Richard D. Zane

The seventh edition of *Roberts and Hedges' Clinical Procedures in Emergency Medicine and Acute Care* continues the book's original concept of providing complete, very detailed, and up-to-date descriptions of many common, and some uncommon, procedures encountered during emergency medicine and acute care practice. The novice may find the discussions and figures devoted to the many procedures somewhat daunting or overwhelming at first; but it is hoped that most will eventually appreciate the simple discussion and complex verbiage contained in the text. The goal is to describe clinical procedures—from simple Steri-Strip application, to loop drainage of an abscess, to tracheal intubation and mechanical ventilation, to skull trephination—as though each were the nascent clinician's first exposure to the concept, but with a depth and attention to detail that the seasoned operator would also deem helpful.

In previous editions it was difficult to find figures or photographs that conveyed the details or elucidated the vagaries to the extent one might want. The newly added color photographs, mostly digital quality, and a cornucopia of additional figures were a much needed update and morphed this edition into an obvious improvement over previous iterations. To make the text more user friendly, procedure boxes have been created, comprising a mini-atlas that allows the clinician to see the entire procedure at a glance. One can even bring the text to the bedside, viewing a single page of sequential images, the quintessential teaching tool for house staff and students. Many of the photographs were taken by me over 42 years of emergency department shifts or created or supplied by Todd W. Thomsen, MD. Some illustrations were borrowed from other sources, such as the wonderful text by Catherine B. Custalow, MD, PhD. This edition has more than 3500 images, half of which are new. More than 70 percent of the new images are the result of the artistic genius of graphics editor Dr. Thomsen. Frank Netter, watch out for Dr. Thomsen; he is rapidly attaining your status and may have already surpassed it in emergency medicine parlance. No doubt Dr. Thomsen has found his calling, blending amazing original art and electronic and digital prowess with equally impressive clinical medicine expertise. Please see Expert Consult for some bonus procedure videos from Todd.

The addition of the ultrasound-guided sections, presented in easily found and readily deciphered boxes, is the result of a gargantuan effort from our new ultrasound editor, Christine Butts, MD, an ultrasonographer extraordinaire. Another achievement of this edition is the inclusion of additional video procedures. Only wished for in other texts, many sections now reference online content that allows the reader to view videos of the procedures actually being performed. "See one, do one, teach one" has taken on new meaning with this text. This edition is now available electronically on such devices as the Kindle and iPad and is still fully searchable online at expertconsult.com.

There are, of course, many ways to approach any patient or any procedure, so this text is not a dictum and is not truly

authoritative. This book does not attempt to define standard of care. The clinician should remember these caveats if involved in a medicolegal scenario. It contains practical hints and successful tactics gleaned from the literature and by years of practice, adeptly described by skilled clinicians. As with previous editions, this version also significantly incorporates the personal opinions and experience of the authors and editors. But this text is simply a clinical guide, not a legal document. Do not reference this book if you testify in court, for either the defense or the plaintiff. Today's dogma too often becomes tomorrow's heresy, and physician hubris is worse than incompetence. Simply stated, emergency medicine and acute care, and the human body too often defy the written word, personal opinion, or local custom and humble even the venerable and the universally praised gray-haired professor.

Many new authors have been added, as well as a number of new concepts and approaches. All procedures have been tweaked. As an example one will not find the novel loop abscess drainage technique, sedation techniques, or ENT and ophthalmology techniques so nicely described elsewhere.

My personal thanks are hereby conveyed to those who contributed to previous editions. The updated chapters often merely refine or further manipulate the scholarly work of others who originally assisted us. The current contributors include an enviable blend of friends and colleagues, some former students of mine, up-and-coming rising stars in their own right, and my prior mentors and role models—all are accomplished physicians and leaders in their own milieu. Many of the editors' names are well known to anyone who reads the literature or attends a continuing medical education activity. All of the associate editors portray and embody the pinnacle of emergency medicine and acute care excellence. Most of the contributors, and all the associate editors, probably know more than I know, and most are likely infinitely more capable and facile with procedures. All are capable of writing a text themselves, and some have already done so; however, some are now enlightened and eschew that primal urge because they now know how difficult it is to write even a single chapter. My able and erudite associate editors, all from prestigious academic teaching programs in emergency medicine, are Arjun S. Chanmugam, MD, MBA; Carl R. Chudnofsky, MD, FACEP; Peter M.C. DeBlieux, MD; Amal Mattu, MD; Stuart P. Swadron, MD, FRCPC, and recently added Michael Winters, MD, FACEP, FAAEM. They provided the bulk of the original editing, but senior editor, Dr. Custalow, read every single word and reviewed every table and figure. Dr. Custalow is a more tenacious editor than the proverbial honey badger in regard to dealing with details, grammar, organization, and style. In the end, my personal bias may be evident, but Dr. Custalow was the fire and fuel for the book's framework. As already stated, Dr. Thomsen made the text come to life with images. I would also like to thank Robert Orman, MD, and Scott D. Weingart, MD, FCCM, who served as video editors on the previous edition.

If any of our editing changed, altered, or misinterpreted the original thoughts of the contributors (and I know in some instances it must have), we apologize; but hard decisions had to be made, and waffling was rarely an option. Our book simply tells you what to do and how and when to do it, but no book can always fit every individual situation. We attempted to squarely address such omnipresent vague topics as prophylactic antibiotics, local customs, and variations in style, and accepted the fact that not all foreign bodies or tendon lacerations will

be identified in the heat of the moment by even the most skilled clinician. The prescient and sagacious clinician knows that the ability to practice medicine from a book is limited, and one learns best from past experiences; and, for certain, the most instructive past experience is one that was not always textbook perfect.

James R. Roberts, MD, FACEP, FAAEM, FACMT

Every shift in the emergency department has the potential to take us into the great unknown. Frequently a patient's presentation challenges our capabilities, and an uncommon procedure may be the only answer. Throughout my training and career, this book you are now holding has been my unwavering companion.

On a recent night shift, I encountered a patient needing two separate procedures, both well within my capabilities as an emergency physician. Yet, I found myself asking, "Do I remember exactly how to do the procedure? What is the best approach? Where are my landmarks?" I was almost positive I could recall the technique correctly, but before breaking skin, I decided a review of *Roberts and Hedges* was in order. Taking this step dispels any doubt and gives me confidence to get the job done well.

Whether it's tapping a septic elbow, checking a compartment pressure, or performing a lateral canthotomy, the refrain is always the same: "How, exactly, do I do this?" becomes "Right, oh yes, I've got this down!"

As we move further into the world of online and on-demand education, some may say that textbooks are a vestige of the past, but I disagree in this instance. Even after decades in print, *Roberts and Hedges* continues to shine as the guiding light of clinical emergency medicine.

Rob Orman, MD
June 1, 2017

Acknowledgments

Gargantuan efforts, clairvoyant and perceptive suggestions, and decidedly prescient and sagacious contributions of many individuals have brought this work to fruition. Not the least of whom were the individual authors who toiled over tedious manuscripts and answered countless queries about the vagaries and vicissitudes of seemingly straightforward clinical procedures.

This book's current edition was championed by Elsevier's Senior Content Strategist, Kate Dimock. All of the initially submitted work was culled, corrected, and collated by the very able Senior Content Development Specialist, Jennifer Ehlers. Senior Project Manager, Rachel McMullen, also toiled over every aspect of the text. My sincere gratitude to them is warmly extended with this acknowledgment. If any reader is contemplating developing their own textbook, snag this team of publishing aficionados if you can.

Of course, the entire work was infused with vim and vigor from Catherine B. Custalow, MD, PhD, and every image was created, beautified, or otherwise superbly orchestrated by Todd

W. Thomsen, MD. The final editing of Arjun S. Chanmugam, MD, MBA; Carl R. Chudnofsky, MD, FACEP; Peter M.C. DeBlieux, MD; Amal Mattu, MD; and Stuart P. Swadron, MD, FRCPC, and Michael Winters, MD, FACEP, FAAEM, completed the task. One might think that these folks have a lot of free time on their hands or, more likely, they burned gallons of midnight oil for the project. It has been an honor to be associated with such icons in the field. The contributing authors are certainly also to be congratulated on a stellar performance.

Thank you all for accomplishing a goal that was once thought, even by me, to be nothing more than a seemingly good idea, but a task too difficult to even contemplate, let alone wantonly attempt. It is hard to believe that the first edition of this book was done in 1985 on an IBM electronic typewriter, before email, scanning, fax, or Microsoft Word. We have come a long way for sure.

James R. Roberts, MD, FACEP, FAAEM, FACMT

Vital Signs and Patient Monitoring Techniques

CHAPTER 1

Vital Signs Measurement

Jillian L. McGrath and Daniel J. Bachmann

Measuring the temperature, pulse, respiratory rate (RR), blood pressure, and pulse oximetry is generally recommended for all emergency department (ED) patients, in addition to assessment of pain in the appropriate patient population. For very minor problems or for some fast-track patients (e.g., suture removal), a full set of vital signs may not be required, and this is best decided on a case-by-case basis rather than by strict protocol. Vital signs may indicate the severity of illness and also dictate the urgency of intervention. Although a single set of abnormal values suggests pathology, findings on triage or the initial vital signs may be spurious and simply related to stress, anxiety, pain, or fear. It would be incorrect and not standard of care to attribute initial triage blood pressure, RR, or pulse rate to specific pathology or to retrospectively assume that diagnostic or treatment interventions should have been initiated based solely on these readings. The greatest utility of vital signs is in their continued observation and trends over time. Deteriorating vital signs are an important indicator of a compromised physiologic condition, and improving values provide reassurance that the patient may be responding to therapy. When a patient undergoes treatment over an extended period, it is essential that the vital signs be repeated as appropriate to the clinical scenario, particularly those that were previously abnormal. In some clinical circumstances, it is advisable to monitor the vital signs continuously.¹

Vital signs should be measured and recorded at intervals as dictated by clinical judgment, the patient's clinical state, or after any significant change in these parameters. Adhering to strict protocols or disease categories is not useful or productive. An abnormal vital sign may constitute the patient's entire complaint, as in a febrile infant, or it may be the only indication of the potential for serious illness, as in a patient with resting tachycardia.²

Emergency medical service (EMS) personnel begin assessment of the patient's status and vital signs in the prehospital setting. Surges of epinephrine and norepinephrine commonly occur during transport by the EMS, and these catecholamines are known to alter vital signs and lead to increases greater than 10% in the heart rate.³ Vagal influences may also influence

EMS-derived vital signs. Prehospital vital signs should always be interpreted with the entire clinical scenario in perspective.

Blood pressure and pulse are frequently evaluated together as a measure of blood volume. Capillary refill is discussed as an assessment of overall perfusion, circulatory volume, and blood pressure. Although body temperature is usually the last vital sign measured during resuscitation, it has special importance for patients suffering from thermal regulatory failure. With these considerations in mind, the current chapter is organized according to the priorities of patient resuscitation and evaluation. Assessment of pain as a vital sign is gaining acceptance and is discussed briefly at the end of this chapter.

Background

CAN BE FOUND ON EXPERT CONSULT

NORMAL VALUES

The range of normal resting vital signs for specific age groups must be appreciated by the clinician to enable identification of abnormal values and their clinical significance. The normal ranges for vital signs are also influenced by gender, race, pregnancy, and residence in an industrialized nation. These ranges have not been validated in ED patients, who have many reasons for abnormalities in vital signs, including anxiety, pain, and altered physiology as a result of their disease states. Ranges of normal vital signs, commonly quoted as normal or abnormal in other settings, serve only as a guide and not an absolute criterion for diagnosis, treatment, further observation, or intervention in the ED.

Published vital sign norms for children are not as well accepted as those for adult patients. [Table 1.1](#) and [Table 1.2](#) report heart rate and RRs by age grouping and percentile for children from birth to 18 years of age. This data represents a large cross-sectional study using 6 months of nurse-documented heart rates and RRs from the electronic records of 14,014 children on general medical and surgical wards at two tertiary-care children's hospitals. Up to 54% of heart rate observations and up to 40% of RR observations in this sample were outside textbook reference ranges.⁸ During the newborn period, normal arterial blood pressure rises rapidly. Values for pulse and respiration in children older than 3 years reflect an average of male and female values for 0- to 1-, 3-, 9-, and 16-year-old populations. The values for blood pressure reflect an average of male and female values for the 1- to 6-month-old and the 3-, 9-, and 16-year-old populations.⁹ Other studies have assessed the reference values for RR in children demonstrating the same variability of pediatric "normal" vital sign ranges.¹⁰⁻¹²

BACKGROUND

Early recognition of vital signs dates to the fourth century BC, when Herophilus first described sphygmology, or palpation of the pulse in terms of size, frequency, force, and rhythm. Chinese clinicians (second century BC) timed the pulse by the RR of the examiner in the belief that four pulsations per respiration was normal for adults. The study of pulses was greatly influenced by Galen, who expanded the subject into a rather complex and obscure art form and wrote 18 books on the subject.⁴

Blood pressure was first measured directly in 1733 by Hales, who recorded arterial pressure in a mare by cannulation with

a brass pipe and a blood-filled glass column.⁵ Frank used large-bore catheters connected to a rubber membrane in a 1903 manometer.⁶ The invention of inflatable cuff manometers (Riva-Rocci, 1896) and discovery of the arterial phase sounds (Korotkoff, 1905) allowed the development of indirect measurement of blood pressure.^{5,6}

Clinical thermometry was introduced by Sanctorius in 1625, with early thermometers being filled with alcohol. Mercury column thermometers were introduced by Fahrenheit in 1714. Although their routine use was supported by Boerhaave, thermometry was not established as routine clinical practice until the 1870s.⁷

For the adult population, normal blood pressure values have been better established. Although systolic blood pressure increases with age, *normotensive* or *normal systolic blood pressure* is defined as 90 to 140 mm Hg, and *normotensive* or *normal diastolic blood pressure* is defined as 60 to 90 mm Hg. The recent literature suggests defining an “optimal” blood pressure as 115/75 mm Hg because values at or below this level have been associated with minimal vascular mortality.¹³ It has been suggested that the definition of hypertension be further expanded to integrate a global cardiovascular risk assessment.^{14,15} Although most patients have similar blood pressure in both arms, Pesola and colleagues found that 18% of their hypertensive population¹⁶ and 15% of their normotensive population had a difference of greater than 10 mm Hg in systolic blood pressure between arms.¹⁷

Within the adult population, optimal definitions for normal systolic blood pressure probably vary with age, and particular differentiation should be made in regard to geriatric patients in the emergency setting. The recent literature suggests redefining values representative of hypotension in the elderly, especially in the setting of trauma. Systolic blood pressure readings ranging from approximately 90 to 120 mm Hg have been associated with occult hypoperfusion and increased mortality in geriatric trauma patients.^{18–20}

In 1928 the New York Heart Association, by consensus, established the normal limits for the resting heart rate as 60 beats/min and 100 beats/min. More recent data indicate that 45 beats/min and 95 beats/min may better define the heart rate limits of normal sinus rhythm in adults of all ages. Spodick and colleagues recommended that the operational definition for the limits of the resting heart rate in adults should be 50 beats/min and 90 beats/min.^{21,22} This view is widely supported among cardiologists,^{23–25} but these ranges have not been validated in the ED setting. There is currently no consensus on what constitutes a normal adult RR; however, an RR range of 12 to 24 breaths/min is generally accepted in the existing literature as the norm for adults.^{26,27}

Pregnancy results in alterations in the normal adult values of pulse and blood pressure. Pregnancy is characterized by significant increases in minute ventilation, and is thought to be due to the combined facilitatory effects of progesterone and estrogen on central and peripheral chemoreflex drives to breathe.²⁸ The resting pulse rate increases throughout pregnancy from 10% to 15% over baseline values. The norms for systolic and diastolic blood pressure are dependent on patient positioning. When a pregnant patient is sitting or standing, systolic pressure is essentially unchanged. Diastolic pressure declines until approximately 28 weeks' gestation, at which time it begins to rise to nonpregnant levels. When a pregnant patient is in the lateral decubitus position, both systolic and diastolic pressure decline until the 28th week and then begin to rise to nonpregnant levels (Table 1.3).²⁹

RESPIRATION

Breathing is initiated and primarily controlled in the medullary respiratory center of the brainstem. The respiratory center is modulated by the pneumotaxic center, which limits the length of the inspiratory signal and greatly influences the RR and apneustic center in the pons.³⁰ Respiratory frequency reveals only a glimpse of the entire clinical picture. The pattern, effort, and volume of respiration may be more indicative of altered respiratory physiology. An abnormality in respiration may be

TABLE 1.3 Vital Signs During Pregnancy in the Lateral Decubitus Position (Means \pm SD)

PARAMETER	Trimester		
	1ST	2ND	3RD
Pulse rate (beats/min)	77 \pm 2	85 \pm 2	88 \pm 2
Systolic BP (mm Hg)	98 \pm 2	91 \pm 2	95 \pm 2
Diastolic BP (mm Hg)	53 \pm 2	49 \pm 2	50 \pm 2

BP, Blood pressure; SD, standard deviation.

a primary complaint or a manifestation of other systemic diseases. Increased RRs may be seen in patients with a variety of pulmonary or cardiac diseases, and acidosis, anemia, temperature, stress, and drugs (such as stimulants and salicylates) can significantly alter the RR in the absence of cardiopulmonary dysfunction.

Indications and Contraindications

The only contraindications to careful measurement of RR are the scenarios of respiratory distress, apnea, and upper airway obstruction, which require immediate therapeutic intervention. RR and respiratory effort should be assessed as soon as patient care demands allow.

The respiratory status of both adults and children plays a crucial role in determining the overall assessment of illness. Although it is a sensitive yet nonspecific indicator of respiratory dysfunction, the RR can also predict nonpulmonary morbidity. Several prehospital and hospital-based illness or injury severity scores feature the RR as a cardinal value. A prehospital RR of less than 10 breaths/min or greater than 29 breaths/min is associated with major injury in 73% of children.³¹ Using tachypnea alone as a predictor of pulmonary pathology, infants with an RR higher than 60 breaths/min are found to be hypoxic 80% of the time.³² Pediatric studies have linked abnormal RRs to in-hospital mortality and the level of care required in the ED.^{33,34} In a retrospective study exploring predictors of critical care admission for adult ED patients who were initially triaged as having low to moderate acuity, an abnormal RR at the first nursing assessment increased the odds of critical care admission by a factor of 1.66.³⁵ An RR higher than 25 breaths/min in prehospital trauma patients was associated with increased mortality.³⁶ Pre-arrest respiratory insufficiency (RR >36 breaths/min or pulse oximetry <90%) was an independent predictor of mortality (odds ratio [OR], 4.2) in patients with EMS-witnessed cardiac arrest.³⁷ Although some studies have associated abnormal RRs in adult ED patients with increased mortality,^{38,39} a 2011 large prospective cohort study of adult patients found that an initial abnormal RR on triage in the ED was not an independent predictor of hospital mortality.⁴⁰

Procedure

To measure RR (inspirations per minute), count the respirations when the patient is unaware that his or her breathing is being observed. Count for a full minute to most accurately determine the RR. The frequency of breathing is less regular than the

pulse, and inaccurate measurement is more likely to occur if the count is taken for a shorter interval. It is common to measure respirations over 15 seconds and multiply by 4, but this can significantly alter the true RR per minute. An infant's RR can easily be determined by observing or palpating the excursion of the chest or the abdominal wall.⁴¹ Infants should be observed for grunting respirations, which are produced by expiration against a partly closed glottis (an attempt to maintain positive airway pressure).

Interpretation

Respiratory Rate

The reproducibility of RR measurements may be limited by significant interobserver variability.^{42,43} Clinicians should recognize this inherent variability and interpret the RR with caution. Rates obtained by nurses versus medical students varied significantly, as did those obtained by medical students versus residents and attending clinicians.⁴⁴ Interobserver variability may account for a difference of up to 6 breaths/min, and variability in the same observer may account for up to 5 breaths/min.⁴⁴ A study comparing RRs obtained by triage nurses with an electronic monitor found that neither provided an accurate measurement of the RR in the ED, suggesting that new clinical strategies for obtaining this vital sign may be necessary.⁴⁵ RR is an independent risk marker for in-hospital mortality in community-acquired pneumonia and should be measured when patients are admitted to the hospital with pneumonia and other acute conditions.⁴⁶

Current texts vary considerably in their definition of a normal RR and cite published values that range from 8 to 24 breaths/min. In a study that specifically investigated normal RRs in an ED (afebrile ambulatory patients without respiratory complaints), females had a mean RR of 20.9 breaths/min and males had a mean RR of 19.4 breaths/min. The researchers concluded that a normal RR in the adult patient population was 16 to 24 breaths/min.⁴⁴ Other studies have provided additional information on normal resting and sleeping RRs in children younger than 7 years.⁹⁻¹⁴ RRs obtained with a stethoscope were higher than those obtained by observation (mean difference, 2.6 breaths/min in awake and 1.8 breaths/min in asleep children). Smoothed percentile curves demonstrated a larger dispersion at birth (5th percentile, 34 breaths/min; 95th percentile, 68 breaths/min), whereas dispersion was less at 36 months of age (5th percentile, 18 breaths/min; 95th percentile, 30 breaths/min).

The RR will generally increase in the presence of fever. It is often difficult to determine whether tachypnea is a primary finding or is simply associated with hyperpyrexia. A study of children younger than 2 years in whom pneumonia was subsequently diagnosed found that age-appropriate limits for resting tachypnea in the presence of fever could be defined. A sensitivity of 74% and specificity of 77% for pneumonia were found when children 6 months of age had an RR higher than 59 breaths/min, when those aged 6 to 11 months had an RR higher than 52 breaths/min, and when those 1 to 2 years old had an RR higher than 42 breaths/min.⁴⁷ Even in the face of physiologic compensation for fever, interpretation of the RR alone can help predict the presence of pulmonary disease.

Respiratory Pattern and Amplitude

Hyperventilation and hypoventilation can result from an extensive variety of disorders and may be related to pulmonary

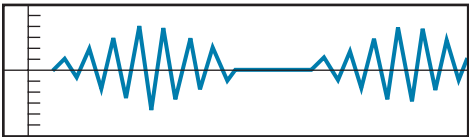

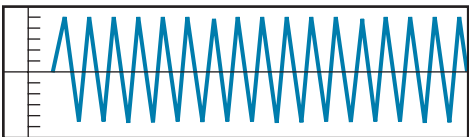

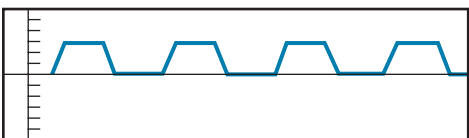

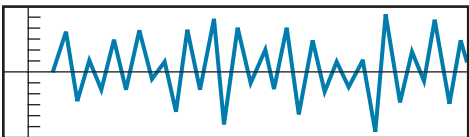

Cheyne-Stokes Respiration	 <p>V_T with a progressive shallow-deep-shallow cycle (30 s–2 min)</p>	CVA, trauma, masses involving a diffuse area of the forebrain, carbon monoxide poisoning, metabolic encephalopathy, altitude sickness, opiate effect
Biot's (Cluster) Respiration	 <p>Periods of rapid respirations of nearly equal depth or V_T followed by regular periods of apnea</p>	CVA or trauma involving the medulla or lower pons, mass effect on the medulla secondary to uncus or tentorial herniation, opiate effect
Kussmaul Respiration/ Hyperpnea	 <p>Hyperventilation characterized by a consistent and deep respiratory pattern; the RR of patients with hyperpnea may be normal or rapid with increased V_T</p>	Severe metabolic acidosis; Kussmaul respiration in diabetic ketoacidosis starts with a rapid and shallow pattern and later becomes rapid and deep
Apneustic Respiration	 <p>Prolonged inspiratory phase followed by prolonged expiratory phases believed to be apneic phases</p>	CVA, trauma, or mass effect involving the pons
Ataxic Respiration	 <p>Erratic breathing pattern with irregular pauses and increasing episodes of apnea (progresses to agonal respiration)</p>	CVA or trauma involving the medulla (indicates a very poor prognosis)

Figure 1.1 Abnormal respiratory patterns. CVA, Cerebrovascular accident; RR, respiratory rate; V_T , tidal volume. (Modified from D'Urbano J: Breathing Patterns, Breath Sounds, 2011. Available at <http://www.BreathSounds.org>.)

or extrapulmonary pathology. Abnormal respiratory patterns can be characteristic of metabolic or central nervous system pathologic conditions (Fig. 1.1) and may aid in the differential diagnosis. Kussmaul respirations describe the hyperventilation pattern seen in diabetic patients with ketoacidosis. Decreased RR is commonly seen with opiate toxicity. Hyperpnea, or a normal RR but clinically significant hyperventilation secondary to increased tidal volume, may be seen with salicylate poisoning.⁴⁸

Recognition of subtle tachypnea can be difficult in the emergency setting, although it can be the solitary indicator of disease. Another instance of pathology that can confuse routine measurement of the RR is diaphragmatic breathing or retractions. The variability in counting respiratory effort versus effective respirations is not generally appreciated in a single recorded value.

Observe the respiratory patterns carefully in children. In infants, it is essential to distinguish normal *periodic breathing* from *apnea*. By definition, periodic breathing consists of three or more respiratory pauses longer than 3 seconds in duration with less than 20 seconds between pauses. There is no associated bradycardia or cyanosis. This contrasts with apnea and is a particular problem in preterm infants. Apnea is defined as a respiratory pause longer than 20 seconds. It may be associated with bradycardia and hypoxia.⁴¹ Periodic breathing and apnea are believed to be disorders on a continuum, both stemming from abnormal physiologic control of respiration. Periodic breathing is considered a benign disorder. Infants with symptomatic apneic episodes that result in apparent life-threatening events are thought to be at increased risk for sudden infant death syndrome.⁴⁹

PULSE

Examine the pulse to establish the cardiac rate and regularity of the rhythm. Though rarely diagnostic, peripheral pulses may yield clues about cardiac disease, such as aortic insufficiency, and information about the integrity of the peripheral vascular supply. Doppler ultrasound has utility in locating a pulse, assessing fetal heart tones beyond the first trimester of pregnancy, evaluating peripheral lower extremity vascular insufficiency with an ankle-brachial index, and assessing blood pressure in infants or in patients with low-flow states.

Physiology

Blood flowing into the aorta with each cardiac cycle initiates a pressure wave. Blood flows through the vasculature at approximately 0.5 m/sec, but pressure waves in the aorta move at 3 to 5 m/sec. Therefore palpated peripheral pulses represent pressure waves, not blood flow.

Indications and Contraindications

Assessment of blood flow by palpation of the pulse can be used to gauge the presence of cardiac contractility and not just the electrical rhythm. Caution should be taken to not overgeneralize the presence or strength of a pulse when predicting blood pressure. The necessity for repeated pulse evaluations is dictated by the clinical complaint and the status of the patient. Continuous monitoring is not routine but may be helpful when the clinical situation predicts significant variability in heart rate, as in the setting of sepsis.^{50,51} An association between absence of a radial pulse or absence of both radial and femoral pulses and hypotension has been demonstrated in hypovolemic trauma patients. The variability in individual response prohibits the use of this parameter as an absolute gauge of blood pressure.⁵²

No contraindications exist to assessment of the pulse rate. Keep in mind a few cautionary notes about examination of the carotid pulse. Avoid concurrent bilateral carotid artery palpation because this maneuver could theoretically endanger cerebral blood flow. Massage of the carotid sinus, found at the bifurcation of the external and internal carotid arteries at the level of the mandibular angle, may result in reflex slowing of the heart rate. To avoid inadvertent carotid sinus massage, palpate the carotid pulse at or below the level of the thyroid cartilage. In adults with atherosclerotic disease, there is a rare risk of precipitating a cerebrovascular event by vigorous palpation of the carotid artery. Minimize this risk by prior auscultation of the carotid artery. If a bruit is present, gently palpate the carotid pulse while avoiding vigorous palpation, or use a Doppler ultrasound probe to assess carotid flow instead.

Procedure

Depending on the clinical scenario, pulses are palpable at numerous sites, although for convenience the radial pulse at the wrist is routinely used. Use the tips of the first and second fingers to palpate the pulse. The two advantages of this technique are that (1) the fingertips are quite sensitive, thereby enabling the pulse to be located easily and counted, and (2) the examiner's own pulse may be erroneously counted if the thumb is used. Pulses are easily palpated at the carotid, brachial, femoral, posterior tibial, and dorsalis pedis arteries. Palpate

the pulse at the brachial artery to appreciate its contour and amplitude. Locate the pulse at the medial aspect of the elbow and note that it is more easily palpated when the elbow is held slightly flexed.⁵³ Determine the pulse rate by counting for 1 minute, particularly if any abnormality is present. Common convention in the acute care setting is to count a regular pulse for 15 seconds and multiply the resulting number by 4 to determine the beats per minute.

In neonates, use direct heart auscultation and umbilical palpation as the methods of choice to determine the heart rate. Instantaneous changes in newborn heart rates are best indicated to the resuscitation team by the clinician tapping out each heartbeat.⁵⁴ In unstable children, palpate the central arteries, particularly the femoral and brachial pulses, instead of the more peripheral arteries. In a comparison of four methods of determining the heart rate in infants, listening at the apex of the heart was found to be more accurate than palpation of the brachial, carotid, or femoral pulses.⁵⁵ Of the sites for palpation of the heart rate, the femoral artery has proved most valuable, especially in hypotensive infants.⁵⁶

Interpretation

Pulse Rate

Consider the individual's physiology when interpreting the pulse. In infants and children, interpret the pulse rate with reference to age (see [Table 1.1](#)). Pulse varies with respiration: it increases with inspiration and slows with expiration. This is known as sinus dysrhythmia and is physiologic.

