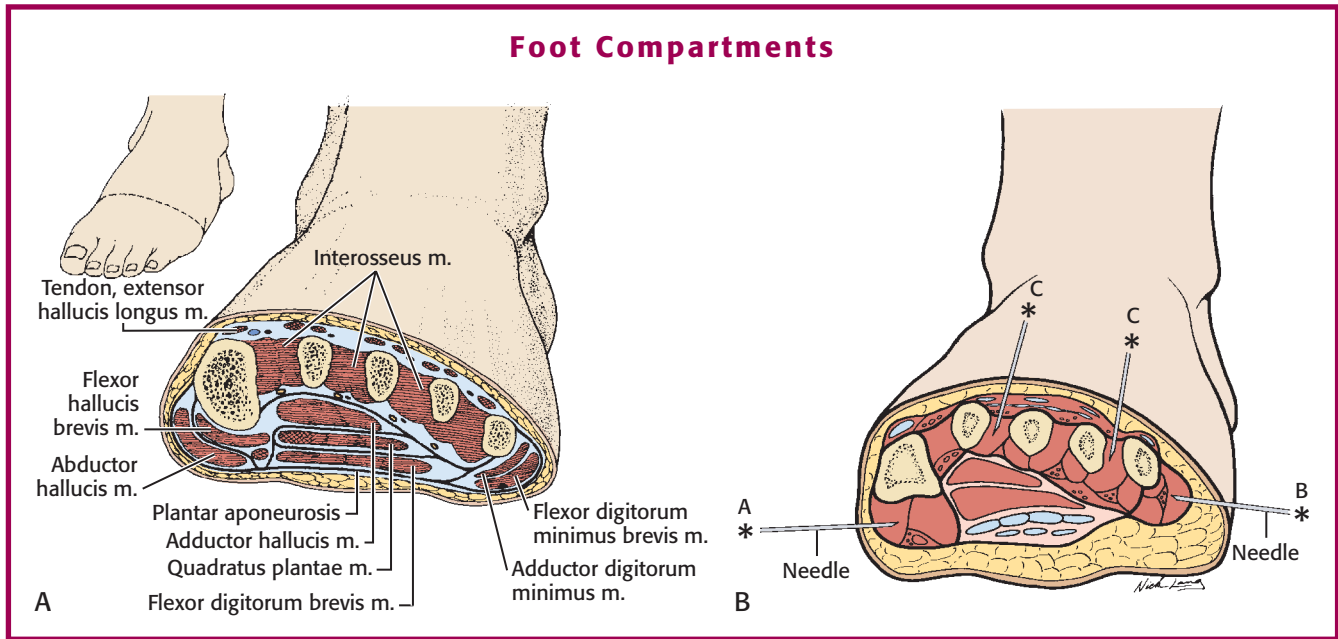

Figure 54.9 A, Compartments of the foot. B, Suggested needle pathways (asterisks) to measure intracompartmental pressure: A, medial; B, lateral; C, interosseous. The central compartment is surrounded by these compartments. *m*, Muscle. (A, From Mubarak SJ, Hargens AR: *Compartment syndromes and Volkmann's contracture*. Philadelphia, 1981, Saunders; B, modified from Myerson M: Acute compartment syndromes of the foot, *Bull Hosp J Dis* 47:251, 1987.)

intermuscular septa medially and laterally. To measure pressure in this compartment, insert the needle perpendicular to the skin at the medial aspect of the foot just inferior to the base of the first metatarsal. Advance the needle through the abductor hallucis muscle to a depth of 3 cm.¹¹⁹ Confirm proper needle depth by observing a rise in pressure during external compression of the central compartment of the foot.

Lateral Compartment (see Fig. 54.9B)

The lateral compartment contains the abductor, flexor, and opponens muscles of the fifth toe. The boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially.¹¹⁹ To measure pressure in this compartment, insert the needle parallel to the plantar aspect of the foot just inferior to the base of the fifth metatarsal. Advance the needle to a depth of 1 to 1.5 cm. Confirm proper needle depth by observing a rise in pressure during external compression of the lateral compartment of the foot.

Intrinsic (Interosseous) Compartment (see Fig. 54.9B)

The intrinsic compartment contains the seven interossei muscles and is bounded by the metatarsals and the interosseous fascia. Pressure in this compartment is measured in two areas, the second and fourth web spaces. Avoid the first web space to prevent inadvertent puncture or disruption of the dorsalis pedis artery or the deep peroneal nerve.¹¹⁹ Insert the needle perpendicular to the skin at the dorsum of the second and fourth web spaces at the base of the metatarsals, and advance the needle to a depth of 1 cm.¹¹⁹ Confirm proper needle depth by observing a rise in pressure during external compression of the intrinsic compartment adjacent to the needle insertion site.

INTERPRETATION OF COMPARTMENT PRESSURE MEASUREMENTS

Compartment pressures must be interpreted within the context of the clinical picture. Inaccurate measurements are far worse than no measurement at all, and clinical evaluation is more telling than pressure measurements alone. To be most accurate, compartment pressures should be measured in the area of highest pressure and greatest tissue damage.^{79,120} Inaccurate measurements may result from placement of the needle into tendon or fascia, plugged needles, defective or poorly calibrated devices, injection of fluid into the compartment, and movement during the procedure. Whitesides and colleagues found a 1 mm Hg increase in compartment pressure for every 1 mL of saline infused into the anterior compartment of the lower extremity.⁶ It is difficult to assess the relevance of this finding, but recognition of the potential for its occurrence is important.

Reports of normal human compartment pressure vary in the literature. In comparing several techniques, Shakespeare and associates found an average normal pressure of 8.5 mm Hg with slightly higher resting pressure in individuals who were physically fit.¹² Willy and coworkers found a mean of 15 mm Hg (± 8 mm Hg) when using an electronic transducer-tipped probe in healthy volunteers.¹⁴ Although the generally accepted range of normal is between 0 and 10 mm Hg, others have noted pressures in normal subjects ranging from 0 to as high as 18 mm Hg.^{1,8,78,121} Even though compartment pressure measurements have not been studied extensively in pediatric populations, one study reported higher resting compartment pressure in children than in adults.⁴³

When properly performed, each method described in this chapter has acceptable accuracy in the clinical setting. Studies

have found standard deviations of between 2 and 6 mm Hg with all the techniques described earlier.^{1,8-10,12} It is generally agreed that the mercury manometer method of measuring compartment pressure is the least accurate. The arterial line system used with a simple (straight) or side-port needle provides a higher degree of accuracy for simple, episodic readings. The Stryker Intra-Compartmental Pressure Monitoring System provides consistent, accurate readings for both episodic and continuous pressure monitoring. The development of miniature transducer-tipped devices is ongoing.¹²² Noninvasive modalities, including MRI, SPECT, myotonometry, electromyography, near-infrared spectroscopy, and ultrasound, continue to be investigated as painless alternatives to needle-driven compartment pressure measurements, and although the early results are promising, they are not currently in widespread use.¹⁶⁻³³

Mubarak and coworkers^{9,123} and Hargens and colleagues¹²⁴ suggested that an absolute compartment pressure of 30 mm Hg is the “critical pressure” requiring fasciotomy. Others have supported these recommendations.^{120,125} However, it is important to note that a compartment pressure of 30 mm Hg does not necessarily precipitate compartment syndrome in the absence of other factors and must be interpreted within the context of the clinical scenario. Although compartment syndrome may develop in some patients at this pressure, in others it will not, as tolerance to increasing pressure appears to be variable.^{1,8,12,78}

Despite a body of literature addressing measurement of compartment pressure, there continues to be no consensus regarding a specific compartment pressure threshold at which fasciotomy should be performed. Obviously, no measured compartment pressure, by itself, is an indication for fasciotomy, but it may guide consultation and further observation. A single pressure reading can be misleading, and trends in pressure provide more information to the clinician. Some argue that an absolute compartment pressure of 30 mm Hg or greater should be the threshold for fasciotomy.^{9,123-125} Matsen found that no patients with a pressure lower than 45 mm Hg had symptoms of compartment syndrome,¹ whereas all patients with a pressure higher than 60 mm Hg had symptoms. Whitesides and colleagues found that fasciotomy was required when intracompartmental pressure approaches 20 mm Hg below diastolic pressure,⁶ whereas McQueen and associates recommended using a perfusion pressure (diastolic pressure minus compartment pressure) of less than 30 mm Hg as a criterion for fasciotomy.¹²⁶ Heppenstall and coworkers concluded that use of either the Whitesides or McQueen criteria would produce similar results and recommended using a ΔP (MAP minus the measured compartment pressure) of 30 mm Hg or less in nontraumatized muscle and a ΔP of 40 mm Hg or less in traumatized muscle as a guide for fasciotomy.^{48,57}

In summary, absolute compartment pressures of 30 mm Hg or higher garner concern for consultation or intervention for

compartment syndrome. Based on pathophysiology, it appears quite reasonable to consider the difference between diastolic blood pressure and the measured compartment pressure (perfusion pressure) as a guide for diagnosing compartment syndrome and a strong consideration for fasciotomy. A compartment pressure within 30 mm Hg of the patient’s diastolic blood pressure, essentially a perfusion pressure of less than 30 mm Hg, is generally considered the threshold for consideration of fasciotomy.^{47,120,127}

Factors other than compartment pressure alone are important in the development of compartment syndrome and the need for fasciotomy. In patients with chronic systemic hypertension, higher compartment pressure may be necessary before nerve injury or muscle ischemia occurs. Situations in which MAP is low (e.g., hypovolemia, peripheral vascular disease) might interfere with the patient’s ability to tolerate even mildly elevated compartment pressure. Finally, the duration of increased compartment pressure is also an important factor in the development and severity of compartment syndrome.

COMPLICATIONS

All invasive monitoring systems are associated with some degree of pain during insertion of the needle or catheter. Adequate analgesia and, when necessary, procedural sedation are often necessary to gain the patient’s cooperation and prevent movement during pressure measurements. When using local anesthetics, avoid injections into the compartment because this can increase pain and result in inaccurate (higher) readings.

Failure to properly use pressure measurement devices may result in inaccurate results and a delay in the diagnosis of compartment syndrome. As with any invasive procedure, care must be taken to minimize bleeding and additional damage to underlying tissue, nerves, or blood vessels. The risk for both local and systemic infection is similar for all the measurement procedures described in this chapter. Strict adherence to aseptic technique and universal precautions is mandatory. This includes sterilization of catheters and the use of sterile solutions in addition to sterile gloves and supplies whenever possible.

Genitourinary, Obstetric, and Gynecologic Procedures

CHAPTER 55

Urologic Procedures

Jonathan E. Davis and Michael A. Silverman

INTRODUCTION

This chapter addresses urologic conditions that are either initially or eventually associated with an emergency procedure or may need to be performed in the absence of a urologic surgeon.

Testicular torsion is a scrotal emergency that can be challenging to diagnose under the best clinical circumstances. Although surgical exploration is the only definitive diagnostic and therapeutic procedure, many urologists prefer an initial diagnostic imaging study prior to surgical exploration, provided imaging can be obtained expediently while simultaneously preparing for operative intervention. This chapter addresses bedside maneuvers for this entity, including manual testicular detorsion.

Emergency penile conditions include paraphimosis and priapism. This chapter addresses bedside paraphimosis reduction techniques, as well as penile aspiration-irrigation-injection for relief of ischemic priapism. In addition, relief of phimosis complicated by the inability to void by means of a dorsal slit of the penile foreskin will be detailed for completeness (Video 55.1).

Access to and the subsequent evaluation of the bladder and urine are clinically important to all emergency practitioners. Various approaches to urine sampling and bladder drainage, including the techniques and complications of male and female urethral catheterization in various clinical situations and emergency suprapubic bladder access, are addressed.

Finally, a discussion of radiographic imaging of the genitourinary (GU) system is provided, with an emphasis on assessing lower urinary tract injury. Although the timing of GU radiologic examinations within the workup of the critically ill, multitrauma patient must be individualized, general guidelines for successful imaging are provided.

TESTICULAR TORSION

Introduction

Although acute scrotal pain comprises less than 1% of overall emergency department (ED) visits, this presentation may provoke great anxiety for the patient or caretaker, given its highly sensitive nature.¹ One of the most challenging aspects of scrotal complaints is that a wide variety of clinical conditions may present in a similar fashion: a male patient complaining of an acute, painful, swollen, and tender hemiscrotum. Although the differential is extensive, testicular torsion is the principle fertility threat that needs to be ruled out. Definitive management of testicular torsion involves surgical exploration and orchiopexy. Manual detorsion, with or without spermatic cord anesthesia, can be attempted while simultaneously preparing for operative intervention.

Procedure Overview

Indications: testicular torsion.

Contraindications: alternative cause of acute scrotal pain.

Complications: worsening ischemia, increased pain.

Equipment:

- for spermatic cord anesthesia: 1% lidocaine (10 mL for an adult, or age-/weight-appropriate local anesthetic dosing for child), 27-gauge (or similar) needle for anesthetic infiltration.
- for manual detorsion: bedside sonography may be helpful in assessing for pre- and postprocedure intratesticular blood flow.

Key Procedure Sequence

1. Initiate urologic consultation and simultaneous preparation for surgical intervention.
2. Administer spermatic cord anesthesia (optional).
3. Administer systemic analgesia or light sedation (optional).
4. Keep the patient comfortable in a reclining or supine position.
5. Stand beside the stretcher (right side if right-hand dominant, or vice versa).
6. Rotate the testicle from medial to lateral (two thirds of torsion occurs lateral to medial).
7. Rotate 180 degrees initially; it may ultimately require two to three rotations to alleviate pain.
8. If mechanically difficult or there is increased pain, detorse in the opposite direction.

9. The end point is relief of pain or return of intratesticular blood flow on sonogram.
10. Consult urology department for definitive surgical scrotal exploration.

Description

Background

An acute scrotum is defined as an acute, painful swelling of the scrotum or its contents, accompanied by local signs or general symptoms.² Although the list of diagnostic possibilities for a patient with an undifferentiated acute scrotum is extensive, early identification and skillful management of testicular torsion is critical as it may threaten testicular viability and future fertility if not managed expediently. Acute epididymitis is commonly the cause of acute scrotal pain in adolescents and adults. Testicular (or epididymal) appendage torsion is another frequent cause of acute scrotal pain in prepubertal boys.

Differentiating testicular torsion from alternative conditions takes precedence over a definitive diagnosis. The presence of an intact cremasteric reflex and testicular sonography are frequently utilized, yet imperfect, diagnostic tools in assessing for testicular torsion.

Anatomy and Physiology

A congenital anomaly of fixation of the testis, termed the *bell-clapper deformity*, is associated with the development of testicular torsion.³ This occurs when the intrascrotal portion of the spermatic cord lacks firm posterior adhesion to the scrotal wall and remains surrounded by the tunica vaginalis (Fig. 55.1A). As a result of the abnormal attachment, the testis may be suspended horizontally.⁴ These anatomic features predispose the affected testis to rotation.

Pathophysiology

Testicular salvage rates decrease with time from the onset of ischemia. A meta-analysis of 1140 patients in 22 series demonstrated a greater than 90% salvage rate with surgery within 6 hours of pain onset.⁵ Testicular atrophy may lead to subfertility. Furthermore, testicular loss may lead to contralateral testicular dysfunction through immune-mediated or other mechanisms.⁵

The testis may torse, detorse, and retorse, so clinicians should be cautious about assigning an exact time as the time of onset and deferring urologic consultation based on an erroneous assumption that the testis is not salvageable. The gold standard for determining testicular viability is intraoperative visualization of the affected testis, which dictates early urologic involvement. Although all clinicians recognize the need for expedient surgery in the setting of known torsion, not all consultants will agree on surgical exploration without some adjunctive testing.

When utilized in the appropriate clinical setting, ultrasound remains the most useful diagnostic modality in the evaluation of GU complaints (Fig. 55.2). A patient with compelling historical and examination findings of testicular torsion does not require any preoperative diagnostic tests. Color flow Doppler ultrasonography (CDUS) may be very helpful in all other cases. The classic sonographic finding suggestive of testicular torsion is diminished intratesticular blood flow. In addition, examination of the spermatic cord with high resolution gray-scale ultrasonography may reveal “coiling” or “kinking” of the cord at the site of torsion.^{6–8} Sonography is used not only to exclude testicular torsion, but also to search for alternative causes of

acute scrotal pain.⁹ In epididymitis, perfusion may be normal (or increased) due to the effects of inflammatory mediators on local vascular beds, although this is a nonspecific finding.^{10,11} An infarcted appendage may be visualized on ultrasound as well.¹² It has been suggested that emergency physicians may be able to accurately assess for intratesticular blood flow in patients presenting with acute scrotal pain using bedside sonography.¹³

Color flow Doppler ultrasound has long been regarded as the diagnostic modality of choice in assessing for testicular torsion. However, false-negative ultrasound results have been reported.^{14–20} Many of these studies are case reports or case series, limited by small numbers and retrospective design. Two larger series reported documented intratesticular blood flow with CDUS in 6 of 23 (26%) and 50 of 208 cases (24%), respectively, of confirmed testicular torsion.^{6,21} Doppler ultrasound may reveal seemingly adequate intratesticular blood flow in partial torsion, which can be very misleading to the practitioner.²²

Radionuclide scintigraphy and CDUS show similar sensitivity, as well as false-negative rates, for the diagnosis of testicular torsion.²³ However, given the widespread availability and expertise with ultrasound technology, combined with the risks of isotope radiation exposure, radionuclide procedures have fallen out of favor. The use of magnetic resonance imaging has been explored, but limitations include speed of imaging and availability.^{24,25}

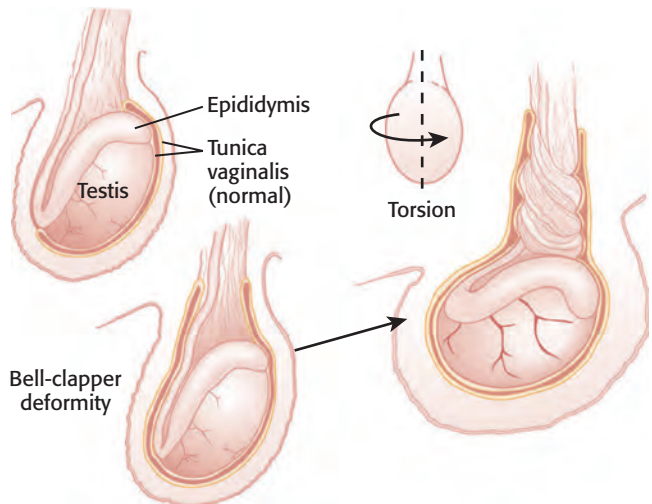

Intravaginal testicular torsion is a congenital bilateral abnormality. The ischemic testis must be detorsed and pexed with nonabsorbable (e.g., nylon, polypropylene, or Prolene [Ethicon Inc.]), rather than absorbable (e.g., chromic, polyglactin, or Vicryl [Ethicon Inc.]), suture. The torsed testis that is pexed with absorbable suture remains at risk for subsequent postoperative torsion. Given the bilateral nature of the congenital abnormality, orchiopexy of the nonischemic contralateral testis is necessary.

Once the diagnosis of testicular torsion is suspected, immediately place a call to notify a urologist of the suspected diagnosis, the perceived need for surgical exploration, and the fact that you will be attempting testicular detorsion while awaiting patient transport to the operating room. At some point before the patient leaves the ED, meticulous charting to document time, suspected diagnosis, notification of the urologist, and any manipulation of the affected testis must be done. All efforts are then focused on attempting testicular detorsion.

Indications

Testicular torsion may be relieved by manual detorsion. A study of 162 cases of testicular torsion revealed that anticipated lateral to medial rotation occurred in 67% of cases, with medial to lateral rotation in the remaining 33%. This challenges the standard dogma of medial to lateral rotation, or “opening the book,” as the standard method for detorsion. There may be a cranial-caudal component to torsion as well. The end point of manual detorsion is relief of pain, or the return of intratesticular blood flow as seen on ultrasound imaging.²⁶ Although manual detorsion may allow for reperfusion of the testis, a lesser degree of residual torsion may remain. Given that infarction can occur with as little as 180 degrees of torsion, immediate surgical exploration after what is thought to be a successful manual detorsion is still advocated. The bottom line is that specialty consultation and plans for possible immediate

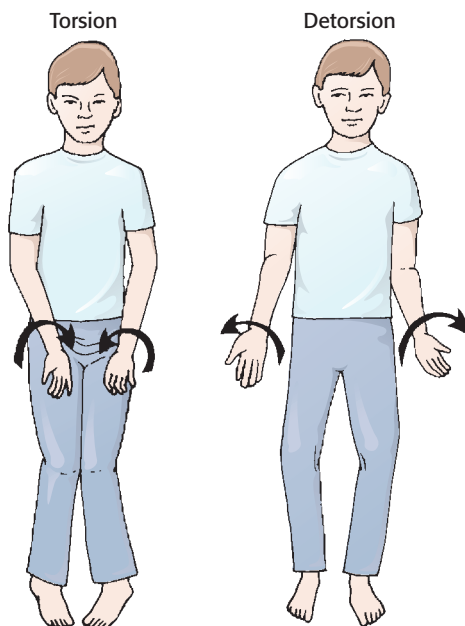

Manual Testicular Detorsion

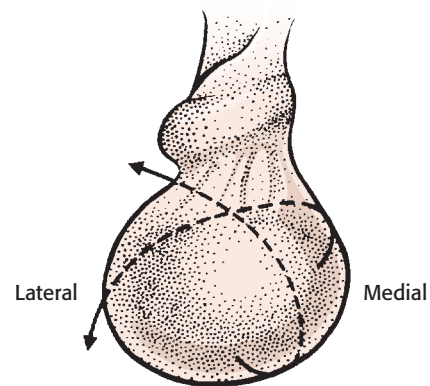

A. Anatomy of testicular torsion. Testicular torsion occurs when the testis twists within the tunica vaginalis. Patients with the bell-clapper deformity (i.e., incomplete fusion of the tunica along the epididymis, which results in incomplete attachment of the testicle to the scrotum) are at higher risk.

B. Spermatic cord block. Grasp the spermatic cord between your thumb and index finger. Use a 30-gauge needle to infiltrate the entire cross section of the spermatic cord and its surrounding rim with anesthetic. This will cause visual ballooning of the grasped segment of the cord. Gently massage this bulge to disperse the anesthetic. Usually about 10 mL is required.

C. Testicular torsion more commonly occurs in a medial direction. Initially attempt detorsion by rotating the testis outward toward the thigh. This is most successful if attempted within the first few hours of torsion, before the onset of significant scrotal swelling. Intravenous narcotics (such as fentanyl) can be administered or a cord block performed before attempting detorsion.

D. Detorsion maneuver. Detorsion of the testicle may require testicular rotation through two planes. To release the cremasteric muscle, rotate the testis in a caudal-to-cranial direction simultaneously with medial-to-lateral rotation. The right testis is shown.

Figure 55.1 **A**, Anatomy of testicular torsion. **B**, Achieve anesthesia of the spermatic cord by injecting lidocaine at the superficial inguinal ring. (**A**, From Snyder HM III: Urologic emergencies. Figure 55.2 Ischemic necrosis of the right testicle secondary to testicular torsion. This patient was evaluated in the emergency department 9 days after the onset of intermittent testicular pain. **A**, Transverse view of the scrotum showing the right testicle to be in a horizontal lie. Also note the cobblestoning of surrounding tissue (*arrow*), indicative of localized edema. **B**, Sagittal view of the right testicle revealing diffuse, round, complex hypoechoic foci (*arrows*), indicative of ischemic necrosis. **C** and **D**, Color flow Doppler imaging revealing no flow in the right testicle and normal flow in the left. Right orchiectomy was required. *LT*, Left; *RT*, right.

surgical exploration need to occur regardless of outcome of the detorsion procedure. Detorsion, however, may convert an emergency procedure to an urgent one.

Contraindications

Presence of an alternative cause of acute scrotal pain is a relative contraindication to the detorsion procedure. However, precise diagnosis may be impossible prior to definitive surgical exploration. A nonanomalous, appropriately fixated testicle should not be adversely affected by an initial trial (e.g., 180 degrees) of manual detorsion if circumstances are highly suspect for spermatic cord torsion.

Procedure: Manual Detorsion and Spermatic Cord Anesthesia

Manual detorsion is performed in the following manner. Advise the patient that the procedure will be uncomfortable and painful and offer systemic analgesia or light sedation if appropriate. The rationale for not using spermatic cord anesthesia with

attempted detorsion is that the anesthesia takes away an important subjective end point: relief of the patient's pain after manipulation of the testis. However, many authors do advocate spermatic cord anesthesia before detorsion, and if anesthesia of the spermatic cord is elected, it can be done in the following manner.

Spermatic Cord Anesthesia

Local anesthesia of the spermatic cord using 1% plain lidocaine is usually done at the external inguinal ring²⁷ (see [Fig. 55.1B](#)). First prepare the skin with an antiseptic solution. The cord can usually be grasped between the thumb and the index finger, and 10 mL of 1% plain lidocaine (for an adult) can be directly injected into the cord. If the cord is swollen, as is often the case in testicular torsion, or if the testicle is lying very high in the hemiscrotum as a result of spermatic cord torsion (so as to preclude grasping), the cord may be palpated at the pubic tubercle as it passes over the pubis and the lidocaine injected at this landmark. Lee and colleagues²⁸ were able to perform

manual detorsion with local spermatic cord anesthesia in 11 of 16 adult cases of torsion; Kresling and associates²⁹ had success in 15 of 16 patients.

Manual Detorsion

The goal of manual detorsion is to reestablish or increase blood flow to a previously ischemic testis. This should be done in conjunction with preparation of the operating suite. It should never delay operative intervention.

Before initiating detorsion, ensure that the patient is as comfortable as possible in a reclining or supine position. Lithotomy position gives the examiner the most access to the patient's genitalia and prevents the patient from retreating during the procedure. If light analgesia and/or sedation are selected, implement them at this time.

Manual detorsion begins with the clinician standing comfortably at the side of the bed or stretcher, preferably on the patient's right side if the clinician is right-handed, or vice versa. Detorsion is begun just as one would open a book (i.e., an initial 180 degree detorsion of the patient's right testis is done in a counterclockwise fashion) (see Fig. 55.1C and D). The patient's left testis is detorsed 180 degrees in a clockwise fashion. Pain relief is an objective end point. If one rotation relieves some but not all the pain, continue with another rotation. The degree of torsion may range from 180 to 1080 degrees with medians of 360 to 540 degrees. Therefore many patients require two or three rotations to alleviate pain. If the initial detorsion is mechanically difficult (which it will be if one is detorsing in the wrong direction) or makes the pain worse, detorse the testis in the opposite direction and observe the result. Approximately one third of testicular torsions occur in the lateral, or unexpected, direction. The objective success of any testicular manipulation can be substantiated by an increase in Doppler signal and the patient's relief of pain.

With successful detorsion, the testicle returns to its normal anatomic position. Resolution of induration and swelling of the spermatic cord, testis, and epididymis will depend on the degree and duration of ischemia. Thus, the more severe the torsion and the longer it has been present, the longer it will take for the edema and induration to resolve. With significant ischemia, the entire epididymis often becomes enlarged like a link sausage (uncommon in epididymitis except in severe cases or those that are initially misdiagnosed or seen late in their clinical course), and the testis becomes quite firm, simulating a testicular tumor. In some authors' experience, these reversible changes usually resolve over 3 to 4 hours.

Aftercare

Provide systemic analgesics as needed for discomfort. Importantly, even though manual detorsion will save an ischemic testicle, it should not be substituted for definitive scrotal exploration.

Complications

In a portion of cases, the testis will torse in the opposite direction (medial to lateral) or have multiple twists. This may become apparent as the clinician assesses the results of the detorsion procedure by palpation, relief of edema, and return or increase of the Doppler signal.

Conclusions

Spermatic cord torsion may be relieved by manual detorsion. In two thirds of cases, this is accomplished by medial to lateral

rotation of the affected testicle. However, in the remaining one third of cases, lateral to medial rotation is necessary to untwist the spermatic cord. In all cases, manual detorsion, even when successful, only serves as a temporizing bridge to definitive surgical management.

PRIAPISM

Introduction

Priapism is defined as prolonged erection of the penis, generally lasting over 4 hours, in the absence of sexual desire or stimulation (Fig. 55.3). This medical condition was named after Priapus, an ancient Greek god of fertility and horticulture who was endowed with oversized genitalia.³⁰

Priapism can be divided into two main categories. Ischemic priapism, also known as *low-flow priapism*, is the most commonly seen variant and is due to painful venous engorgement of the corpora cavernosa and requires emergency treatment. Non-ischemic (high-flow) priapism is quite rare and is often painless. It is caused by increased arterial inflow to the penis as a result of traumatic arteriocavernosal fistulas and does not require urgent treatment.

Ischemic priapism can be thought of as a compartment syndrome of the penis.³¹ The corpora cavernosa becomes engorged with stagnant, oxygen-depleted venous blood due to either an intraluminal obstruction of venous blood flow or an inability of the penile muscle tissue to adequately contract and augment venous outflow.³²

Procedure Overview

Indications: failure of an initial trial of subcutaneous or oral terbutaline (optional).

Contraindications: high-flow (nonischemic) priapism, stuttering priapism.

Complications: hematoma formation, infection, systemic absorption, and subsequent effects of α -adrenergic agents; permanent impotence may result from priapism regardless of promptness of therapeutic interventions.

Equipment: see later.

Figure 55.3 Typical appearance of priapism. It has many causes, is painful, often recurrent, and can lead to impotence. Many cases can be effectively treated in the emergency department (ED), but definitive ED intervention is not a mandated standard of care.

Key Procedure Sequence

1. Administer parenteral opioid analgesic or light sedation.
2. Give a trial of 0.25 to 0.5 mg subcutaneous terbutaline (repeat in 15 minutes), or 5 mg terbutaline by mouth (optional).
3. Give an intracorporal injection of α -adrenergic agents and, if necessary, repeat every 20 minutes for a total of three doses (minimally invasive approach).
4. If unsuccessful, aspirate 20 to 30 mL of corporal blood.
5. If detumescence is not achieved, irrigate with saline or a dilute α -adrenergic agonist solution (aspirate-irrigate-aspirate cycle, as needed).
6. A visible change from venous (dark red) to arterial (bright red) blood is a marker of success.
7. For persistent erections, consult urology for possible shunt placement (cavernosum-spongiosum shunt).
8. If the procedure is successful, loosely wrap the penis in an elastic bandage.
9. A 3-day course of an oral α -adrenergic agent is reasonable at the time of discharge.
10. Arrange for urgent urology follow-up and administer strict return precautions.