Although *bradycardia* is most commonly defined as a heart rate lower than 60 beats/min in adults, a well-conditioned athlete may have a normal resting heart rate of 30 to 40 beats/min.^{57,58} As discussed earlier, a redefinition of bradycardia to less than 45 beats/min and tachycardia to greater than 95 beats/min has been proposed based on a normal healthy population.^{22,59} Such definitions include 95% of the population and do not address any given individual's normal baseline rate.

Consider whether a patient's abnormal pulse rate is a primary or secondary condition. Examine the entire set of vital signs when attempting to discern the cause of the abnormal rate. For example, hyperthermia causes sinus tachycardia. Drug fever, typhoid fever, and central neurogenic fever are considerations when no corresponding tachycardia is found in a patient with elevated body temperature. Hypothermia, with its reduced metabolic demands, may be associated with bradycardia. Some disease states are defined by their effect on heart rate, such as thyrotoxicosis with tachycardia or myxedema coma with bradycardia.

Consider the medications that the patient may be taking or the presence of a mechanical pacemaker. Digitalis compounds, β -blockers, and antidysrhythmics may alter the normal heart rate and the ability of this vital sign to respond to a new physiologic stress. These cardioactive medications may cause the abnormality in the patient's heart rate. Nonprescription drugs can be equally significant in their effect on heart rate. Sympathomimetic drugs such as cocaine and methamphetamine increase heart rate, as do anticholinergic drugs.

Heart Rhythm

In addition to determining the pulse rate, obtain information about the regularity of the pulse by palpation. An irregular pulse suggests atrial fibrillation or flutter with variable block, and accurate assessment of the pulse should be carried out by

auscultation of the apical cardiac sounds. The apical pulse is frequently greater than the peripheral pulse because of inadequate filling time and stroke volume, with resultant nontransmitted beats. A greater pulse deficit generally reflects more severe disease.⁶⁰

Pulse Amplitude and Contour

Accurate examination and description of pulse amplitude and contour can provide additional clinical information and aid in decision making. Superimposition of one pathophysiologic state on another may modify the pulse. For example, sepsis may result in variable pulse amplitudes, depending on the stage in the development of the disease. Early in sepsis, cardiac output increases and vascular resistance decreases, causing bounding pulses. In advanced sepsis or septic shock, falling cardiac output and increased vascular resistance are seen, and pulses are diminished.⁶¹ Definable age-related changes in pulse amplitude and contour can be identified. Such changes are due to an increase in arterial stiffness, resulting in increased pulse wave velocity and progressively earlier wave reflection. This leads to increased pulse amplitude in the elderly at all commonly measured sites (carotid, femoral, and radial).⁶¹ In addition to these age-related changes, pulse wave analysis may be useful in determining arterial stiffness and the likelihood of atherosclerotic disease in a vascular laboratory setting.⁶² If present globally, weak pulses can be a significant finding in hypotensive patients, or an indication of limb ischemia if isolated to one extremity. Bounding pulses can be seen with a widened pulse pressure and are discussed later in the section on blood pressure. Routine measurement of pulse amplitude is not reproducible by simple palpation and requires instrumentation not available in EDs.

Pulses During Cardiopulmonary Resuscitation

Palpated femoral pulses during chest compression may represent either forward arterial blood flow or “to-and-fro” movement of blood from the right side of the heart to the venous system. A carotid pulse is preferred when assessing the adequacy of chest compressions during cardiopulmonary resuscitation (see Chapter 17).

ARTERIAL BLOOD PRESSURE

Systolic blood pressure changes with each heartbeat. Changes in arterial blood pressure over time may indicate success of treatment or worsening of the patient’s overall condition. An abrupt reduction in a patient’s arterial blood pressure usually indicates the need for immediate intervention or reconsideration of therapy. The current section discusses indirect blood pressure monitoring; intraarterial techniques are considered elsewhere. Discussion of the specific use of the Doppler device for measurement of pulse and blood pressure and for measurement of orthostatic blood pressure and changes in pulse follow this section. Despite an association between the absence of hypotension and the presence of a radial pulse or between hypotension and the absence of both radial and femoral pulses in the setting of trauma, the variability in individual responses prohibits the use of this parameter as an absolute gauge of blood pressure.⁵³

Physiology

Arterial blood pressure indicates the overall state of hemodynamic interaction between cardiac output and peripheral vascular

resistance. Arterial blood pressure is the lateral pressure or force exerted by blood on the vessel wall. It indirectly measures perfusion, and blood flow equals the change in pressure divided by resistance. Because peripheral vascular resistance varies, a normal blood pressure does not confirm adequate perfusion.⁶³ Mean arterial blood pressure (MAP) can be estimated by adding one third of the pulse pressure (i.e., the difference between systolic and diastolic blood pressure) to diastolic pressure or by using the following measure^{64,65}:

$$\text{MAP} = \frac{\text{Diastolic pressure} \times 2 + \text{Systolic pressure}}{3}$$

Many modern bedside telemetry monitors automatically incorporate MAP measurements into the blood pressure systolic and diastolic pressure readings.

Indications and Contraindications

Patients with minor ambulatory complaints unrelated to the cardiovascular system may not necessarily need their blood pressure measured in the ED, and those with hemodynamic instability need frequent monitoring of blood pressure. In children, there is a significant amount of variability regarding standard situations that require measurement of blood pressure. In general, the younger the patient, the less likely blood pressure will be measured.^{66,67} In newborns, infants, and even toddlers, capillary refill is sometimes substituted for standard blood pressure measurement, although viewing these tests as equivalent can lead to significant errors.

In low-flow states, Doppler measurement of blood pressure may be obtained rapidly. Repeated measurements will provide an evaluation of the adequacy of resuscitation in patients whose blood pressure cannot be auscultated by standard techniques and in those in whom intraarterial blood pressure measurements are either contraindicated or technically unobtainable.^{68,69} Placing a catheter for direct intraarterial measurement of blood pressure may be performed safely in the ED, but is not standard of care and has a higher risk for complications. In particular, direct measurement of arterial pressure during pulseless electrical rhythms may help discriminate between a severe shock state and otherwise nonresuscitatable status.^{70,71} Alternative noninvasive devices for continuous blood pressure measurement (CBPM) have been introduced clinically, with varying success. One common method of CBPM uses finger cuffs equipped with infrared (IR) photoplethysmography and sophisticated technology for quantification of finger blood pressure levels. Finapres (Ohmeda, Madison, WI) was the first commercial product using this technique, and several newer products are on the market today. A number of commercial systems use an alternative method of arterial applanation tonometry to measure CBPM. Further study is needed for the validation of devices using these techniques.^{72,73}

Relative contraindications to specific extremity blood pressure measurement include an arteriovenous fistula, ipsilateral mastectomy, axillary lymphadenopathy, lymphedema, and circumferential burns over the intended site of cuff application.

Equipment

Two types of blood pressure monitoring equipment are currently available and used in EDs: cuff type and noninvasive waveform analysis.

Cuff Type

The equipment required for indirect blood pressure measurement includes a sphygmomanometer (cuff with an inflatable bladder, inflating bulb, controlled exhaust for deflation, and manometer) and a stethoscope, Doppler device (for auscultation), or oscillometric device.⁷⁴⁻⁷⁶ A common practice in the prehospital and interhospital transport setting is to forego auscultatory blood pressure measurements with a stethoscope and instead obtain systolic values only by palpation of the first Korotkoff sound. This practice, though sometimes the only feasible method of obtaining any value in a noisy environment, poses a significant potential for error.

According to the American Heart Association guidelines, the sphygmomanometer cuff should be an appropriate size for the patient to ensure an accurate reading. The width of the bladder should be at least 40% of the distance of the limb's midpoint (i.e., from the acromion process to the lateral epicondyle). This published figure of the ideal width, when studied in a validation review, may be higher, up to approximately 50%.⁷⁷ The length of the bladder should be 80% of the midarm circumference or twice the recommended width.⁶⁸ Discrepancies in matching upper arm size with cuff size have been demonstrated to produce significant errors in critically ill populations when compared with invasive intraarterial blood pressure measurements.⁷⁸ The availability of appropriately sized cuffs appears to be a pervasive problem, especially as approximately 80% of patients do not fit the standard 12-cm large cuffs.⁷⁹ In one study, 90% of aneroid devices had only one size of cuff available.⁸⁰ A second study phase from this group showed no marked improvement in agreement of oscillatory and invasive measurements, despite using the correct cuff size.⁸¹

The manometers in common use are either aneroid, digital, or mercury gravity column, though the mercury type is much less common in modern use. All three types of manometers are convenient for bedside use, although the mercury gravity column must be placed vertically to ensure accurate measurements. An aneroid manometer uses a metal bellows that elongates with the application of pressure. This elongation is mechanically amplified and transmits the motion to the indicator needle.

Manometers require annual servicing. Mercury columns may require the addition of mercury to bring the edge of the meniscus to the zero mark. The air vent or filter at the top of the mercury column should also be checked for clogging. An aneroid manometer should be calibrated against a mercury column at least yearly. If the aneroid indicator is not at zero at rest, the device should not be used.⁸² Digital manometers may not be validated for all patient groups and could give inaccurate readings.

Automatic sphygmomanometers may improve physiologic monitoring with their alarm and self-cycling capabilities. They offer indirect arterial blood pressure measurement with little pain and without the risks associated with invasive arterial lines.⁸³ Accuracy of measurements does not suffer during rapid cycling, and the potential for vascular injury from nearly continuous arterial compression dictates that most automated blood pressure units will revert back to less frequent (i.e., every 15 to 20 minutes) cycling as a safety precaution. Oscillometric blood pressure monitors detect motion of the blood pressure cuff transmitted from the underlying artery. A sudden increase in the amplitude of arterial oscillations occurs with systolic pressure and MAP, and an abrupt decrease occurs with diastolic pressure.⁸⁴

There appears to be less variability with the oscillometric blood pressure method than with the auscultatory method in children. These results are not generalizable to the neonatal population, and errors are commonly encountered even when exhaustive measures are taken to control the environment.

In adult patients, numerous studies have focused on the reliability of auscultatory versus automated blood pressure measurements. Mercury column versus Dinamap readings showed increased disparity when systolic blood pressure was greater than 140 mm Hg, the range at which accuracy should be most rigorously sought to correctly identify hypertension. In general, automated blood pressure devices yield higher systolic and lower diastolic blood pressure.⁸⁵ The range of error in automated devices was, on average, 4.0 to 8.6 mm Hg.^{86,87} Unfortunately, these studies represent populations without critical illness and do not reflect the accuracy of readings at the extremes of hypertension and hypotension, thus making generalization to an ED population difficult.^{87,88} Like most durable medical equipment, sphygmomanometers are subject to deterioration with use. Automatic sphygmomanometer validation is a form of calibration and deserves quality control and traceability to ensure accurate results.⁸⁸

Procedure

Obtain indirect blood pressure measurements at the patient's bedside by palpation, auscultation, Doppler, or oscillometric methods. The technique is straightforward and accurate when the equipment is well maintained, calibrated, and used by clinicians who follow accepted standards. The patient may be lying or sitting, as long as the site of measurement is at the level of the right atrium and the arm is supported.^{68,76} Unless the arm is kept perpendicular to the body with the elbow resting on a desk, measurements will be 9 to 14 mm Hg higher, regardless of body position.^{77,89} Allowing the arm to be parallel to the body when supine and supporting the arm perpendicular to the body when measuring blood pressure may create a pseudo-drop in blood pressure. These changes are thought to be dependent on the mechanical properties of the arteries themselves and not associated with hydrostatic pressure alone.⁹⁰

To palpate arterial blood pressure, inflate the cuff to 30 mm Hg above the level at which the palpable pulse disappears. Once properly inflated, palpate directly over the artery and deflate the cuff at a rate of 2 to 3 mm Hg/sec. Report the initial appearance of arterial pulsations as the palpable blood pressure. This practice, known as the Riva-Rocci palpatory technique, has shown mixed results in yielding accurate estimations of blood pressure. One study determined that the average underestimation of systolic blood pressure was 6 mm Hg.⁹¹ Another operative study looking at the combination of palpated systolic blood pressure and observed visual return of continuous pulse oximetry reported an underestimation of 10 to 20 mm Hg.⁸⁷ The same technique is used with the Doppler device, and the palpated pulse is replaced with the Doppler auditory signal. Measurement of arterial pressure by palpation and Doppler yields only estimates of systolic blood pressure. The Doppler method is preferred when determining blood pressure in infants.⁸⁸

When auscultating blood pressure at the brachial artery, apply the blood pressure cuff approximately 2.5 cm above the antecubital fossa with the center of the bladder over the artery.⁷⁶ Apply the bell of the stethoscope directly over the brachial artery with as little pressure as possible.⁹² *Systolic arterial blood*

Figure 1.2 Korotkoff sounds. The first audible sound occurs in systole, and the sound disappears in diastole. (From Burnside JW, McGlynn TJ: *Physical diagnosis*, ed 17, Baltimore, 1986, Williams & Wilkins.)

pressure is defined as the first appearance of faint, clear, tapping sounds that gradually increase in intensity (Korotkoff phase I). *Diastolic blood pressure* is defined as the point at which the sounds disappear (Korotkoff phase V).⁹³ In children, phase IV defines diastolic blood pressure (Fig. 1.2).⁷ Phase IV is marked by a distinct, abrupt muffling of sound when a soft, blowing quality is heard.

It is best to auscultate over the brachial artery because of accepted standardization of the measured values. Alternative sites include the radial, popliteal, posterior tibial, or dorsalis pedis arteries, although any fully compressible extremity artery may be used. Studies evaluating direct and indirect blood pressure measurements have demonstrated good correlation between these methods.^{94,95}

Occasionally it may not be feasible to obtain proximal upper extremity blood pressure measurements because of patient access issues, particularly those encountered in the prehospital setting. Forearm measurements may be obtained more easily, though correlation to standard proximal upper extremity values has been controversial. An earlier study showed fair correlation to a brachial cuff measurement (within 20 mm Hg in 86% of systolic measurements and 94% of diastolic measurements).⁹⁶ A subsequent study demonstrated that forearm measurements cannot routinely replace upper arm measurements to determine blood pressure (the potential variance from an upper arm measurement is ± 19 mm Hg for systolic pressure).⁹⁷ Alternatively, noninvasive finger blood pressure measurements have shown promise when compared with standard upper extremity readings. The overall discrepancy in an ED study was 0.1 mm Hg with a standard deviation of ± 5.02 mm Hg when

comparing finger blood pressure and invasive MAP via radial artery cannulation.⁹⁸

Novel noninvasive continuous finger cuff technology offers the benefit of uninterrupted monitoring and has the advantage over invasive techniques of being safer and immediately available. Noninvasive finger cuff measurements have shown reasonable correlation, even in critically ill populations in the ED.⁷³ Wrist blood pressure has been shown to have good average accuracy in the surgical environment when compared with oscillometric devices. Patient comfort is reported to be greater with these devices. The typically stated contraindications to the acquisition of upper arm blood pressure (limitation after mastectomy, etc.) may not apply.⁹⁹

The accuracy of the palpatory, Doppler, and oscillometric methods has also been investigated.^{100–102} When phase I and V Korotkoff sounds are used, indirect methods typically underestimate systolic and diastolic pressure by several millimeters of mercury.^{100–103} During shock, the palpatory and auscultatory methods underestimate simultaneous direct arterial pressure measurements.¹⁰⁴ The flush method, in which the return of color after deflation of the cuff is used to estimate blood pressure in infants, may underestimate systolic blood pressure by up to 40 mm Hg.¹⁰⁵ This method is unreliable and not recommended.

Complications

Complications of indirect blood pressure measurements are minimal when the proper procedure is followed. Inadvertent prolonged application of an inflated blood pressure cuff may result in falsely elevated diastolic pressure and ischemia distal to the site of application.⁷⁸ Invasive blood pressure monitoring is associated with a number of potential problems (see Chapter 20).

Interpretation

Normal blood pressure increases with decreasing distance from the heart and aorta. Blood pressure tends to increase with age and is generally higher in males. Individual factors that influence blood pressure include body posture, emotional or painful stimuli, environmental influences, vasoactive foods or medications, and the state of muscular and cerebral activity. Exercise and sustained isometric muscular contraction increase blood pressure in proportion to the strength of the contraction. A normal diurnal pattern of blood pressure consists of an increase throughout the day with a significant, rapid decline during early, deep sleep.¹⁰⁶

Normal lower limits of systolic blood pressure in infants and children can be estimated by adding 2 times the age (in years) to 70 mm Hg. The 50th percentile for a child's systolic arterial blood pressure from 1 to 10 years of age can be estimated by adding 2 times the age (in years) to 90 mm Hg. Children older than 2 years are considered hypotensive when systolic blood pressure is less than 80 mm Hg.¹⁰⁷ Children are able to maintain MAP until very late during shock.¹⁰⁸ The finding of a normal blood pressure in a child with signs of poor perfusion should not dissuade the clinician from appropriate treatment. Most adults are considered hypotensive if systolic blood pressure is lower than 90 mm Hg, but some individuals normally exhibit a systolic pressure in that range. In the elderly, the presence of normotension within defined or published limits may not be reassuring. When considering systolic blood pressure cutoffs

for trauma patients, 85 mm Hg for patients aged 18 to 35 years, 96 mm Hg for patients aged 36 to 64 years, and 117 mm Hg for those older than 65 years have been proposed as new standards for hypotension.¹⁸ When accompanied by signs of shock, immediate treatment is indicated. In patients with shock, blood flow cannot be reliably inferred from heart rate and blood pressure values.^{109,110}

Hypertension

Adults are hypertensive if either systolic or diastolic pressure consistently exceeds 140 or 90 mm Hg, respectively.^{111,112} A meta-analysis showed strong correlation of blood pressure to vascular (and overall) mortality down to at least 115/75 mm Hg.¹¹³ Some authors have suggested altering the blood pressure definitions to include an “optimal” blood pressure of 115/75 mm Hg.¹³ Other authors have suggested incorporating blood pressure into a global cardiovascular risk assessment that includes other associated risk factors.^{14,15} The applicability of population norms for hypertension in a stressful emergency situation is controversial. One should not make diagnostic or therapeutic decisions based solely on an abnormal initial measurement. Patients with hypertension require repeated measurements to assess whether therapy is required in the ED. Because sustained hypertension may be seen in more than one third of initially hypertensive ED patients, careful evaluation and follow-up are required.¹¹⁴ Unfortunately, elevated blood pressure readings are still almost uniformly ignored or unrecognized in the emergency setting, particularly in children.¹¹⁵ The phenomenon of *white coat hypertension* (WCH) is defined as a persistent elevation in blood pressure in the clinical setting only. The prevalence of WCH is between 20% and 94%, depending on the frequency of reassessment in the clinical setting.¹¹⁶ It is unclear whether patients who have isolated hypertension in the clinical setting (WCH) are at increased risk for the development of hypertension and subsequent end-organ damage.¹¹⁷

Measurement Errors

Erroneous blood pressure measurements may result from several factors.¹¹⁸ Falsely low blood pressure may be caused by using an overly wide cuff, by placing excessive pressure on the head of the stethoscope, or by rapid cuff deflation.^{119,120} Falsely high blood pressure may be caused by the use of an overly narrow cuff, anxiety, pain, tobacco use, exertion, an unsupported arm, or slow inflation of the cuff.¹²¹ There appears to be a statistically significant difference in the error rate associated with patients weighing more than 95 kg, whether from obesity or as a result of muscular upper arms from body building.^{122,123}

Of note, 41% of adults observed at the University of Pittsburgh required non-standard-sized cuffs, and the use of small cuffs was associated with a mean error of 8.5 and 4.6 mm Hg in systolic and diastolic pressure, respectively.¹²⁰ Other studies have confirmed relatively high rates of inappropriately diagnosed hypertension in obese patients based on erroneous cuff size.¹²² Other specific study populations in this area have been critically ill patients, in whom disparate cuff size can lead to significant inaccuracies based on arm circumference.⁸⁴

Hypotensive patients have unreliable Korotkoff sounds, but Doppler measurements are well correlated with direct arterial systolic pressure measurements in these patients.¹²⁴ An auscultatory gap can be appreciated in hypertensive patients and may mislead the clinician. It is heard during the latter part of phase I and should not be confused with diastolic readings. Auscultation

until the manometer reading approaches zero should prevent misinterpretation. In patients with aortic insufficiency or hyperthyroidism, in those who have just finished exercising, and in children younger than 5 years, measurement of diastolic blood pressure should occur at Korotkoff phase IV. Extremes of blood pressure, both hypotension and hypertension, have been found to be factors contributing to measurement errors in critically ill pediatric patients. Predictably, falsely high readings for noninvasive versus invasive measurements have been obtained in hypotensive patients and falsely low values in hypertensive states.¹²⁵

Irregular heart rates may also interfere with accurate determination of blood pressure. Take a second or third reading, with 2 minutes of deflation between recordings, and obtain an average when premature contractions or atrial fibrillation are present.

Hemiplegic patients may exhibit different blood pressures in the affected and unaffected arms.¹²⁶ A flaccid extremity tends to yield lower systolic and diastolic pressure, whereas a spastic extremity tends to yield higher values than the extremity with normal motor tone. Although these differences are generally small, it is preferable to monitor blood pressure in the unaffected limb.

Numerous errors may occur in the accurate measurement of blood pressure. The only way to combat these errors is to first be cognizant of practices contributing to them. Unfortunately, few nurses can identify causes of potentially erroneous readings. In a study examining nurses' ability to obtain accurate readings, proper technique in determining systolic blood pressure could be identified 61% of the time; diastolic blood pressure, 71% of the time; and an auscultatory gap, 54% of the time. Nurses were able to correctly identify faulty equipment 58% of the time, assess cuff size 57% of the time, determine appropriate inflation pressure 29% of the time, note the appropriate deflation rate 62% of the time, and determine correct arm positioning 14% of the time.¹²⁷

There is an increasing number of patients with heart failure, those receiving bridging measures to transplantation, or those treated with long-term circulatory augmentation devices in the form of left ventricular assist devices (LVADs); therefore it is useful to understand the difficulty in interpreting blood pressure measurements in these patients. All types of VADs fit into two categories: (1) pulsatile and (2) nonpulsatile. Pulse and blood pressure readings in patients with pulsatile VADs (Thoratec, HeartMate XVE, Novacor, C-Pulse) are comparable to values in the general non-VAD population. Nonpulsatile VADs (HeartAssist 5, Incor and Excor, Jarvik 2000, VentriAssist, MTIHeart LVAD, HVAD/MVAD, DuraHeart, DeBakey LVAD, HeartMateII/III) function by either centrifugal or axial blood flow, and this has a significant impact on the ability to detect pulses.¹²⁸ Typically, these patients appear to be well-perfused with adequate skin warmth and capillary refill even though pulses may be absent. Blood pressure readings can be obtained with these nonpulsatile flow devices, and diastolic blood pressure, pulse pressure values, and MAP vary significantly depending on the speed of the pump.¹²⁹

Pulse Pressure

The difference between systolic and diastolic pressure is termed pulse pressure. For example, if the blood pressure is 120/80 mm Hg, the pulse pressure is 40 mm Hg. Increased pulse pressure (i.e., ≥ 60 mm Hg) is commonly observed with anemia, exercise, hyperthyroidism, arteriovenous fistula, aortic

regurgitation, increased intracranial pressure, and patent ductus arteriosus. A narrowed pulse pressure (≤ 20 mm Hg) may be a manifestation of hypovolemia, increased peripheral vascular resistance (as seen in early septic shock), or decreased stroke volume. A narrowed pulse pressure is classically noted in aortic stenosis and pericardial tamponade. Traditional vital sign measurements, such as systolic blood pressure and oxygen saturation, often fail to predict mortality or indicate the need for life-saving interventions or reductions in central blood volume until after the onset of cardiovascular collapse. There is evidence that an early indicator of reduced central blood volume in the presence of stable vital signs is the reduction in pulse pressure.¹³⁰

Differential Brachial Artery Pressure

The presence of a systolic blood pressure difference of 10 to 20 mm Hg between the arms suggests a normal condition. If greater, it may indicate advanced focal atherosclerosis, coarctation of the aorta proximal to the left subclavian artery, type A aortic dissection, aortic arch syndromes, or other vascular processes preferentially affecting one extremity. The utility of upper extremity bilateral blood pressure measurements has recently come into question. One study found a 10-mm Hg systolic or diastolic difference in 53% of patients in the emergency setting and a 20-mm Hg or higher difference in 19% of patients.¹³¹ Although these numbers have not generally been found to be of this magnitude in metaanalyses,¹³² the unique setting of the study in the ED makes correlation particularly salient for the emergency physician. The reliability of peripheral pulse deficits in diagnosing or excluding type A aortic dissection is a frequently cited reason for evaluating blood pressure in both arms. In a metaanalysis, Teece and Hogg noted that the successful use of the absence of a clinical pulse deficit to exclude thoracic dissection in patients with chest pain was just 31%, and the authors concluded that peripheral pulse deficits are far too insensitive to warrant their use as a means of excluding thoracic aortic dissection in patients with chest pain.¹³³ Given that many in the general population have significant differences in blood pressure in each arm, the diagnostic value of this frequently cited indication for obtaining bilateral brachial blood pressure is unproven. Essentially, most patients with a type A aortic dissection will not have a measurable blood pressure discrepancy between the arms, and most of those who do have such a finding will not have dissection.

Brachial pressure differences did not appear to be linked to age, gender, race, MAP, cardiovascular risk, or final discharge diagnosis. Smaller interarm differences have been reported in the ED setting (18% in hypertensive patients and 15% in normotensive patients when a cutoff greater than 10 mm Hg was used).^{16,17} Though not tested, a method proposed to minimize these differences in the ED is to take simultaneous blood pressure readings from both the left and right extremities with two calibrated automated blood pressure units.¹³⁴

Pulse-Pressure Variation

Fluid resuscitation is an integral piece of the management of patients with circulatory failure, though administration of the proper amount and rate of parenteral fluids can be challenging. Fluid responsiveness, or the ability of the left ventricle to increase stroke volume in response to fluid administration, is an emerging concept that helps to address this challenge.¹³⁵ This concept is based on the physiology of the Frank–Starling

curve and the knowledge that pulse pressure (systolic pressure minus diastolic pressure) is directly proportional to stroke volume. The variation in pulse pressure seen with the respiratory cycle, or *pulse-pressure variation*, reflects the magnitude of respiratory change on stroke volume. This is best demonstrated by the influence of mechanical ventilation on right ventricular preload. Studies have shown that a pulse-pressure variation of greater than 13% is highly predictive of fluid responsiveness in mechanically ventilated patients.¹³⁶

Though many methods exist to assess fluid responsiveness, the standard method is done with passive leg raising (PLR). This “self-volume challenge” increases preload through translocation of venous blood from the lower extremities to the thorax. A patient who exhibits a rise of more than 10% in their aortic blood flow (measured with esophageal Doppler) or cardiac index (measured with thermodilution) is considered a “fluid responder,” which is indicative of the need for further fluid administration.¹³⁵ This concept is becoming increasingly useful in optimizing the fluid management of critically ill patients.

Pulsus Paradoxus

Normal respiration briefly decreases systolic blood pressure by approximately 10 mm Hg during inspiration. Pulsus paradoxus occurs when there is a greater than 12-mm Hg decrease in systolic blood pressure during inspiration. Pulsus paradoxus may occur in patients with chronic obstructive pulmonary disease, pneumothorax, severe asthma, or pericardial tamponade.¹⁰⁴

To measure a paradoxical pulse, have the patient lie comfortably in the supine position at a 30- to 45-degree angle and breathe normally in an unlabored fashion (which are unusual conditions in a patient suspected of having cardiac tamponade, severe asthma, chronic obstructive pulmonary disease, or pneumothorax).¹³⁷ Inflate the blood pressure cuff well above systolic pressure and slowly deflate it until the systolic sounds that are synchronous with expiration are first heard (Fig. 1.3). Initially, the arterial pulse will be heard only during expiration and will disappear during inspiration. Deflate the cuff further until arterial sounds are heard throughout the respiratory cycle. Palpation at the radial or femoral arteries may yield complete disappearance during inspiration. When present, this technique is a quick bedside confirmation of the possibility of severe tamponade.

An alternative method for determination of pulsus paradoxus is by visually observing the loss of the pulse oximetry waveform and then its reappearance.¹³⁸ The plethysmographic method has been validated in intensive care unit settings.

If the difference between inspiratory and expiratory pressure is greater than 12 mm Hg, the paradoxical pulse is abnormally wide.^{137,138} Most patients with proven tamponade have a difference of 20 to 30 mm Hg or greater during the respiratory cycle.^{137–139} This may not be true of patients with very narrow pulse pressures (typical of advanced tamponade), who have a “deceptively small” paradoxical pulse of 5 to 15 mm Hg.^{139–141}

Pulsus paradoxus has been correlated with the level of impairment of cardiac output by tamponade. In an uninjured patient with pericardial effusion, a pulsus paradoxus greater than 25 mm Hg (in the absence of relative hypotension) is both sensitive and specific for moderate or severe versus mild tamponade.^{137,142} An echocardiographic study found that an abnormal pulsus paradoxus had a sensitivity of 79%, a specificity of 40%, a positive predictive value of 81%, and a negative predictive value of 40% for right ventricular diastolic

PROCEDURE FOR THE MEASUREMENT OF PULSUS PARADOXUS

The patient should be reclining at a 30° to 45° angle and instructed to breathe normally.