Description

Background

Priapism is manifested by a persistent, usually painful, penile erection, unrelated to sexual stimulation and not relieved by ejaculation.

Over one third of patients with severe priapism may suffer permanent erectile dysfunction despite treatment, with obvious functional and emotional sequelae.³²

Anatomy and Physiology

Priapism is characterized clinically by a soft glans penis and spongy urethra in the presence of two erect penile bodies (corpora cavernosa) (Fig. 55.4). Two important concepts are

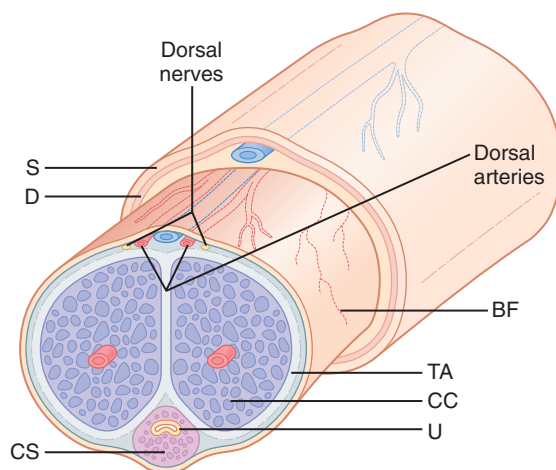

Figure 55.4 Anatomy of the penile shaft. The corpora cavernosa communicate with each other, and thus unilateral injections/aspirations suffice in the treatment of acute priapism. BF, Buck's fascia; CC, corpora cavernosa; CS, corpus spongiosum; D, dartos; S, skin; TA, tunica albuginea; U, urethra. (From Bostwick DG, Cheng L, editors: *Urologic surgical pathology*, ed 2, St. Louis, 2008, Mosby.)

worthy of mention. First, there is communication of blood flow between the corpora cavernosa, therefore in most cases the operator needs to access only one of the corpora. Secondly, introduction of vasoactive or other agents into the corpora is akin to an intravenous injection, so systemic effects may be precipitated, particularly after partial or full detumescence is achieved.

Pathophysiology

The pathophysiology of priapism is complex. The pharmacologic basis for treatment is based on manipulating blood flow via the α - and β -adrenergic receptors. Priapism is believed to result from increased arterial inflow of blood into the corpora cavernosa secondary to dilatation of the cavernosal arteries. Relaxation of the cavernosal tissue occurs and secondary compression of the emissary veins leads to engorgement of both corpora cavernosa during an erection. When the cavernosal pressure approaches the arterial pressure, blood flow is markedly reduced. Ischemic or low-flow priapism results after several hours of continuous painful erection, leading to intracavernosal acidosis and sludging of blood, with subsequent thrombosis of the cavernosal arteries, fibrosis of the corporal tissue, and irreversible impotence.

High-flow priapism is less common than low-flow priapism and usually results from traumatic production of arteriocavernosal fistulas. It is not associated with intracavernosal ischemia or acidosis and is therefore painless and may be treated electively rather than emergently.

In the past, priapism was most often encountered as a complication of a number of medical (e.g., hematologic, neoplastic, and drug-related) conditions (Table 55.1). Today, many cases are iatrogenic, resulting from the current practice of using vasoactive substances (e.g., papaverine and phentolamine) and other newer erectile dysfunction medications to induce penile erections in impotent men. Sickle cell disease continues to be a leading cause of priapism.³³ Sickle cell patients may experience such a high rate of recurrence that home self-injection of vasoactive drugs into the penis has been advocated. Cocaine use is one etiology that is likely underreported.³⁴ A drug screen may unravel some discrepancies between clinical findings and history. As an end result, vasoactive drugs promote engorgement of the corpora cavernosa and reduction in venous outflow, which may result in low-flow or ischemic priapism.³⁵⁻³⁷ Several phosphodiesterase inhibitors and prostaglandin E1 are the drug treatments for impotence approved by the U.S. Food and Drug Administration (FDA). These medications act by increasing penile blood flow and enhancing smooth muscle relaxation. The incidence of priapism with these medications is quite low, particularly with the phosphodiesterase inhibitors.³⁸ Penile rigidity due to a non-deflating penile prosthesis (pseudopriapism) or malignant replacement of the corpora in patients with bladder or prostate cancer should not be confused with true priapism.

Indications

The emergency clinician should attempt to identify reversible causes for low-flow priapism and, often in conjunction with a urologic surgeon, initiate specific corrective therapy as soon as possible. Low-flow priapism in children and young adults may be due to sickle cell disease and such cases may respond to noninvasive standard anti-sickling measures. However, the role of transfusion therapy in patients with priapism due to sickle cell anemia is uncertain.³⁹

TABLE 55.1 Selected Causes of Ischemic Priapism

CATEGORY	EXAMPLES
Medications	
Impotence agents	Intracavernosal therapies (prostaglandin E1, papaverine, phentolamine)
	Oral agents (sildenafil)
Anticoagulants	Heparin, warfarin
Antihypertensives	Hydralazine, prazosin, doxazosin
Antidepressants	Trazodone, fluoxetine, sertraline, citalopram
Antipsychotics	Phenothiazines, atypical antipsychotics
Hormones	Gonadotropin-releasing hormones, testosterone
Illicit substances	Cocaine, marijuana, alcohol
Miscellaneous	Hydroxyzine, metoclopramide, omeprazole, total parenteral nutrition, general anesthetics
Hematologic/Oncologic Disorders	
Sickle cell disease	
Hematologic malignancies	Leukemia, myeloma
Other malignancies	Prostate, bladder, metastatic cancer
Central Nervous System	
Brain	Cerebrovascular accident
Brain stem	Medulla injury
Spinal cord	Spinal stenosis, spinal cord injury, lumbar disk herniation
Others	
Genitourinary trauma	Straddle injury
Infections	Malaria, rabies
Toxins	Black widow, scorpion, carbon monoxide
Metabolic	Amyloidosis, gout, hypertriglyceridemia
Idiopathic	

Regardless of the etiology, this distressing condition is first treated with adequate analgesia, often consisting of parenteral opioids, with or without benzodiazepines.

A urologic surgeon typically manages acute priapism. However, emergency treatment for ischemic priapism will frequently need to be initiated while awaiting specialty consultation. The classic teaching is that the initial treatment, oral (or

BOX 55.1 Suggested Algorithm for the Initial Treatment of Acute Priapism in the Emergency Department

Proceed with treatment of acute priapism in the following order until detumescence is achieved:

1. Parenteral narcotic analgesia/sedation.
2. Terbutaline, 0.25 to 0.5 mg subcutaneously (may be repeated in 15 minutes), or terbutaline, 5 mg orally (one dose only).
3. Intracorporal injection of adrenergic agents. May repeat every 20 minutes for a total of three doses.
4. If unsuccessful, perform corporal aspiration of 30 to 60 mL of blood, followed by observation. If detumescence is not achieved, irrigate (inject and remove 10- to 20-mL aliquots) with a diluted α -agonist solution (e.g., phenylephrine, 10 mg in 500 mL of normal saline, or 1 mg epinephrine in 1 L of normal saline). Multiple irrigations may be required. The initial aspiration removes venous blood (dark red), and return of arterial blood (bright red) may serve as a marker of success.
5. For persistent erections, consult urology for possible corpus cavernosum-spongiosum shunt placement.
6. If treatment is successful in the emergency department, discharge is possible. A 3-day course of an oral α -adrenergic agent such as pseudoephedrine to promote continued vasoconstriction is recommended. The value of this intervention is unproven, however.
7. For patients with recurrent priapism secondary to sickle cell disease, consider intramuscular injections of leuprolide (Lupron) (consult a hematologist for recommended doses).

subcutaneous) terbutaline, is the same regardless of the inciting etiology, although its utility and efficacy are debated.⁴⁰⁻⁴² It is thought that terbutaline, a β_2 -adrenergic agonist, increases venous outflow from the engorged corpora by way of relaxation of venous sinusoidal smooth muscle. Terbutaline is of unproved benefit; however, given its limited propensity for adverse effects, a trial is reasonable in select circumstances while awaiting specialty consultation.⁴³

If terbutaline fails to work rapidly, the next step is penile blood aspiration, saline irrigation of the corpora cavernosum, and intracorporal instillation of an α -adrenergic receptor agonist such as dilute phenylephrine or epinephrine.

Contraindications

A subtype of ischemic priapism is known as stuttering priapism. This entity is typically observed in patients with sickle cell disease. Patients experience recurrent episodes of priapism that often last less than 3 hours and often do not require emergency treatment unless symptoms become markedly prolonged.⁴⁴ High-flow (nonischemic) priapism is treated surgically (elective repair).

Procedure

A suggested algorithm for the initial treatment of acute nonischemic priapism in the emergency setting is presented in Box 55.1. Options for treatment include:

1. Minimally invasive technique (direct intracorporal injection of α -adrenergic agent, without aspiration or irrigation).

TABLE 55.2 Adrenergic Agents Used for Intracavernous Injections

AGENT	DOSE	VOLUME
Phenylephrine ^a	0.2–0.5 mg	Dilute with saline; final volume, 1 mL ^a
Epinephrine (1:1000)	0.1 mg (0.1 mL)	Dilute with 0.9 mL saline; final volume, 1 mL
Lidocaine (2%) with epinephrine (1:100,000) (local anesthetic solution)	40 mg lidocaine 0.02 mg epinephrine (2 mL)	1 mL injected into each side of the corpus cavernosum; final volume, 2 mL ^b

^aSingle side injected with the entire amount. See text for preparation of the phenylephrine injection solution.

^bTotal amount divided into two doses. Inject each side with half the total volume (1 mL) or inject the total volume (2 mL) into one side.

From Roberts JR, Price C, Mazzeo T: Intracavernous epinephrine: a minimally invasive treatment for priapism in the emergency department, *J Emerg Med* 36(3):285–289, 2009.

2. Aspiration of corporal blood
 - a. may be performed with or without saline irrigation.
 - b. following aspiration, may be followed by injection of α -adrenergic agent.
 - c. alternatively, corpora can be irrigated with a dilute α -adrenergic agent-containing solution.

Minimally Invasive Technique: Simple Injection

Relief of priapism by simple injection of vasoactive solutions into the corpus cavernosum has been reported.⁴⁵ Intercavernous injection therapy for the management of priapism is simple to perform, less traumatic, and less invasive than aspiration and irrigation. This minimally invasive procedure may be attempted as an initial approach. This same procedure may be used as a self-injection technique for home treatment of recurrent priapism. With this technique, a 25- to 27-gauge needle is used to inject vasoactive substances into the corpus at the proximal end of the penis (2–4 cm distal to the shaft origin), with the goal of pharmacologically reversing priapism (Fig. 55.5A). Often, this can be accomplished without anesthesia. One option is to draw up 0.5 mg (0.5 mL) of phenylephrine and add 0.5 mL of saline diluent for a final volume of 1 mL (Table 55.2). Puncture the corpus with the needle at the 10 o'clock or 2 o'clock position at the base of the penis (with 12 o'clock being the dorsal vein of the penis), aspirate blood to confirm position, and inject the solution. If detumescence is not achieved in 20 to 30 minutes, give a repeat injection, up to a total of three injections. In one small study, successful detumescence was achieved in eight of nine patients by simple intracorporal injection of phenylephrine with this regimen, with three or fewer injections required.⁴⁶ Alternatively, 0.1 mg of epinephrine (0.1 mL of 1:1000) diluted with 0.9 mL of saline may be used (1 mL total volume). Regardless of medication used, only one side needs to be injected, but two or three injections might be necessary. Wait at least 20 minutes after each injection before additional interventions. Note that this is essentially an intravenous injection and systemic effects may occur. As such, proceed with caution in patients with cardiovascular disease. Success has also been noted by injecting the corpus cavernosum with 1 mL of the local anesthetic lidocaine (2%) with epinephrine (1:100,000) into each side, or 2 mL into one side.⁴⁵

Aspiration/Irrigation Technique

Box 55.2 lists the equipment needed for aspiration and irrigation of the corpus cavernosum. This procedure entails drainage of blood from the erect penis, irrigation with saline if necessary

BOX 55.2 Equipment Needed for Aspiration of the Corpus Cavernosum for Low-Flow Priapism

27-gauge needle (for penile block)
 1-mL syringe (for local anesthetic)
 1% lidocaine without epinephrine (for penile block)
 Sterile drapes
 Gauze sponges
 Chlorhexidine preparation solution
 19-gauge butterfly needles (for aspiration)
 Two 10-mL to 30-mL syringes (for aspiration)
 Sterile basin for aspirated blood
 Blood gas syringe with cap
 Irrigation fluid (one of the following vasoactive agents^a is diluted with 500 mL of normal saline and 20 to 30 mL is administered in small aliquots; 5000 units of heparin added to the solution is optional):
 Phenylephrine, 10 mg/500 mL of saline
 Norepinephrine, 1 mg/500 mL of saline
 Epinephrine, 0.5 mg/500 mL of saline

^aSystemic absorption of vasoactive agents may occur and result in adverse cardiovascular effects.

(e.g., inadequate return of blood with lack of detumescence), and finally the instillation of a vasoactive medication. Alternatively, irrigation with aliquots of a dilute vasoactive solution may be effective (aspirate-infuse-aspirate cycle as needed).

Place the patient in the supine position. Parenteral analgesia and sedation are suggested. Local anesthesia at the puncture site is recommended. An injection of 1% plain lidocaine placed at the base of the penis for a dorsal penile nerve block or placement of a circumferential penile block can be performed, but are usually not necessary (see Fig. 55.5B). Prepare and drape the penis in sterile fashion. Grasp the shaft of the penis with your nondominant thumb and index finger. Palpate the engorged corpus cavernosum laterally (2 and 10 o'clock positions) and insert a 21- to 19-gauge butterfly needle into the corpus cavernosum.⁴⁷

Alternatively, a 20-gauge intravenous catheter may be used, but the butterfly needle is preferred. A dialysis access butterfly needle may also be used (Fig. 55.6). If palpation fails to demonstrate the corpus, blindly inserting the needle at either

Management of Acute Priapism

A. Minimally Invasive Method

10 o'clock approach

2 o'clock approach

- Anesthesia is not required. Use a small-gauge needle to inject a small aliquot of an adrenergic agent into the corpus at 10 or 2 o'clock at the proximal end of the penile shaft. (Only one side need be injected.)
 - Aspirate blood (2) to confirm placement prior to injection.
 - Consider a repeated injection after 20 minutes if unsuccessful, but be wary of the systemic effects of adrenergic agents (especially if repeated doses or injections are given during partial detumescence).
- Maximum: 3 to 5 doses, 10 to 30 minutes apart

Adrenergic Agents

- 0.2 to 0.5 mg of phenylephrine per dose (refer to text for instructions on dilution)
- 0.1 mg of epinephrine (0.1 mL of a 1:1000 solution) mixed with 0.9 mL of saline

(Use a 1-mL tuberculin syringe to draw up these small volumes.)

B. Aspiration and Irrigation Method

This patient experienced 18 hours of priapism after penile self-injection of papaverine as therapy for impotence.