1. Inflate a standard blood pressure cuff until Korotkoff sounds over the brachial artery disappear.
2. Lower pressure in the cuff a few millimeters of mercury per second until the first Korotkoff sounds appear during expiration.
3. Maintain pressure at this level and observe the disappearance of sounds during inspiration. Record this cuff pressure.
4. Very slowly lower cuff pressure until Korotkoff sounds are heard throughout the respiratory cycle. Record this cuff pressure.
5. The difference between pressures recorded in the two previous steps is then recorded as the measurement (in millimeters of mercury [mm Hg]) of pulsus paradoxus. A pulsus paradoxus >12 mm Hg is abnormal but nonspecific (see text).

B

Figure 1.3 A, Measurement of pulsus paradoxus. Note that systolic pressure varies during the respiratory cycle. Inspiration normally decreases systolic blood pressure slightly (termed paradoxical pulse), but if the difference between inspiratory and expiratory systolic pressure is greater than 12 mm Hg, the paradoxical pulse is abnormally wide. B, Technique for measurement of pulsus paradoxus. (A, From Stein L, Shubin H, Weil M: Recognition and management of pericardial tamponade. *JAMA* 1973;225:504. Copyright 1973, American Medical Association. Reproduced with permission.)

collapse.¹⁴²⁻¹⁴⁴ The absence of a paradoxical pulse does not rule out tamponade.

In the pediatric population, pulsus paradoxus has been studied to determine the severity of obstructive and restrictive pulmonary disease,¹⁴³ most commonly asthma. A value of 15 mm Hg or greater correlates well with the clinical score, peak expiratory value, flow rate, oxygen saturation, and subsequent need for admission.¹⁴⁴

Despite the disease entities that a widened pulsus paradoxus may suggest, it is a difficult test to perform adequately with only a sphygmomanometer. Because it is a useful clinical tool, new aids should be developed and used to reliably predict this important vital sign.¹⁴⁵

Shock Index

The ratio of pulse rate to systolic blood pressure has been suggested as a measure of clinical shock. The shock index (SI) has a normal range of 0.5 to 0.7. Although calculating the SI is not standard of care in the ED, a number of clinical scenarios have been studied in which the SI can be used as a predictor of severe illness or injury. An SI above 0.85 to 0.90 suggests acute illness in medical patients and a marked increase in the potential for gross hemodynamic instability in trauma

patients.¹⁴⁶⁻¹⁴⁹ The SI has been studied for use in a variety of clinical scenarios from severe pneumonia to first-trimester risk for ectopic pregnancy to sepsis. It has been found to be a valid gauge of the severity of illness.¹⁵⁰⁻¹⁵² Some studies have found that the initial pulse rate alone had nearly the same predictive power as the SI for the severity of illness. Although the SI appears to correlate with the left ventricular stroke work index, it has little correlation with systemic oxygen transport in patients with hemorrhagic and septic shock.¹⁵³

DOPPLER ULTRASOUND FOR EVALUATION OF PULSE AND BLOOD PRESSURE

Principles of Doppler Ultrasound

Doppler ultrasound is based on the Doppler phenomenon. The frequency of sound waves varies depending on the speed of the sound transmitter in relation to the sound receiver. Doppler devices transmit a sound wave that is reflected by flowing erythrocytes, and the shift in frequency is detected. Frequency shift can be detected only for blood flow greater than 6 cm/sec.

Indications and Contraindications

Doppler ultrasound is commonly used in the ED for the measurement of blood pressure in low-flow states, evaluation of lower extremity peripheral perfusion, and assessment of fetal heart sounds after the first trimester of pregnancy. Doppler's sensitivity allows detection of systolic blood pressure down to 30 mm Hg in the evaluation of a patient in shock. In a patient with peripheral vascular disease in whom there is concern about the adequacy of peripheral perfusion, the ankle-brachial index provides a rapid, reproducible, and standardized assessment.¹⁵² Fetal heart sounds provide a baseline assessment of any pregnant patient with 12 weeks' gestation or longer in the setting of abdominal trauma or fetal distress as a result of a complication of pregnancy. The use of Doppler ultrasound for the evaluation of deep venous thrombosis is a valuable tool, and specific training and experience are required to attain proficiency. Discussion of this topic is beyond the scope of this chapter.

Equipment

A nondirectional Doppler device has a probe that houses two piezoelectric crystals. One crystal transmits the signal and the other receives it. Reflected signals are converted to an electrical signal and fed to an output that transforms them to an audible sound.

Probes with a frequency of 2 to 5 MHz are best for detecting fetal heart sounds. Frequencies of 5 to 10 MHz are appropriate for limb arteries and veins. The probes should be monitored periodically for electrical damage and integrity of the crystals. The sphygmomanometers used in conjunction with the Doppler device should be calibrated periodically, as described in the section on evaluation of blood pressure.

Procedure

Place the Doppler probe against the skin with an acoustic gel used as an interface. The gel ensures optimal transmission and

reception of the ultrasound signal and protects the crystals. In an emergency, water-soluble lubricant (e.g., Surgilube or K-Y Jelly) may be substituted for commercial acoustic gel. Angle the probe at 45 degrees along the length of the vessel to optimize frequency shifts and signal amplitude.

To evaluate peripheral perfusion, place a sphygmomanometer cuff proximal to where the arterial pulse is being evaluated and inflate it. Place the probe over the arterial pulse and slowly deflate the cuff. The pressure at which flow is first heard is the systolic pressure under the cuff, and not the pressure at the level of the Doppler probe.

In the evaluation of peripheral vascular disease, one may determine the ankle-brachial index. It is standard for this procedure to be performed in a formal vascular laboratory, and an approximation of pressures can be determined in the ED (Fig. 1.4 and Video 1.1). Usually, only the ankle-brachial index is considered for ED purposes. Examine both brachial arteries at the medial aspect of the antecubital fossa. Angle the probe until the most satisfactory signal is obtained. Inflate the cuff and slowly deflate it until the systolic pulse is heard.

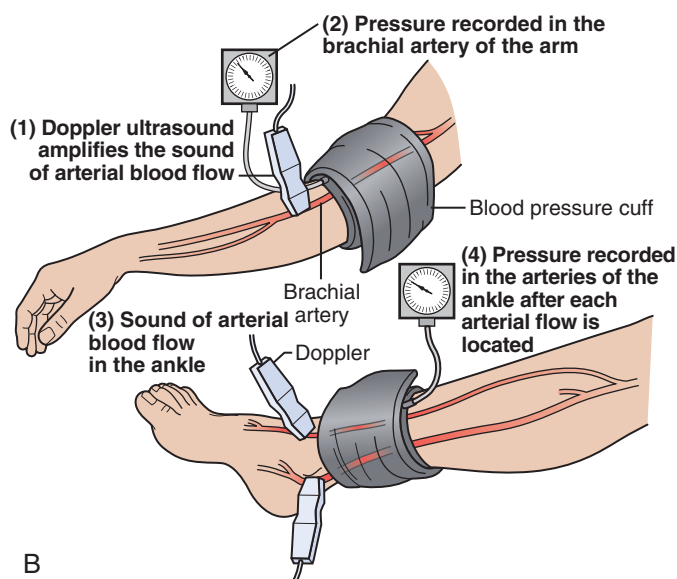

Figure 1.4 A, Handheld Doppler device with a speaker. Devices with an attached stethoscope are also used. B, Peripheral vascular testing is performed in a vascular laboratory, but an approximation of the integrity of the peripheral arterial circulation can be gleaned in the emergency department by using Doppler to determine systolic blood pressure in the foot and arm and calculate the ankle-brachial index.

Repeat the procedure for the posterior tibial and dorsalis pedis arteries of both lower extremities. This procedure may be done with oscillometric devices and lacks sensitivity in identifying disease.¹⁵³

In evaluating fetal heart tones, because of variable positioning of the fetus, an examination of several locations and angles over the uterus must be performed in search for the optimal signal. It is best to begin in the mid-suprapubic area and then explore the uterus via angulation of the probe. Once tones are located, move the probe along the abdomen to reach a position closer to the origin of the sound. Distinguish fetal heart tones from placental flow by differentiating the quality of the fetal heart tones, which will not match the maternal pulse. The placental flow and maternal pulse should be identical.

Interpretation

As noted earlier, in low-flow states Doppler ultrasound can detect blood pressure as low as 30 mm Hg. Calculate the ankle-brachial index of each limb by dividing the higher systolic pressure of the posterior tibial or the dorsalis pedis artery of the limb by the higher of the systolic pressures in the brachial arteries. In normal individuals, the index should be greater than 1.0 (Fig. 1.5). Patients with mild to moderate claudication have values between 0.4 and 0.9. Values lower than 0.4 indicate severe impairment and are consistent with critical limb ischemia.¹⁵⁴ When the lower extremity has been amputated or injured, brachial-brachial indices can be used (i.e., comparison of systolic blood pressure in the injured or diseased upper extremity with the other extremity). Patients with ankle-brachial index values of 0.9 or lower have increased cardiovascular morbidity and mortality.¹⁵⁵ One study of 323 penetrating extremity wounds found that an ankle-brachial index (or brachial-brachial index) lower than 0.9 was 72.5% sensitive and 100% specific for vascular injuries.¹⁵⁶ Segmental lower extremity pressure measurements may help identify the level of the obstruction (Table 1.4).¹⁵⁷ Obese patients, diabetic patients, or those with calcified vessels that are not compressible may have abnormally high systolic pressure (e.g., 250 to 300 mm Hg) and indices that do not accurately reflect flow. Normal fetal heart tones should be between 120 and 140 beats/min. Fetal heart tones may be heard as early as the 12th week of gestation.

VITAL SIGN DETERMINATION OF VOLUME STATUS

Many techniques have been advocated to assess volume status. Unfortunately, most procedures lack a database against which to judge their reliability. Recommended methods include evaluation of skin color; skin turgor; skin temperature; supine, serial, and orthostatic vital signs; neck vein status; transcutaneous oximetry; and hemodynamic monitoring (e.g., monitoring of central venous pressure). Serial vital sign measurements have been used for assessing blood loss, but they do not reliably detect small degrees of blood loss.^{154,158,159} Up to 15% of the total blood volume can be lost with minimal hemodynamic changes or any alteration in supine vital signs.^{158,160} A decrease in pulse pressure occurs with acute blood loss,¹⁶¹ but the patient's baseline blood pressure values are often unknown. Clinical examination of neck veins adds useful information and is less precise than measurement of central venous pressure. Most

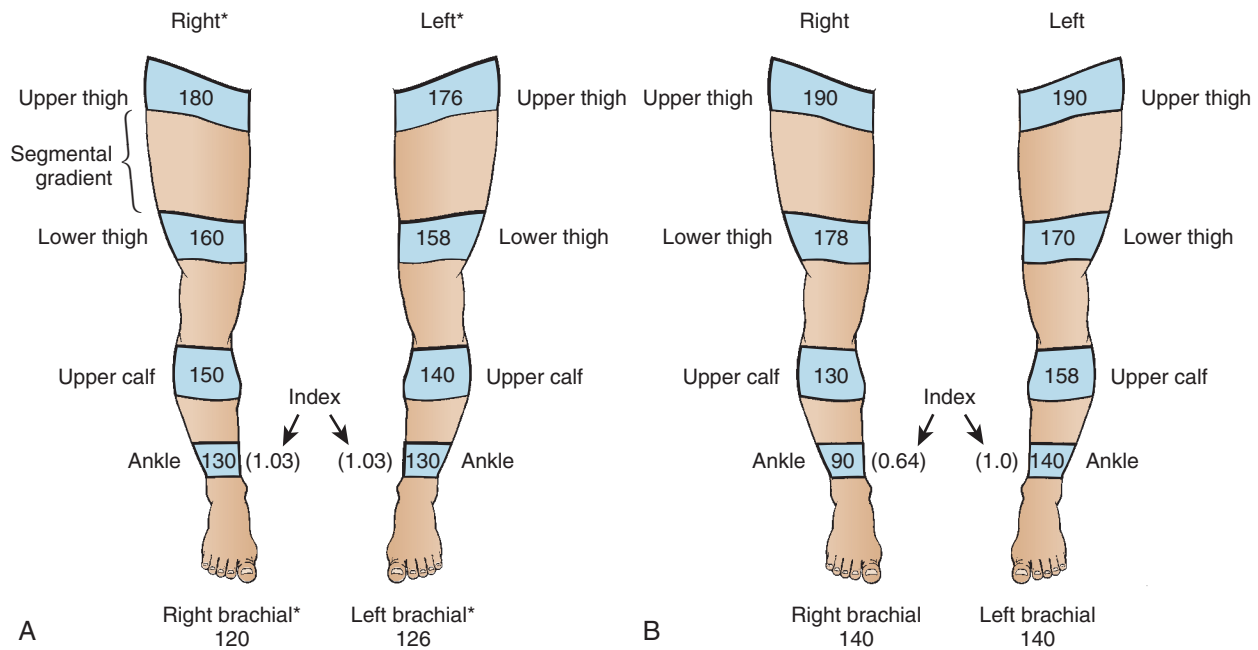

Figure 1.5 **A**, Typical pressures in a normal individual. Findings, based on resting pressure, show no evidence of occlusive disease of the large- or medium-sized arteries. Normal findings are as follows: (1) ankle-to-brachial pressure index of 1.0 or higher; (2) all segmental pressure gradients lower than 30 mm Hg; and (3) upper thigh pressure at least 40 mm Hg above brachial pressure. *Systolic pressure in mm Hg. **B**, Typical pressures in a patient with obstruction of the right popliteal or tibial arteries. Significant findings are as follows: (1) ankle-to-brachial pressure index less than 0.9 in the right leg; (2) abnormally high gradient from the ankle to below the knee and again from below to above the knee in the right leg; and (3) upper thigh pressure 50 mm Hg higher than brachial pressure, consistent with normal flow at the aorta-iliac level. Findings are suggestive of right popliteal occlusion or right anterior and posterior tibial occlusion, or both. (From *Doppler evaluation of peripheral arterial disease: a clinical handbook*, ed 5, Fredericksburg, VA, Sonicaid, Inc. Reproduced with permission.)

clinicians use skin color, temperature, and moisture as a reflection of skin perfusion and sympathetic tone. This is not an accurate guide to circulatory volume because the vasomotor tone of the skin is affected by numerous diseases, as well as by emotional and environmental factors. Capillary refill has been advocated as a noninvasive test for hypovolemia, and it has been found to be inaccurate in adults (see the following discussion regarding its use in children).¹⁶² The ideal test for determining volume status would rapidly and accurately detect 5% or greater depletion of volume with a noninvasive technique. At present, no such test exists.

ORTHOSTATIC VITAL SIGNS MEASUREMENT

Orthostatic vital signs have historically been used to evaluate patients with fluid loss, hemorrhage, syncope, or autonomic dysfunction. They are also used to assess the patient's response to therapy. The clinician is often concerned with accurate detection of acute blood loss or volume depletion. When the clinical syndrome of shock exists, assessment of a deficit in blood volume poses little difficulty. It is preferable that loss of volume be detected before loss of physiologic compensation and clinical shock occur.

Although orthostatic testing is commonly cited as a method to detect hypovolemia, it is frequently misleading and has less clinical value than often touted. The medical literature is inconsistent regarding values representative of a positive or

negative orthostatic test, and its value for estimating volume status is probably overstated. In patients with an acute loss of less than 20% of total blood volume, orthostatic vital signs have been shown to lack both sensitivity and specificity.¹⁶¹

Physiologic Response to Hypovolemia

Acute blood loss or severe hypovolemia related to dehydration decreases venous return.¹⁶³ This can be seen with acute blood loss (usually greater than 20% of blood volume), severe burns, or prolonged vomiting or diarrhea that depletes body fluids. As a result, cardiac output falls and clinical manifestations of shock ensue. Several compensatory mechanisms are initiated by acute hypovolemia (Box 1.1). The dominant compensatory mechanism in shock is a reduction in carotid sinus baroreceptor inhibition of sympathetic outflow to the cardiovascular system. This increased sympathetic outflow results in several effects: (1) arteriolar vasoconstriction, which greatly increases peripheral vascular resistance; (2) constriction of venous capacitance vessels, which increases venous return to the heart; and (3) an increase in the heart rate and force of contraction, helping maintain cardiac output despite significant loss of volume.¹⁶⁰

The value of sympathetic reflex compensation is illustrated by the fact that 30% to 40% of blood volume can be lost before death occurs. When sympathetic reflexes are absent, a loss of only 15% to 20% of blood volume may cause death.¹⁶⁰ Increased sympathetic nerve activity results in the commonly recognized physical signs of shock, including pallor, cool clammy

^aTypical pressures in a normal individual. The findings, based on resting pressures, show no evidence of occlusive disease of the large- or medium-sized arteries. Normal findings are as follows: (1) ABI of 1.0 or higher; (2) all segmental pressure gradients lower than 30 mm Hg; and (3) upper thigh pressure at least 40 mm Hg above brachial pressure.

^bTypical pressures in a patient with obstruction of the right popliteal or tibial arteries. Significant findings are as follows: (1) ABI less than 0.9 in the right leg; (2) abnormally high gradient from the ankle to below the knee and again from below to above the knee in the right leg; and (3) upper thigh pressure 50 mm Hg higher than brachial pressure, consistent with normal flow at the aorta-iliac level. The findings are suggestive of right popliteal occlusion or right anterior and posterior tibial occlusion, or both.

^cTypical pressures in a patient with obstruction of the abdominal aorta or bilateral iliac obstruction. Significant findings are as follows: (1) ABI of less than 0.9 in both legs; (2) all segmental gradients lower than 30 mm Hg; and (3) both upper thigh pressures relatively low with respect to brachial pressure. The findings are suggestive of severe aortoiliac occlusive disease. ABI, Ankle-brachial index.

skin, rapid heart rate, muscle weakness, and venous constriction. An inadequate immediate compensatory response will result in dizziness, altered mental status, or loss of consciousness.¹⁶⁴ The central nervous system response to ischemia further stimulates the sympathetic nervous system after arterial pressure falls below 50 mm Hg.¹⁶⁰ Subsequent compensatory mechanisms that work to restore blood volume to a normal level include the release of angiotensin and antidiuretic hormone (vasopressin). This causes arteriolar vasoconstriction, conservation of salt and water by the kidneys, and a shift in fluid from the interstitium to the intravascular space.¹⁶⁴

Several investigators have examined the changes in blood pressure and pulse that occur in supine patients with blood loss.^{158,159,161,165} Collectively, these studies have shown variable individual hemodynamic responses to acute blood loss of up to 1 L. The frequent inability to detect significant loss of volume

BOX 1.1 Homeostatic Mechanisms in Hemorrhagic Shock

- Sympathetic reflex compensation
 - Arteriolar vasoconstriction
 - Venous capacitance vasoconstriction
 - Increased inotropic and chronotropic cardiac activity
 - Central nervous system ischemic response
- Selective increase in cerebral and coronary perfusion by means of local autoregulation
- Increased oxygen unloading in tissues
- Restoration of blood volume
 - Renin-angiotensin-aldosterone axis activation
 - Antidiuretic hormone secretion
 - Transcapillary refill
 - Increased thirst resulting in increased fluid intake
 - Increased erythropoiesis

with supine vital signs, and the observation that syncope frequently develops in patients with acute volume loss on rising, led to the investigation of the use of orthostatic vital signs to detect occult hypovolemia.

Physiologic Response to Changes in Posture

When an individual assumes the upright posture, complex homeostatic mechanisms compensate for the effects of gravity on the circulation to maintain cerebral perfusion with minimal change in vital signs. These responses include (1) baroreceptor-mediated arteriolar vasoconstriction; (2) venous constriction and increased muscle tone in the legs and the abdomen to augment venous return; (3) sympathetic-mediated inotropic and chronotropic effects on the heart; and (4) activation of the renin-angiotensin-aldosterone system.¹⁶⁴ These compensatory mechanisms preserve cerebral perfusion in the upright position with minimal changes in vital signs. When a normal individual stands, the pulse increases by an average of 13 beats/min, systolic blood pressure falls slightly or does not change, and diastolic pressure rises slightly or does not change.¹⁶⁵ In patients with vasodepressor syncope, the normal compensatory reflexes that preserve cerebral perfusion with changes in posture are altered. The normally increased sympathetic tone on standing is paradoxically inhibited, and an exaggerated enhancement of parasympathetic activity (bradycardia) occurs and can lead to syncope.¹⁶⁶

Few data exist regarding the true effect of acute blood loss on postural vital signs, and this parameter varies greatly among individuals experiencing hypovolemia. One study of 23 young adult volunteers from whom 500 to 1200 mL of blood was withdrawn found no reliable change in postural blood pressure, and a consistent postural increase in pulse of 35% to 40% was noted after 500-mL blood loss.¹⁵⁹ Of the six individuals from whom approximately 1000 mL of blood was withdrawn, only two were able to tolerate standing, and each had a postural increase in pulse of greater than 30 beats/min. The other four individuals experienced severe symptoms on standing, followed by marked bradycardia and syncope if they were not allowed to lie down.

Following phlebotomy of 450 to 1000 mL of blood from healthy volunteers, the criterion of an increase in pulse of 30

BOX 1.2 Summary of Orthostatic Tilt Testing**TEST PROCEDURE**

1. Blood pressure and pulse are recorded after the patient has been supine for 2 to 3 minutes.
2. Blood pressure, pulse, and symptoms are recorded after the patient has been standing for 1 minute; the patient should be permitted to resume a supine position immediately if syncope or near-syncope develop.

POSITIVE TEST

1. Increase in pulse of 30 beats/min or more in adults *or*
2. Presence of symptoms of cerebral hypoperfusion (e.g., dizziness, syncope)

"The predictive ability of orthostatic vital signs to assess volume status is often overestimated in clinical practice. This suggested guide is based on the ability of the change in pulse and patient symptoms to distinguish between no acute blood loss and 1000-mL acute blood loss in healthy, previously normovolemic volunteers (sensitivity of 98% for detecting 1000-mL acute blood loss.¹⁶¹ This guide may not be applicable to elderly patients, sick children, medicated patients, and those with autonomic dysfunction.

beats/min or the presence of severe symptoms (syncope or near-syncope) during a supine-to-standing test accurately distinguished between 1000-mL blood loss and no blood loss. The sensitivity and specificity of using the aforementioned criteria for detecting 1000-mL blood loss (Box 1.2) were both 98%, for an accuracy of 96% (2% false-negative results and 2% false-positive results). The investigators were unable to consistently detect blood loss of 500 mL with these criteria.¹⁶¹ In a similar study, the change in heart rate with postural changes after 500-mL phlebotomy was more discriminatory for blood loss than were changes in blood pressure or a change in the bioimpedance-based stroke index. Of note, these authors found that a change in heart rate of 30 beats/min or greater was 13.2% sensitive and 99.5% specific for 500-mL blood loss and that a change in heart rate of 20 beats/min or greater was 44.7% sensitive and 95.4% specific. The finding of a significant rise in pulse, though insensitive for 500-mL blood loss, was relatively specific in these healthy adult blood donors.¹⁶⁷ In the most recent metaanalysis of orthostatic vital signs (1999), the authors concluded that a large postural pulse change (>30 beats/min) or severe postural dizziness precluding the completion of vital sign measurements is required to clinically diagnose hypovolemia secondary to acute blood loss. The analysis demonstrated that orthostatic vital signs are often absent after moderate amounts of blood loss, thus significantly limiting the test's sensitivity (22%) in this scenario.¹⁶⁸ A consensus statement defined orthostatic hypotension as a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg within 3 minutes of standing and reinforces the theory that this is a physical finding rather than a disease process.¹⁶⁴

Variables Affecting Orthostatic Vital Signs

Many conditions affect the compensatory mechanisms that allow patients to assume the upright posture. Most of the conditions that affect postural blood pressure regulation involve a pathologic condition that affects the sympathetic nervous

system or the use of medications that alter normal cardiovascular compensatory functions. Orthostatic hypotension caused by autonomic insufficiency is not usually accompanied by tachycardia, and the orthostatic hypotension produced by acute volume depletion is commonly accompanied by a pronounced reflex tachycardia. Even in normal individuals, passive tilting generates a high incidence of orthostatic syncope.¹⁶⁹

Because of decreased vasomotor tone, limited chronotropic response, and other factors, the elderly have a higher incidence of orthostatic hypotension leading to syncope and fall-related injuries.¹⁷⁰ Carotid sinus hypersensitivity may play a greater role than orthostasis in geriatric syncope.¹⁷¹ Note that drugs that antagonize the normal autonomic compensatory mechanisms can also produce orthostatic changes. These changes can be severe enough to produce frank syncope, especially in the elderly. A study of patients with syncope seen in an ED found that orthostatic hypotension was considered to be the cause of the syncope in 24%, and that the largest proportion of these cases were drug related. Patients with orthostatic hypotension as the cause of syncope were older, had more comorbid conditions, and were found to be more frequently taking antihypertensive medications.¹⁷² Advanced patient age is an independent risk factor for orthostatic blood pressure changes and does not appear to have a direct correlation to the presence of chronic cardiovascular disease, disability, or body mass index.¹⁷³ A study assessing vital sign changes prior to ward cardiac arrest found significant differences between elderly and nonelderly patients in the predictive value of the Modified Early Warning Score, noting more accurate detection of cardiac arrest by vital sign changes in nonelderly patients.¹⁷⁴

Patients with hypertension may also have abnormal vasomotor responses to tilt testing and demonstrate more instability.¹⁷⁵ Chronic anemia patients, who exhibit compensated blood volume, seem to have the same postural response as normal individuals.¹⁷⁶ Ethanol ingestion exaggerates postural pulse changes and mimics the hemodynamic changes seen with acute blood loss.¹⁷⁷

The utility of orthostatic vital signs in children has been questioned. Healthy adolescents had changes in heart rate of 21.5 ± 21.2 beats/min and variable changes in systolic blood pressure (+19 to -17 mm Hg) after 2 minutes of standing.¹⁷⁸ A study comparing mildly dehydrated children with normal children found a significant difference in the orthostatic rise in pulse, and no difference in orthostatic blood pressure. The investigators concluded that an orthostatic increase in pulse of greater than 25 beats/min constitutes a positive tilt test and less than 20 beats/min constitutes a negative test (sensitivity of 75%, specificity of 95%, and predictive value of 92% when using near-syncope or an increase in heart rate greater than 25 beats/min).¹⁷⁹

Another complicating factor in interpreting orthostatic vital signs is the development of paradoxical bradycardia in the presence of blood loss. Bradycardia in the face of hemorrhage has generally been considered a preterminal finding of irreversible shock, and bradycardia has been documented in hypovolemic, conscious trauma patients as well. It has been reported that when orthostatic syncope occurs, it is accompanied by hypotension and often bradycardia.^{158,161} Many central nervous system factors can contribute to vagally mediated syncope in ED patients with acute traumatic blood loss, including pain, the sight of blood, anxiety, and nausea. This paradoxical bradycardia may be more frequently associated with rapid and massive bleeding. Patients with more gradual blood loss tend

to have a more typical tachycardic response. When the patient's clinical findings are consistent with loss of volume or shock, the clinician should not allow the absence of tachycardia to change the assessment.

Indications and Contraindications

When the volume status of a patient is assessed with the use of orthostatic vital signs, several points should be remembered. Many factors influence orthostatic blood pressure, including age, preexisting medical conditions, medications, and autonomic dysfunction. It must be emphasized that data relating the effect of blood loss to orthostatic vital signs are limited to phlebotomized healthy volunteers. Great care must be used when extrapolating these data to patients with anemia, dehydration, or painful trauma. The clinician must consider the patient's clinical condition when interpreting orthostatic vital signs in the evaluation of a patient with potential volume depletion.

Orthostatic vital signs can be considered an adjunct for the evaluation of any patient with known or suspected loss of blood volume or a history of syncope. Contraindications to orthostatic measures include supine hypotension, the clinical syndrome of shock, severely altered mental status, the setting of possible spinal injuries, and lower extremity or pelvic fractures.

The use of medications that block the normal vasomotor and chronotropic response to orthostatic tests is also a contraindication to using this test for the assessment of volume status. When the patient's volume status is believed to be adequate and the clinician seeks to determine whether specific medications may have affected the patient's ability to respond to postural changes, the test may be useful. In these situations, the primary finding may be the sensation of near-syncope with little or no change in vital signs.

Orthostatic vital signs are often used to assess a patient's response to therapy. In patients receiving intravenous rehydration therapy, serial orthostatic vital signs are widely used to judge the end point of therapy before release. In one study, individual orthostatic vital sign response to saline infusion in women with hyperemesis gravidarum was associated with other measures of rehydration, including weight gain and decreased urine specific gravity.¹⁸⁰ Although the individual improvement in orthostatic vital signs in response to rehydration was of clinical value, the initial orthostatic vital signs were considered insufficient as the sole indicator of clinical dehydration in this population.

Technique

To obtain orthostatic vital signs, record the blood pressure and pulse after the patient has been in the supine position for 2 to 3 minutes (see [Box 1.2](#)). Allow the patient to rest quietly and do not perform any painful or invasive procedures during the test.

Next, ask the patient to stand and be prepared to assist if severe symptoms or syncope develop. A supine-to-standing test is more accurate than a supine-to-sitting one. If severe symptoms develop on standing, defined as syncope or extreme dizziness requiring the patient to lie down, the test is considered positive and should be terminated. If not symptomatic, allow the patient to stand for 1 minute and then record the blood pressure and pulse. A 1-minute interval resulted in the greatest difference between control and 1000-mL phlebotomy groups in one study.¹⁶¹

A number of studies have been conducted on normotensive, normovolemic patients to assess end points for orthostatic vital sign parameters. Such studies have included sitting-to-standing methods and varying rates of postural changes,¹⁸¹ including lying times of 5 to 10 minutes and standing times of 0 to 2 minutes.¹⁸² Arm position may affect postural changes in blood pressure and should be held constant to accurately assess orthostatic change.¹⁸³ Complications include syncope with resulting falls and injuries.

Interpretation

The most sensitive criteria for orthostasis are tachycardia or symptoms of cerebral hypoperfusion (e.g., near-syncope). Although changes in blood pressure may be seen, they are too variable to be an indicator of loss of blood volume. Specific population-based thresholds for changes in pulse rate and blood pressure have some value in identifying patients at high risk for significant loss of blood volume, but great individual variability limits the use of this technique as a screening test. That is, a loss of 500 mL, and occasionally more, may be associated with a negative orthostatic vital sign assessment.^{171,184} The use of serial measurements to ascertain the response to therapy in patients considered to be at risk for loss of volume appears to have clinical utility.¹⁸⁵

In the setting of suspected blood loss, if the patient has a rise in pulse of 30 beats/min or manifests severe symptoms and if other complicating factors have been excluded, blood loss is highly likely (2% false-positive rate). The presence of a negative test indicates only that acute blood loss of 1000 mL is unlikely (2% false-negative rate) and that blood loss of 500 mL cannot be excluded (43% to 87% false-negative rate).^{161,171,184,186} Orthostatic changes in the SI were no more sensitive than established tilt test criteria in discriminating normal individuals from those with moderate acute blood loss (450 mL).¹⁸⁵

Criteria for significant orthostatic changes in blood pressure cannot be definitively set for the following reasons: (1) large variability in postural blood pressure has been found in the adult ED population^{186,187}; (2) the results of studies using passive tilt tables cannot be extrapolated to the bedside use of orthostatic vital signs; (3) studies using healthy patients with acute blood loss may not reflect the orthostatic changes seen in the elderly, those with chronic bleeding, dehydration, other medical problems, or in association with certain medications; and (4) many studies of orthostatic changes did not use a criterion standard in their determinations.

In summary, orthostatic vital sign testing is common in the ED, but this procedure has limited proven value. The clinical interpretation of orthostatic changes in blood pressure and pulse varies widely. Although this intervention may occasionally yield information not obtained through other means, the authors do not consider orthostatic blood pressure testing a standard of care in the evaluation of ED patients.

CAPILLARY REFILL

The capillary refill test is a measurement of the interval of time from the release of pressure on the nail bed or soft tissue sufficient to blanch the nail bed or superficial soft tissue, until the return to normal coloration. Delayed capillary refill is an indication of reduced skin turgor, often as a result of volume depletion or limited perfusion. Measurement of capillary refill time (CRT)

appears to be somewhat accurate in children, and its accuracy in assessing dehydration and reduced perfusion in adults is highly suspect.^{162,188} Skin elasticity is the characteristic that allows skin to spring back to its original shape after it has been deformed, and the speed of refilling the capillary bed after compression is responsible for the return of color to the skin.

Indications and Contraindications

CRT should not be determined from a dependent extremity, from a recently burned or injured extremity, or at the site of an infection or acute injury. Because CRT can be used without additional equipment and takes only a few seconds to perform, it can be a useful bedside assessment of perfusion and dehydration when used in conjunction with other objective signs of the adequacy of perfusion. It should not be considered accurate as a stand-alone tool. Capillary refill is not an appropriate alternative to measuring blood pressure in pediatric patients.

Procedure

The preferred sites for determining CRT are the nail bed, the thenar surface of the palm, and the heel. Alternative sites may have different CRTs, and the current standards are best developed for capillary refill determined at the nail bed.¹⁸⁹ Regardless of the site chosen, position the extremity at approximately the level of the right atrium. The minimum pressure necessary to produce blanching yields the most reproducible values. Release the nail bed and begin timing with a stopwatch or simply by counting out “one-thousand-one, one-thousand-two” for an approximation of the interval. Stop the clock when the nail bed becomes pink again. Interobserver reliability has been shown to be moderate, with kappa values of less than 0.5 in the evaluation of both adults and children.^{190,191}

Interpretation

The normal CRT increases with age and is slightly longer in female patients. It is further increased by degrees of dehydration or hypoperfusion. Hypothermia, hyponatremia, congestive heart failure, malnutrition, and edema all increase CRT. Environmental conditions such as ambient air temperature can falsely alter capillary refill.¹⁹² Fever alone did not appear to prolong or shorten CRT in children,¹⁹³ and a study of healthy adults found a 5% decrease in CRT for each degree Celsius rise in patient temperature.¹⁹²

The main difficulty in interpreting CRT is that normal values in healthy patients fall into a wide range. In 30 normal infants 2 to 24 months of age, mean CRT was 0.8 ± 0.3 second. Measurements obtained from the nail bed were more reproducible than those from the heel.¹⁸⁸ Combined results from four studies evaluating capillary refill revealed a pooled sensitivity of 0.60 (95% confidence interval [CI], 0.29 to 0.91) and a specificity of 0.85 (95% CI, 0.72 to 0.98) for detecting 5% dehydration in children.¹⁹⁴ The presence of a 2-second or longer delay in CRT when combined with any two or more of the findings of absent tears, dry mucous membranes, or ill general appearance predicted clinical dehydration (>5% deficit in body weight) in children (1 month to 5 years of age) with 87% sensitivity and 82% specificity.¹⁹³ A 2015 systematic review including 21 studies suggests applying a cutoff of 3 seconds or more to define abnormal CRT in infants and children over 7 days of age.¹⁹⁵

Frequent monitoring of capillary refill may be useful in assessing responses to rapid fluid resuscitation in children. A normal CRT of 2 seconds or less has been shown to correlate with superior vena cava oxygen saturation of 70% or higher in critically ill children.¹⁸⁹ The role of serial CRT measurements for assessing the response to rehydration in adults is unknown, and it does not appear to be useful for assessing acute loss of blood volume. Lima and colleagues¹⁹⁶ studied the prognostic value of the subjective assessment of peripheral perfusion in critically ill patients following initial resuscitation. When an abnormal CRT was defined as greater than 4.5 seconds, coupled with extremity coolness, these parameters identified patients who had been hemodynamically stabilized and continued to have more severe organ dysfunction and higher lactate levels. In adults, CRT was found to be less sensitive and less specific than orthostatic vital signs in detecting 450-mL blood loss during blood donation.¹⁶² However, a 2014 study showed CRT, measured as a continuous variable in a cohort of admitted medical patients, was associated with an increased 1-day and 7-day all-cause mortality.¹⁹⁷

In summary, assessment of CRT is a common technique used in the ED, and, in reality, this procedure has limited proven value, clinical interpretation is very subjective, and use varies widely. Although this intervention may occasionally yield information not obtained through other means, predominantly in children, the authors do not consider such testing an absolute standard of care in the evaluation of ED patients.

TEMPERATURE

Detection of abnormal body temperature may facilitate proper diagnosis and evaluation of patients' complaints in the ED. An inability to maintain normal body temperature is indicative of a vast number of potentially serious disorders, including infections, neoplasms, shock, toxic reactions, and environmental exposures.^{198–202} Fever in neutropenic, immunocompromised, or intravenous drug-abusing patients may be more reliable than laboratory tests or clinician assessment in diagnosing serious illness.^{198,203} Infants are particularly sensitive to thermal stress and may demonstrate lower body temperatures during critical illness.^{200,204} In one study, although higher rates of serious bacterial infection were found in neonates who had documented fever (OR, 3.23) on admission, only 8.4% of neonates with historical fever were later diagnosed with serious bacterial infection.²⁰¹ Pretriage or home assessment of body temperature is fraught with difficulty and unreliability. Whether taken by the oral, rectal, or tympanic routes, reports of fever at home are very difficult to interpret in the clinical setting.^{199,202} Some studies report rates as low as 13% in frequency when measuring temperature in the critically ill or injured,²⁰⁵ and temperature and Glasgow Coma Scale were the least frequently documented physiologic observations (less frequent than RR, oxygen saturation, heart rate, and systolic blood pressure) across ED, critical care, and medical/surgical unit settings despite temperature representing a key sign of systemic inflammatory response syndrome.²⁰⁶

Physiology

Under normal conditions, the temperature of deep central body tissues (i.e., core temperature) remains at $37^{\circ}\text{C} \pm 0.6^{\circ}\text{C}$ ($98.6^{\circ}\text{F} \pm 1.08^{\circ}\text{F}$).²⁰⁷ Core body temperature can be maintained

within a narrow range, whereas environmental temperature varies from as much as 13°C to 60°C (55°F to 140°F),²⁰⁷ and surface temperature rises and falls with environmental and other influences. Mean oral temperature is 36.8°C ± 0.4°C (98.2°F ± 0.7°F).²⁰⁸ Maintenance of normal body temperature requires a balance of heat production and heat loss. Heat loss occurs by radiation, conduction, and evaporation by approximately 60%, 18%, and 22%, respectively. Heat loss is increased by wind, water, and lack of insulation (e.g., clothing). Sweating, vasodilation, and decreased heat production serve to decrease temperature. Piloerection, vasoconstriction, and increased heat production serve to increase body temperature. Heat production is increased by shivering, fat catabolism, and increased thyroid hormone production.

Temperature is controlled by feedback mechanisms operating through the hypothalamus. Heat-sensitive neurons in this area increase their rate of firing during experimental heating. Receptors in the skin, spinal cord, abdominal viscera, and central veins primarily detect cold and provide feedback to the hypothalamus that signals an increase in heat production. Stimuli that change core body temperature result in reflex changes in mechanisms that increase either heat loss or heat production.^{207,208}

Indications and Contraindications

Clinicians generally measure body temperature to determine whether it is outside the normal range and as an indication of pathologic conditions that can affect core body temperature. Measurement of actual core body temperature requires the placement of invasive monitors, such as an esophageal or pulmonary artery (PA) probe. Clinicians commonly use estimates of core body temperatures to conveniently and safely assess abnormalities in core temperature. All noncore body sites and methods have inherent limitations in accuracy, and clinicians have come to accept these shortcomings in assessing most patients.

Measurement of oral temperature requires a cooperative adult or child. Patients who are uncooperative, hemodynamically unstable, septic, or in respiratory distress (with an RR > 20 beats/min) require a method of measuring temperature other than the traditional oral route.²⁰⁹ This group includes children younger than 5 years and patients who are intubated. Ingestion of hot or cold beverages has shown they can alter oral temperature readings for 5 to 30 minutes, and can falsely elevate a normal temperature or mask a fever.²¹⁰

Special techniques of measuring core body temperature may be indicated in certain patients (e.g., those with profound hypothermia, frostbite, or hyperthermia). Measurement of core body temperature is indicated in these individuals because it accurately measures the effects of treatment. This is the group of patients who will benefit the most from continuous temperature measurements.²¹¹

Measurement Sites

Core Body Temperature

The following sites accurately reflect core body temperature and changes in it: the distal third of the esophagus, the tympanic membrane (TM) (with a direct thermistor in contact with the anterior inferior quadrant of the TM),^{212,213} and the PA.^{214,215} Other sites may represent core body temperature under certain conditions; for example, (1) the rectum when the temperature

is obtained at least 8 cm from the anus with an indwelling thermistor and the body temperature is relatively constant, and (2) the bladder when measured with an indwelling thermistor.²¹⁶

Rectal temperature is often considered the criterion standard for body temperature in ambulatory patients and it is often used routinely in children younger than 3 years.²¹⁷ Advantages include accuracy, sensitivity, and availability. One intensive care unit study found that rectal probe temperatures demonstrated limited variability or bias when compared with PA temperatures.²¹⁸ Disadvantages include longer intervals for measurement, safety concerns, and inconvenience. Neutropenia and recent rectal surgery represent relative contraindications to measurement of rectal temperature. Thermistor probes (i.e., small thermocouples with instantaneous readouts) for esophageal and vascular temperature measurement provide continuous temperature readouts when attached to a potentiometer. Thermistor probes are available for measurement of esophageal, bladder, and rectal temperature with appropriate monitors.

Peripheral Body Sites Approximating Core Temperature

A body temperature measurement by IR radiation can be detected from the ear, including the auditory canal and TM; it is easy to use, hygienic, convenient, and quick. It can be used as a general screening technique, particularly in cases when temperature is not of great importance, such as in minor trauma. Though clearly superior to axillary temperature readings,²¹⁹ controversy remains regarding the sensitivity and specificity of IR TM readings in the ED. In a cohort of ICU patients, agreement of tympanic with PA temperature was inferior to that of urinary temperature. Compared with PA temperatures, Δ (limits of agreement) were 0.36°C (−0.56°C, 1.28°C), −0.05°C (−0.69°C, 0.59°C), and 0.30°C (−0.42°C, 1.01°C) for tympanic, urinary, and axillary temperatures, respectively.²²⁰ It is possible that alterations of regional blood flow accompanying critical illness (TMs may behave as an extension of the skin or the mucous membrane in the critically ill) and the peripheral vasoconstriction that occurs with inotropes and some forms of shock may occur in the TM, making such measurements less accurate in this population.

More work is being done in the pediatric population, with an overall sensitivity of between 50% and 80% and a specificity of 85%. The lower sensitivities are found in newborns and infants younger than 3 years.^{221–223} Systematic reviews of pediatric studies have pooled data suggesting 65% sensitivity, which is unacceptable in the clinical setting.²²⁴ A 2010 study found that neither TM nor skin thermometers could reliably predict rectal temperature, and it concurred that these methods could not replace rectal temperature measurement as the “gold standard” for detecting fever in the pediatric population.²²⁵ Adult studies, though generally more favorable in recommending TM temperatures, have shown gaps in reliability as well.²²⁶ However, a 2011 systematic review suggested that TM and oral thermometry provides an accurate measure of core temperature in critically ill adults with fever.²²⁷ Temporal artery scanning to detect fever is increasingly being examined. In general, these devices show better sensitivity in detecting fever in infants than TM thermistors do (66% versus 49% sensitivity) and may be useful in excluding fever,²²⁸ defined as a rectal temperature higher than 38.3°C if the temporal artery readings are lower than 37.7°C.²²⁹ The point can be argued that a sensitivity of 60% in any population lacks the required sensitivity

to be useful clinically. A theoretical disadvantage of TM temperatures might be a falsely elevated estimate of the core temperature in the presence of otitis media. In one study, TM thermometers accurately reflected oral temperatures in children with otitis media.²³⁰

In a group of pediatric patients receiving anesthesia, measurements taken at the temporal artery were similar to nasopharyngeal thermometer recordings, and the axillary temperature was lower than the temporal artery and nasopharyngeal temperatures.²³¹

Prehospital providers who might wish to measure IR TM temperature at low ambient temperatures should be aware that below 24.6°C, the TM readings will greatly underestimate core temperatures.²³² EMS personnel should also be aware that in a cohort of exhausted marathon runners, rectal and IR TM temperatures have only moderate correlation.²³³ External thermometry may be unreliable in the setting of heat-related illness or hypothermia; if these diagnoses are clinically suspected and the IR TM temperature does not confirm an abnormal temperature, a measurement by rectal or esophageal probes should be obtained for diagnosis and during treatment.²³⁴

Axillary and tactile temperature assessments have been demonstrated to be unreliable and insensitive. They should not be used as screening methods for core temperature abnormalities in the ED.^{235–237} Single-use Tempa-DOT thermometers show progressive temperature dot darkening with increasing temperature, and these thermometers have been adopted by many EDs. These temperature devices have been shown to have 100% sensitivity and approximately 80% specificity for identification of fever when temperature was obtained orally in both adults and children.²³⁸ The most rudimentary method for temperature measurement, parental assessment by tactile touch, is associated with a measured fever approximately 75% of the time.²³⁹ Clinician estimation of fever is almost identical (70%).²⁴⁰

Procedure

Begin the temperature measurement by selecting the body site. Consider the accuracy of using a certain site to reflect core temperature, the sensitivity of the site to changes in temperature, the convenience, the time required, the safety, and the availability of the site.²⁴¹ Insert the temperature probe and allow the probe to equilibrate with the temperature of the local body tissues.

Proper placement of the temperature probes significantly influences the results of oral, rectal, esophageal, and vascular temperatures.^{242–245} Obtain sublingual oral temperatures in either the right or the left posterior sublingual pocket with the mouth closed.²⁴² Though anxiety-producing for parents, biting and breaking a mercury thermometer is generally inconsequential with regard to ingestion of either glass or mercury. Obtain a rectal temperature with the patient in the left or right lateral decubitus position and advance the probe gently to a depth of 3 to 5 cm to ensure accurate, atraumatic results.²⁴⁶ Complications associated with rectal temperature measurements are extremely rare and include rectal perforation, pneumoperitoneum, bacteremia, dysrhythmias, and syncope.²⁴¹ Falsely low supranormal rectal temperature measurements may be seen during shock.²⁴⁷ Rectal temperature may also lag behind changes in core temperature. An esophageal catheter or PA probe can be placed for measurement of core body temperature, and these techniques are not typically used in the ED.

Though not commonly used, measurement of the temperature of a freshly voided urine specimen can validate measurement of temperature at other body sites.²⁴⁸ Urinary bladder temperature measurement has been demonstrated to be similar to PA catheter temperature.²⁴⁹

Digital electronic probes are commonly used for the measurement of oral temperature in ambulatory patients.²⁵⁰ Electronic methods of temperature measurement are based on the thermocouple principle. Modern electronic thermometers signal when extrapolation of the temperature-time curve has occurred. Current *in vitro* standards call for an accuracy of $\pm 0.1^\circ\text{C}$ ($\pm 0.18^\circ\text{F}$) over the range of 37°C to 39°C (98.6°F to 102.2°F). Disadvantages include factors that affect clinical accuracy and sensitivity. Disposable single-use oral thermometers are now available and are as reliable as mercury or TM thermometers.²⁵¹ In the pediatric population, pacifier thermometers record supralingual readings in infants. The average time needed to record a reading with a pacifier thermometer is 3 minutes and 23 seconds, thus making its application in emergency medicine limited, although its sensitivity (72%) and specificity (98%) rival that of alternative methods.²⁵² Various IR ear thermometers are available commercially with varying operating temperature ranges, features, and reported accuracy.²⁵³ Complications associated with axillary, oral, ear IR, and liquid crystal thermometers are rare or unreported. TM perforation and pain have been reported as complications of placement of the thermistor probe in the auditory canal.

Interpretation

Normal values for body temperature are affected by the following variables: (1) site and methods used for measurement; (2) perfusion; (3) environmental exposure; (4) pregnancy; (5) activity level; and (6) time of day. Clinicians must interpret body temperature with knowledge of the range of normal values at the intended site of measurement. Although core body temperature remains nearly constant ($37.0^\circ\text{C} \pm 0.6^\circ\text{C}$ or $98.6^\circ\text{F} \pm 0.18^\circ\text{F}$), surface temperature rises and falls with changes in ambient temperature, exercise, and time of day. The definition of fever varies by the site of measurement and is defined by a temperature greater than 2 standard deviations above the mean. Fever has been defined as an oral temperature of 37.8°C or higher (100.0°F),²⁴⁶ a rectal temperature of 38.0°C or higher (100.4°F),²⁵⁴ or an IR ear temperature of 37.6°C or higher (99.6°F).²⁴⁶ Based on measurement of temperatures in normal, healthy infants, it is recommended that fever be defined as a rectal temperature of 38°C or higher in infants younger than 30 days, 38.1°C or higher in infants 30 to 60 days (1 to 2 months), and 38.2°C or higher in infants 60 to 90 days old (2 to 3 months).²⁵⁵ Hypothermia has been defined as a core body temperature lower than 35°C ($<95^\circ\text{F}$), and hyperthermia has been defined as a core body temperature higher than 41°C ($>105.8^\circ\text{F}$) with accompanying symptoms and signs.²⁵⁶ A useful nomogram and formulas for conversion of centigrade to Fahrenheit are provided in Fig. 1.6.

Temperature probes that depend on transfer of heat energy from local tissues to the probe require a period of equilibration and reliable tissue contact at the intended body site. Acceptable equilibration times for mercury-in-glass thermometers in oral, rectal, and axillary sites are 7, 3, and 10 minutes, respectively. Used in a predictive mode, electronic digital thermometers generally require 30 seconds for oral or rectal temperature

Figure 1.6 Temperature conversion scale. To change Celsius (centigrade) to Fahrenheit, multiply the Celsius temperature by $\frac{9}{5}$ and add 32. To change Fahrenheit to Celsius, subtract 32 from the Fahrenheit number and multiply by $\frac{5}{9}$.

TABLE 1.5 Normal Ranges and Suggested Febrile Thresholds for Human Body Temperature (in Healthy Resting Patients)

BODY SITE	TYPE OF THERMOMETER	NORMAL RANGE (°C)	FEVER (°C)
Core ^a	Electronic	36.4–37.9	38.0
Oral	Mercury in glass, electronic	35.5–37.7	37.8
Rectal	Mercury in glass, electronic	36.6–37.9	38.0
Ear	Infrared emission	35.7–37.5	37.6 ^b

^aTemperature obtained with a properly positioned pulmonary artery, esophageal, or tympanic membrane thermistor.

^bFor unadjusted ear temperature using the Thermoscan Pro-1 (Thermoscan, Inc., San Diego, CA).

equilibration. The predictive mode uses temperature changes versus time to predict an equilibration temperature.

Normal ranges and suggested febrile thresholds for common body sites and methods should be considered in the interpretation of temperature values (Table 1.5). Interpretation of temperature measurements during clinical assessment must consider the use of antipyretics, level of activity, pregnancy, environmental exposure, and patient age. Body temperature is increased during sustained exercise, pregnancy, and the luteal phase of the menstrual cycle. Temperature also increases in the late afternoon because of diurnal variation. Body tempera-

ture is generally reduced with advanced age, and age may have an impact on the magnitude of fever. Axillary temperatures have a low sensitivity but a high specificity for fever. Axillary temperatures should not be used to screen for fever.

Oral temperature measurements are affected by the ingestion of hot or cold liquids,²²⁷ tachypnea,²⁵⁷ and cold ambient air.²⁵⁸ Before taking an oral temperature the examiner should inquire about these features and possibly delay taking the temperature. A 2.7°C (4.9°F) reduction in oral temperature measurement was found when the probe was placed under the tip of the tongue instead of under the posterior sublingual pocket.²⁴² Given the extrapolation that occurs with rapidly reading thermocouple devices and IR detectors, it is not surprising that the sensitivity of these devices for detection of fever is only 86% to 88%.²⁵⁹ Many clinicians have adopted the adage that when an elevated temperature is suspected or crucial in decision making and not evident with an oral thermocouple probe or IR TM thermometer, measurement with a mercury-in-glass thermometer is indicated.

When rapid changes in body temperature occur, oral and TM temperature measurements appear to be more reliable than rectal temperature. In 20 adults examined during open-heart surgery, oral temperatures showed a better correlation with blood temperature during rapid cooling and rewarming.²⁴³ Additionally, esophageal temperature measurements showed a faster response rate compared to temperature measured in the bladder when cold saline infusion was used to induce mild hypothermia in cardiac arrest patients.²⁴⁴

Infrequently, ED patients require constant monitoring of temperature (e.g., in cases of profound hypothermia or hyperthermia). This can usually be performed by using a bladder or esophageal probe attached to a potentiometer. Patients with indwelling central venous or pulmonary arterial catheters may have electronic thermistors inserted into the central circulation to measure core body temperature. As noted earlier, rectal temperature measurements are less desirable for monitoring patients undergoing rapid changes in core temperature. Periodic IR TM temperature monitoring may represent one useful option in a hypothermic patient.²⁶⁰

Interpretation of ear IR temperatures requires knowledge of the mode of thermometer operation and ambient temperature. Occlusion of the ear canal by cerumen may produce a falsely low reading.²⁶¹ Most IR ear thermometers have different modes that allow users to predict the equivalent temperature at other body sites. IR ear thermometers appear to be moderately sensitive for fever.²⁶² If these devices are used, the clinician must be aware of the potential for a falsely low temperature. When in doubt, the measurement should be repeated with a more standard method.

Patients, parents, and caregivers often misinterpret the significance of a fever, and the term “fever phobia” has been coined to describe the ubiquitous and unsubstantiated fear that fever, by itself, is harmful or has diagnostic or prognostic significance.²⁰² Some of the highest fevers are the result of benign viral infections. Fever has been demonstrated to increase the body’s immune response, making aggressive fever reduction counterproductive. Most individuals, especially children, feel better when a high fever is lowered. Uninitiated medical personnel may contribute to the incidence of fever phobia. Routine administration of antipyretics in the ED for any fever, regardless of the degree of discomfort, has fueled unwarranted concern and may result in potentially harmful interventions, unnecessary testing and treatments, avoidable side effects of

medications, and additional patient anxiety. Mandatory medical evaluation for any fever, the use of alcohol sponge baths, waking a sleeping child to administer antipyretics, alternating ibuprofen with acetaminophen, around-the-clock use of antipyretics, and misconceptions about fever causing brain damage are some of the myths that are still extant in some EDs and throughout the general population. An ED protocol stating that any child be afebrile, demonstrate a significant decrease in hyperpyrexia, or even have a temperature reading repeated before discharge has no scientific validity.

PAIN AS A VITAL SIGN

Background

One of the goals of modern medicine has been to understand, accurately assess, and adequately treat pain. A paradigm shift has occurred in which pain is viewed as a mechanism to provide a mechanical warning of actual or potential damage to cells and tissues in a specific area. An individual's pain should certainly be addressed early in the ED encounter, but reflex interventions aimed at immediately relieving all a patient's pain are inappropriate and potentially counterproductive in the long run. Importantly, the concept of using pain as "the fifth vital sign" can be problematic, and this concept has not met with universal agreement.²⁶³ Literal interpretation of this concept can be fraught with problems, and because of the subjective nature of pain, measurement and interpretation are, by nature, imprecise. An overemphasis on rigorously quantifying pain and aggressively treating a specific number on the pain scale has the potential to expose patients to unneeded opioids, result in unrealistic expectations by patients, and lead to opioid dependence or addiction.

Pain can cause sympathetically mediated changes in vital signs, but standard vital signs (pulse, respiration, blood pressure) do not meaningfully correlate with the level of perceived pain. It is a common error to relate changes in vital signs, or lack thereof, as an indication of a patient's true level of pain. A 2006 retrospective study of patients with confirmed painful diagnoses showed no clinically significant associations between self-reported triage pain scores and heart rate, blood pressure, or RR.²⁶⁴ Contentions that the judicious use of analgesics will obscure a clinical condition or otherwise adversely affect clinical care are antiquated and unscientific. Adequate pain control may facilitate the overall ED encounter for both the patient and clinician.

Initiatives mandating documentation of pain as the fifth vital sign have not been associated with improvement in pain management.²⁶⁵ A prospective, multicenter study evaluating the current state of ED pain management practices concluded that there is high pain intensity, as demonstrated by intense pain on arrival (median rating, 8 of 10), and suboptimal pain management practices. It also showed assessment of pain occurring in 83% of patients, 40% of patients receiving no analgesics, lengthy delays in analgesic administration, and a large proportion of patients reporting moderate to severe pain at discharge (74%).²⁶⁶ Assuming weight-based dosing for acute pain management, analgesic regimens did not conform to the recommended regimens in a study of ED patients.²⁶⁷ Mandating the recording of a triage pain score has been shown to improve time to initial analgesic treatment.²⁶⁸ Acute or chronic pain is the most common chief complaint of more than 50% of ED

patients, with the figure approaching 75% in some studies.²⁶⁹ Reliably quantifying pain should be the goal of ED clinicians and is an appropriate step in the triage process.