For corpus irrigation the irrigation needle can be placed through a simple skin wheal, or perform a penile dorsal nerve block by injecting 1% plain lidocaine at the base of the dorsal aspect of the penis. The dorsal nerves are relatively superficial and deep injections are not required.

Insert no smaller than a 19-gauge butterfly needle into the corpus via the proximal penile shaft at either the 2 o'clock or the 10 o'clock position and aspirate. Only one side need be punctured. Slow steady suction will be most successful, whereas excessive suction may halt the aspiration. Do not puncture the corpus via the glans (see text). After initial aspiration, irrigate (slowly inject and withdraw) 10- to 20-mL aliquots of vasoactive solution until detumescence persists.

After detumescence with the first aspiration or with aspiration-irrigation-aspiration of a vasoactive medication (see text), wrap the penis with an elastic bandage to discourage re-erection and to compress the puncture site. Note: Acceptable procedures include aspiration alone followed by instillation of a small aliquot of epinephrine (0.1 mg) and combined multiple aspirations and irrigations with a vasoactive solution. The end point is the appearance of bright red arterial blood and/or persistent detumescence.

Figure 55.5 Management of acute priapism. The minimally invasive technique (A) consists of directly injecting the corpus with a small aliquot of an adrenergic agent. This is often successful and can be used at home by a motivated patient with recurrent problems (such as sickle cell disease). It may require multiple injections and 15 to 20 minutes to be effective.

Figure 55.6 An 18-gauge dialysis or butterfly catheter can be used for irrigation of the corpora if simple aspiration or injections of medication are unsuccessful. Using needles smaller than 19-gauge is usually counterproductive.

10 o'clock or 2 o'clock will usually gain access to this large vascular structure. Because there is communication of blood flow between both sides, the operator needs access to only one of the corpora. Either side may be punctured. The site of needle placement is typically anywhere from the base to the proximal shaft, 2 to 4 cm distal from the shaft origin. The glans should not be used as a puncture site.

The needle is advanced at a 45-degree angle, using constant suction. Blood is usually readily aspirated; once it is obtained do not advance the needle further. Next, stabilize the needle. Avoid deep penetration to minimize the risk of injury to the cavernosal artery during this procedure.

Aspirate an initial 20 to 30 mL of corporal blood while milking the corpus with the nondominant hand. Do not apply excessive suction because this often halts the aspiration. A common error is to use too much suction with a 60-mL syringe. Using a 10-mL syringe, and changing it if it fills with blood, is preferable. Use of a butterfly reduces the danger of dislodging the needle when changing syringes.

Continue aspiration until the original egress of dark blood ceases and bright red arterial blood returns or when complete detumescence is obtained and persists. Because multiple anastomoses exist between the two corpora cavernosa, bilateral aspiration is not required. If there is inadequate return of blood with a lack of detumescence, consider irrigating with 20 to 30 mL of saline.

If detumescence is achieved after initial aspiration with or without saline irrigation, no further treatment may be required. If this is successful, some clinicians advise instilling an aliquot of vasoactive substance. Phenylephrine is recommended as the agent of choice as it may minimize the risk of cardiovascular side effects more commonly seen with other sympathomimetic agents.⁴² Inject 0.1 to 0.5 mg of phenylephrine (in 1 mL of normal saline). It is important to note that the recommended concentration for instillation is similar to that recommended for the minimally invasive technique detailed earlier. Lower concentrations in smaller volumes should be used for patients with cardiovascular risk factors or for children. If irrigation is performed with a dilute vasoactive substance as delineated hereafter, additional medication instillation is not suggested.

If detumescence is not achieved following aspiration (with or without saline irrigation), irrigation with a dilute vasoactive substance is another option. A number of dilute irrigation solutions have been suggested, but none have been proven to be superior. Some suggest 20 to 30 mL of a phenylephrine/normal saline solution (10 mg of phenylephrine in 500 mL of normal saline) as the exchange for 20 to 30 mL of aspirated corporal blood. Some clinicians add 2500 to 5000 units of heparin to the solution, but the use of heparin is of unproven value. Alternatively, 1 mg of epinephrine can be added to 1 L of saline, with irrigation performed using 20- to 30-mL aliquots. It is important to note that corporal irrigation is performed with a much less concentrated solution (phenylephrine, 20 µg/mL) as compared with that used for the minimally invasive technique or vasoactive instillation of 1 mL aliquots following detumescence detailed earlier (phenylephrine, 500 µg/mL).

Note that the corpus cavernosum has ready access to systemic circulation, and injecting a drug into it is essentially the same as an intravenous injection. When detumescence occurs, the unmetabolized drug enters the systemic circulation; therefore vasoactive drug dosages should be monitored carefully.

Aftercare

Observe the patient in the ED for recurrence. Although the ideal observation period is unknown, 2 hours has been suggested.⁴⁵ Fig. 55.5B, step 4 demonstrates the entire penis loosely wrapped with elastic (ACE, 3M) bandage to prevent hematoma formation at the injection site(s). Strict return precautions must be provided for priapism recurrence, and urgent urology follow-up should be ensured. A short course of an oral α -adrenergic agent, such as pseudoephedrine for 3 days, is often recommended.⁴⁵ However, the value of this intervention is of questionable value and unproven benefit.

Complications

Although hematoma formation or infection can occur with properly performed aspiration, these complications are infrequent. Injected or instilled vasoactive agents can be absorbed systemically, with the potential for toxic effects.⁴⁸ Therefore the intracavernosal use of vasoactive agents is relatively contraindicated in patients with conditions sensitive to these agents (e.g., severe hypertension, dysrhythmias, monoamine oxidase inhibitor use, etc.). Blood pressure and cardiac rhythm should be monitored throughout the procedure if the patient is at risk. Failure to aspirate blood is a potential complication, usually because of a misplaced needle, applying excessive suction, or if blood has clotted. Because impotence is a well-recognized complication of priapism regardless of the cause or the promptness of therapeutic intervention, the patient should be advised regarding this potential long-term consequence.

Conclusions

Because prolonged priapism increases the risk of subsequent erectile dysfunction, an aggressive management strategy is advised. After 4 hours of persistent priapism, there is heightened release of inflammatory cytokines in the acidotic and hypoxic corpora cavernosa. Inflammation may include smooth muscle changes including cell death and fibrosis, which may cause permanent erectile dysfunction.⁴⁹ Recurrence is not uncommon, and some patients require multiple procedures on a recurring basis. Surgical shunting procedures by the urology team might be required if these other measures are met without success.

PARAPHIMOSIS

Introduction

Paraphimosis is the inability to completely reduce the penile foreskin distally, back to its natural position overlying the glans penis. This condition occurs exclusively in uncircumcised males and is a urologic emergency.

Paraphimosis may occur at any age, but often occurs in the extremes of life (Fig. 55.7). The condition can be quite subtle and may be either unrecognized or misdiagnosed as an allergic reaction, penile trauma, infection, or edema resulting from systemic volume overload (e.g., congestive heart failure, nephrotic syndrome) (Fig. 55.8).

Iatrogenic paraphimosis may occur following urinary catheterization or medical examination if the foreskin is not returned to its native location overlying the glans. Poor hygiene

or balanoposthitis are also associated with development of paraphimosis. Inflammation can result in contracture of the distal foreskin. Later when the foreskin is retracted proximally over the compressible glans, the contracted foreskin forms a constrictive band and gets stuck in the retracted position.

Procedure Overview

Indications: emergency reduction of paraphimotic foreskin.

Contraindications: none.

Complications: skin tears or lacerations; failure of the reduction procedure necessitates surgical intervention (dorsal slit or definitive circumcision).

Equipment: for simple manual reduction, all that is needed is a topical anesthetic lubricant. Adjunctive equipment for alternative reduction techniques and maneuvers as described in this chapter are optional.

Figure 55.7 Paraphimosis often occurs in the extremes of life. **A**, Uncircumcised boy with paraphimosis. This may be mistaken for infection or localized trauma, especially if it is unclear whether circumcision has been performed. Always seek this history. **B**, Paraphimosis, pictured here, may be mistaken for penile trauma, angioedema, or infection. Note that the swollen tissue is proximal to the coronal sulcus (*asterisk*). The cause of paraphimosis in this case was failure to replace the foreskin after a catheter change in an uncircumcised nursing home patient. Before reduction, the catheter is usually removed. When the edema is minimal, the catheter may be left in place during reduction. **C**, Appearance of the penis after catheter removal and foreskin reduction.

Figure 55.8 **A**, This edematous foreskin may have numerous causes, from benign edema to paraphimosis, and at first glance the cause might not be obvious. This patient has paraphimosis that is appreciated by careful inspection to identify **B**, the normal coronal sulcus and **C**, a phimotic foreskin band proximal to the glans.

Key Procedure Sequence

1. Apply a topical anesthetic lubricant to the distal penis (foreskin and glans).
2. Administer a systemic analgesic (optional).
3. Compress the foreskin and glans with a snugly grasped hand.
4. Use the thumbs to invert the glans penis proximally through the phimotic ring.
5. Use the index and long fingers to reduce the phimotic ring distally.
6. If unsuccessful, try alternate maneuvers to reduce edema before reattempting manual reduction.
7. Consider an optional trial of glans adjuncts: administer an ice pack or a compressive bandage to reduce glans edema.
8. Consider an optional trial of foreskin adjuncts: administer micropuncture wounds, use sugar, or use hyaluronidase to reduce foreskin edema.
9. If unsuccessful, reduce the paraphimosis surgically by dorsal slit or definitive circumcision.
10. Arrange urgent urology follow-up following reduction.

Description

Background

Paraphimosis is a urologic emergency that must be treated promptly to prevent glans necrosis. Paraphimosis can be managed in the ED without the need for emergency specialty consultation, but if possible, urology involvement will be needed for postprocedure management. There are many reported methods of successful paraphimosis reduction (Video 55.2). The most commonly employed initial maneuver involves manual compression of the distal penis to decrease edema, followed by reduction of the glans penis back through the proximal constricting band of foreskin (phimotic ring).⁵⁰

Anatomy and Physiology

The penis consists of the paired corpora cavernosa, or erectile bodies, which lie dorsal to the corpus spongiosum (see Fig. 55.4). The corpus spongiosum surrounds the penile urethra. The corpora cavernosa and the corpus spongiosum are wrapped by a thin connective tissue layer, the tunica albuginea. The glans is the distal portion (head) of the penis. The foreskin, or prepuce, in uncircumcised males lies over the glans and can be retracted proximally to expose the glans. The coronal sulcus distinguishes the glans penis from the penile shaft (see Figs. 55.7B and 55.8B).

Pathophysiology

Patients will present with a red, painful, and swollen glans penis associated with an edematous, proximally retracted foreskin that forms a circumferential constricting band. The penile shaft proximal to the constricting band is typically soft. The entrapped foreskin forms a constricting band on the penile shaft. Compression inhibits venous drainage of the glans and results in a cycle of progressive glans edema. The normal anatomy and identification of the foreskin may be obscured by edema, and the condition can be asymmetric and rather bizarre appearing (Fig. 55.9, step 1). Glans edema may become so severe that arterial flow is compromised, which can result in necrosis and gangrene of the glans penis.

Indications

Emergency reduction is indicated whenever a paraphimosis exists.

Contraindications

There are no contraindications.

Procedure

Manual Reduction Technique

The current standard for reducing paraphimosis is manual reduction. This can be accomplished by using a nonirritating topical anesthetic lubricant applied to the inner surface of the foreskin (not to the shaft of the penis) and the glans to reduce friction and decrease the discomfort of the procedure. A penile block may be performed if necessary (see Fig. 55.9, steps 2 and 3). If there is significant discomfort or patient apprehension, systemic analgesia or procedural sedation may be useful adjuncts. For young children, general anesthesia may be necessary.⁵¹

Compress the foreskin and glans with a snugly grasped hand for several minutes to reduce as much edema fluid as possible (see Fig. 55.9, steps 4–6). Use the thumb to push the glans through the foreskin that has been encircled by the entire palm (see Fig. 55.9, step 7). Alternatively, place the index and long fingers of both hands in apposition just proximal to the phimotic ring. Align both thumbs on the urethral meatus. Apply constant force with the thumbs to try and invert the glans penis proximally while using the index and long fingers to reduce the phimotic ring distally over the glans penis and into its normal anatomic position (see Fig. 55.9, step 8). Successful reduction results in the appearance of an uncircumcised penis with a phimotic foreskin (see Fig. 55.9, steps 9 and 10). The key to success in both these maneuvers is the application of slow, steady pressure.

Adjunctive Techniques to Assist in Manual Reduction

Several alternative methods for reducing the edema have been described in the literature. These methods can be used before attempting manual reduction, or if simple manual reduction fails.

Babcock clamps (noncrushing tissue clamps) can be used to reduce the paraphimotic foreskin⁵² (Fig. 55.10A). Apply six to eight Babcock clamps spaced evenly around the foreskin, straddling the phimotic ring (one edge just proximal and the other edge just distal to the phimotic ring). Grasp all clamps and apply simultaneous distal traction to pull the phimotic ring over the glans. After reduction, remove the clamps. It is important to inspect the foreskin for injuries.

Other techniques focus on reduction of glans or foreskin edema (or both), followed by reduction of the paraphimosis. Diminished glans edema facilitates foreskin reduction to its natural position. One suggested maneuver is to apply an ice pack. In the “iced-glove” method, use cold compression to reduce foreskin swelling and induce vasoconstriction in the glans penis⁵³ (see Fig. 55.10B). Half fill a large glove with crushed ice and water, and tie the cuff end securely. Invaginate the thumb of the glove and then draw it over the lubricated paraphimotic penis. Hold the thumb of the glove securely in place over the glans for 5 to 10 minutes. The combination of cooling and compression usually decreases the edema sufficiently to permit manual reduction of the foreskin. Wrapping the penis in a compressive bandage is another alternative. A 2-inch compressive bandage (such as an ACE [3M] bandage or similar)

Paraphimosis Reduction

This patient had asymmetric paraphimosis. Note that the glans is edematous, as is the foreskin. A circumferential constricting band is found proximal to the glans and foreskin.

Perform a penile block in cases that will require significant manipulation. First, block the dorsal penile nerves by depositing anesthetic at the 2 and 10 o'clock positions on the dorsal aspect of the shaft of the penis.

Complete a ring block of the penis by depositing anesthetic circumferentially around the proximal part of the shaft.

Compress the foreskin and glans by grasping it with the palm of your hand and applying pressure for several minutes.

Alternatively, wrap an elastic bandage around the distal end of the penis for several minutes. This step is often omitted, which makes the procedure unnecessarily difficult.

Note that manual compression substantially reduced the amount of swelling (compare with step 1; the foreskin and glans were taut prior to compression).

Grasp the shaft of the penis with one hand and apply force onto the urethral meatus with the thumb of your other hand. Push the glans forward while sliding the foreskin distally.

Alternatively, grasp the penis with the fingers of both hands just proximal to the phimotic ring, and use your thumbs to apply constant pressure on the glans.

The key to success is the application of slow, steady pressure. Note that the glans has retracted into its normal position and only the edematous foreskin is visible.