Procedure/Interpretation

The Joint Commission goals mandate that all hospitals develop comprehensive programs for the measurement, treatment, and documentation of pain. There is no perfect measurement tool suitable for the wide variety of patients and clinical scenarios experienced in EDs.²⁷⁰ Pain is a complex, subjective, multifaceted, personal experience that is difficult to easily quantify in all individuals. The perfect pain assessment tool for the ED setting would be simple and rapid to administer while providing a precise, reliable, and valid measure of pain regardless of a patient's age, cultural background, and cognitive or physical impairments. Currently no tool meets all the criteria necessary to satisfy this definition. The primary focus should be to allow patients to report and rate their pain from a personal viewpoint, as it is widely accepted that health professionals cannot rate pain intensity as accurately as patients themselves.^{271,272} A patient's self-report of the pain is considered the gold standard for the initial assessment of pain and tracking of a response to interventions, although such reporting does not mandate specific interventions.²⁷³

Multiple unidimensional acute pain measurement instruments have been published and many have been independently validated. Common instruments include the verbal rating scale, numerical rating scale, visual analog scale (VAS), and graphic rating scales. The most used pain scale in the ED is the 1 to 10 VAS. The VAS uses a 10-cm line bounded on each end by perpendicular stops and descriptors. Zero equates to no pain, and 10 equates to the worst pain ever experienced. The initial score is not as important as change during treatment. Generally, a change in VAS scores has been shown to be valid and reliable if self-completion is appropriate.²⁷⁴ There is wide variability in this technique, and at least a 13-mm to 30-mm (1.3-cm to 3-cm) change on the scale is required to validate clinically relevant worsening or relief.²⁷³ Low completion rates may be seen in patients with visual or cognitive impairment.²⁷⁵ Graphic rating scales are useful for patients with limited cognitive and expressive ability, especially children. They may also be helpful to overcome language or cultural differences. A systematic review recently evaluated a variety of graphic scales in pediatric patients and supported use of the Faces Pain Scale (FPS), the Faces Pain Scale-Revised (FPS-R), the Oucher Pain Scale, and the Wong-Baker Faces Pain Rating Scale (WBFPRS).²⁷⁶ In an ED survey, the WBFPRS was the most common (81.7% of responding facilities) pain measurement tool used for pediatric pain assessment.²⁷⁷ Scale ratings may overestimate or underestimate pain in certain patients and do not mandate a specific pain reduction approach. This is better driven by clinician evaluation and consideration of the entire scenario. Such ratings rarely correlate with the seriousness of a patient's medical condition. It is not uncommon for patients to rate their pain a 12 on a scale of 1 to 10 in an attempt to emphasize their personal experience, anxiety, or fear of receiving inadequate analgesia. It may be a patient's perception that a higher rating will expedite treatment, prompt higher doses of medications, or otherwise engender more compassionate care. A common erroneous tactic or subterfuge of litigation proceedings is to incriminate a clinician's diagnosis, treatment, or disposition based on the patient's rendition of the pain scale.

Overall Goal of Pain Relief

The goal of pain management in the ED is to adequately relieve or control pain without compromising diagnosis, treatment plans, or the safety of the patient and population. Although the theoretically ideal objective is to totally relieve pain, this goal is difficult to consistently achieve in the complex ED milieu, and should not be the standard of care. Pain relief is best accomplished by combining clinician experience, real-time clinical judgment, repeated evaluation, and discussion with the patient and family. Concerns about safety and the potential for abuse of addictive pharmaceuticals often weigh into the decision-making process for emergency physicians, and universal prescriptive reporting services can be used to assist in patient care and safe prescribing practices.^{278,279} Strict adherence to

protocols, patient self-reporting on any pain scale, or reliance on a dogmatic approach to relief of a patient's pain can be fraught with peril. It is best to treat the patient, not the pain scale.

In summary, although the routine use of patient-reported pain scales may facilitate the administration of analgesics and be somewhat useful in trending response to analgesia, experienced clinicians and the authors recognize their limitations in an ED clinical setting. With certainty, one cannot conclude that any specific pain scale has any diagnostic or prognostic value. Pain scales are best used to raise awareness that pain—and prudent efforts to relieve it—is addressed in the ED.

Devices for Assessing Oxygenation and Ventilation

Andrew Miller and Joshua Nagler

SPIROMETRY

For patients with acute exacerbations of asthma and chronic obstructive pulmonary disease (COPD), accurately estimating the severity of airflow obstruction is a critical component of their care. A focused history plus physical examination is the cornerstone of this assessment in the practice of emergency medicine. Wide variation exists in the ability to accurately diagnose airway obstruction, and a significant proportion of patients with marked airflow obstruction present without dyspnea. This blunted perception of disease severity may be a contributor to fatal and near-fatal asthma attacks.^{1,2} Similarly, patients presenting with acute exacerbations of asthma may experience subjective resolution of their symptoms after therapy, even when severe airflow obstruction is still present. Given these difficulties in recognizing airflow obstruction, objective measurement provides valuable information.

Spirometry is measurement of the volume of air exhaled during forced expiration. It can be interpreted as a function of time to determine the flow rate. Spirometry gives the most complete picture of lung mechanics and is the centerpiece of pulmonary function testing. Many parameters can be derived from a spirogram, the most useful of which are forced vital capacity (FVC), which is the total volume exhaled during a forced expiratory maneuver, and forced expiratory volume in 1 second (FEV₁), which is the average flow rate during the first second of the forced expiratory maneuver (Fig. 2.1).

The advent of small handheld devices allows convenient spirometric evaluation in the emergency department (ED). The most common objective measurement of respiratory mechanics used in the ED is peak expiratory flow rate (PEFR). PEFR is the maximum flow of gas achieved during a forced expiratory maneuver. It correlates well with standard spirometry and has been studied extensively in the ED and outpatient setting.³⁻⁵

Indications

Evaluation of Acute Asthma Attacks

Currently, no standards exist for the measurement of pulmonary function parameters in ED patients, and practices vary widely. Most patients with asthma exacerbations can be evaluated, treated, and given a disposition with no further pulmonary function testing other than PEFR if quantitative assessment is deemed prudent. Several consensus guidelines recommend obtaining an objective measure of airflow obstruction in all patients seen in the ED with an acute exacerbation of asthma.⁶⁻⁸ Other guidelines have proposed that the decision to measure PEFR in patients with acute asthma should be individualized.⁹ It is reasonable that mild and easily reversible disease be evaluated and treated according to clinical judgment. If any

pulmonary function parameters are to be used, their use should be optimized, including measurements at arrival, after initial treatment, and periodically thereafter.⁶⁻⁸

Evaluation of Exacerbations of COPD

PEFR and spirometry testing can yield objective data on airflow obstruction during the ED evaluation of COPD exacerbations. Though used by some ED practitioners, consensus guidelines do not recommend routine use of these tests in the acute setting.^{10,11}

Differentiating Causes of Dyspnea

PEFR has been studied for its ability to differentiate between COPD and congestive heart failure (CHF).^{12,13} Insufficient data exist to recommend its routine use for this purpose in the ED.

Evaluation of Neuromuscular and Chest Wall Disease

Diseases of the chest wall and neuromuscular system can cause respiratory compromise. Though not commonly done in the ED, pulmonary function testing and assessment of negative inspiratory force can quantify the degree of impairment and help determine the level of admission needed.

Contraindications

Need for Immediate Intervention

Patients with severe respiratory compromise should receive aggressive therapy without delaying care for pulmonary function testing. Although portable pulmonary function testing may guide management, providing immediate intervention for those in distress should be the priority. Formal pulmonary function testing has limited value for acute exacerbations, and such assessments are most predictive when patients are at their baseline functional status.

Conditions That May Be Worsened by Increased Intrathoracic Pressure

Significant elevations in intrathoracic pressure will develop in patients performing a forced expiratory maneuver. Pneumothorax and pneumomediastinum may be exacerbated by the forced expiratory maneuver and aneurysms of the aorta or the cerebral vasculature could theoretically rupture with increased pressures. The presence of these conditions should be considered a relative contraindication to pulmonary function testing.

Equipment

Spirometers can be divided into two categories. Volume spirometers measure the amount of gas exhaled as a function of time. These devices tend to be cumbersome and are not ideally suited to the ED. Flow spirometers measure the flow of gas past a certain point and use that information to extrapolate volume and time data. These machines are smaller, simpler to use, and more portable. Flow spirometers determine gas flow by measuring the difference in pressure between two points in a tube (pneumotachograph), cooling of a heated wire (hot wire anemometer), or revolutions of a rotating vane. Most handheld spirometers also measure PEFR.

The most commonly used device to measure PEFR is the “mini-Wright” peak-flow meter (Fig. 2.2). These meters provide accurate and reproducible measurements of PEFR.¹⁴ Variation exists between types and brands of peak-flow flow

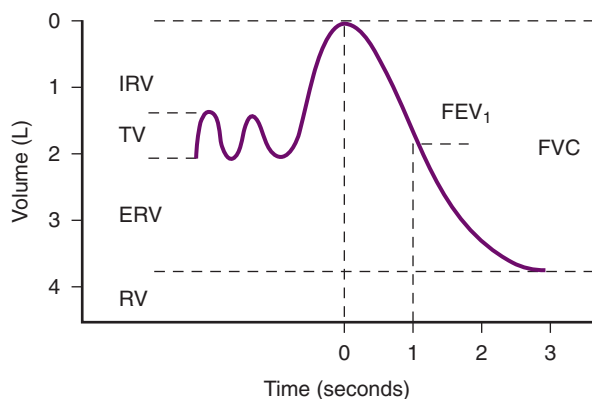

Figure 2.1 Diagrammatic representation of spirometry values. *ERV*, Expiratory reserve volume; *FEV₁*, forced expiratory volume in 1 second; *FVC*, forced vital capacity; *IRV*, inspiratory reserve volume; *RV*, residual volume; *TV*, tidal volume.

Figure 2.2 The “mini-Wright” peak flow meter.

meters, so comparative measurements should ideally be recorded with the same brand of peak-flow flow meter when possible.

Procedure

Calibrate the spirometer in accordance with the manufacturer’s directions and examine the peak-flow flow meter to ensure that the measurement bar is resting at the zero line before beginning the procedure. For multi-patient devices, attach a disposable mouthpiece to the input orifice.

Before starting the test, explain the procedure and allow unfamiliar patients to practice a few times. Ideally, the patient should be in the standing position or, if not feasible, be seated upright in bed. Ask the patient to elevate the chin and hold the neck in a slightly extended position. A nose clip is not required for PEFR measurements, but may be useful when performing formal spirometry testing.

After a period of normal breathing, ask the patient to take a maximal inspiration with the lips sealed around the mouthpiece while taking care to keep the tongue from partially obstructing the mouthpiece. Because airflow is greatest when the lung volumes are highest and the airways are larger, the test is accurate only if performed after maximal inspiration. Request the patient to initiate a rapid, forceful expiration as soon as possible after reaching maximal inspiration (Fig. 2.3). Coach the patient throughout the procedure and remind the patient to continue to make a forceful and complete exhalation. The PEFR usually occurs during the first 100 msec of expiration. In contrast, when performing spirometry, it is essential that the patient exhale fully. With both tests it is important to have a rapid, forceful exhalation rather than a slow, sustained one. Obtain three separate measurements for both spirometry and PEFR.

Figure 2.3 Measurement of the peak expiratory flow rate (PEFR) with a portable disposable peak flow meter. Ask the patient to take a maximal inspiration with the lips sealed around the mouthpiece and then initiate a rapid, forceful expiration immediately afterward. Three separate measurements should be obtained. Be sure to zero the device before each test. PEFR is the easiest and most common pulmonary function test used to evaluate asthma in the emergency department. Trends are more important than actual values because individual baselines vary widely. PEFR alone cannot be used to make accurate clinical decisions on admission or discharge.

TABLE 2.1 Approximate Values

	FEV ₁ (L)	FVC (L)	FEV ₁ /FVC Ratio (%)
Male	3.0–5.0	3.5–6.0	75–85
Female	2–3.5	2.5–4.0	75–85

FEV₁, Forced expiratory volume in 1 second; *FVC*, forced vital capacity. Modified from Hankinson JL, Odencrantz JR, Fedan KB: Spirometric reference values from a sample of the general US population, *Am J Respir Crit Care Med* 159:179, 1999.

PEFR measurements are very sensitive to technique and patient effort. Even a small decrease in effort can lead to considerable degradation of results.⁷ In addition, any deviation from technique can lead to inaccurate results and a faulty estimation of the degree of airway obstruction. Therefore emergency physicians should directly observe and guide their patients when performing this testing.¹⁵

Interpretation

Obstructive diseases are characterized by a disproportionate decrease in airflow (FEV₁) in relation to the volume of gas exhaled (FVC).¹⁰ A decreased FEV₁/FVC ratio with preservation of FVC indicates the presence of airflow obstruction. Restrictive diseases decrease total lung capacity and therefore decrease FVC to a greater degree than FEV₁. Decreased FVC with a normal or increased FEV₁/FVC ratio is indicative of restriction. It is useful to consider the FEV₁/FVC ratio when attempting to determine whether a patient has airflow obstruction. In patients with an established diagnosis of obstructive disease, FEV₁ is the test that best reflects changes in lung function. Typical values are shown in Table 2.1. These values are dependent on age, gender, ethnicity, and height and can be predicted from mathematical equations.^{16,17}

Isolated measurements of PEFR are not reliable in making the diagnosis of asthma because of significant variation between individuals. It is appropriate to use PEFR to monitor the degree of airflow obstruction in known asthmatics.

Although measures of airflow obstruction are not standalone tests, when considered along with other clinical factors, they can guide decisions regarding the disposition of patients with acute asthma exacerbations. The highest of three PEF_R or FEV₁ measurements should be used and, whenever possible, compared with the patient's personal best.⁶⁻⁸ In circumstances in which previous best values are unknown or thought to be inaccurate, comparison with predicted values is appropriate. References are available for predicted PEF_R values for adults by race and ethnicity.^{16,18-20} Values for children are presented in Tables 2.2 and 2.3. The National Asthma Education and Prevention Program has used the results of FEV₁ and PEF_R testing to classify the severity of asthma exacerbations (Table 2.4).⁸

Table 2.2 Predicted Peak Expiratory Flow Rate in Males 8-20 Years of Age

CAN BE FOUND ON EXPERT CONSULT

Table 2.3 Predicted Peak Expiratory Flow Rate in Females 8-18 Years of Age

CAN BE FOUND ON EXPERT CONSULT

Multiple guidelines and articles have advocated specific cutoff values for PEF_R and FEV₁ to guide decisions on disposition.⁶⁻⁸ There is variation across these guidelines and no consensus that absolute cutoffs should exist.⁸ Spirometric values including PEF_R and FEV₁ should be viewed as additional data points to be considered, along with other clinical variables such as response to inhaled bronchodilators, in determining the disposition of asthmatics seen in the ED. Poor response to treatment or failure to recover PEF_R or FEV₁ to greater than 70% of personal best are examples of factors that might favor admission rather than outpatient management of acute asthma exacerbations.

NONINVASIVE OXYGENATION MONITORING: PULSE OXIMETRY

Pulse oximetry, or noninvasive measurement of the percentage of hemoglobin bound to O₂, provides real-time estimates of arterial saturation in the range of 80% to 100% and gives early warning of diminished capillary perfusion while avoiding the discomfort and risks associated with arterial puncture. Pulse oximetry has become the standard of care in a wide variety of clinical settings.

Technology

Oximetry is based on the Beer-Lambert law, that states the concentration of an unknown solute dissolved in a solvent can be determined by light absorption. Pulse oximetry combines the principles of optical plethysmography and spectrophotometry. The probe, set into a reusable clip or a disposable patch, is made up of two photodiodes, which produce red light at 660 nm and infrared (IR) light at 900 to 940 nm, and a photodetector, which is placed across a pulsatile vascular bed. Pulse oximeter sensors are typically placed on the finger, with the light centered over the nailbed, not the fat pad. However, other locations such as the toes and earlobes are used in some

Figure 2.4 Factors influencing light absorption through a pulsatile vascular bed. (From McGough EK, Boysen PG: Benefits and limitations of pulse oximetry in the ICU. *J Crit Illness* 4:23, 1989.)

TABLE 2.4 Severity of Asthma Exacerbations According to Objective Measures of Airflow Obstruction

% OF PERSONAL BEST OR PREDICTED (FEV ₁ OR PEF _R)	SEVERITY OF EXACERBATION

31–50	Severe
51–80	Moderate
>80	Mild

FEV₁, Forced expiratory volume in 1 second; PEF_R, peak expiratory flow rate.

settings such as pediatrics. These particular wavelengths are used because the absorption characteristics of oxyhemoglobin and reduced hemoglobin are quite different at the two wavelengths. The majority of the light is absorbed by connective tissue, skin, bones, and venous blood. The amount of light absorbed by these substances is constant with time and does not vary during the cardiac cycle. A small increase in arterial blood occurs with each heartbeat, thereby resulting in an increase in light absorption (Fig. 2.4). By comparing the ratio of pulsatile and baseline absorption at these two wavelengths, the ratio of oxyhemoglobin to reduced hemoglobin is calculated.

Because the pulse oximeter uses only two wavelengths of light, it can distinguish only two substances. Pulse oximeters measure “functional saturation”: the concentration of oxyhemoglobin divided by the concentrations of oxyhemoglobin plus reduced hemoglobin. The disadvantage of functional saturation is that the denominator *does not include other hemoglobin species that may be present, such as carboxyhemoglobin and methemoglobin*. The advantage of using only two wavelengths in the oximeter is that the cost, size, and weight of the device are reduced. Alternative devices, such as the CO-oximeter, use four or more wavelengths to measure “fractional saturation,” and are able to quantify additional hemoglobin species.

Physiology

Arterial O₂ saturation (SaO₂) measures the large reservoir of O₂ carried by hemoglobin, 20 mL of O₂/100 mL of blood,

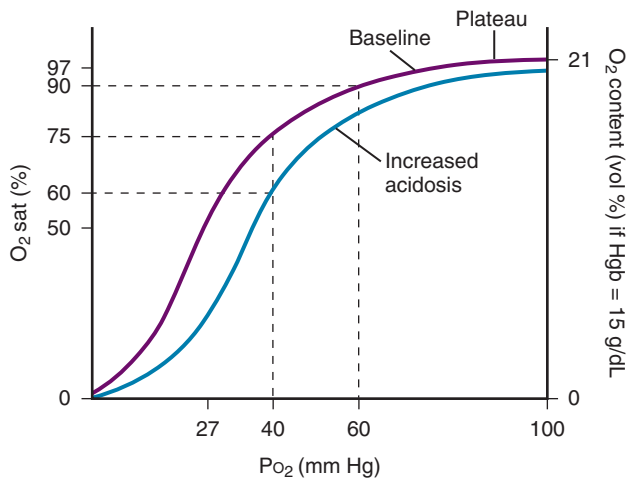

Figure 2.5 Oxyhemoglobin dissociation curve. Measurements of SaO_2 are relatively insensitive in detecting significant changes in PaO_2 at high levels of oxygenation because these SaO_2 values fall on the plateau portion of the curve (labeled). Hence, O_2 saturation is an insensitive way of detecting early compensation in patients with asthma.

and arterial O_2 partial pressure (PaO_2) measures only the relatively small amount of O_2 dissolved in plasma, approximately 0.3 mL of O_2 /100 mL of blood. SaO_2 correlates well with PaO_2 , but the relationship is nonlinear and is described by the oxyhemoglobin dissociation curve (Fig. 2.5). In hypoxemic patients, small changes in SaO_2 represent large changes in PaO_2 because these SaO_2 values fall on the steep portion of the curve. Conversely, measurements of SaO_2 are relatively insensitive in detecting significant changes in PaO_2 at high levels of oxygenation because these SaO_2 values fall on the plateau portion of the curve.

Currently available pulse oximeters are accurate and precise when saturation ranges from 70% to 100%.²¹ This range is satisfactory because for most patients an O_2 saturation of 80% is as much an urgent warning as is one lower than 70%. Testing of pulse oximeters has shown that at 75% saturation, bias is scattered uniformly between underestimation and overestimation.

Clinical Utility

Pulse oximetry peripheral oxygen saturation (SpO_2) offers an advantage in assessing the adequacy of oxygenation over arterial blood gas analysis by providing continuous measurements. Direct measurement of SaO_2 requires blood gas values coupled with knowledge of the actual hemoglobin levels in a patient's blood. SaO_2 measurement is estimated with pulse oximetry. In this chapter we equate SaO_2 and SpO_2 .

There are limited data on the clinical efficacy of pulse oximetry monitoring in the ED.^{22–24} Anesthesia studies have demonstrated that continuous monitoring of saturation can improve detection of hypoxemia and related events, though this practice has not been shown to impact major clinical outcomes such as mortality or transfer to the intensive care unit (ICU).²⁵ Nonetheless, there may be benefit to use in emergency medicine, particularly in those with primary cardiopulmonary disease or critically ill patients. Rapid recognition of adverse physiologic events should allow prompt initiation of therapeutic interventions.

BOX 2.1 Clinical Applications of Pulse Oximetry

- Assessing the adequacy of preoxygenation before ET intubation
- Monitoring oxygenation during emergency airway management
- Monitoring the ventilator and changes in FiO_2
- Providing an early indicator of ventilator dysfunction
- Assisting in routine weaning from O_2 therapy
- Monitoring patients in acute respiratory distress
- Monitoring during procedural sedation and analgesia
- Monitoring during interhospital and intrahospital transport

FiO_2 , Fractional concentration of inspired O_2 .

Indications

Recommended uses for pulse oximetry fall into two broad categories: (1) as a real-time indicator of hypoxemia, continuous oximetry monitoring can be used as a warning system because many adverse patient events are associated with arterial desaturation, and (2) as an end point for titration of therapeutic interventions to avoid hypoxia (Box 2.1).

Pulse oximetry can also be used to assess peripheral perfusion and evaluate for possible ischemia in the extremities. Although clinical experience validates its use, minimal data are available for such utilization in the ED. Vascular surgeons will use a pulse oximetry probe on a finger or toe to assess the results of vascular surgery on the arm or leg. Peripheral artery occlusion from peripheral artery disease may be suggested by comparison of pulse oximetry readings in the extremities. Decreased peripheral oxygenation may be detected in patients with compartment syndrome, traumatic arterial injury, and external compression of the proximal circulation (Fig. 2.6).

Procedure

The location for the probe is determined by the clinical situation and the types of probes available (Fig. 2.7). A reusable clip-on probe works well on digits that are easily accessible. Other sites include the earlobe, the nasal bridge, the septum, the forehead/temporal artery, and the foot or palm of an infant. More central locations may provide better readings in cold ambient temperature or during movement. Tape and splints can be used to secure oximetry probes and minimize motion.

The computer analyzes the incoming data to identify the arteriolar pulsation and displays this parameter as beats per minute. Newer devices also display a pulse plethysmograph (Fig. 2.8). Simultaneously, O_2 saturation is displayed on a beat-to-beat basis. Some machines have hard-copy capability and can provide paper documentation of the patient's status. Machines differ in their display when a pulsatile flow is not detected. Either the reading will not display at all, or the SaO_2 value will be given along with a poor-signal quality warning. It is important to evaluate serial measurements and to verify that the measurements correlate with other clinical markers.

Interpretation

Patients with normal physiologic gas exchange have an O_2 saturation between 97% and 100%. When SaO_2 falls below 95%, hypoxemia may be present, which may be baseline for some patients with cardiac or lung disease. O_2 saturation below

Figure 2.6 Pulse oximetry can be used to assess the distal circulation after vascular surgery for trauma and to initially evaluate other causes of decreased peripheral perfusion. **A**, This patient had a markedly swollen and ischemic finger from a tight ring. **B**, Although the need for immediate removal of the ring is clinically obvious, a pulse oximetry probe confirmed ischemia with an O_2 saturation of 61%. The uninvolved fingers registered 99%. Following ring removal the saturation returned to normal, thus suggesting that fasciotomy need not be performed. **C**, When a discharged EpiPen caused a pale finger, injection of phentolamine was considered. **D**, When pulse oximetry demonstrated a saturation of 96% (97% to 98% in the other fingers), injection was not performed and the circulation spontaneously normalized over a period of 30 minutes.

Figure 2.7 Pulse oximeter sensors. **A**, Reusable adult sensor, attached to finger. **B**, Single-use adult sensor, attached to finger. **C**, Single-use pediatric sensor, attached to toe. Note that the light source is centered over the nail, not the fat pad. See text for various parameters that affect pulse oximetry readings.

90% represents hypoxemia. As with spirometry, an isolated, low early measurement of SaO_2 does not mandate admission because of the potential for rapid response to therapy. Low SaO_2 readings should be heeded as important clinical warning signs. Pulse oximetry may be affected by numerous extrinsic factors, and a decline in O_2 saturation with serial measurements should always prompt an evaluation of respiratory status and adequacy of circulation.

Although pulse oximetry represents a significant advance in noninvasive monitoring of oxygenation, clinicians must recognize and understand its limitations.^{21,26} Pulse oximetry measures only O_2 saturation. In contrast to arterial blood gas determination, pulse oximetry provides no direct information on pH or the arterial partial pressure of CO_2 ($PaCO_2$). Nonetheless a room-air SaO_2 value of 97% or higher strongly rules against hypoxemia and moderate to severe hypercapnia. A

Figure 2.8 Patient monitor displaying a pulse plethysmograph (*arrow*). The patient's heart rate (84) and O₂ saturation (95) are also displayed (*blue numbers*).

room-air SaO₂ value of 96% or less has been demonstrated to be 100% sensitive and 54% specific for detecting hypoxemia (PaO₂ <70 mm Hg), and 100% sensitive and 31% specific for detecting hypercapnia (PaCO₂ >50 mm Hg). Using a cutoff value of 92% or less for room-air SaO₂ is more accurate in identifying hypoxemia in patients with COPD.

Pulse oximetry is not a substitute for monitoring ventilation because of the variable lag time between the onset of hypoventilation or apnea and a change in O₂ saturation. During procedural sedation, monitoring of ventilation is a more desirable goal for prevention of hypoxemia and hypercapnia than simple pulse oximetry (see section on **Procedural Sedation and Analgesia** under Carbon Dioxide Monitoring later in this chapter). Hypoventilation and the resultant hypercapnia may precede a decrease in hemoglobin O₂ saturation by many minutes. Supplemental O₂ may mask hypoventilation by delaying the eventual O₂ desaturation that pulse oximetry is designed to monitor and recognize. Other limitations of pulse oximetry are summarized in **Box 2.2**.

Sources of Interference

Effects of Dyshemoglobinemias

In patients with methemoglobinemia or elevated carboxyhemoglobin levels, pulse oximetry does not accurately depict quantitative changes in hemoglobin O₂ saturation.²¹ Carboxyhemoglobin results in falsely elevated SaO₂ estimates of hemoglobin O₂ saturation. Low quantities of methemoglobin will reduce pulse oximetry readings by approximately half the actual methemoglobin percentage. Large quantities of methemoglobin (>10%) can result in a stable pulse oximetry reading of 85% regardless of the actual SaO₂. Because pulse oximetry will variably underestimate the percentage of abnormal hemoglobin, a CO-oximeter or blood gas sample for quantitative analysis is required for confirmation of these conditions.

Fetal Hemoglobin

Full-term newborns can have up to 75% of total hemoglobin in the form of fetal hemoglobin and up to 5% in the form of carboxyhemoglobin. Although fetal hemoglobin interferes with the spectrophotometric method, pulse oximetry will remain accurate. A CO-oximeter may erroneously interpret the

BOX 2.2 Factors Affecting Pulse Oximetry Readings

Severe anemia: Satisfactory readings obtained down to a hemoglobin level of 5 mg/dL

Motion artifact: See text regarding probe sites

Dyes: Transient effect unless resulting in methemoglobinemia

Light artifact: Minimize by covering the probe with opaque material

Hypoperfusion: An inadequate pulse signal will be displayed
Electrocautery: Minimize by increasing the distance of the sensor from the surgical site

Deep pigmentation: Use the fifth finger, earlobe, or other area with lighter pigmentation

Dark nail polish: Remove with acetone or place a sensor sideways on the digit

Dyshemoglobinemias (e.g., carboxyhemoglobin and methemoglobin): Falsely elevate true oxygen saturation readings

Elevated bilirubin: Accurate up to a bilirubin level of 20 mg/dL in adults; no problem reported in jaundiced children

High saturation: Pulse oximetry not useful for monitoring hyperoxemia in neonates

Fetal hemoglobin: No effect on pulse oximetry; falsely reduced CO-oximetry readings

Venous pulsations: Artificially lower O₂ saturation; choose a probe site above the heart

Dialysis graft (arteriovenous fistula): No difference from the contralateral extremity unless the fistula is producing distal ischemia

carboxyhemoglobin level as elevated and the oxyhemoglobin level as artificially reduced. Therefore when fetal hemoglobin levels are high, CO-oximetry readings should not be used to confirm pulse oximetry readings.

Low Perfusion

To function properly, pulse oximeters require a pulsating vascular bed. Vasoconstriction related to hypotension, hypothermia, or the administration of vasoconstricting drugs may reduce the pulsatile component to less than 0.2% of the total signal. At this level, the true signal cannot be distinguished from background noise. Modern pulse oximeters have signal strength detectors and will display a message indicating an inadequate pulse signal when perfusion is compromised. Changing the location of the sensor to an area with higher perfusion, such as an earlobe or the forehead, may improve the pulse signal.

Intravenous Dyes

A number of dyes and pigments interfere with the accuracy of pulse oximetry.²⁷ Methylene blue, the treatment of methemoglobinemia, absorbs light at 660 nm, which is similar to the absorption of reduced hemoglobin, and can significantly decrease pulse oximeter saturation readings to as low as 1%. Low readings can also be seen with other intravenous dyes such as indigo carmine, indocyanine green, and fluorescein, although the rapid clearance of these agents minimizes this phenomenon.

Bilirubin

Hyperbilirubinemia does not affect the accuracy of pulse oximetry, but it may have an effect on absorption at the lower wavelengths used by CO-oximeters and result in a discrepancy between pulse oximeter and CO-oximeter readings.

Skin Pigmentation

The accuracy of pulse oximeters is somewhat reduced by darkly pigmented skin. This effect is probably due to a shift in the light-emitting diode's output spectrum as the light output is increased. This effect is small and results in only a slight decrease in accuracy. Placing the probe on an area of lighter pigmentation, such as the fifth finger or an earlobe, is suggested to minimize this effect.

Nail Polish

Data suggest that some nail polishes may affect the accuracy of pulse oximetry.^{28,29} Turning the probe sideways on the finger may improve accuracy, although removing any nail polish with acetone is the favored solution. The accuracy of SaO₂ readings in the setting of synthetic nails is unknown. If a poor signal is obtained through a synthetic nail, either the nail should be removed or an alternative site should be used for placement.