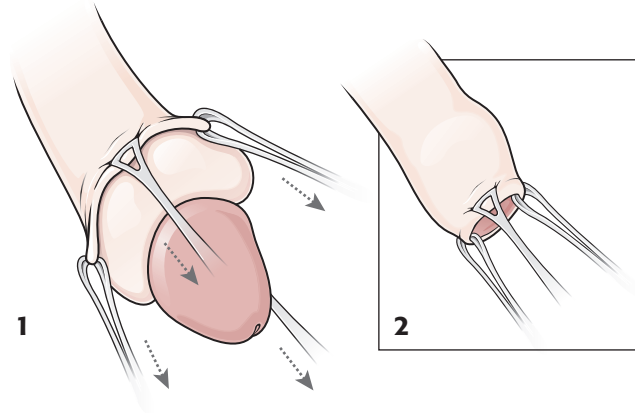

Successful reduction results in the appearance of an uncircumcised penis with a phimotic foreskin.

Figure 55.9 Paraphimosis reduction. (Step 8, from Neuwirth H, Frasier B, Cochran ST: Genitourinary imaging and procedures by the emergency clinician, *Emerg Med Clin North Am* 7:1, 1989.)

Paraphimosis Reduction: Alternative Techniques

A. Babcock Clamps

Babcock clamps will not crush tissue. 1, Place six to eight clamps so that they are evenly spaced on the distal edge of the foreskin and straddling the phimotic ring. 2, Grasp all clamps and apply simultaneous distal traction to pull the phimotic ring over the glans.

B. Iced-Glove Method

1 Fill a large glove halfway with crushed ice and water.

2 Securely tie the cuff end and invaginate the thumb of the glove.

3 Draw the invagination over the lubricated paraphimotic penis and hold it in place for 5 to 10 minutes. The combination of cooling and compression decreases edema and facilitates foreskin reduction.

Figure 55.10 Paraphimosis reduction: alternative techniques.

can be wound snugly around the penis from the glans to the base, and removed in 5 to 7 minutes.⁵⁴

Alternatively, techniques focusing on reduction of foreskin edema have been advocated (Box 55.3). The Dundee technique involves creating multiple micropunctures of the edematous foreskin and then expressing edema fluid.⁵⁵ Hyaluronidase has been reported to result in rapid reduction of prepuce edema that facilitates manual reduction of the foreskin. This enzyme, when injected into the swollen retracted foreskin, causes hydrolysis of hyaluronic acid that, in turn, increases tissue permeability so the edema in the foreskin is diffused out into the surrounding penile tissue.⁵⁶ There have even been advocates of a noninvasive way to reduce the foreskin edema via the application of granulated sugar to the penis. Sugar forms an osmotic gradient that draws out edema fluid, but this may take several hours.⁵⁷ Publications on these alternative procedures are generally observational in design with very small numbers. To date, there have not been any large studies of comparative effectiveness; as such it is difficult to recommend any one method as superior.⁵⁸

If the previous methods are unsuccessful, it may be necessary to incise the constricting phimotic tissue to permit reduction

BOX 55.3 Adjunctive Methods to Reduce Foreskin Edema

Dundee micropuncture technique: Make approximately 20 puncture holes in the edematous foreskin tissue with a 26-gauge (or similar) needle and express the fluid.⁵⁴

Hyaluronidase technique: Inject 1 mL of hyaluronidase (150 U/mL) by tuberculin syringe into one or two sites in the edematous foreskin to reduce edema fluid immediately.⁵⁵

Sugar technique: Granulated sugar has been studied, but a better alternative for patients in the emergency department is to soak a swab in 50 mL of 50% dextrose solution and leave it wrapped around the paraphimotic foreskin for 1 hour.⁵⁶

Iced-glove technique: see Fig. 55.10B.

of the foreskin over the glans by dorsal slit procedure.⁵⁹ In adults, this can generally be carried out under penile-block anesthesia, but procedural sedation or general anesthesia may be necessary for young children.

Aftercare

Observe the patient to ensure adequate local hemostasis, ability to void spontaneously, and recovery from analgesia or sedation, if utilized. Replacing the foreskin to its native position following examination, catheter placement, sexual activity, or any other manipulation is essential to preventing recurrent episodes. Patients should be referred to a urologist for evaluation of possible surgical options, including circumcision.

Complications

Penile shaft laceration or simple tearing of edematous and taut penile skin may occur during manual or surgical paraphimotic reduction. Simple suturing is all that is required for most injuries. If reduction of a paraphimosis cannot be achieved by other means, surgical interventions should be considered.

Conclusions

Emergency manual or surgical reduction of the edematous foreskin is mandatory to restore proper circulation, relieve discomfort, and permit resolution of potential serious sequelae: skin ulceration and gangrene. It must be done as soon as a paraphimosis is recognized. Once the foreskin is successfully reduced, urgent referral for dorsal slit or definitive circumcision is necessary.

PHIMOSIS

Introduction

Phimosis is constriction of the foreskin (prepuce) that limits its retraction proximally over the glans (Fig. 55.11). Uncircumcised infants and young children often have a physiologic phimosis due to adhesions between the prepuce and glans. This is in contrast to a pathologic phimosis, where failure to retract results from distal scarring of the prepuce.

Circumcision (removal of the foreskin), rendering phimosis and paraphimosis anatomically impossible, is commonplace in

Figure 55.11 Phimosis is constriction of the foreskin that inhibits retraction over the glans. Ordinarily, treatment is not required; however, dilation of the phimotic opening may be required if the patient is unable to void or if urethral catheterization must be performed. (From Studdiford JS, Altshuler M, Salzman B, et al, editors: *Images from the Wards: Diagnosis and Treatment*. Philadelphia, 2009, Saunders.)

America. However, circumcision rates vary with religious affiliation, racial and ethnic group, as well as socioeconomic status.

Phimosis does not ordinarily require any treatment. However, a patient with phimosis may present acutely to the ED when he is unable to void spontaneously as a result of distal urethral obstruction. It may prevent or make urethral catheterization more challenging. In such situations, the phimotic opening may need to be dilated. An alternative strategy is to crush a portion of the foreskin followed by an incision (dorsal slit), using local anesthesia with or without parenteral analgesia or sedation to allow access to the urethral meatus. This procedure can be readily performed in the acute care setting when necessary.

Procedure Overview

Indications:

- (1) phimosis and the inability to void or perform urethral catheterization;
- (2) as definitive treatment following successful foreskin reduction in a patient with paraphimosis; or
- (3) phimotic ring incision and foreskin reduction in a patient with an otherwise irreducible paraphimosis.

Contraindications: none.

Complications: injury to the urethral meatus or glans penis, bleeding at site of tissue injury (when tissue is crushed and then cut).

Equipment: see later.

Key Procedure Sequence

1. Clean and drape the penis with sterile towels.
2. Inject local anesthesia: lidocaine without epinephrine.
3. Use toothed forceps to test for adequate local anesthesia.
4. If anesthesia is inadequate, consider dorsal nerve block or “ring block” at the base of the penis.
5. Advance both jaws of a hemostat proximally between the inner layer of the foreskin and glans.
6. Use a hemostat to separate preputial adhesions.
7. Remove the hemostat, reinsert one jaw, and use the hemostat to crush interposed foreskin tissue.
8. Cut the resultant crushed foreskin tissue longitudinally with straight scissors.
9. Use absorbable sutures to reapproximate leaves of foreskin resulting from the cut (if necessary).
10. With success, the prepuce is easily retracted for exposure of the glans penis and urethral meatus.

Description

Background

Phimosis is constriction of the foreskin that limits retraction of the foreskin over the glans. Phimosis does not ordinarily require any treatment. However, phimosis may present acutely to the ED when a patient is unable to void spontaneously as a result of distal urethral obstruction.

Anatomy and Physiology

A physiologic phimosis in young uncircumcised boys consists of a pliant, unscarred preputial orifice on physical examination. The foreskin gradually becomes retractile over time as a result of intermittent erections and keratinization of the

inner epithelium. By 3 years of age, the foreskin can easily be retracted in 90% of patients, with nearly all becoming retractile by late adolescence.^{60,61}

Pathophysiology

A pathologic phimosis exists when the failure to retract results from distal scarring of the prepuce. This is typically a subacute condition that may present acutely to the ED when a patient is unable to void spontaneously as a result of distal urethral obstruction. Pathologic phimosis is caused by local trauma, infection, chemical irritation, complications of circumcision (insufficient tissue removal), or poor hygiene.

Patients with acute phimosis complain of penile pain over hours to days. On examination, the physician will discover a tender foreskin that is not easily retracted. Although the prepuce may be gently manipulated to allow a better exam, do not attempt forced retraction. Forceful retraction contributes to future adhesion and stricture formation.

Indications

Dorsal slit of the foreskin is performed in any emergency situation to gain access to the urethral meatus for urethral catheterization. In the setting of paraphimosis, a dorsal slit may be used as a definitive treatment following simple foreskin reduction, or for phimotic ring incision and reduction in a patient with an otherwise irreducible paraphimosis. Elective circumcision rather than dorsal slit of the foreskin is the definitive procedure of choice in nonemergency situations.

Contraindications

None.

Procedure

Box 55.4 lists the equipment needed to perform dorsal slit of the foreskin. With the patient in the supine position, clean and drape the penis with sterile towels. Clipping of the pubic hair is unnecessary. Infiltrate lidocaine without epinephrine into the dorsal midline of the foreskin just beneath the superficial fascia throughout the course of the proposed incision, starting proximally at the level of the coronal sulcus and proceeding distally to the tip of the foreskin (Fig. 55.12, step 1). Consider mixing equal volumes of lidocaine with bupivacaine. After several minutes, grasp the foreskin with toothed forceps to test for anesthesia. The operator must be certain that the inner surface of the foreskin is also anesthetized. If this area is not numb, use a dorsal nerve block or ring block at the base of the penis (Fig. 55.13).⁶² Systemic analgesia or procedural sedation may be useful adjuncts as well.

After achieving adequate local anesthesia, systemic analgesia, or procedural sedation if needed, take a straight hemostat and

carefully advance both jaws of the hemostat proximally to the area of the coronal sulcus between the inner layer of the foreskin and the smooth glans penis, carefully separating any existing preputial adhesions (see Fig. 55.12, step 2). Take care that the meatus and urethra are visualized or palpated at all times to avoid inadvertent injury during this maneuver. Once release of adhesions is complete, open the hemostat, and place one jaw of the hemostat in the recently developed plane between the glans penis, opened to tent the skin to ensure proper placement, and the superior overlying inner layer of foreskin. Advance the hemostat to the level of the coronal sulcus and then close it, effectively crushing the interposed anesthetized foreskin. Leave the closed hemostat in place for 3 to 5 minutes, then remove it and cut the resultant serrated crushed foreskin longitudinally with straight scissors throughout the extent of the crushed tissue.

Normally, the incised, anatomically approximated skin edges bleed and ooze. Not infrequently, these skin edges of the foreskin separate into two layers, the outer foreskin and the inner foreskin (see Fig. 55.12, step 3). Absorbable chromic or Vicryl (Ethicon Inc.) (4-0 to 5-0 for children, 3-0 to 4-0 for adults) running hemostatic sutures may be placed, each beginning proximally at the apex of the dorsal slit and carried distally, reapproximating the two leaves of foreskin. Standard antibiotic ointment may be used to lubricate the suture material and facilitate passage of the suture through the delicate foreskin tissue.

After successful dorsal slit of the foreskin, the prepuce is easily retracted for cleansing of the glans penis or exposure of the urethral meatus. Postprocedural conscientious foreskin reduction to its normal anatomic position must be ensured after any distal penile manipulation to avoid paraphimosis.

If reduction of a paraphimosis cannot be achieved with other means, then surgical interventions should be considered. Fig. 55.14 describes the dorsal slit procedure for paraphimosis reduction, which involves carefully sterilizing the field, anesthetizing the penis on the dorsal aspect, followed by a linear incision.

Aftercare

Ideally, a definitive elective circumcision is recommended after a dorsal slit. Some patients complain about the appearance of their incised foreskin (“beagle ears”) and the relative inconvenience during urination, whereas others are pleased they no longer have their phimosis and decline further treatment (see Fig. 55.12, step 4).

Complications

Injury to the urethral meatus, urethra, and the glans penis may occur if the hemostat or straight scissors are blindly and unknowingly introduced into the urethra. Bleeding may occur if the hemostat has not adequately crushed the foreskin or if the scissor incision is made lateral to the serrated crushed tissue. The latter two problems are easily resolved with the previously described running hemostatic suture.

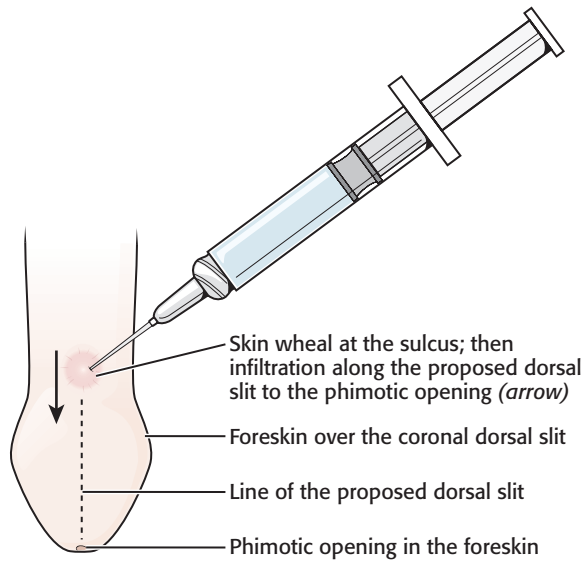

Conclusions

Dorsal slit of the foreskin is performed in any emergency situation either to gain access to the urethral meatus for urethral catheterization or as definitive treatment after simple foreskin reduction, or phimotic ring incision and foreskin reduction in a patient with an otherwise irreducible paraphimosis. This minor operative procedure can be readily performed in the acute care setting when necessary.

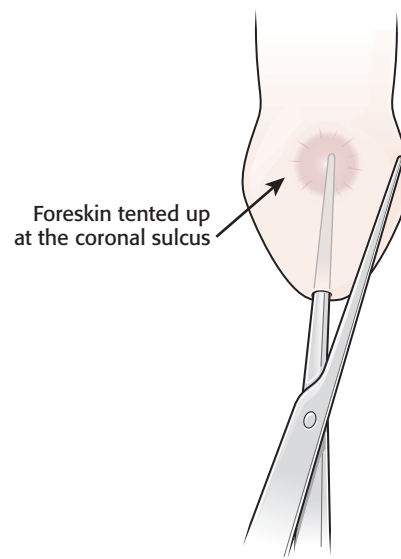

BOX 55.4 Equipment Necessary for the Dorsal Slit Procedure

- 1% lidocaine without epinephrine
- 5-mL syringe
- 27-gauge needle
- 1 straight Crile clamp
- 1 straight scissors
- 1 needle holder
- 4-0 absorbable suture

Dorsal Slit (Phimosis Treatment)

1. Infiltrate plain lidocaine without epinephrine into the dorsal midline of the foreskin just beneath the superficial fascia throughout the course of the planned incision. Begin at the coronal sulcus and proceed distally to the tip of the foreskin. Alternatively, consider a dorsal nerve block or ring block of the penis (see Fig. 55.13).

2. Insert both jaws of the hemostat to the level of the coronal sulcus and carefully separate any adhesions. Remove the hemostat, then reinsert only one jaw, and advance again to the coronal sulcus. Close the instrument and crush the foreskin. Leave the hemostat in place for 3 to 5 minutes. Remove the hemostat then use straight scissors to cut along the crushed tissue.