High Saturation

Because the O₂ dissociation curve plateaus at saturation levels greater than 90%, a large increase in PaO₂ results in only a small increase in saturation. An error of a few percentage points could represent a large error in PaO₂. This is inconsequential for most adult patients and is of extreme importance for neonates, who are at risk for retinopathy caused by hyperoxemia.

Venous Pulsations

The increased venous pulsations resulting from right heart failure and tricuspid regurgitation can interfere with accurate readings and lead to artificially lower O₂ saturation because the pulse oximeter interprets any pulsatile measurement as arterial. Placing the probe on a site above the heart may improve accuracy. Some pulse oximeters have the capability of synchronizing pulsations at the probe site to electrocardiographic (ECG) signals, thus enhancing the signal-to-noise ratio.

Anemia

Because pulse oximetry depends on light absorption by hemoglobin, it becomes less accurate and less reliable in conditions of severe anemia.

Ambient Light

Because the pulse oximeter's photodetector is nonspecific, high-intensity ambient light can produce interference. Surgical, fluorescent, and heating lamps are common sources of light interference. This problem can be corrected by wrapping the probe with a light barrier, such as a dark cloth or other opaque material.

Motion

Motion of the probe can produce considerable artifact and inaccurate readings. Correlating a pulse oximetry signal with an ECG waveform or using alternative probe sites, such as the ear or toe, may reduce motion artifact. Newer-generation pulse oximetry signal-processing technology has greatly reduced the effect of motion artifact.³⁰

Probe Site

The finger is the most common probe site used for adult pulse oximetry. If the finger is inaccessible or unsuitable, other probe sites, such as the earlobe, nose, and forehead (using reflectance instead of transmittance), may be used. It should be noted, though, that forehead and nasal bridge probes may be less accurate than finger and ear probes. In infants and small children, an adhesive sensor unit is preferred and frequently placed on the fingers and toes. Probes can also be secured in place over the palm, heel, or lateral aspect of the foot with a gauze or wrap.

Electrocautery

Electrical interference from devices such as electrocautery can impair the accuracy of pulse oximetry. Such interference can be reduced by increasing the distance between the surgical site and the probe.

Conclusions

Pulse oximetry is a widely available technology that provides an easy, noninvasive, and generally reliable method of monitoring oxygenation. Because measurements are continuous, pulse oximetry allows earlier detection of hypoxic episodes than intermittent arterial blood gas analysis does. Frequent measurements can lead to earlier corrective measures and prevention of adverse consequences.

Future Directions

New devices that focus on regional detection of O₂ saturation, specifically cerebral oximetry, are being studied for various clinical applications relevant to emergency medicine. This technology uses near-IR spectroscopy to obtain tissue level O₂ saturations. Data are emerging to support cerebral oximetry monitoring to assess quality of cardiopulmonary resuscitation (CPR) and to predict return of spontaneous circulation for these patients.^{31–35} Early studies have also suggested a role for cerebral oximetry in monitoring patients with altered mental status, including pharmacologically induced sedation.^{36–39} Currently there are no clear guidelines on when this technology should be used in an ED setting, and its growing experience may direct future applications in end-organ perfusion monitoring.

CO₂ MONITORING

Capnography is a noninvasive measurement of the partial pressure of CO₂ in an exhaled breath. Measurement of CO₂ at the airway can be displayed as a function of time (CO₂ concentration over time) or as an exhaled tidal volume (CO₂ concentration over volume). This chapter focuses on the use of time-based capnography because it can be adapted for use in both intubated and nonintubated patients, and therefore is the only form of CO₂ monitoring used by the emergency medical service (EMS) and the predominant form used in the ED.

The relationship of CO₂ concentration to time is graphically represented by the CO₂ waveform or capnogram (Fig. 2.9). The maximum CO₂ concentration at the end of each tidal breath is the end-tidal CO₂ pressure (PETCO₂). Changes in the shape of the capnogram are diagnostic of disease conditions,

Figure 2.9 Normal capnogram. The maximum CO_2 concentration at the end of exhalation of each tidal breath and at the beginning of inhalation is the *end-tidal CO_2 pressure* (PETCO_2), depicted by *D* on this graph. CO_2 pressure at *D* will be displayed numerically on the screen. See text for further explanation of the physiology of this graph. (From Krauss B, Hess DR: Capnography for procedural sedation and analgesia in the emergency department, *Ann Emerg Med* 50:172, 2007.)

and changes in PETCO_2 can be used to assess disease severity and response to treatment.

Oxygenation and ventilation are distinct physiologic functions that are assessed in both intubated and spontaneously breathing patients. Pulse oximetry provides real-time feedback about oxygenation, and capnography provides breath-to-breath information about all of the following: ventilation (how effectively CO_2 is being eliminated by the pulmonary system); perfusion (how effectively CO_2 is being transported through the vascular system); and metabolism (how effectively CO_2 is being produced by cellular metabolism).

Terminology

The ancient Greeks believed there was a combustion engine inside the body that gave off smoke (*capnos* in Greek) in the form of a breath. A capnometer is a CO_2 monitor that displays a number (i.e., PETCO_2). A capnograph is a CO_2 monitor that displays a number and a waveform (i.e., the capnogram).

Technology

Capnography became a routine part of anesthesia practice in Europe in the 1970s and in the United States in the 1980s. Capnography was incorporated into the American Heart Association (AHA) guidelines in 2000 and the American College of Emergency Physicians (ACEP) guidelines in 2001 and has become the standard of care for verification of endotracheal (ET) tube placement.

Most capnography technology is built on IR radiation techniques. These techniques are based on the fact that CO_2 molecules absorb IR radiation at a very specific wavelength (4.26 μm), with the amount of radiation absorbed having a close to exponential relationship to the CO_2 concentration present in the breath sample. Detecting these changes in IR radiation levels by using appropriate photodetectors sensitive in this spectral region allows the CO_2 concentration in the gas sample to be calculated.

Figure 2.10 End-tidal CO_2 sensors. **A**, Mainstream sensor. This device measures CO_2 directly from the proximal end of an endotracheal tube. **B**, Sidestream sensor. This cannula-type device allows concomitant CO_2 sampling and low-flow O_2 delivery to the patient.

CO_2 monitors measure gas concentration or partial pressure by using one of two configurations, depending on the location of the sensor: mainstream or sidestream (Fig. 2.10). Mainstream devices measure CO_2 directly from the airway, with the sensor located at the proximal end of the ET tube. Sidestream devices measure CO_2 by aspirating a small sample from the exhaled breath through tubing and a sensor located inside the monitor. Mainstream systems are configured only for intubated patients because the sensor is located on the ET tube. Sidestream systems do not require an ET tube because the sensor is located inside the monitor and may therefore be used in either intubated or nonintubated patients. The airway interface for intubated patients is an airway adapter placed on the hub of the ET tube. For spontaneously breathing patients, a nasal-oral cannula is used. This allows concomitant CO_2 sampling and delivery of low-flow O_2 to the patient.

Sidestream systems can be high-flow (requiring 150 mL/min of CO_2 in the breath sample to obtain an accurate reading) or low-flow (requiring 50 mL/min of CO_2). Low-flow sidestream systems have a lower occlusion rate (from moisture or patient secretions) and are more accurate in patients with low tidal volumes (neonates, infants, and patients with hypoventilation and low-tidal volume breathing).⁴⁰

CO_2 monitors can be either quantitative or qualitative (Fig. 2.11). Quantitative devices measure the precise PETCO_2 as either a number (capnometry) or a number and a waveform (capnography). Qualitative devices measure the range in which PETCO_2 falls (e.g., 0 to 10 mm Hg, >35 mm Hg) as opposed to a precise value (e.g., 38 mm Hg). The most commonly used qualitative device is the colorimetric PETCO_2 detector, which consists of a piece of specially treated litmus paper that turns color when exposed to CO_2 . Its primary use is for verification of ET tube position. If the tube is in the trachea, the resultant exhalation of CO_2 will change the color of the litmus paper; if the tube is in the esophagus with no CO_2 in the breath, no change in color will take place.

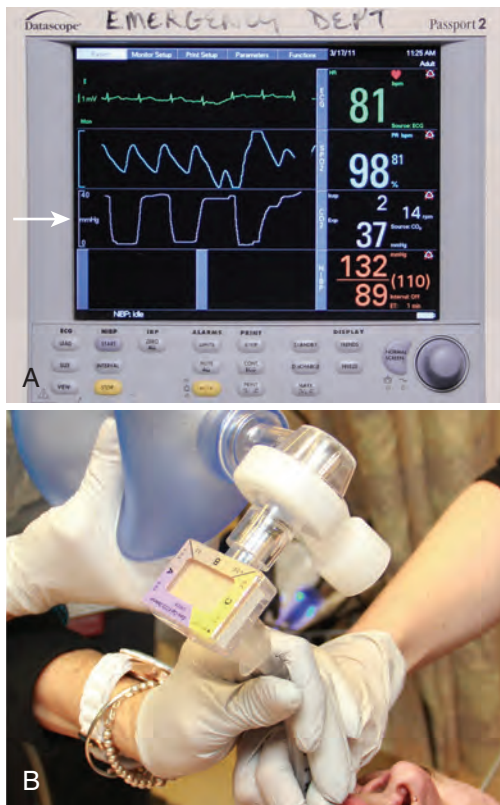

Figure 2.11 CO₂ monitors. **A**, Quantitative monitor. A capnography waveform (*arrow*) is displayed, as is a capnometry numerical reading (37). **B**, Qualitative device. This simple colorimetric detector is used to verify endotracheal tube position and changes color when exposed to CO₂.

Physiology

The capnogram, which corresponds to a single tidal breath, consists of four phases (ascending phase, alveolar plateau, inspiratory limb, dead space ventilation) (see Fig. 2.9). Each phase has conventionally been approximated as a straight line.^{41,42} Phase I (dead space ventilation, A to B) represents the beginning of exhalation in which dead space is cleared from the upper airway. Phase II (ascending phase, B to C) represents the rapid rise in CO₂ concentration in the breath stream as CO₂ from the alveoli reaches the upper airway. Phase III (alveolar plateau, C to D) represents the CO₂ concentration reaching a uniform level in the entire breath stream (from alveolus to nose) and concludes with a point of maximum CO₂ pressure (PETCO₂). *This is the number that appears on the monitor display.* Phase IV (D to E) represents the inspiratory cycle in which the CO₂ concentration drops to zero as atmospheric air enters the airway.

A normal capnogram, for patients of all ages, is characterized by a specific set of elements: it includes the four distinct phases just described, the CO₂ concentration starts at zero and returns to zero (i.e., there is no rebreathing of CO₂), a maximum CO₂ concentration is reached with each breath (i.e., PETCO₂), the amplitude is dependent on PETCO₂, the width is dependent on the expiratory time, and there is a characteristic shape for all subjects with normal lung function.

Patients with normal lung function, irrespective of age, will have a characteristic rectangular- or trapezoidal-shaped capnogram and a narrow PETCO₂-PCO₂ gradient (0 to 5 mm Hg),

A Normal patient: Trapezoidal capnogram

B COPD patient: Rounded capnogram, upward sloping alveolar plateau (*arrow*)

Figure 2.12 Capnogram shape in **A**, normal subjects and **B**, patients with chronic obstructive pulmonary disease (COPD). (From Krauss B, Deykin A, Lam A, et al: Capnogram shape in obstructive lung disease, *Anesth Analg* 100:884, 2005.)

with PETCO₂ accurately reflecting PaCO₂. Patients with obstructive lung disease will have a more rounded ascending phase and an upward slope in the alveolar plateau (Fig. 2.12).⁴³ In patients with abnormal lung function from \dot{V}/\dot{Q} mismatch, the gradient will widen, depending on the severity of the lung disease, and PETCO₂ will be useful only for trending ventilatory status over time and not as a spot check because it may not correlate with PaCO₂.

Indications for Intubated Patients

- Verification of ET tube placement
- Continuous monitoring of tube location during transport
- Gauging the effectiveness of resuscitation and prognosis during cardiac arrest
- Titrating PETCO₂ levels in patients with suspected increases in intracranial pressure
- Determining prognosis in patients after trauma
- Determining the adequacy of ventilation

Verification of ET Tube Placement

Unrecognized misplaced intubation (UMI) is placement of an ET tube in a location other than the trachea that is not recognized by the clinician. This life-threatening condition has been extensively documented in the EMS literature, with reported UMI rates most commonly between 7% to 10%.⁴⁴

After intubation, the presence of a waveform with all four phases indicates that the ET tube is through the vocal cords. A flatline waveform following intubation indicates esophageal placement except in selected conditions, including obstruction of the ET tube, complete airway obstruction distal to the tube, tracheal placement with inadequate pulmonary blood flow as a result of poor chest compressions, or prolonged cardiac arrest with no circulating CO₂ because of cessation of cellular metabolism.

The accuracy of PETCO₂ in confirming the tracheal location of an ET tube varies according to the type of CO₂ technology used. In patients who are not in cardiac arrest, qualitative colorimetric PETCO₂ and quantitative capnography studies have demonstrated 100% sensitivity and specificity for tracheal placement.⁴⁵ In marked contrast, the use of clinical signs for verification has been shown to be unreliable. Fogging or condensation of the tube, chest wall movement, and auscultation

for breath sounds have all been demonstrated to incorrectly identify tube location in some cases, including esophageal intubations.

Although the accuracy of PETCO₂ in verifying ET tube placement is 100% in patients with spontaneous circulation or low-perfusion states, sensitivity for tracheal placement in cardiac arrest patients ranges from 62% to 100%, depending on the type of CO₂ monitoring used and the duration of the arrest.^{45,46} Data are limited regarding specificity of capnography to detect esophageal intubations in cardiac arrest. When a waveform is present in an intubated patient in cardiac arrest, the ET tube can be assumed to be in the trachea. Absence of a waveform may result from esophageal intubation or a correctly placed ET tube in a patient with insufficient pulmonary blood flow.

Colorimetric studies have shown variable sensitivity because the exhaled CO₂ concentration can fall below the detection threshold. It is particularly important when evaluating PETCO₂ studies to distinguish those involving qualitative colorimetric detection from those using capnography.

Monitoring Tube Position During Transport

UMI (as a result of either initial misplacement of the ET tube or subsequent dislodgment during transport) can have catastrophic consequences and is largely preventable. Capnography has been demonstrated to help prehospital providers recognize ET tube dislodgment leading to more rapid correction of tube position.⁴⁷ Continuous monitoring of tube position during transport (prehospital to hospital, interhospital, or intrahospital) is essential for patient safety. PETCO₂ confirmation of initial ET tube placement with continuous monitoring of tube position is an accepted standard of care by the American Society of Anesthesiologists and is recommended by other national organizations.⁴⁸

Gauging the Effectiveness of CPR

Studies using animal models in the 1980s demonstrated that PETCO₂ levels reflect cardiac output during CPR and can be used as a noninvasive measure of cardiac output. A landmark study in 1988 demonstrated this principle in humans (Fig. 2.13).⁴⁹ During cardiac arrest, when alveolar ventilation and metabolism are essentially constant, PETCO₂ reflects the degree of pulmonary blood flow. Therefore PETCO₂ can be used as a gauge of the effectiveness of cardiac compressions. Effective cardiac compression leads to higher cardiac output, and the resultant increase in perfusion corresponds to a rise in PETCO₂ from baseline.⁵⁰ The 2010 AHA Consensus statement on CPR Quality, endorsed by the ACEP, recommends monitoring end-tidal CO₂ (ETCO₂) during CPR to improve chest compression performance if ETCO₂ is <10 mm Hg, and, by expert opinion, titrating to a goal ETCO₂ of >20 mm Hg.⁵¹

Indicator of ROSC

A peak in PETCO₂ is the earliest sign of return of spontaneous circulation (ROSC) and may occur before palpable or measurable hemodynamic signs (pulse or blood pressure).⁴⁹ When the heart is restarted, the dramatic increase in cardiac output and the resulting increase in perfusion lead to a rapid increase in PETCO₂ from baseline as the CO₂ that has built up in the blood during cardiac arrest is effectively transported to the lungs and exhaled.

The AHA guidelines emphasize the importance of continuing chest compressions without interruption until a perfusing

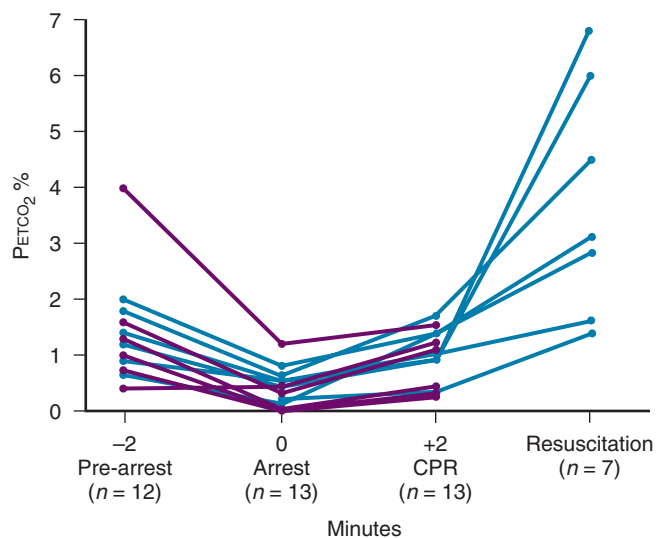

Figure 2.13 End-tidal carbon dioxide concentration (PETCO₂) pattern during cardiac arrest. CPR, Cardiopulmonary resuscitation. (Adapted from Falk JL, Rackow ED, Weil MH: End-tidal carbon dioxide concentration during cardiopulmonary resuscitation, *N Engl J Med* 318:607, 1988.)

rhythm is reestablished. Experimental evidence indicates that interruptions in chest compressions are followed by sustained periods during which flow gradually returns to pre-interruption levels. Capnography provides a means of monitoring the patient's physiological response to ongoing resuscitative efforts with minimal interruption to compressions for the purpose of checking for pulses. Reestablishment of a perfusing rhythm will be immediately accompanied by a dramatic increase in PETCO₂.

Assessing Prognosis After Initiation of Cardiac Arrest Resuscitation

Multiple factors can affect the recorded ETCO₂ values during cardiac arrest resuscitations.⁵² PETCO₂ can be used as a prognostic indicator of ROSC and survival in adult cardiac arrest patients. In multiple studies, PETCO₂ levels of 10 mm Hg or lower measured 20 minutes after the initiation of advanced cardiac life support accurately predicted death in patients with cardiac arrest. This prognostic value of measuring PETCO₂ has been demonstrated in both animal and human studies.⁵³

Identifying the Cause of Cardiac Arrest

Though not generally used clinically, differences in PETCO₂ may be seen depending on the cause of the cardiac arrest. Animal studies reported higher PETCO₂ values at the onset of cardiac arrest caused by primary asphyxia than after arrest caused by ventricular fibrillation. Prehospital cardiac arrest studies have demonstrated higher PETCO₂ results in patients with cardiac arrest secondary to respiratory or asphyxia causes than for those with primary cardiac etiologies.^{52,54}

Titrating ETCO₂ in Patients With Suspected Increased Intracranial Pressure

PETCO₂ monitoring has been shown to play a role in controlled ventilation in patients with head injury and suspected increased intracranial pressure. CO₂ levels affect blood flow to the brain, with high CO₂ levels resulting in cerebral vasodilation and

low CO₂ levels resulting in cerebral vasoconstriction. Sustained hypoventilation (PETCO₂ ≥50 mm Hg) is detrimental to patients with increased intracranial pressure because it results in increased cerebral blood flow and potential worsening of intracranial pressure.

Sustained hyperventilation is also detrimental and associated with worse neurologic outcome in severely brain-injured patients. Unless a patient is actively herniating, ventilation with CO₂ monitoring to achieve normocapnia is recommended. The benefit of continuous PETCO₂ monitoring for this indication has been demonstrated in many prehospital-based studies. Severe head-injury patients monitored with continuous PETCO₂ have better controlled ventilation, linked to improved outcome in traumatic brain injury patients.⁵⁵

PETCO₂ monitoring has also demonstrated prognostic value in determining outcome in trauma victims requiring prehospital ET intubation. Specifically, lower PETCO₂ levels 20 minutes post intubation are associated with poor survival.⁵⁶

Indications for Capnography in Spontaneously Breathing Patients

In spontaneously breathing, nonintubated patients, capnography can be used in a variety of clinical indications,⁵⁷ including:

- Rapid assessment of critically ill, injured, or seizing patients through assessment of the airway, breathing, and circulation (ABCs)
- Assessment and triage of victims of chemical terrorism and mass casualty
- Gauging the severity and response to treatment in patients with acute respiratory distress
- Determining the adequacy of ventilation in patients with altered mental status
- Detecting metabolic acidosis (including diabetic ketoacidosis and gastroenteritis)

Assessment of Critically Ill, Injured, or Seizing Patients

The ABCs of critically ill or injured patients can be assessed rapidly by using the capnogram and PETCO₂. The presence of a normal waveform denotes a patent airway and spontaneous breathing. Normal PETCO₂ (35 to 45 mm Hg) signifies adequate perfusion.

Capnography can be used to assess and triage critically ill or injured patients and actively seizing patients. Unlike pulse oximetry, capnography is not affected by motion artifact and provides reliable readings in low-perfusion states.

Capnography is a reliable, accurate monitoring modality for actively seizing patients. Capnographic data (respiratory rate [RR], PETCO₂, and capnogram) can be used to distinguish among:

- Seizing patients with apnea (flatline waveform, no PETCO₂ readings, and no chest wall movement)
- Seizing patients with ineffective ventilation (small waveforms, low PETCO₂)
- Seizing patients with effective ventilation (normal waveform, normal PETCO₂)

Assessment and Triage of Victims of Chemical Terrorism and Mass Casualty

EDs and EMS systems have focused on training to identify and effectively manage mass casualty and chemical terrorism events. Capnography can serve as a noninvasive assessment

tool to quickly identify the common life-threatening complications of chemical terrorism.⁵⁸ It can rapidly detect the common airway, respiratory, and central nervous system adverse events associated with nerve agents, including apnea, upper airway obstruction, laryngospasm, bronchospasm, respiratory failure, seizures, and coma (Table 2.5).

Table 2.5 Capnographic Identification of Life-Threatening Complications of Nerve Agents
CAN BE FOUND ON EXPERT CONSULT

Gauging Severity and Response to Treatment of Patients in Acute Respiratory Distress

Capnography provides dynamic monitoring of ventilatory status in patients with acute respiratory distress from any cause, including asthma, bronchiolitis, CHF, COPD, croup, and cystic fibrosis. By measuring PETCO₂ and RR with each breath, capnography provides immediate information on the clinical status of the patient. RR is measured directly from the airway (nose and mouth) with an oral-nasal cannula and provides a more reliable reading than does impedance respiratory monitoring. In upper airway obstruction and laryngospasm, impedance monitoring detects chest wall movement, interprets this as valid breathing, and displays an RR even though the patient is not ventilating. In contrast, capnography will detect absence of air movement and therefore shows a flatline waveform.

PETCO₂ trends can be assessed rapidly, especially in tachypneic patients. For example, a patient with an RR of 30 breaths/min will generate 150 PETCO₂ readings in 5 minutes. This provides sufficient information to determine whether the patient's ventilation is worsening despite treatment (increasing PETCO₂), stabilizing (stable PETCO₂), or improving (decreasing PETCO₂) (Fig. 2.14).

Procedural Sedation and Analgesia

Pulse oximetry is the standard technique for monitoring procedural sedation in the ED, but capnography is more likely

Figure 2.14 PETCO₂ trending in patients with acute respiratory distress. The dynamic ventilatory information provided by PETCO₂ trends can be used to gauge response to treatment in patients with acute respiratory distress. Trends show worsening despite treatment (increasing PETCO₂), stabilized (stable PETCO₂) ventilatory status, or improving (decreasing PETCO₂) ventilatory status.

Modified from Krauss B: Capnography as rapid assessment and triage tool for chemical terrorism, *Pediatr Emerg Care* 21:493, 2005.

Figure 2.15 Capnographic detection of apnea. The CO₂ flatline indicates complete absence of air movement. Note that the EKG and pulse oximetry initially appear normal in this patient with a respiratory arrest.

to detect the common adverse airway and respiratory events associated with procedural sedation and analgesia.^{59–61} In 2014 The ACEP gave capnography during procedural sedation a Level B recommendation:

Capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED.

Capnography is the earliest indicator of airway or respiratory compromise and will show an abnormally high or low PETCO₂ well before pulse oximetry detects a falling oxyhemoglobin saturation, especially in patients receiving supplemental oxygen (Fig. 2.15).^{61,62} Capnography provides a non-impedance-based RR directly from the airway, which is more accurate than impedance-based respiratory monitoring, especially in patients with obstructive apnea or laryngospasm.

Both central and obstructive apnea can be detected almost instantaneously by capnography (Table 2.6). Loss of the capnogram, in conjunction with no chest wall movement and no breath sounds on auscultation, confirms the diagnosis of central apnea. Obstructive apnea is characterized by loss of the capnogram with continued chest wall movement and absent breath sounds. The response of the capnogram to airway alignment maneuvers can further distinguish upper airway obstruction from laryngospasm.

Capnography is more sensitive than clinical assessment of ventilation in detecting apnea along with other respiratory complications. This leads to more awareness of respiratory complications associated with procedural sedation, which is followed by appropriate and timely interventions.^{59–62}

Because the amplitude of the capnogram is determined by PETCO₂ and the width is determined by the expiratory time, changes in either of these parameters affect the shape of the capnogram. Hyperventilation (increased RR, decreased PETCO₂) results in a low-amplitude and narrow capnogram. Classic hypoventilation (decreased RR, increased PETCO₂) results in a high-amplitude and wide capnogram (see Table 2.6). Acute bronchospasm results in a capnogram with a curved ascending phase and an upsloping alveolar plateau (Fig. 2.12). A PETCO₂ reading higher than 70 mm Hg in patients without chronic ventilation problems indicates respiratory failure.

Two types of drug-induced hypoventilation occur during procedural sedation and analgesia (see Table 2.6).⁶³ Bradypneic hypoventilation (type 1), commonly seen with opioids, is

characterized by increased PETCO₂ and increased PaCO₂. RR is depressed proportionally greater than tidal volume, resulting in bradypnea, an increase in expiratory time, and a rise in PETCO₂, graphically represented by a high-amplitude, wide capnogram (see Table 2.6).

Bradypneic hypoventilation follows a predictable course, with PETCO₂ increasing progressively until respiratory failure and apnea occur. Although there is no absolute threshold at which apnea occurs, patients with acute increases in PETCO₂ to above 80 mm Hg are at significant risk.

Hypopneic hypoventilation (type 2), commonly seen with sedative-hypnotic drugs, is characterized by normal or decreased PETCO₂ and increased PaCO₂ because airway dead space remains constant (e.g., 150 mL in the normal adult lung) and tidal volume decreases. Tidal volume is depressed proportionally greater than RR, thereby resulting in low-tidal volume breathing and leading to an increase in the fraction of airway dead space (dead space volume/tidal volume). As tidal volume decreases, the airway dead space fraction increases, resulting in an increase in the PaCO₂-PETCO₂ gradient. Even though PaCO₂ is increasing, PETCO₂ may remain normal or decrease, graphically represented by a low-amplitude capnogram.

Hypopneic hypoventilation follows a variable course. Three possibilities exist: (1) ventilation may remain stable with the low-tidal volume breathing resolving over time as drug levels in the central nervous system decrease following redistribution, (2) hypoventilation may progress to periodic breathing with intermittent apneic pauses (which may resolve spontaneously or progress to central apnea), or (3) hypoventilation may progress directly to central apnea.

The low-tidal volume breathing that characterizes hypopneic hypoventilation increases dead space ventilation as a result of inhibition of the normal compensatory mechanisms by drug effects. Minute ventilation, which normally increases to compensate for an increase in dead space, does not change or may decrease. As minute ventilation decreases, arterial oxygenation decreases. PETCO₂ may initially be high (bradypneic hypoventilation) or low (hypopneic hypoventilation) without significant changes in oxygenation, particularly if supplemental O₂ is given. Therefore a drug-induced increase or decrease in PETCO₂ does not necessarily lead to O₂ desaturation and may not require intervention.

Determining the Adequacy of Ventilation in Patients With Altered Mental Status

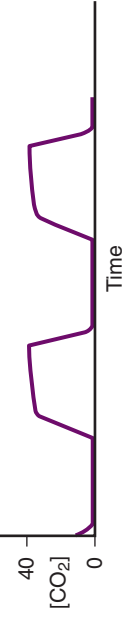

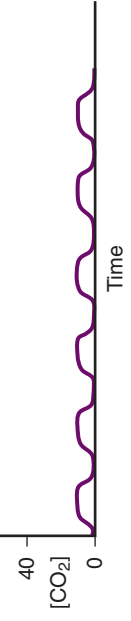

Patients with altered mental status, including those with alcohol intoxication, intentional or unintentional drug overdose, patients requiring chemical restraint, and postictal patients (especially those treated with benzodiazepines), may have impaired ventilatory function. Capnography can differentiate between patients with effective ventilation and those with ineffective ventilation, as well as provide continuous monitoring of ventilatory trends over time to identify patients at risk for worsening respiratory depression.

Detection of Metabolic Acidosis

In addition to its established uses for assessment of ventilation and perfusion, capnography is a valuable tool for assessing metabolic status by providing information on how effectively CO₂ is being produced by cellular metabolism.