3. *A*, Use straight scissors to cut along the crushed tissue. The exposed glans is shaded. (*a*¹, outer layer of the foreskin; *a*, inner layer of the foreskin). *B*, Retract the cut edges of the foreskin drawn back around the glans penis. If hemostasis is required, first suture *a*¹ to *a* and then sew the remainder of the cut edges together. *C*, The ventral transposed foreskin will assume a beagle-ear deformity after the dorsal slit procedure has been completed.

4. Postoperative appearance of the dorsal slit showing the beagle ear. A formal, complete circumcision can be performed after the inflammation has resolved, if desired.

Figure 55.12 Dorsal slit treatment of phimosis.

URETHRAL CATHETERIZATION

Introduction

Urethral catheterization seems a simple task: insertion of one tube into a larger tube. Nonetheless, many difficulties might arise. Patients often remember catheterization as either painful

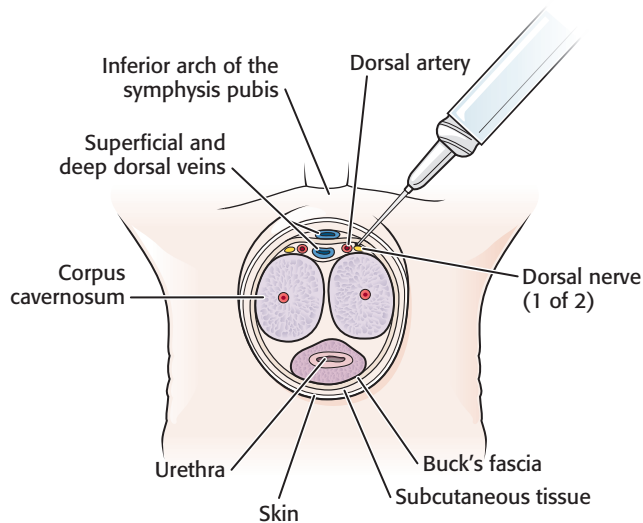

or uneventful depending on the operator's expertise, confidence, and gentleness.

The merits of various approaches to urine specimen collection depend on the patient's age and clinical setting.

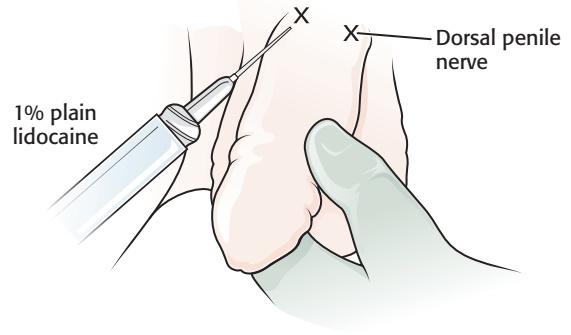

Urethral catheterization is definitive and routinely used to collect urine for analysis and culture in infants and young children who are not yet potty-trained. For older children

Regional Anesthesia of the Penis

A. Dorsal Nerve Block

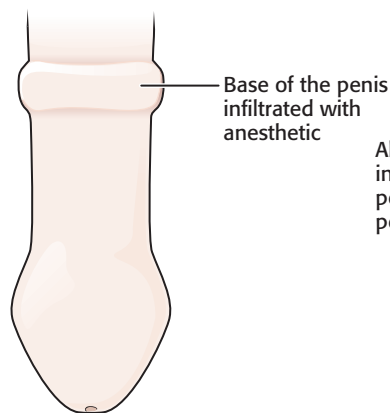

1. The penis has two dorsal penile arteries and two nerves running together and one dorsal penile vein in the midline. A dorsal nerve block at the base of the penis will provide anesthesia of only the dorsum of the penis.

2. To perform the dorsal block, inject at the base of the penis lateral to the midline at approximately the 10 and 2 o'clock positions.

B. Ring Block

Alternatively, infiltrate subcutaneous lidocaine (without epinephrine) in a circumferential fashion for a (ring) field block at the base of the penis. This technique provides anesthesia to the entire distal end of the penis.

Figure 55.13 Regional anesthesia of the penis. Consider the use of supplemental intravenous analgesia or procedural sedation, or both, based on the clinical scenario. (A1, From Soliman MG, Tremblay NA: Nerve block of the penis for postoperative pain relief in children, *Anesth Analg* 57:495, 1978. Reproduced by permission.)

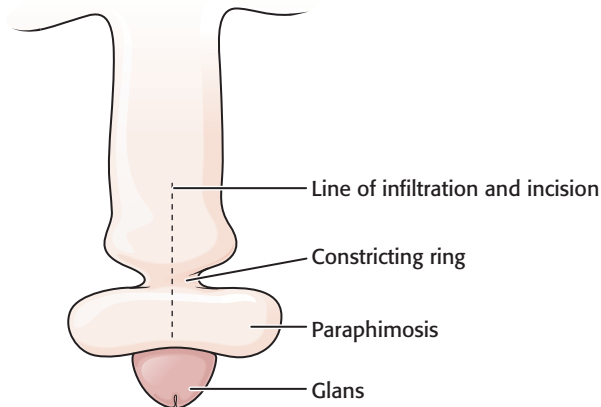

who can follow direction, midstream urine collection is a reasonable alternative approach to specimen collection.

In adult men without anatomic lesions, first-voided midstream specimens can define the presence or absence of culture-proven bacteriuria.⁶³ This certainly represents a simple, noninvasive and user-friendly approach to urine collection in the busy ED setting.

In adult women, properly collected clean-catch midstream specimens have been found to be as bacteriologically reliable as catheterized specimens.⁶⁴ A few caveats are worth mentioning. Ideally, patients must sit backward on the toilet when collecting

the specimen (i.e., patient facing the wall behind the toilet, which theoretically promotes labial spreading). Of more concern is the fact that such studies excluded patients with vaginitis, urologic abnormalities, pregnancy, and vaginal bleeding. These diagnoses represent the clinical circumstances for which urine is commonly examined in young women visiting the ED. In this at-risk population, catheterized urine specimens are optimal. However, this needs to be balanced with the reality that catheterization may introduce unnecessary patient discomfort and resource utilization, as well as the risk of introducing bacteria into the bladder.⁶⁵

Dorsal Slit (Paraphimosis Treatment)

1. Infiltrate local anesthetic from the constricting band of the paraphimosis proximally along the dorsal aspect of the penis. Make an incision along this line.

2. A diamond-shaped defect will result from the linear incision of the foreskin. Approximate the two apices of the dorsal slit (a and b) after the foreskin is reduced.

Figure 55.14 Dorsal slit treatment of paraphimosis. This procedure may be necessary if manual reduction of paraphimosis (see Fig. 55.9) is unsuccessful.

Urethral Catheterization

Indications

Acute urinary retention
Obstructive uropathy
Urine output monitoring in any critically ill or injured patient
Collection of a sterile urine specimen for diagnostic purposes
Intermittent bladder catheterization in patients with neurogenic bladder dysfunction
Urologic study of the lower urinary tract

Contraindications

Situations in which a less invasive procedure is sufficient
Trauma patient with suspected urethral injury

Complications

Urethral trauma and hemorrhage
Paraphimosis (if the foreskin is not reduced after the procedure)
Infection
Undesirable catheter retention (nondeflating balloon)

Equipment

Review Box 55.1 Urethral catheterizations: indications, contraindications, complications, and equipment.

Procedure Overview

Indications: bladder access for urinary drainage or evaluation of bladder urine.

Contraindications: when other less invasive procedures will be equally effective and informative; relatively contraindicated in certain pelvic or GU trauma until urethral integrity is assured.

Complications: mechanical (false passage, iatrogenic paraphimosis following foreskin retraction for urethral access),

infection, bleeding, undesired catheter retention, complications of long-term catheter use.

Equipment: the equipment listed in Review Box 55.1 is included in most standard catheterization trays and must be available before attempting urethral catheterization.

Key Procedure Sequence

1. Identify the urethral meatus; expose it with the nondominant hand.

2. Cleanse the meatus and surrounding tissues with antiseptic solution.
3. With the dominant hand, cleanse the area in a circular motion, from the meatus outward.
4. Lubricate the catheter (sterile), and pass it through the meatus towards the bladder.
5. For males: consider instilling 5 mL of 2% viscous lidocaine (or similar) into the urethra prior to passing the catheter.
6. For females: discard any catheter that has inadvertently entered the vagina.
7. Pass the catheter fully into the bladder, confirm its placement by the flow of urine. For men, continue to insert the catheter fully.
8. Inflate the balloon with 10 mL of air or water.
9. If resistance or obvious discomfort is felt, deflate the balloon and attempt repositioning.
10. After successful passage and balloon inflation, gently withdraw the catheter until resistance is met.
11. Connect the catheter to a drainage bag. Always reduce the penile foreskin if present to avoid inadvertent iatrogenic paraphimosis.

Description

Background

Patients are often apprehensive about catheterization. If the clinician shows concern regarding positioning and exposure, the patient will be reassured. Although adequate exposure may be obtained in the frog-leg position, the use of an examination table with stirrups (lithotomy position) is ideal, especially for female catheterization.

Anticipation and preparation of all materials necessary for urethral catheterization beforehand are reassuring to the patient. It is frustrating for the health care provider and upsetting to the patient when the patient is told “not to move or touch anything” while a search is made for additional equipment. Most catheterizations are performed using a standard catheterization tray. Often, these trays contain more equipment than is truly needed. This necessitates opening the tray and establishing a sterile field at the bedside, selecting those items that will be needed, and discarding the rest of the equipment. Once the penis or labia has been touched in preparation for the procedure, the touching hand (usually nondominant) is contaminated and ideally should not be handling any of the sterile equipment. When a standard catheterization tray is not used or is not available, go through the anticipated procedure mentally and secure all the appropriate equipment before actually starting the procedure.

Anatomy and Physiology

Female Catheterization

The female urethra is a short (~4 cm) straight tube, usually of wide caliber, lying on top of the vagina. It must be approached between the double labia, and the urethral meatus is occasionally hidden and not obvious. This is in contrast to most males, except those with hypospadias. If the female patient nervously adducts her legs, successful catheterization will be very difficult if not impossible.

The female urethral meatus is oval but may appear as an anteroposterior slit with rather prominent margins situated directly superior to the opening of the vagina and approximately 2.5 cm inferior to the glans clitoridis (Fig. 55.15). It is the first

of three orifices encountered when examining any female genitalia cephalad to caudad in the lithotomy position. The urethral meatus might be especially difficult to find in the very young infant and the older, postmenopausal woman. Anticipation of this and knowledge of the anatomic variances will help to modify any patient discomfort associated with needless catheter tip probing, which is an unsettling experience for both the patient and the catheterist.

Occasionally, the urethral meatus recedes superiorly into the vagina and is not immediately visible because of either prior surgical procedures or atrophic postmenopausal changes. Anticipation of such cases will allow the examiner to gently advance a nondominant index finger into the vagina in the superior midline. The urethral meatus can usually be palpated then visualized as a soft mound surrounded by a firmer ring of supporting periurethral tissue. Rarely, the meatus will have receded so far superiorly and intravaginally that it cannot be visualized at all, and catheterization must be carried out by palpation alone. From the meatus (if the patient assumes a supine position), the urethra proceeds straight back to slightly downward as it advances into the bladder just behind the symphysis pubis (Fig. 55.16A).

In women with a urethrocele or cystourethrocele, in whom the urethra or the bladder falls into the vagina, the “normal” urethral course might be significantly more posterior. The normal anatomic relationships in these situations may be re-created by spreading the index and long fingers and placing them along the superior vaginal wall and gently applying upward support (see Fig. 55.16B). This reconstitutes the normal anatomic relationships and permits straight, rapid urethral catheterization. Because the female urethra is so short, only half the total length of the catheter has to be inserted before it is safe to inflate the balloon.

Male Catheterization

Because the urethral meatus is usually evident in most males, it might seem a simple matter to insert a urethral catheter,⁶⁶ yet catheterization can be quite difficult. The normal male urethra is approximately 20 cm long from the external urethral meatus to the bladder neck (Fig. 55.17). The posterior prostatic urethra is approximately 3.5 cm long, and the contiguous external sphincter or urogenital diaphragm that encompasses the membranous urethra is 4 cm from the bladder neck. In males, any catheter must be fully inserted to the balloon-inflating side-arm channel before it is safe to inflate the balloon. At the first egress of urine from the catheter, the balloon is just passing through the membranous urethra. The catheter balloon still has approximately 3 to 4 cm to go before clearing the bladder neck. Inflation of the Foley balloon at any point before full insertion of the catheter might result in iatrogenic urethral injury.

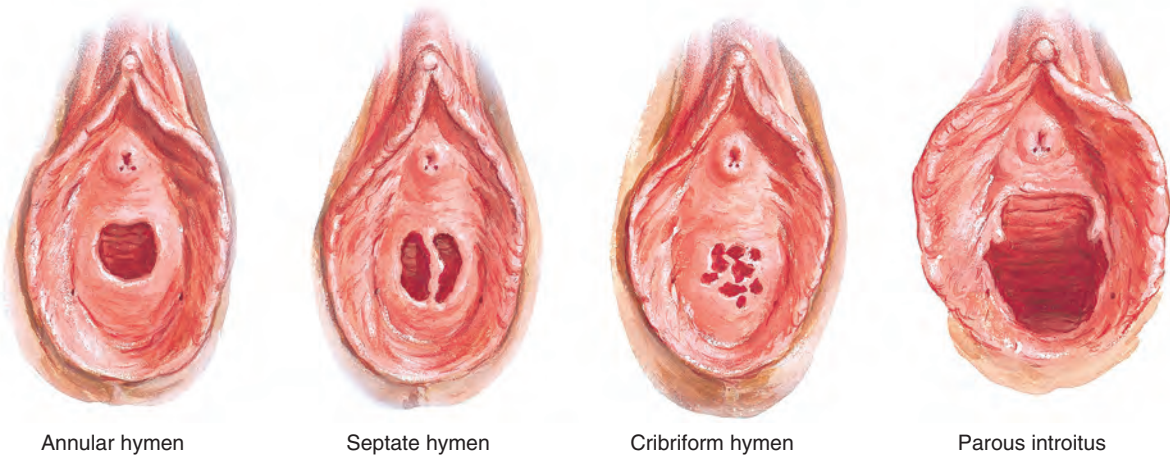

The male urethra is relatively fixed at the level of the urogenital diaphragm and symphysis pubis; traction downward on the penis kinks and promotes urethral folding at the level of the penile suspensory ligament (Fig. 55.18A), which creates a level of spurious obstruction. For this reason, the penis should always be held taut and upright during any urethral instrumentation, including catheterization (see Fig. 55.18B). The catheter then needs to make only a single curve rather than a complex S-curve as it traverses into the bladder.

Pathophysiology

See Table 55.3: Approach to Difficulties in Male Catheterization.