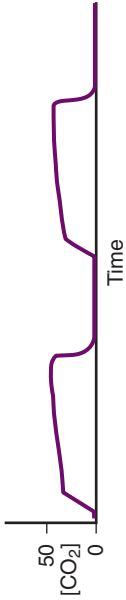

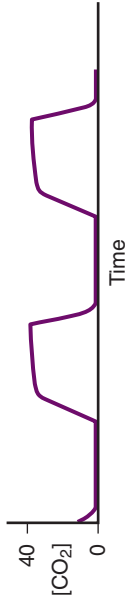

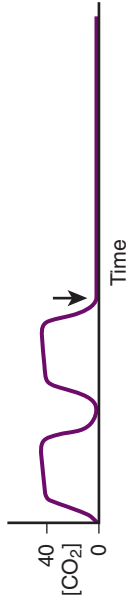

Studies have shown that PETCO₂ and serum bicarbonate (HCO₃) are well correlated in patients with diabetes and gastroenteritis. PETCO₂ can be used as an indicator of metabolic

PETCO₂, End-tidal carbon dioxide pressure; RR, respiratory rate; SpO₂, oxygen saturation as measured by pulse oximetry.

Figure 2.16 PETCO₂-HCO₃ correlation in patients with diabetes. (From Fearon DM, Steele DW: End-tidal carbon dioxide predicts the presence and severity of acidosis in children with diabetes, *Acad Emerg Med* 9:1373, 2002.)

acidosis in these patients (Fig. 2.16).⁶⁴⁻⁶⁶ As the patient becomes acidotic (i.e., HCO₃ decreases), a compensatory respiratory alkalosis develops with an increase in minute ventilation and a resultant decrease in PETCO₂. By increasing minute ventilation, these patients are able to lower arterial CO₂ tension to help correct the underlying acidemia. The more acidotic, the lower the HCO₃, the higher the RR, and the lower the PETCO₂.

PETCO₂ can be used to distinguish diabetics in ketoacidosis (metabolic acidosis, compensatory tachypnea, low PETCO₂) from those who are not (non-acidotic, normal RR, normal PETCO₂).^{64,65} Capnography could be utilized as a potential triage tool to determine the need for intravenous access and rapid assessment by a physician versus delayed physician assessment and potentially starting oral rehydration for patients with concerns for diabetic- or dehydration-related metabolic acidosis.

Limitations

Significant technical problems have historically restricted the effective clinical use of capnography. Such problems include interference with the sensor by condensed water and patient secretions in both mainstream and high-flow sidestream devices,

cross-sensitivity with anesthetic gases in conventional CO₂ sensors, lack of ruggedness for intrahospital and interhospital transport, and power consumption issues related to portable battery operation time. These issues have largely been resolved in the newer-generation capnography monitors.

Problems with accuracy continue to affect high-flow sidestream systems. When the tidal volume of the patient drops below the flow rate of the system (e.g., neonates, infants, hypoventilating patients with low-tidal volume breathing), the monitor will entrain room air, thereby falsely diluting PETCO₂ and slurring the ascending phase of the waveform.⁶⁷

Early capnography airway interfaces (i.e., nasal cannula) had difficulty providing consistent measurements in mouth-breathing patients and those who alternated between mouth and nose breathing. The newer oral-nasal interface has addressed these problems.

Capnography is most effective when assessing a pure ventilation, perfusion, or metabolism problem. Capnographic findings in patients with mixed ventilation, perfusion, or metabolism problems are difficult to interpret. For example, in patients with complex pathophysiology, a ventilation problem may elevate PETCO₂, and a perfusion problem may simultaneously lower PETCO₂. Absolute values and even trends over time may be difficult to interpret in these situations.

Although capnography in patients in cardiac arrest is 100% specific for tracheal placement of the ET tube, its sensitivity for esophageal placement is uncertain.

CONCLUSION

Capnography is a versatile noninvasive diagnostic modality for monitoring ventilation, perfusion, and metabolic status in both intubated and nonintubated patients. Clinical applications include verification and continuous monitoring of ET tube placement; determination of the efficacy of CPR in cardiac arrest; ventilatory monitoring of head-injured patients; assessment of vital signs in patients who are critically ill, injured, seizing, or undergoing procedural sedation or have altered mental status; evaluation of patients in acute respiratory distress; and detection of metabolic acidosis.

Respiratory Procedures

CHAPTER 3

Basic Airway Management and Decision Making

Brian E. Driver and Robert F. Reardon

Basic airway procedures are often overlooked in favor of more exciting intubation devices and techniques, but basic procedures are critically important and often lifesaving. Establishment of a patent airway, oxygenation, and bag-mask ventilation (BMV) remain the cornerstones of good emergency airway management (Videos 3.1–3.11).^{1,2} These techniques can be used quickly and in any setting. They allow practitioners to keep apneic patients alive until a definitive airway can be established.²

Extraglottic devices, such as laryngeal mask airways (LMAs) and the King Laryngeal Tube (LT), are also important for the initial resuscitation of apneic patients and for rescue ventilation when intubation fails.^{3–5}

This chapter describes basic airway skills, including opening the airway, oxygen (O₂) therapy, BMV, and extraglottic airway (EGA) devices. These are the skills that providers can rely on when other airway techniques are difficult or impossible. Mastery of these skills will help providers manage difficult, anxiety-provoking emergency airways.

THE CHALLENGE OF EMERGENCY AIRWAY MANAGEMENT

Although other specialists are sometimes available, most emergency airways are managed by emergency medicine providers.⁶ Airway management in the emergency department (ED) is unique and significantly different from airway management in the controlled setting of an operating room. Additionally, conventional airway management tools may be ineffective in the uncontrolled emergency environment. Major challenges include hypoxia; shock; full stomach, and the presence of emesis, blood, or excessive secretions in the airway. Many patients are uncooperative and combative, making it impossible to properly examine the airway before choosing an intubation technique. Medical history, allergies, and even the current diagnosis are often unknown before emergency airway management begins. Time constraints, lack of patient cooperation, and risk for

emesis and aspiration limit the use of some techniques, such as awake intubation. In trauma patients, the risk for cervical spine injury limits optimal head and neck positioning for BMV and laryngoscopy. All these factors increase the risk for complications from emergency airway management,^{6,7} and approximately 0.5% to 1% of all emergency airways require a surgical approach.^{6,8} The increasing use of video laryngoscopy may reduce the incidence of emergency surgical airways.

BASIC AIRWAY MANAGEMENT TECHNIQUES

Opening the Airway

The first concern in the management of a critically ill patient is patency of the airway. Upper airway obstruction commonly occurs when patients are unconscious or sedated. It can also be due to injury to the mandible or muscles that support the hypopharynx. In these situations, the tongue moves posteriorly into the upper airway when the patient is in a supine position. Upper airway obstruction caused by the tongue can be relieved by positioning maneuvers of the head, neck, and jaw; the use of nasopharyngeal or oropharyngeal airways; or the application of noninvasive positive pressure ventilation (NPPV).

Manual Airway Maneuvers

Airway obstruction in unconscious patients is often due to posterior displacement of the tongue (Fig. 3.1A). Research in patients with obstructive sleep apnea using NPPV supports the concept that the airway collapses like a flexible tube.^{2,9} Upper airway obstruction often causes obvious snoring or stridor, but it may be difficult to discern in some patients. All unconscious patients are at high risk for upper airway obstruction.

More than 40 years ago, Guildner¹⁰ compared different techniques for opening obstructed upper airways and found that the head-tilt/chin-lift and jaw-thrust techniques were both effective (Fig. 3.1B and C). The jaw-thrust maneuver (anterior mandibular translation to bring the lower incisors anterior to the upper incisors) is the most important technique for opening the upper airway.^{2,11}

It is widely accepted that the jaw-thrust-only (without head tilt or chin lift) maneuver should be performed in patients with suspected cervical spine injury,¹² but there is no evidence that it is safer than the head-tilt/chin-lift maneuver.¹³ The American Heart Association (AHA) concluded that airway maneuvers are safe during manual in-line stabilization of the cervical spine but highlighted evidence that all airway maneuvers cause some spinal movement. Both the chin-lift and the

Manual Airway Maneuvers

Figure 3.1 Manual airway maneuvers. **A**, The most common cause of airway obstruction in an unconscious patient is the tongue. Initial maneuvers for opening the airway include **B**, head tilt/chin lift and **C**, jaw thrust. The jaw-thrust maneuver is the most important technique.

jaw-thrust maneuvers have been shown to cause similar substantial movement of the cervical vertebrae.^{14–18} However, there is no evidence that this movement worsens existing spinal cord injury or causes new spinal cord injury in patients with cervical spine fractures. Most experts believe that airway interventions performed for patients with cervical spine injury are safe.^{19–21} The AHA recommends that “if healthcare providers suspect a cervical spine injury, they should open the airway using a jaw thrust without head extension. Because maintaining a patent airway and providing adequate ventilation are priorities in CPR, use the head tilt–chin lift maneuver if the jaw thrust does not adequately open the airway.”²²

Importantly, the addition of NPPV may relieve airway obstruction when simple manual positioning maneuvers fail. Meier and colleagues⁹ showed that adding NPPV to the chin-lift and jaw-thrust maneuvers decreased stridor and improved the nasal fiberoptic view of the glottic opening in anesthetized children. The use of NPPV for patients with upper airway obstruction should not be considered a definitive solution.

The Jaw-Thrust Maneuver

The jaw-thrust maneuver is the most important technique used to open the upper airway. To perform the jaw-thrust maneuver, place the tips of the middle or index fingers behind the angle of the mandible (see [Fig. 3.1C](#)). Lift the mandible toward the ceiling until the lower incisors are anterior to the upper incisors. This maneuver can be performed in combination with the head-tilt/chin-lift maneuver or with the neck in the neutral position during in-line stabilization.

The Head-Tilt/Chin-Lift Maneuver

To perform the head-tilt/chin-lift maneuver, place the tips of the index and middle fingers beneath the patient’s chin (see [Fig. 3.1B](#)). Lift the chin cephalad and toward the ceiling. The upper part of the neck will naturally extend when the head tilts backward during this maneuver. Apply digital pressure on only the bony prominence of the chin and not on the soft tissues of the submandibular region. The final step in this maneuver is to use the thumb to open the patient’s mouth while the head is tilted and the neck is extended.

The Triple Airway Maneuver

The “triple airway maneuver” is described by some authors as a valuable method for maintaining a patent upper airway.^{2,12} The most common description of this maneuver is head tilt, jaw thrust, and mouth opening.^{2,12} Evidence demonstrates that the upper airway is more patent when the mouth is closed.^{23–25} Although the triple maneuver is commonly mentioned in the anesthesia literature as a valuable technique, no studies exist to support the assertion that this technique is more effective than the head-tilt/chin-lift or jaw-thrust maneuvers.

Patient Positioning

The best way to position a patient’s head and neck for opening the upper airway is to mimic how patients position themselves when they are short of breath, with the neck flexed relative to the torso and with atlanto-occipital extension.² This is known as the *sniffing position* and was described by Magill almost 100 years ago.²⁶ In normal-sized supine adults this is accomplished by elevating the head approximately 10 cm while tilting the head back, so that the plane of the patient’s face tilts slightly toward the provider at the head of the bed (see [Chapter 4, Fig. 4.8](#)).^{2,27–29} Morbidly obese patients require much more head elevation to achieve the proper sniffing position. This can be accomplished by building a ramp of towels and pillows under the upper torso, head, and neck or by using a Troop Elevation Pillow (Mercury Medical, Clearwater, FL) or similar device ([Fig. 3.2](#)).^{30–33} Rather than elevating the head by a standard height, the goal of head elevation is to achieve horizontal alignment of the external auditory meatus with the sternum. This is the best position for opening the upper airway in morbidly obese patients.^{32–35}

The sniffing position is contraindicated in patients with cervical spine injuries. The best technique for opening the airway in this situation is a simple jaw-thrust maneuver with anterior mandibular translation to bring the lower incisors anterior to the upper incisors (see [Fig. 3.1C](#)).^{2,11} In obese patients, fat deposition on the upper back results in neck extension when the patient’s head is resting on the bed. In these patients, it is acceptable to carefully elevate the head

Figure 3.2 The best position for opening the upper airway in morbidly obese patients is elevation of the head, neck, and shoulders so that the external auditory meatus is aligned with the sternum. This can be accomplished with purpose-built pillows; however, similar results may be achieved with other devices or a ramp of towels and pillows.

with a towel or pillow to move the head and neck into a more neutral position even in the setting of cervical spine trauma.

In young children, the sniffing position is often achieved without lifting the head because the occiput of a child is relatively large, so the lower cervical spine is normally flexed when the child is lying supine on a flat surface.

Airway management is usually easiest when patients are in the supine position, but the lateral position may be best for patients who are actively vomiting and those with excessive upper airway bleeding or secretions. Some evidence suggests that rotating patients to the lateral position may not prevent aspiration.³⁶ Patients with suspected cervical spine injury should have their head immobilized with manual in-line stabilization if they need to be rolled to the lateral position. Airway management maneuvers will be more difficult when patients are in the lateral position.

Foreign Body Airway Obstruction

Awake patients with partial airway obstruction can usually clear a foreign body on their own. Intervention is required when the patient is not moving air or has altered mental status. Some patients with upper airway obstruction can be ventilated and oxygenated with aggressive high-pressure BMV, so always try this if standard BMV fails. Massive aspiration of vomitus is often a fatal event because of inability of the patient and clinician to adequately clear the airway.

Abdominal Thrusts (Heimlich Maneuver), Chest Thrusts, and Back Blows (Slaps)

The International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiopulmonary Care⁴ evaluated the evidence for different techniques to clear foreign body airway obstruction. They found good evidence for the use of chest thrusts, abdominal thrusts, and back blows or slaps. Insufficient evidence exists to determine which technique is the best and which should be used first.

The technique of subdiaphragmatic abdominal thrusts to relieve a completely obstructed airway was popularized by Dr. Henry Heimlich and is commonly referred to as the *Heimlich maneuver*.³⁷ The technique is most effective when a solid food bolus is obstructing the larynx. In a conscious patient, stand behind the upright patient. Circle the arms around the patient's midsection with the radial side of a clenched fist placed on the abdomen, midway between the umbilicus and xiphoid. Then grasp the fist with the opposite hand and deliver an inward and upward thrust to the abdomen (Fig. 3.3A). A successful maneuver will cause the obstructing agent to be expelled from the patient's airway by the force of air exiting the lungs. Abdominal thrusts are relatively contraindicated in pregnant patients and those with protuberant abdomens. Potential risks associated with abdominal thrusts include stomach rupture, esophageal perforation, and mesenteric laceration, compelling the rescuer to weigh the risks and benefits of this maneuver.³⁸⁻⁴³ Use a sternal hand position for pregnant patients (Fig. 3.3B).

If a choking patient loses consciousness, use chest compressions in an attempt to expel the obstructing agent (Fig. 3.3C).⁴ The theory is the same as the Heimlich maneuver, with high intrathoracic pressure created to push the obstruction out of the airway. Some data suggest that chest compressions may generate higher peak airway pressure than the Heimlich maneuver.⁴⁴ After 30 seconds of chest compressions, remove the obstructing object if you see it, attempt 2 breaths, and then continue cardiopulmonary resuscitation (CPR; 30 compressions to 2 breaths). Every time you open the airway to give breaths, look for the object and remove it if possible, and then continue CPR if necessary.

Back blows are recommended for infants and small children with a foreign body obstructing the airway. Some authors have argued that back blows may be dangerous and may drive foreign bodies deeper into the airway, but there is no convincing evidence of this phenomenon.^{45,46} Anecdotal evidence suggests that back blows are effective.⁴⁷⁻⁴⁹ No convincing data, however, indicate that back blows are more or less effective than abdominal or chest thrusts. Back blows may produce a more pronounced increase in airway pressure, but over a shorter period than with the other techniques. The AHA guidelines suggest back blows in the head-down position (Fig. 3.3D) and head-down chest thrusts in infants and small children with foreign body airway obstruction (Fig. 3.3E).⁴ The AHA does not recommend abdominal thrusts in infants because they may be at higher risk for iatrogenic injury. From a practical standpoint, back blows should be delivered with the patient in a head-down position, which is more easily accomplished in infants than in larger children. It is recommended that suction be performed on newborns rather than giving them back blows or abdominal thrusts.⁵⁰

Any patient with a complete airway obstruction may benefit from chest compressions, abdominal thrusts, or back blows. It is important to realize that more than one technique is often required to clear obstruction of the airway by a foreign body, so multiple techniques should be applied in a rapid sequence until the obstruction is relieved. Perform a finger sweep of the patient's mouth only if a solid object is seen in the airway.

Perform CPR on all unconscious patients with airway obstruction. Aggressive high-pressure BMV should be attempted, as this may distend the trachea enough to allow air to bypass the obstruction. In cases in which obstructive foreign bodies cannot be removed under direct visualization

Heimlich Maneuvers

Figure 3.3 A-E, Heimlich maneuvers (see text).

and aggressive positive pressure ventilation has failed, practitioners with advanced airway skills and proper equipment can try to push a subglottic foreign body beyond the carina, usually into the right main stem bronchus.

Suctioning

Patient positioning and airway-opening maneuvers are often inadequate to achieve complete airway patency. Ongoing hemorrhage, vomitus, and particulate debris frequently require suctioning. Several types of suctioning tips are available. A large-bore dental-type suction tip is the most effective in clearing vomitus from the upper airway because it is less likely to become obstructed by particulate matter. The tonsil tip (Yankauer) suction device can be used to clear hemorrhage and secretions. Its rounded tip is less traumatic to soft tissues, but the tonsil tip device is not large enough to effectively suction vomitus.

A large-bore dental-type tip device, such as the HI-D Big Stick (SSCOR Inc, Sun Valley, CA) suction tip, should be readily available at the bedside during all emergency airway management (Fig. 3.4). The large-bore tip allows rapid clearing of vomitus, blood, and secretions.

Figure 3.4 HI-D Big Stick suction tip (SSCOR, Inc., Sun Valley, CA) and 5/16-inch tubing.

A limiting feature of many suction catheters is the diameter of the tubing. Vomitus may obstruct the standard 1/4-inch-diameter catheter.⁵¹ A 5/8- or 3/4-inch-diameter suction tube (Kuriyama Tubing, 5/16-inch inner diameter, 0.44-inch outer diameter, clear; www.grainger.com) has been shown to significantly decrease suction time for viscous and particulate material (see Fig. 3.4).⁵²

Keep suctioning equipment connected and ready to operate. Everyone participating in emergency airway management should know how to use it. Interposition of a suction trap close to the suction device prevents clogging of the tubing with particulate debris.

No specific contraindications to airway suctioning exist. Complications of suctioning may be avoided by anticipating problems and providing appropriate care before and during suctioning maneuvers. Nasal suction is seldom required, except in infants, because most adult airway obstruction occurs in the mouth and oropharynx.

Avoid prolonged suctioning because it may lead to significant hypoxia, especially in children. Do not exceed 15 seconds for suctioning intervals and administer supplemental O₂ before and after suctioning. Naigow and Powasner⁵³ found that suctioning consistently induced hypoxia in dogs and that it was best avoided by hyperventilation with high-concentration O₂ before and after suctioning. Hypoxia was also prevented in children by pre-oxygenation prior to endotracheal (ET) suctioning attempts.⁵⁴

When feasible, perform suctioning under direct vision or with the aid of the laryngoscope. Forcing a suction tip blindly into the posterior pharynx can injure tissue or convert a partial obstruction to a complete obstruction.

Oropharyngeal and Nasopharyngeal Artificial Airways

Indications and Contraindications

Once the airway has been opened with manual maneuvers and suctioning, artificial airways, such as nasopharyngeal and

oropharyngeal airways can facilitate both spontaneous breathing and BMV. In semiconscious patients who require a head-tilt/chin-lift or jaw-thrust maneuver to open their airways, hypoxia may develop because of recurrent obstruction if these maneuvers are discontinued. Oxygen supplementation and a nasopharyngeal airway may be all the support that is necessary to maintain a functional airway.

Patients who are unresponsive or apneic are usually easier to ventilate with a bag-mask device when an oropharyngeal airway is in place. In the ED, patients who tolerate an oropharyngeal airway should generally be intubated.

Artificial Airway Placement

The simplest and most widely available artificial airways are the oropharyngeal and nasopharyngeal airways (Fig. 3.5). Both are intended to prevent the tongue from obstructing the airway by creating a passage for air between the base of the tongue and the posterior pharyngeal wall. The oral airway may also prevent teeth clenching. In cases of severe upper airway edema, such as angioedema, these devices may not function properly or be able to bypass the obstruction. The oropharyngeal airway may be inserted by either of two procedures. One approach is to insert the airway in an inverted position along the patient's hard palate (Fig. 3.5, step 2). When it is well into the patient's mouth, rotate the airway 180 degrees and advance it to its final position along the patient's tongue, with the distal end of the artificial airway lying in the hypopharynx (Fig. 3.5, step 3). A second approach is to open the mouth widely, use a tongue blade to displace the tongue, and then simply advance the artificial airway into the oropharynx (Fig. 3.5, step 4). No rotation is necessary when the airway is placed in this manner. This technique may be less traumatic, but it takes longer.

The nasopharyngeal airway is very easy to place. It may be easiest to place it on the patient's right naris so that the bevel is facing the septum on insertion. Be sure to lubricate the device before insertion (Fig. 3.5, step 6). Some clinicians insert a nasopharyngeal airway to dilate the nasal passages for 20 to

Oropharyngeal and Nasopharyngeal Airways

Indications

Facilitation of spontaneous breathing and bag-valve-mask ventilation in patients requiring head-tilt/chin-lift or jaw-thrust maneuvers

Contraindications

Nasopharyngeal

Significant facial and basilar skull fractures

Complications

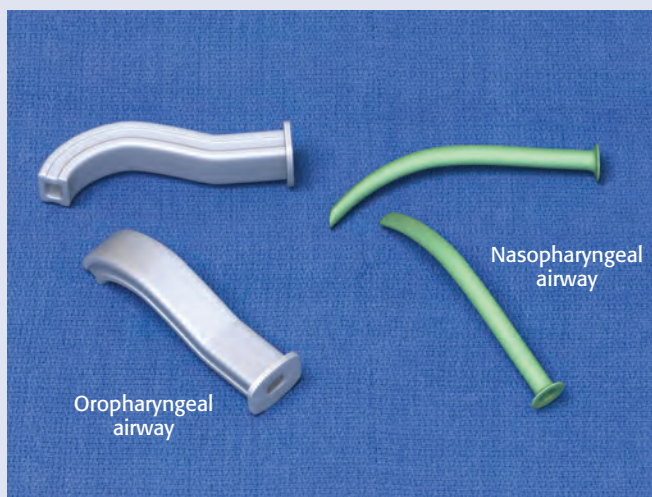

Oropharyngeal

Vomiting (in patients with an intact gag reflex)
Airway obstruction (if the tongue is pushed against the posterior pharyngeal wall during insertion)

Nasopharyngeal

Epistaxis
Deterioration requiring intubation (semiconscious patient)

Equipment

Oropharyngeal Airway Insertion

For oropharyngeal airway insertion, first measure. An airway of correct size will extend from the corner of the mouth to the earlobe or the angle of the mandible.

Open the patient's mouth with your thumb and index finger, then insert the airway in an inverted position along the patient's hard palate.

When the airway is well into the mouth, rotate it 180°, with the distal end of the airway lying in the hypopharynx. It may help to pull the jaw forward during passage.

Alternatively, open the mouth widely and use a tongue blade to displace the tongue inferiorly, and advance the airway into the oropharynx. No rotation is required with this method.

NASOPHARYNGEAL AIRWAY INSERTION

For nasopharyngeal airways, a device of correct size will extend from the tip of the nose to the earlobe.

Generously lubricate the airway prior to insertion.

Advance the airway into the nostril and direct it along the floor of the nasal passage in the direction of the occiput. Do *not* advance in a cephalad direction!

Advance the airway fully until the flared external tip of the device is at the nasal orifice.

Figure 3.5 Oropharyngeal and nasopharyngeal airway insertion.

30 minutes before nasotracheal intubation. Simply advance it into the nostril and direct it along the floor of the nasal passage in the direction of the occiput, not cephalad (Fig. 3.5, step 7). Advance it fully until the flared external tip of the airway is located at the nasal orifice (Fig. 3.5, step 8).

Both oropharyngeal and nasopharyngeal airways are available in multiple sizes. To find the correct size of either device, estimate its size by measuring along the side of the patient's

face before insertion. An oropharyngeal airway of the correct size will extend from the corner of the mouth to the tip of the earlobe (see Fig. 3.5, step 1); a nasopharyngeal airway of the correct size will extend from the tip of the nose to the tip of the earlobe (see Fig. 3.5, step 5).

Both oropharyngeal and nasopharyngeal airways provide airway patency similar to that achieved with the head-tilt/chin-lift maneuver. The nasal airway is better tolerated by

semiconscious patients and is less likely to induce emesis in those with an intact gag reflex.

Complications

The nasopharyngeal airway may cause epistaxis and may be dangerous in patients with significant facial and basilar skull fractures. Semiconscious patients with nasopharyngeal airways may deteriorate and require intubation, so they should be monitored closely.

The oropharyngeal airway may induce vomiting when placed in patients with an intact gag reflex. It may also cause airway obstruction if the tongue is pushed against the posterior pharyngeal wall during insertion. The oropharyngeal airway should not be used as a definitive airway.

OXYGEN THERAPY

Adequate O₂ delivery depends on the inspired partial pressure of O₂, alveolar ventilation, pulmonary gas exchange, oxygen-carrying capacity of blood, and cardiac output. The easiest factor to manipulate is the partial pressure of inspired O₂, which is accomplished by increasing the fraction of inspired oxygen (FiO₂) with supplemental O₂.

Indications and Contraindications

Resuscitate all patients in cardiac or respiratory arrest with 100% O₂. The most certain indication for supplemental O₂ is the presence of arterial hypoxemia, defined as an arterial oxygen partial pressure (PaO₂) lower than 60 mm Hg or arterial oxygen saturation (SaO₂) less than 90%.⁵⁵ Normal individuals will begin to experience memory loss at a PaO₂ of 45 mm Hg, and loss of consciousness occurs at a PaO₂ of 30 mm Hg.^{56–58} Chronically hypoxemic patients can adapt and function with a PaO₂ of 50 mm Hg or lower.⁵⁹

When tissue hypoxia is present or suspected, give O₂ therapy.^{55,60} Shock states resulting from hemorrhage, vasodilatory states, low cardiac output, and obstructive lesions can all lead to tissue hypoxia and benefit from supplemental O₂. Whatever the cause of the shock state, administration of O₂ is indicated until the situation can be thoroughly evaluated and cause-specific therapy instituted. It is reasonable to administer O₂ to hypotensive patients and those with severe trauma until tissue hypoxia can definitively be excluded.⁶¹

Respiratory distress without documented arterial hypoxemia is a common indication for O₂ administration, although no evidence exists to support this practice.⁶¹ Unless ET intubation is planned, respiratory distress without hypoxemia should generally not be considered an indication for oxygen supplementation.

Oxygen therapy is often recommended for acute myocardial infarction, but there is no difference in outcomes between patients receiving O₂ and those receiving room air after myocardial infarction.⁶² A randomized trial of room air versus O₂ supplementation for patients with acute ST-elevation myocardial infarction demonstrated that patients who received O₂ had larger infarction size, as assessed by peak myocardial enzymes and cardiac magnetic resonance imaging at 6 months.⁶³ The AHA recommends O₂ in myocardial infarction only for patients with hypoxemia, signs of heart failure, shock, or respiratory distress.^{64,65}

Although O₂ is routinely administered to acute stroke patients, there is no convincing evidence that this practice is

beneficial without documented hypoxia, and it is not recommended by current guidelines.^{66,67}

Administer 100% O₂ to patients with carbon monoxide poisoning. The half-life of carboxyhemoglobin is 4 to 5 hours in a patient breathing room air but can be decreased to approximately 1 hour by the administration of 100% O₂ by non-rebreather face mask at atmospheric pressure.⁶⁸

There are no contraindications to O₂ therapy when a definite indication exists. The risks associated with hypoxemia are grave and undeniable. Never withhold oxygen therapy from a hypoxemic patient for fear of complications or clinical deterioration. Carbon dioxide retention is not a contraindication to O₂ therapy. Rather, it demands that the clinician administer O₂ carefully and recognize the potential for respiratory acidosis and clinical deterioration. Although the mechanism for the development of respiratory acidosis in patients with chronic obstructive pulmonary disease (COPD) who are administered O₂ is debated, its occurrence is not.^{69,70} Use caution when administering supplemental O₂ to hypoxic patients with arterial carbon dioxide pressure higher than 40 mm Hg, but do not withhold it.

Oxygen Administration During Cardiac Arrest and Neonatal Resuscitation

The AHA guidelines for cardiopulmonary resuscitation and emergency cardiovascular care address the potential harm of oxygen therapy and hyperoxemia following cardiac arrest and during neonatal resuscitation, and provide recommendations for best use. Recommendations from the guidelines are summarized in [Box 3.1](#). Although it is still prudent to administer oxygen in the prehospital and ED setting, additional research may alter these recommendations. As a general guideline, fear of oxygen toxicity should not prevent the use of O₂ when there is an indication, but use the minimum concentration of O₂ necessary to achieve the therapeutic goals.