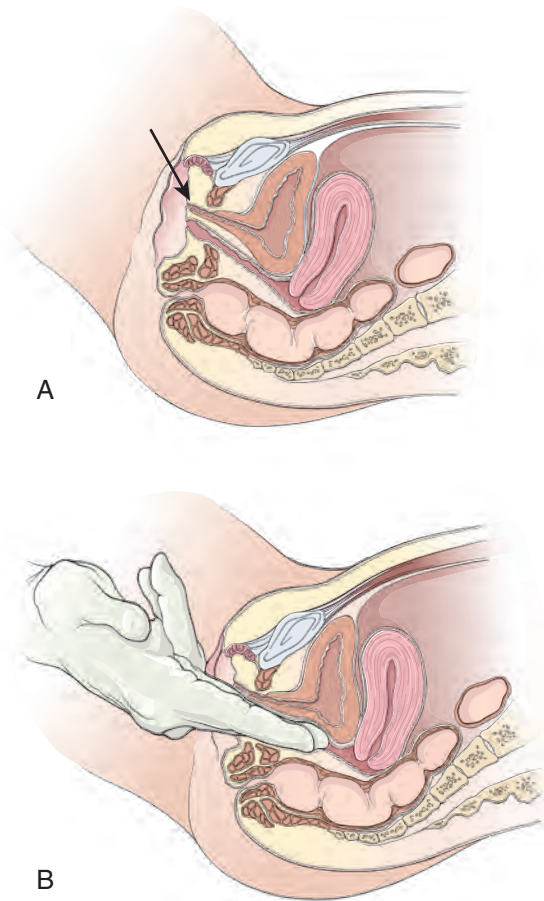

Figure 55.16 Female urethra. **A**, Normal sagittal anatomy of the female urethra (*arrow*). **B**, In a patient with a cystocele/urethrocele or prolapsed bladder, the normal anatomy may have to be re-created for passage of a catheter. Insert two fingers into the vagina and lift upward while passing the catheter.

Indications

Urinary catheterization and instrumentation are rarely a primary cause of urinary infection in otherwise healthy patients who urinate normally and carry small amounts of postvoid residual urine. As with any procedure, catheterization needs to be limited to those clinical situations in which the benefits outweigh the risks. The following are considered to be indications for urethral catheterization:

1. Acute urinary retention.
2. Urethral or prostatic obstruction leading to compromised renal function.
3. Urine output monitoring in any critically ill or injured patient.
4. Collection of a sterile urine specimen for diagnostic purposes.
5. Intermittent bladder catheterization in patients with neurogenic bladder dysfunction.
6. Urologic study of the lower urinary tract.

Contraindications

Urethral catheterization should be avoided when other less invasive procedures will be equally effective and informative. A traditional relative contraindication to urethral catheterization is the trauma patient with suspected urethral injury as evidenced

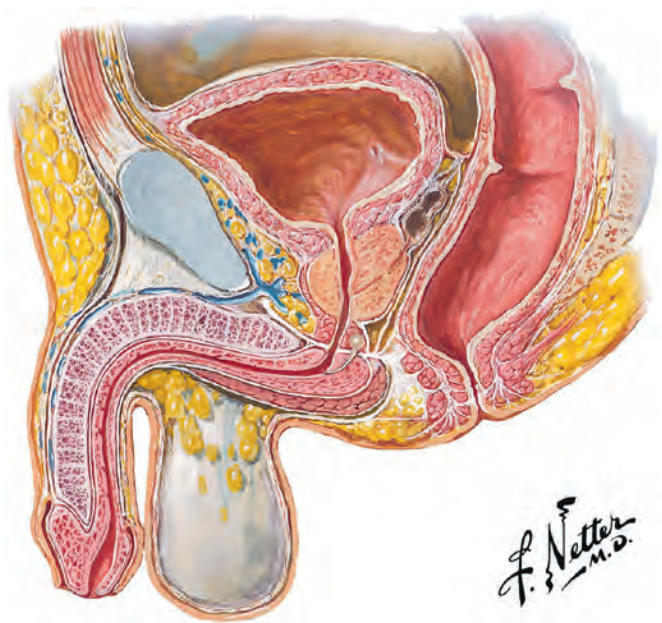

Figure 55.17 Male urethra. The male urethra is approximately 20 cm long from the meatus to the neck of the bladder. The prostatic urethra and membranous urethra can be up to 7 cm combined. Thus, it is essential to advance the urethral catheter to the hilt before balloon inflation to avoid urethral injury. (Netter illustration from <https://www.netterimages.com>. Elsevier, Inc. All rights reserved.)

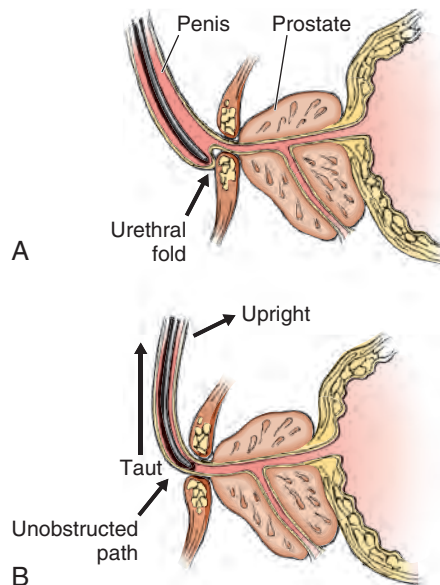

Figure 55.18 **A**, The urethra may fold and kink if the penis is not held taut and upright during passage of a catheter. This will halt the advancement of a catheter, even though there is no other anatomic blockage. **B**, The taut and upright position allows an unobstructed path for the catheter.

by blood at the urethral meatus, an abnormal-feeling or high-riding prostate on rectal examination, penile, scrotal, perineal hematoma, or radiographic evidence of urethral/bladder trauma. In the setting of a severely fractured pelvis or diastasis of the pubic symphysis, urethrogram should always precede attempts at catheterization. Although some authors,⁶⁷ and more liberal

TABLE 55.3 Approach to Difficulties in Male Catheterization

CONDITION	ISSUE	WORK-AROUND STRATEGY
Phimosis	Inability to identify the urethral meatus because of a tight phimotic opening	Dilate the phimotic opening sufficiently to identify the urethral meatus and blindly pass the catheter Dorsal slit of the foreskin to expose the glans and urethral meatus in extreme cases
Foreskin edema	Edema may obscure the glans penis and urethral meatus	Attempt to identify the cause of the edema; exclude paraphimosis and foreign body strangulation Manually compress the swollen foreskin by hand or between opposing cold packs If unsuccessful, snugly wrap the distal penis in a compressive dressing for 10 min
Meatal stenosis	The urethral meatus may be either congenitally or secondarily narrowed by scarring	Trial of a smaller-caliber catheter If a larger-caliber catheter is necessary, meatal dilation or meatotomy might be necessary under the direction of a urologist
Urethral stricture	May develop as a result of trauma, infection (especially STDs), lower urinary tract instrumentation, or long-term indwelling catheter drainage	Trial with a coudé catheter However, manual force should not be used to negotiate or to dilate urethral strictures because it may lead to false passages, bleeding, and future increased scarring Consideration of urethral dilation with the use of filiforms and followers under the direction of a urologist
External urethral sphincter spasm	Voluntary or involuntary contraction of the urogenital diaphragm (external sphincter) produces spurious urethral resistance at approximately 16 cm from the meatus	Encourage the patient to lay supine and take slow, deep breaths while consciously trying to relax the perineum and rectum Plantar flexion of the toes and ankles may also aid in relaxation of the pelvic floor Gentle but steady pressure exerted on the syringe or the catheter along with the aforementioned steps may aid in passage The external sphincter is composed of striated muscle and fatigues within a few minutes If continued resistance, assume an anatomic abnormality and consider RUG before further instrumentation
High bladder neck	Enlarged intravesical portion of the prostate with a secondary high-riding bladder neck Typically resistance encountered after the catheter has been passed 16–20 cm into the urethra	Slow instillation or injection of 20–30 mL of sterile lubricating jelly If unsuccessful, consider a trial with a coudé catheter; may be enhanced by digital compression of the prostate during digital rectal examination
Pelvic trauma, straddle injury	Partial or complete urethral injury might occur Injudicious catheterization has the potential for conversion of a partial injury (may heal with little or no scarring) to a complete urethral injury (often requires surgical repair and usually results in some degree of postoperative morbidity) Blood at the urethral meatus, a high-riding or abnormal-feeling prostate on rectal examination, and penile, scrotal, or perineal ecchymoses might be evidence of potential urethral or bladder injury but have poor sensitivity ⁶⁶	Consider precatheterization RUG in suspected cases Maintain a low threshold for urologic consultation Suprapubic catheter placement may be necessary in certain cases

RUG, Retrograde urethrography; STDs, sexually transmitted diseases.

clinical protocols, allow for gentle attempts at catheter passage in the presence of the previously discussed traditional contraindications, these findings necessitate strong consideration of retrograde urethrography (RUG) to delineate urethral integrity before any attempted urethral catheterization.⁶⁸

Procedure Equipment

The equipment listed in [Review Box 55.1](#) is included in most standard catheterization trays and must be at hand before attempting urethral catheterization. Check the list of contents before opening the tray because some trays do not include certain items. For most routine adult in-and-out catheterizations, a 14-Fr red rubber catheter or Foley balloon catheter is adequate ([Fig. 55.19](#)). In neonates or infants, a small feeding tube taped in place produces the least amount of urethral trauma. In older boys, a red rubber catheter or Foley balloon catheter may be used. [Table 55.4](#) lists age-appropriate sized catheters or feeding tubes for children.⁶⁹

A 14- to 18-Fr coude catheter should be considered after unsuccessful passage of a straight Foley balloon catheter or in any male patient with known enlargement of the median prostatic lobe ([Fig. 55.20](#)). If a coude catheter is not available,

Figure 55.19 Urethral catheters. A wide variety of types and sizes of catheters are available. For most adult catheterizations, a 14-Fr or 16-Fr Foley catheter is sufficient. For male patients with prostatic enlargement, a 14-Fr to 18-Fr coude catheter may be used (see [Fig. 55.20](#)). For patients with gross hematuria, a large (20 Fr and up) three-way catheter is ideal because it allows continuous bladder irrigation and its large diameter allows the passage of blood clots.

TABLE 55.4 Pediatric Urethral Catheter Size

AGE GROUP	PEDIATRIC CATHETER SIZE ^a
Infants (yr)	5- to 8-Fr feeding tube
1–3	8-Fr feeding tube
4–6	10-Fr feeding tube
7–12	10- to 12-Fr red rubber catheter (Robinson)
> 12	14-Fr red rubber catheter (Robinson)

^aSizes are approximate; 6-Fr is the smallest balloon catheter and is quite flimsy, and therefore 8 Fr is recommended; 12-Fr is the smallest coude catheter.

a larger 18- to 22-Foley balloon catheter can be attempted. In a male patient with a urethral stricture in whom attempts at catheterization with a straight Foley or coude catheter have failed, retrograde cystoscopy, passage of a guidewire, or passage of filiforms/followers under the direction of a urologist is the next step. If immediate bladder access is required in any emergency, suprapubic placement of a Foley balloon catheter using the Seldinger technique can be performed (as described in the later section on [Suprapubic Cystostomy](#)).⁷⁰

General Procedure ([Figs. 55.21](#) and [55.22](#))

As stated previously, urethral catheterization must be done using sterile technique. Both male and female patients have special urethral meatal considerations. In the uncircumcised or partially circumcised male, control of the penile foreskin is paramount to ensuring success. Before establishing a sterile field, retract the available foreskin to its fullest extent proximal to the glans penis ([Fig. 55.23A](#)). Unfold a standard 4 × 4 gauze pad, then refold it in its longest dimension and carefully wrap it around the retracted foreskin at the level of the coronal sulcus (see [Fig. 55.23B](#)). This will prevent the tendency for lubricant-associated normal anatomic foreskin reduction during catheterization and provide a continuously dry and sterile field. Secure the folded 4 × 4 gauze pad surrounding the foreskin between the nondominant long and ring fingers when beginning the procedure and do not release until the procedure is completed. This position leaves the nondominant index finger and thumb available for manipulating the catheter. After catheterization, remove the 4 × 4 gauze pad and reduce the penile foreskin to its normal anatomic position to prevent the development of an iatrogenic paraphimosis.

After exposing the urethral meatus in the female and the glans penis and urethral meatus in the male, use an antiseptic solution soaked into cotton balls or oversized cotton-tipped applicators to cleanse the exposed meatus and surrounding tissues. This is best done by hand but can also be done using the plastic forceps in the catheterization tray. Begin the cleansing in a circular motion on the urethral meatus and proceed outward, intentionally moving any debris toward the periphery and thus creating a sterile field.

Figure 55.20 Coude catheter. A coude catheter is used for men with prostatic enlargement. It features a semirigid curved tip that helps the catheter traverse the median lobe of the enlarged prostate gland. When inserting the coude, the curved tip should be pointing upward toward 12 o'clock, that is, pointing toward the dorsal aspect of the penis.

Male Urethral Catheterization and Bladder Irrigation

1 Prepare your equipment and place a sterile fenestrated drape around the penis. If the patient is uncircumcised, retract the foreskin prior to the procedure (see Fig. 55.23).

2 Use your nondominant hand to hold the penis, and cleanse the meatus and surrounding tissue with antiseptic. Your nondominant hand is now contaminated and should not let go of the penis or handle sterile equipment until the insertion has been completed.

Viscous lidocaine (Urojet)

3 Inject the urethra with 5 to 10 mL of 2% viscous lidocaine to distend the urethra and provide topical anesthesia. A commercially available Urojet syringe (depicted here) is ideal. If possible, wait 5 to 10 minutes for maximum anesthetic effect.

4 Hold the penis taut and upright with your nondominant hand while you pass the catheter into the urethra (see Fig. 55.18).

Catheter advanced to the hilt before balloon inflation

5 Advance the catheter to the hilt before inflating the balloon with the recommended amount of air or water. If there is obvious resistance or patient discomfort, immediately deflate and reevaluate the position of the catheter.

6 After balloon inflation, slowly withdraw the catheter until the balloon is against the bladder neck and precluding further withdrawal. Connect to a drainage system if one is not preattached.

7 Affix the catheter to the thigh with tape or a catheter-specific attachment device. Note that a three-way catheter was placed in this patient with gross hematuria.

Drainage port
Irrigation port
Inflation port

8 To irrigate the bladder, attach the irrigation port to a 2- to 4-L bag of saline irrigation fluid. (Hand irrigation with a 60-mL catheter-tipped syringe is an alternative.) Attach the drainage port to a large-volume collection bag.

Irrigation fluid

9 Continuously infuse the irrigant into the bladder. Rates of 1 to 2 L/hr are acceptable, provided that the amount of irrigant drained equals the amount infused.

10 Monitor output carefully during the procedure. The goal of irrigation is to obtain clear urinary effluent.

Figure 55.21 Male urethral catheterization and bladder irrigation.

Female Urethral Catheterization

Place the patient in the frog-leg position: the hips externally rotated and slightly flexed and the knees bent.

Place a sterile fenestrated drape over the area. Strict attention to sterile technique is required.

Use your nondominant hand to spread the labia and identify the urethral meatus. This hand is now considered contaminated and should not release the labia or handle sterile equipment throughout the procedure.

Cleanse the urethral meatus with antiseptic in progressively increasing concentric circles.

Insert the catheter into the meatus under direct vision. If the catheter accidentally enters the vagina, it should be discarded and a new one used (to prevent iatrogenic infection).

Once the catheter is in the bladder and urine returns in the tubing, advance the catheter several centimeters farther and inflate the balloon with the recommended amount of water or air.

Gently retract the catheter until the balloon encounters the bladder neck and resistance is felt.

Attach the catheter to a collection device (if not already preconnected), and affix the catheter to the patient's thigh with tape or a connection device.

Figure 55.22 Female urethral catheterization.

Lubricate an appropriately sized catheter (14- to 16-Fr is commonly used in adults) with viscous rather than inspissated lubricating jelly. Injection of the male urethra with 5 mL of 2% viscous lidocaine or a syringe filled with anesthetic lubricant can be helpful for topical anesthesia and urethral distention. Regardless, advise the patient of mild urethral discomfort and the potential urge to void. Gently pass the catheter by hand, or with the aid of a hemostat or plastic forceps, into the urethra and upward into the bladder. During slow, gentle passage of the catheter, be aware of the anatomic considerations discussed

previously. Any catheter that inadvertently enters the vagina should be discarded.

After passing the catheter fully in all male patients, slowly inflate the balloon with 10 mL of air or tap water. Sterile water or saline is not required. Most 5-mL balloons will easily accommodate 30 to 50 mL of air or water without bursting. Obvious resistance or patient discomfort on balloon inflation should signal potential erroneous urethral positioning and mandates reevaluation. If this occurs, immediately deflate the Foley balloon and reposition or slightly withdraw the catheter,

Figure 55.23 **A**, In this uncircumcised male, the foreskin has been fully retracted for placement of a catheter. **B**, A gauze pad allows a firm grasp on the foreskin to prevent movement during catheterization. Reduce the foreskin to its original position once the catheter is in place.

Figure 55.24 **A**, The urethral meatus cannot be found in the markedly edematous penis in this patient with massive anasarca. **B**, Wrap the penis in an elastic bandage for 8 to 10 minutes. **C**, Much of the edema is reduced with compression alone. **D**, An assistant stabilizes the penile shaft with the thumb and index finger (*arrow*) while the operator (*asterisk*) spreads the redundant tissue with forceps to visualize the meatus deep within the swollen tissue and advances the catheter.

then pass it fully again before balloon reinflation. If this is unsuccessful a second time, remove the catheter. At this point, RUG is recommended to evaluate the urethra for a potential obstructive problem or false passage (see later section on RUG). It may be difficult or impossible to pass a Foley catheter in a male with a markedly edematous penis (Fig. 55.24). If this cannot be accomplished, a suprapubic catheter may be required.

After successful catheter passage and Foley balloon inflation, slowly withdraw the catheter until the approximation of the balloon with the bladder neck precludes further withdrawal.

Then connect the catheter to either a sterile leg bag or a closed-system bedside drainage bag. If the patient will be released with an indwelling Foley catheter, it can be initially connected to a leg bag, which is then comfortably fastened to the lower thigh and upper calf. The patient and family must be instructed regarding proper care of the catheter and drainage device. In most other cases, the catheter may be secured to either the thigh or the lower abdomen (preferred with males) with adhesive tape or simply placed under the knee and left to drain dependently into the bedside drainage bag.

Bladder Irrigation

After prostate surgery (transurethral resection) or in other clinical scenarios, blood clots may form in the bladder and cause acute urinary retention. Blood loss can be significant. This condition is usually easily relieved by the use of a large three-way irrigation catheter. A 22F to 26F Foley three-way catheter is preferred. Infuse saline irrigation fluid continuously into the bladder, while allowing the egress of fluid and blood clots. Continue the procedure until the bladder remains decompressed or bleeding stops (see Fig. 55.21, steps 8-10). Gravity alone usually provides adequate ingress-egress of fluid, but gentle syringe irrigation with 60-mL aliquots of saline may be used. Irrigation can be brisk, 1 to 2 L/hr or more, as long as the volume of drained saline is equal to the volume infused. Infuse saline (supplied in 2- or 4-L bags) by gravity. As stated previously, syringe irrigation of a Foley catheter with 60-mL aliquots is an acceptable alternative. The goal is to obtain clear urine.

Difficult Urethral Catheterization

Difficult urethral catheterization (DUC) is a common urologic problem. In females, this is due primarily to vaginal atrophy with retraction of the meatus into the vagina. This can typically be overcome by placing the patient in the lithotomy position, using a speculum, or guiding the catheter blindly with the provider's index and middle fingers. However, DUC in males may present greater challenges. Common causes in males include urethral strictures, bladder neck contracture, false passage, and prostate disease. Trial of a coudé catheter is generally the first-line approach to DUC. Alternatives utilized by urologists include flexible cystoscopy, passage of a guidewire, or filiforms/followers.⁷¹ Suprapubic cystostomy should generally be considered an option of last resort given its inherent complications. Various causes and approaches to DUC in the emergency care setting are presented in Table 55.3.

Aftercare

Systemic antimicrobial prophylaxis should not be used routinely in patients with short- or long-term catheterization to reduce catheter-associated bacteriuria or urinary tract infection because of concern about selection of antimicrobial resistance.⁷²

Complications

Although urethral catheterization performed by skilled personnel in appropriate circumstances has an acceptable complication rate, untoward sequelae of catheterization are not unusual.

Mechanical

False passages might be established in any area of the urethra when force is exerted on the catheter. In an uncircumcised patient, negligence in reducing the retracted foreskin to its normal anatomic position after urethral catheterization or instrumentation might lead to painful paraphimosis and associated complications.

Bleeding

Hematuria is common immediately, even after an atraumatic catheterization. Careful monitoring of symptom trajectory is prudent, as most often, postprocedure hematuria resolves rapidly and spontaneously.

Infection

The incidence of bacteriuria associated with indwelling catheterization is 3% to 8% per day, and the duration of catheteriza-

tion is the most important risk factor for the development of catheter-associated bacteriuria.⁷² However, in hospitalized, elderly, debilitated, or postpartum patients, the rate might be considerably higher. Urinary catheterization is the leading cause of nosocomial infection.⁷² Given widespread patient safety, as well as value-based reimbursement initiatives, additional scrutiny is prudent regarding the necessity of initial catheter placement, as is expeditious catheter removal as soon as feasible.

Long-Term Catheter Use

By 1 month, nearly all patients with an indwelling catheter will be bacteriuric.⁷² Other less frequent complications of long-term indwelling urethral catheterization include bladder stones, recurring bladder spasm, periurethral abscesses, urethral stricture formation, bladder perforation,⁷³ and urethral erosion.⁷⁴

Undesirable Catheter Retention

Catheters may be retained because of balloons that do not deflate (see the next section) or, very rarely, because of a knot that has spontaneously developed in the catheter.

Removal of a Nondeflating Catheter. Occasionally an indwelling catheter balloon fails to deflate, leading to undesired retention of the Foley catheter in the bladder. This problem has challenged and frustrated many clinicians and has produced a number of ingenious solutions. Unfortunately, pretesting Foley catheter balloons by trial inflation and deflation before insertion does not eliminate the potential for a nondeflating Foley catheter balloon.

A common cause of the nondeflating catheter balloon is the malfunction of the flap-type valve in the balloon lumen of the catheter, which normally allows fluid to fill the balloon of the catheter but prevents passive egress (Fig. 55.25, step 1).⁷⁵ The ideal solution is one that resolves the problem, deflating the balloon, without creating another problem: that is, unnecessary bladder irritation or balloon fragmentation. Of the methods recommended to decompress nondeflating catheter balloons, the only technique that approaches the ideal directly attacks this flap-valve deformity.

The inflate-deflate channel normally prevents the passive egress of inflating fluid or air. Occasionally, cutting off the inflation port will deflate the balloon, but usually, the problematic area is further along the catheter, closer to the bladder. Once the port has been removed, use a needle/syringe in the inflation channel to suck out balloon fluid (see Fig. 55.25, step 4). Cutting the catheter closer to the bladder may fortuitously cut off the offending area, but be careful not to cut off an excessive length of exposed catheter.

The inflation channel may have a valve defect or be filled with debris (see Fig. 55.25, step 2). If cutting the balloon port and using a needle/syringe is unsuccessful, it is best to insert a thin, rigid wire into the balloon-port lumen in an attempt to deflate the valve-flap defect sufficiently and promote the escape of fluid from the balloon (see Fig. 55.25, step 3). Occasionally, the balloon itself may be punctured by this wire. The wire stylets from a central venous or angiographic catheter, guidewires from ureteral catheters, and very small, well-lubricated ureteral catheters themselves have all been reported to be successful. When a ureteral catheter guidewire was used in one series, 34 of 39 balloons were deflated without fragmentation.⁷⁶

Once a malfunctioning balloon has been deflated, inspect the balloon itself for missing fragments. If a piece of the balloon

Removal of a Nondeflating Catheter

1

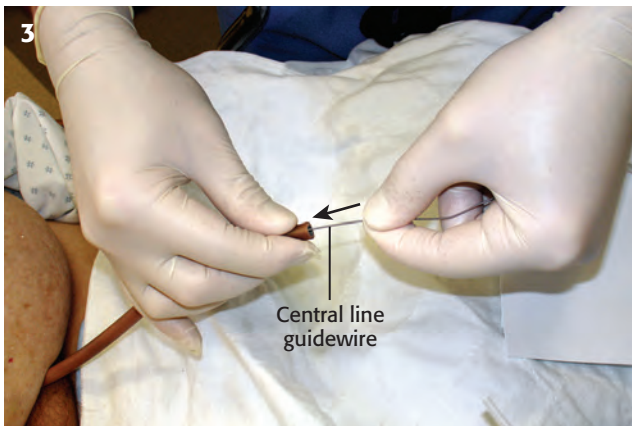

A flaplike defect in the inflating channel of a balloon catheter may prevent balloon deflation. A wire stylet (from a central venous catheter kit) can be passed down the inflating channel to raise the flap and deflate the balloon.

Note that the entire inflation channel is filled with debris (arrow), thus preventing egress of fluid from the retaining balloon.

3

Cut the catheter, remove the inflation port, and advance the stiff end of a guidewire through the inflation channel. The wire may puncture the balloon or clear the channel so that fluid escapes.

4

Once the channel has been cleared, insert a 20-gauge needle gently into the inflation channel to aspirate the balloon fluid.

5

In the case of a nondeflating suprapubic balloon, you can try to insert a 25-gauge spinal needle parallel to the catheter to puncture the balloon. Maintain traction on the catheter to stabilize the balloon during the procedure.

6

This balloon demonstrates "cuffing" where the balloon deflated asymmetrically and got caught up during withdrawal.

Figure 55.25 Removal of a nondeflating catheter. (1, From Eichenberg HA, Amin M, Clark J: Nondeflating Foley catheters, *Int Urol Nephrol* 8:171, 1976. Reproduced by permission.)

TABLE 55.5 Alternative Methods of Removing Nondeflating Catheters

METHOD	COMMENTS
Needle puncture of the balloon (see Fig. 55.25, step 5)	Overinflate the balloon (50–100 mL of saline) Draw the balloon against the bladder neck Use local anesthesia for the suprapubic approach Use a 25- to 27-gauge spinal needle to puncture the balloon Ultrasound guidance may be helpful
Hyperinflation of the balloon	High rate of balloon fragmentation: 100 of 100 in one report ⁷⁴ Postprocedure cystoscopic inspection of the bladder essential Consider adding 50–100 mL of saline into the bladder to cushion the effects of subsequent balloon rupture if no urinary retention is present Inject up to 200 mL of air into a 5-mL balloon to induce rupture
Injection of an erosive substance into the balloon port (e.g., mineral oil)	This technique has fallen out of favor High rate of balloon fragmentation: 95 of 100 in one report ⁷⁴ Associated with chemical cystitis

is missing, arrange for subsequent cystoscopy to look for and remove the fragments.

Alternative methods of nondeflating catheter removal are presented in Table 55.5.

A variation on the nondeflating balloon is “cuffing,” essentially an asymmetrical deflation in which the balloon does not deflate flush with the catheter. The irregularity becomes more pronounced as the catheter is withdrawn into the urethra, preventing easy withdrawal. This occurs more often when balloon fluid is quickly aspirated and less often with more gradual fluid withdrawal. Inflate the balloon again and try slow deflation if this occurs. Reinflating the balloon to a smooth surface with 0.5 to 1 mL of saline during withdrawal may also obviate this.

Traumatic Foley Catheter Removal

Occasionally, uncooperative or demented patients will pull out their Foley catheter with the balloon still inflated (Fig. 55.26). One would intuit that urethral injury is possible; however, there remains limited data on the incidence or type of injury from this maneuver or how to deal with this situation. Usually, there is blood at the meatus, and it may be difficult to know whether the patient can spontaneously urinate. If the patient can spontaneously urinate, it would seem reasonable to gently pass another Foley catheter to avoid urethral obstruction by tears or clots and allow healing of urethral trauma with a new catheter in place. Most of the time, however, the clinician has minimal data yet is faced with the decision on how to approach this conundrum. Surprisingly, this incident does not usually result in significant urethral injury. It is assumed that a new catheter will be required, either to continue the original catheter indication or to provide a stent while any urethral injury heals. In the absence of available urologic consultation, gentle attempts at passage of another Foley catheter are reasonable, without a routine retrograde urethrogram (described later in this chapter). If the catheter does not pass easily, stop and perform a retrograde urethrogram to assess the nature and extent of the pathology. Most of the time, simply replacing the catheter will be the most prudent approach. Prophylactic antibiotics are reasonable under these circumstances. Complete eversion and prolapse of the bladder have been rarely associated with this misadventure.⁷⁷

Conclusions

Access to and the subsequent evaluation of bladder urine are at times clinically important to emergency practitioners. The merits of various approaches to urine specimen collection depend on the patient’s age and clinical setting. Urethral catheterization generally provides a relatively safe and effective means of bladder access.

SUPRAPUBIC ASPIRATION

Introduction

Suprapubic aspiration of the bladder, first reported as a method of collecting urine for bacteriologic study in 1956,⁷⁸ offers the clinician a relatively simple means of obtaining uncontaminated bladder urine. It is utilized primarily in young children, although there are limited indications for this procedure in adults as well.

It has been demonstrated that with proper technique, suprapubic aspiration consistently provides an uncontaminated urine specimen capable of distinguishing true bacteriuria from contamination.^{79,80} However, the perception and demonstration of increased discomfort and procedural failure rate has led to a precipitous decline in its use, particularly outside of the neonatal intensive care unit.^{80–82} Nevertheless, suprapubic aspiration continues to be considered the gold standard method of urine collection.⁸³

Despite the lack of experience by most currently practicing clinicians, the procedure may still be necessary in girls with labial adhesions and boys with phimosis. The relatively recent introduction of ultrasound technology has led to a significant improvement in success rates, and likely in the comfort of the clinician performing the procedure.^{84–86}

Procedure Overview

Indications: provides the clinician with a urine sample that is reliable for bacteriologic interpretation.

Contraindications: infection at proposed puncture site.

Complications: infection or hematoma at puncture site; simple penetration of the bowel with a needle is considered an innocuous event and requires no specific treatment.

Figure 55.26 Traumatic Foley catheter removal. **A**, This patient pulled out his Foley catheter with the balloon inflated. Blood appeared at the meatus. His mental status prevented assessment of his ability to void spontaneously. Given the large volume of the inflated balloon and gross blood, it was decided to perform retrograde urethrography, although some would simply try to gently pass a new catheter. **B**, Place a balloon-tipped catheter into the meatus and inflate with 1 to 2 mL of air or water. **C**, Squeeze the glans while an assistant slowly injects contrast material. **D**, Overzealous injection resulted in venous uptake of the dye and spillage on the patient's leg. The urethra is intact. A new catheter was easily passed.

Equipment: skin cleansing agent, local anesthetic, needle (usually 22-gauge) and syringe for puncture and aspiration procedure.

Key Procedure Sequence