Oxygen Delivery Devices

A common misconception is that oxygen delivery devices can be cleanly separated into low-flow and high-flow categories. Almost any oxygen delivery device can be used across a wide range of flow rates. In fact, it is the source oxygen flow rate, not the device applied, that is the primary driver of the FiO₂ received by the patient.

Delivery of oxygen at low-flow rates provides gas flow that is less than the patient's inspiratory flow rate. The difference between the patient's inspiratory flow and the flow delivered by the device is met by a variable amount of room air being drawn into the system. Patients with normal respiratory rates and tidal volumes will require less outside air than those in respiratory distress, and therefore patients not in respiratory distress typically receive a higher FiO₂ than patients in respiratory distress, assuming equivalent supplemental oxygen flow rates. As a patient's inspiratory flow changes, so will the FiO₂ that they receive from a low-flow device.^{71,72}

Delivery of high-flow oxygen, with rates that match or exceed the inspiratory flow of the patient (generally >30 L/min), provides a significantly higher FiO₂ than low-flow. High-flow oxygen can achieve FiO₂ values of more than 90%.

The prongs of a nasal cannula deliver a constant flow of O₂ that accumulates in the nasopharynx and provides a reservoir of oxygen-enriched air for inspiration. The FiO₂ delivered by

BOX 3.1 Recommendations for Oxygen Administration During Adult and Neonate Resuscitation: Excerpts From the Guidelines of the American Heart Association

OXYGEN SUPPLEMENTATION DURING CARDIAC ARREST

The goals of cardiopulmonary resuscitation are to restore energy to the heart so it can resume normal function, and ensure adequate energy supply to the brain during resuscitation. Oxygen is vital to these goals, and during cardiac arrest blood flow is the major limiting factor to adequate oxygen delivery to the heart and brain. Thus, 100% FiO₂ should be administered during cardiac arrest for adults, children, and neonates to maximize oxygen delivery to vital organs.^{139,143,238}

OVERVIEW OF POST-CARDIAC ARREST SUPPLEMENTAL OXYGEN FOR ADULTS AND CHILDREN^{143,239}

Although 100% oxygen may have been used during initial resuscitation, providers should titrate inspired oxygen to the lowest level required to achieve an arterial oxygen saturation of ≥94%, to avoid potential oxygen toxicity. It is recognized that titration of inspired oxygen may not be possible immediately after out-of-hospital cardiac arrest until the patient is transported to the emergency department or, in the case of in-hospital arrest, the intensive care unit. The optimal FiO₂ during the immediate period after cardiac arrest is still debated. The beneficial effect of high FiO₂ on systemic oxygen delivery should be balanced with the deleterious effect of generating oxygen-derived free radicals during the reperfusion phase. Animal data suggests that ventilations with 100% oxygen (generating PaO₂ >350 mm Hg at 15 to 60 minutes after return of spontaneous circulation [ROSC]) increase brain lipid peroxidation, increase metabolic dysfunctions, increase neurologic degeneration, and worsen short-term functional outcome when compared with ventilation with room air or an inspired oxygen fraction titrated to a pulse oximeter reading between 94% and 96%. Data from human studies is mixed, with no clear evidence of harm or benefit from hyperoxia. There is no physiologic reason to expect that a PaO₂ > 350 mm Hg is necessary or beneficial after cardiac arrest, and very well may be harmful.

Once the circulation is restored, it is reasonable to use the highest available oxygen concentration until the oxyhemoglobin saturation or partial pressure of oxygen can be measured. As an arterial oxyhemoglobin saturation of 100% may correspond to a PaO₂ anywhere between ~80 mm Hg and 500 mm Hg, in general it is appropriate to wean FiO₂ when saturation is 100%. If the oxyhemoglobin saturation is 100%, it is reasonable to reduce the oxygen supplementation, provided that the oxyhemoglobin saturation can be maintained at ≥94%. The goal oxyhemoglobin

saturation is 94% to 99%. Avoiding hypoxia is more important than avoiding hyperoxia.

ASSESSMENT OF OXYGEN NEED AND ADMINISTRATION OF OXYGEN IN THE NEONATE IMMEDIATELY AFTER BIRTH^{238,240}

Oxyhemoglobin saturation may normally remain in the 70% to 80% range for several minutes following birth, thus resulting in the appearance of cyanosis during that time. Clinical assessment of skin color is a very poor indicator of oxyhemoglobin saturation during the immediate neonatal period and that lack of cyanosis appears to be a very poor indicator of the state of oxygenation of an uncompromised baby following birth.

Optimal management of oxygen during neonatal resuscitation becomes particularly important because of the evidence that either insufficient or excessive oxygenation can be harmful to the newborn infant. Hypoxia and ischemia are known to result in injury to multiple organs. Conversely there is growing experimental evidence, as well as evidence from studies of babies receiving resuscitation, that adverse outcomes may result from even brief exposure to excessive oxygen during and following resuscitation. Two metaanalyses of several randomized controlled trials comparing neonatal resuscitation initiated with room air versus 100% oxygen showed increased survival when resuscitation was initiated with air.

It is recommended that the goal in babies being resuscitated at birth, whether born at term or preterm, should be an oxygen saturation value in the interquartile range of preductal saturations measured in healthy term babies following vaginal birth at sea level (see later). These targets may be achieved by initiating resuscitation with air or blended oxygen and titrating the oxygen concentration to achieve an SpO₂ in the target range using pulse oximetry. If the baby is bradycardic (heart rate <60 beats per minute) after 90 seconds of resuscitation with a lower concentration of oxygen, oxygen concentration should be increased to 100% until recovery of a normal heart rate.

ASSESSMENT OF OXYGEN NEED AND ADMINISTRATION OF OXYGEN IN THE NEONATE

Targeted Preductal SpO₂ After Birth

1 min	60–65%
2 min	65–70%
3 min	70–75%
4 min	75–80%
5 min	80–85%
10 min	85–95%

nasal cannulas is determined by many factors, including the respiratory rate, tidal volume, pharyngeal geometry, and O₂ flow. Most importantly, at a constant O₂ flow rate, FiO₂ varies inversely with the respiratory rate.⁷³ Despite this limitation, nasal cannulas are very comfortable for patients and are the most common O₂ delivery device. They can be used with higher flow rates for brief periods of time, but are uncomfortable to use in this manner and cause nasal dryness and irritation. Nasal cannulas are generally set to 2 to 4 L/min, which provides approximately 30% to 35% FiO₂.⁷³ Although it may seem intuitive, patients using a nasal cannula should be reminded

that they should not smoke while oxygen is being delivered (Fig. 3.6).

Simple masks receive a constant flow of O₂ from the O₂ source and have multiple vent holes. During inspiration the oxygen-enriched air that has accumulated in the mask, along with room air entrained through the vent holes, is inhaled. During expiration, 200 mL (the approximate volume of the mask) of exhaled gas is deposited in the mask, with the rest exiting through the vent holes. The continuous flow of O₂ then partially washes out the mask before the next inspiration. The mask itself provides the reservoir of oxygen-rich gas for

Figure 3.6 This patient suffered serious facial burns and potential airway burns when she smoked a cigarette while oxygen was being delivered through a nasal cannula.

inhalation. A complex interplay between mask volume, tidal volume, respiratory rate, and O_2 flow determines the FiO_2 delivered to the patient. At a flow rate of 10 L/min, FiO_2 is approximately 45% to 65% in healthy patients.⁷⁴ Notably, if the flow is increased to 30 L/min, FiO_2 increases to 80% to 90%.⁷⁴ FiO_2 approximations at lower flow rates do not account for a patient in respiratory distress; as minute ventilation and inspiratory flow increase, FiO_2 will invariably decrease. This is also true for partial non-rebreather masks.

A partial non-rebreather mask incorporates a bag-type reservoir to increase the amount of O_2 available during inspiration, thereby requiring less outside air to be entrained. Non-rebreathing masks are similar to partial rebreathing masks but have a series of one-way valves. One valve lies between the mask and the reservoir and prevents exhaled gas from entering the reservoir. Two valves in the side of the mask permit exhalation while preventing the entry of outside air. In practice, one of these valves is often removed to permit inhalation in the event of interruption of flow of O_2 to the mask. Though the exhalation ports may limit rebreathing of expired gas, room air still leaks avidly around the poorly sealed edges of the mask if the patient's inspiratory flow is greater than the set flow rate. This outside air and the exhaled gas remaining in the mask dilute the O_2 from the reservoir and prevent the mask from providing 100% O_2 . Oxygen flow to the mask should be sufficient to prevent collapse of the bag during inspiration. As with all oxygen devices that do not seal perfectly to the patient's face, the FiO_2 delivered varies with the patient's respiratory pattern. Many clinicians have the misconception that a non-rebreathing mask with a source oxygen flow rate of 15 L/min can provide an FiO_2 near 100%. In practice, a non-rebreathing mask usually delivers an FiO_2 of approximately 70% when set at 15 L/min.^{75,76} FiO_2 increases to 90% and higher when flow rates are set to 45 L/min.⁷⁶ This technique is rarely used because most clinicians don't realize that higher oxygen flow rates can be achieved by simply dialing a standard flow meter to "flush" (the highest rate possible) or replacing standard oxygen flow meters with flow meters capable of measuring flow up to 70 L/min, with flush capabilities of 90 L/min (Fig. 3.7).

Figure 3.7 A standard flow meter can measure flow up to 15 L/min, but can usually achieve flow rates > 40 L/min when fully opened to "flush"; the maximum possible flow rate is usually marked on the flow meter. Flow meters capable of precisely measuring flow up to 70 L/min are commercially available, which allow the clinician to deliver higher flow rates and thus higher FiO_2 .

Figure 3.8 The Venturi mask, also known as an air entrainment mask, delivers a known oxygen concentration to patients requiring controlled oxygen therapy. Venturi mask kits include multiple color-coded interchangeable oxygen dilution jets that are selected and placed in the base of the mask tubing to provide a specific FiO_2 . Marked on each jet is the flow rate of wall oxygen required to deliver the specific FiO_2 associated with that diluter. For example, a blue jet provides 24% FiO_2 when 2 L/min is delivered from the wall oxygen source. There are stepwise increments, from the white jet providing 28% FiO_2 at 4 L/min, up to the green jet providing 60% FiO_2 at 15 L/min. (Photo courtesy Dr. Ronan O'Driscoll.)

The Venturi mask is a titratable oxygen delivery device that is widely available, though it is used more frequently in the inpatient and intensive care unit setting than in the ED (Fig. 3.8). It is important to understand that although Venturi masks are often referred to as *high flow* systems they cannot provide FiO_2 above 35%. The primary advantage of the Venturi mask system is that FiO_2 can be precisely controlled between 21%

and 35% for patients who may not tolerate a higher or imprecise FiO_2 . Room air is pulled into the system through entrainment ports and mixes with the O_2 provided from the O_2 source. The proportion of entrained air—and therefore FiO_2 —is constant and determined by the velocity of the O_2 jet and the size of the entrainment ports. Because the total gas flow (O_2 plus air through the entrainment ports) meets or exceeds the patient's inspiratory flow rate, no additional entrainment of air occurs around the mask, thereby minimizing changes in FiO_2 as the patient's respiratory pattern changes.^{71,72} The mask is continuously flushed by the high flow of gas, which prevents the accumulation of exhaled gas in the mask. Venturi masks are packaged with multiple inserts, each with a different size orifice for O_2 inflow. FiO_2 is determined by selecting the appropriate colored insert and O_2 flow rate according to the manufacturer's instructions. All Venturi mask settings and inserts provide a total gas flow of 30 L/min, which matches the inspiratory flow rate of a resting adult. However, a patient in respiratory distress may have an inspiratory flow rate of 50 to 100 L/min.⁷² If the patient's inspiratory flow rate exceeds the total gas flow delivered by the mask, additional air will be entrained around the mask, and inspired FiO_2 will decrease. This is especially true with masks rated above 35% FiO_2 , which generally can only provide high FiO_2 if minimal room air is entrained around the edges of the mask. Caution should be used with masks rated above 35% in patients with respiratory distress because FiO_2 may be significantly reduced with high inspiratory flow rates.

High-flow nasal cannula oxygen (HFNC) is the delivery of heated, humidified oxygen at high flow rates (up to approximately 60 L/min) through wide-bore nasal cannulas. HFNC is hypothesized to deliver a higher FiO_2 than face mask oxygen because the nasopharynx acts as a natural reservoir that refills with oxygen after each breath,⁷⁷ though at high flow rates face mask oxygen probably also fills the nasopharynx. HFNC requires three components: wide-bore nasal prongs, a humidifier, and a gas delivery device to control flow. Whereas HFNC requires additional equipment and a brief set-up for each patient, it delivers very high FiO_2 and is better tolerated by patients than face mask oxygen and NPPV.^{76,78} At flow rates of 15 L/min FiO_2 is 70% to 80%,⁷⁹ and at flow rates of 45 L/min FiO_2 is 90% or higher.⁷⁶ These FiO_2 values remain relatively constant, even when the patient's mouth is open.⁷⁷ Commercially available HFNC systems use flow rates of 5 to 40 L/min and are capable of delivering an FiO_2 of close to 100%. High-flow oxygen by nasal cannula is not well tolerated unless it is humidified, so commercially available systems (Vapotherm [Exeter, NH], Fisher and Paykel Nasal High Flow [Auckland, New Zealand], Aquinox [Smiths Medical, St. Paul, MN]) deliver oxygen with nearly 100% humidity. HFNC additionally provides low levels of positive airway pressure in the range of 1 cm H_2O to 3 cm H_2O , which increases as the flow rate increases.^{76,80} HFNC devices are popular in neonatal and pediatric intensive care units and are commonly used for respiratory support after extubation and for management of respiratory disease in neonates.^{81,82}

HFNC has been demonstrated to increase tidal volumes and increase end-expiratory lung volumes after cardiac surgery,⁸³ and was associated with lower rates of escalation to more invasive modes of ventilation in two ED studies.^{84,85} A landmark trial that randomized patients with acute hypoxemic respiratory failure without hypercapnia to receive HFNC, face mask oxygen, or NPPV found similar intubation rates but lower 90-day

mortality in the HFNC group.⁸⁶ Though the results of this trial are not necessarily generalizable to ED patients, it does demonstrate that HFNC provides similar oxygenation support for patients with severe hypoxemia as compared to NPPV. This makes HFNC a useful tool for patients who do not need immediate tracheal intubation and may be susceptible to lung injury from mechanical ventilator-induced barotrauma.

Procedure

In selecting the proper delivery device, consider the clinical condition of the patient and the amount of O_2 needed. Venturi systems should generally be used for patients who need precise control of FiO_2 , such as COPD patients with chronic respiratory acidosis. Nasal cannulas and face masks set at lower flow rates are appropriate for patients who need supplemental O_2 but do not require precise control of FiO_2 . Patients with significant hypoxemia, end-organ dysfunction, or respiratory distress require a higher FiO_2 delivery system.

Frequent clinical assessment and blood oxygen saturation (SpO_2) monitoring are needed in all patients receiving O_2 therapy. Equilibration of SaO_2 after changes in supplemental O_2 occurs within 5 minutes.⁸⁷ FiO_2 should be titrated to achieve therapeutic goals while minimizing the risk for complications. An SaO_2 of 90% to 95% ($\text{PaO}_2 \approx 60\text{--}80$ mm Hg) is an appropriate target for most patients receiving supplemental O_2 .⁶¹ Increases above these levels do not add appreciably to the O_2 content of blood and are unlikely to confer an additional benefit. One may exceed these parameters in patients with shock and end-organ dysfunction, but the added risk and small potential benefit should be considered on an individual basis.

An initial FiO_2 of 24% to 28% delivered by Venturi mask is indicated for patients with hypoxemia and chronic respiratory acidosis.^{61,69} Periodic blood gas analysis or capnography is imperative for those at risk for respiratory acidosis.^{88–90} In patients with COPD-associated hypercapnia, an SaO_2 of 90% ($\text{PaO}_2 \approx 60$ mm Hg) should be the goal of O_2 therapy.^{88–90} Mechanical ventilation should be considered when oxygenation goals cannot be achieved without progressive respiratory acidosis.

Preoxygenation Prior to Endotracheal Intubation

Preoxygenation prior to ET intubation is one of the most important aspects of emergency airway management, and is a different concept than supplemental oxygenation. Whereas the goal of supplemental oxygenation is to maintain normoxemia, the goal of preoxygenation is to replace all nitrogen in the lungs with oxygen, thereby creating a reservoir of oxygen available to the body during the intubation process. Preoxygenation and oxygen therapy during apnea are discussed fully in Chapter 4.

Complications of Oxygen Therapy

Worsening of CO_2 retention leading to progressive respiratory acidosis and obtundation in patients with COPD is the complication most likely to be seen in the ED. This phenomenon is well documented and was first described by Barach in 1937.⁹¹ It has been attributed to several mechanisms, including loss of hypoxic respiratory drive, ventilation-perfusion (V/Q) mismatch, and decreased hemoglobin affinity for CO_2 (Haldane

effect). This avoidable complication is best prevented by administering O₂ to chronic CO₂ retainers only when there is an indication, administering it at the smallest effective dose, and carefully monitoring clinical, capnographic, and arterial blood gas parameters.

Exposing the brain and lung to excessive concentrations of O₂ can lead to toxicity and, in severe cases, can cause acute respiratory distress syndrome (ARDS). Injury to the pulmonary parenchyma occurs as a result of the formation of reactive oxygen species. Oxygen toxicity is of special concern in premature neonates, in whom prolonged hyperoxemia can lead to retinopathy. No data describe what concentration or duration of exposure to O₂ leads to toxicity, but presumably both these factors and individual patient characteristics determine the likelihood of toxicity. The benefits of O₂ therapy in the ED usually outweigh the risk for O₂ toxicity. Fear of toxicity should not prevent the use of O₂ when there is an indication but should encourage the clinician to use the minimum concentration of O₂ necessary to achieve therapeutic goals. High concentrations of O₂ are well tolerated over short periods and may be lifesaving.

In patients receiving high concentrations of supplemental O₂, nitrogen in the alveoli is largely replaced by O₂. If this O₂ is then absorbed into the blood faster than it can be replaced, the volume of the alveoli will decrease and absorptive atelectasis can occur. Airway obstruction potentiates this problem by preventing the rapid replacement of absorbed gas.

BAG-MASK VENTILATION

BMV is the single most important technique for emergency airway management.^{1,11,92} Bag-mask devices are widely available and are standard equipment in all patient care settings. Although the bag-mask method of ventilation appears to be simple, it can be difficult to perform correctly. Good BMV skills are a prerequisite to more advanced methods of emergency airway

management.¹ Manually opening the airway, properly positioning the head and neck, placing an oropharyngeal airway device, and achieving a tight face mask seal are the keys to good BMV.

Indications and Contraindications

BMV is the most common initial technique for ventilation of apneic patients and for rescue ventilation after failed intubation.^{1,2} Many authors note that BMV is relatively contraindicated in patients with a full stomach, those in cardiac arrest, and those undergoing rapid-sequence intubation.² These patients have a high risk for stomach inflation and subsequent aspiration. Unfortunately, these are the patients for whom ED providers most commonly use BMV. In ED situations, the need for ventilation and oxygenation always takes priority over potential aspiration.²

The only contraindication to attempting BMV is when application of a face mask is impossible (Fig. 3.9). It is often impossible to achieve an effective face mask seal on patients with significant deforming facial trauma and those with thick beards. An intermediate ventilation device, such as an LMA, is a better choice for initial ventilation in such patients.

BMV Technique

Achieving adequate ventilation with a bag-mask device requires an open upper airway and a good mask seal. Overly aggressive BMV causes stomach inflation and increases the risk for aspiration. The goal is to achieve adequate gas exchange while keeping peak airway pressure low. Squeezing the bag forcefully creates high peak airway pressure and is more likely to inflate the stomach. Several studies have shown that increased tidal volume is associated with higher peak airway pressure and increased gastric inflation.^{93–95} Decreased inspiratory time (faster bag squeeze) increases peak airway pressure and gastric inflation.^{96,97} Therefore the best method of BMV is to provide a tidal volume of approximately 500 mL delivered over 1 to 1.5 seconds.⁹⁷

Bag-Mask Ventilation

Indications

Initial ventilation technique in apneic patients
Rescue ventilation after failed intubation

Contraindications

Situations when application of a face mask is impossible
(e.g., deforming facial trauma, thick beards)

Complications

Inability to ventilate
Gastric inflation

Equipment

Figure 3.9 Large beards and facial trauma make it difficult or impossible to obtain a tight seal against the face for bag-mask ventilation. For this patient, a laryngeal mask airway is probably the best first-line oxygenation device.

Using a ventilator (instead of a resuscitation bag) to provide the proper tidal volume and inspiratory time is an alternative to using a bag-valve device.⁹⁸ Effective ventilation and oxygenation should be judged by chest rise, breath sounds, SpO₂, and capnography.

A variety of mask configurations are available to facilitate a tight seal. The most common mask used in ED situations is a transparent disposable plastic mask with a high-volume, low-pressure cuff. This type of mask eliminates the need for an anatomically formed mask and can be used for a wide variety of patients with different facial features. Various mask sizes are available.

For a single rescuer, only one hand can be used to achieve the seal because the other must squeeze the bag. The rescuer must apply pressure anteriorly while simultaneously lifting the jaw forward. The thumb and index finger provide anterior pressure while the fifth and fourth fingers lift the jaw. The C-E clamp technique is often the most effective if an assistant is not available: the thumb and index finger form a “C” to provide anterior pressure over the mask, whereas the third, fourth, and fifth fingers form an “E” to lift the jaw (Fig. 3.10, steps 1 and 2). Generally, well-fitting intact dentures should be left in place to help ensure a better seal with the mask.

In the ED setting it is best to hold the face mask with two hands and have an assistant squeeze the bag. If face mask ventilation is difficult, the most experienced provider should hold the face mask while the less experienced provider squeezes the bag.

There are two different methods for two-handed face mask control. The traditional technique is the double C-E method, where the thumb and index finger of both hands encircle the top of the mask (Fig. 3.10, step 3) and the third, fourth, and fifth fingers of both hands form an “E” to lift both sides of the mandible to meet the mask (Fig. 3.10, step 4). The problem with the double C-E technique is that it is difficult to perform a good jaw thrust with the hands in this position.

The best two-handed method is to hold the mask in place with the thenar eminence of both hands (Fig. 3.10, step 5) and use the long fingers under the angle of the mandible to perform a jaw thrust, while also pressing the mask firmly against the face (Fig. 3.10, step 6). This technique allows the operator to perform a good jaw lift (create mandibular protrusion or an “underbite”) and create a good mask seal with the strongest muscles of the hands (Fig. 3.11).^{99,100} This method is best for patients with difficult mask ventilation, and it also allows inexperienced providers and those with small hands to do a better job with face mask ventilation.¹⁰⁰ In addition, it is important to remember to use oropharyngeal or nasopharyngeal airways (or both) whenever face mask ventilation is difficult.

All bag-mask devices should be attached to a supplemental O₂ source (with a flow rate of 15 L/min or higher) to avoid hypoxia. A significant problem with the bag-mask method is the low percentage of O₂ achieved with some reservoirs. The amount of O₂ delivered is dependent on the ventilatory rate, the volumes delivered during each breath, the O₂ flow rate into the ventilating bag, the filling time for reservoir bags, and the type of reservoir used. For adults, a bag-mask device should have an inspiratory valve, a 1500-mL bag reservoir, and one-way exhalation port to provide adequate oxygenation during use.⁷⁵ If the bag-mask system does not have a one-way exhalation port, room air will be entrained and the FiO₂ will be diluted significantly.

Pediatric bag-mask devices should have a minimum volume of 450 mL. Pediatric and larger bags may be used to ventilate infants with the proper mask size, but care must be maintained to administer only the volume necessary to effectively ventilate the infant. Avoid pop-off valves because the airway pressure required for ventilation under emergency conditions can exceed the pressure of the valve.^{101,102}

Previously it had been contended that mask ventilation could be made more difficult after administration of paralytic agents.¹⁰³ However, many studies demonstrate that BMV after paralysis is generally easier and provides larger tidal volumes.^{104–108} It is generally not necessary to test whether the patient can be successfully mask-ventilated before administration of paralytic agents, however it is prudent to assess for markers of difficult BMV (see **Complications** later).

BMV may be the best method of prehospital airway support in trauma patients and children. Murray and colleagues¹⁰⁹ performed a large retrospective study suggesting that patients with severe head injury had a higher risk for mortality if they were intubated in the prehospital setting. In the same year, Gausche and colleagues¹¹⁰ reported that neurologic outcomes and ultimate survival rates after prehospital pediatric resuscitation with BMV by emergency medical service (EMS) providers were as good as those with tracheal intubation.

Complications

The main complications of BMV are gastric inflation and inability to ventilate. Langeron and colleagues¹¹¹ performed a large prospective study of adults undergoing general anesthesia and reported a 5% incidence of difficult mask ventilation. The incidence is obviously much higher in the emergency setting. Risk factors for difficult BMV include presence of a beard, severe facial trauma, obesity, lack of teeth, age older than 55 years, history of snoring, short thyromental distance, limited mandibular protrusion, and decreased pulmonary compliance (severe asthma, COPD, ARDS, term pregnancy) (Box 3.2).^{111–114}

Bag-Mask Ventilation

One-handed technique

The “C-E” clamp technique provides the most effective seal.

Use your thumb and index finger to form a letter “C” and provide anterior pressure on the mask.

Use your third, fourth, and fifth fingers to lift the mandible up into the mask. It may be possible to place the fifth finger behind the mandible and perform a jaw thrust.

Two-handed technique

The traditional technique is the “double C-E” method.

Use the thumb and index fingers of both hands to encircle the top of the mask.

Use the third, fourth, and fifth fingers of each hand to lift both sides of the mandible to meet the mask. It is difficult to do a good jaw lift with this method.

A better two-handed method is to hold the mask in place with the thenar eminences of both hands.

Use the long fingers under the mandible to do a jaw lift while also pressing the mask firmly against the face. This allows the operator to do a good jaw lift and create a good seal with the strongest muscles of the hands.

Figure 3.10 Bag-mask ventilation. It is best to hold the face mask with two hands and have an assistant squeeze the bag. If face mask ventilation is difficult, the most experienced provider should hold the mask while the less experienced provider squeezes the bag.

BOX 3.2 Risk Factors for Difficult Mask Ventilation

Presence of a beard
Obesity
Lack of teeth
Age older than 55 years

History of snoring
Short thyromental distance
Limited mandibular protrusion

It may be best to paralyze patients who are not spontaneously breathing but still awake enough to interfere with BMV.

When mask ventilation is technically difficult, higher peak airway pressure is often required to provide adequate tidal volume. In these situations, gastric inflation is more likely and aspiration may occur. Be vigilant to recognize complications early and take corrective action. Even when BMV is easy and

a good technique is used, some gastric distention will generally occur. Minor gastric distention should not be considered substandard in the setting of prolonged BMV.

Cricoid Pressure (Sellick Maneuver)

In 1961, Sellick described the use of cricoid pressure to prevent regurgitation during anesthesia, and this technique has since become known as Sellick maneuver, though more properly termed cricoid pressure.¹¹⁵ The purpose of this technique is to apply external force to the anterior cricoid ring to push the trachea posteriorly and compress the esophagus against the cervical vertebrae. In theory, cricoid pressure compresses the distensible upper esophagus but not the airway because the cricoid ring is fairly rigid.

There is no good evidence that cricoid pressure prevents esophageal regurgitation,^{116,117} though it can prevent gastric

Figure 3.11 A good example of bag-mask ventilation using the preferred two-handed technique. Using this method allows the strongest muscles of the hands to perform a jaw thrust, which pulls the face into the mask to create a seal.

inflation during BMV,^{115,116,118–121} thereby reducing the risk for subsequent regurgitation and vomiting. However, cricoid pressure has been demonstrated to reduce tidal volumes, increase peak inspiratory pressure, and prevent adequate air exchange when applied during BMV.^{118,120–129} Cricoid pressure also decreases successful insertion of and intubation through LMAs.^{130–137}

BMV can produce gastric inflation, especially if high volume and high pressure are used. To avoid gastric inflation, ventilate with a small volume (500 mL or 6 to 8 mL/kg) and avoid high peak pressure by using a long inspiratory time (1 second). In addition, most airway experts recommend applying cricoid pressure during BMV to further decrease the risk for gastric inflation.^{2,138} It should be noted that the routine use of cricoid pressure during BMV of patients in cardiac arrest is not recommended by the AHA guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.¹³⁹ Cricoid pressure should be released immediately if there is any difficulty ventilating with a face mask in an emergency setting.¹¹⁷ In addition, it is reasonable to release or relax cricoid pressure during insertion of an LMA or if ventilation with the LMA is difficult.^{116,117,136} It may also be reasonable to release cricoid pressure during laryngoscopy and tracheal intubation (discussed in Chapter 4).

Some authors believe that improper technique is to blame for the many reported failures of cricoid pressure.^{116,139} The proper technique for applying cricoid pressure is to place the thumb and middle finger on either side of the cricoid cartilage, with the index finger in the center anteriorly.¹¹⁵ Apply 30 N (6.7 lb) of force to the cricoid cartilage in the posterior direction.^{116,138} As a reference, approximately 40 N of digital force on the bridge of the nose will usually cause pain.¹¹⁶

EXTRAGLOTTIC AIRWAY DEVICES

EGAs are devices that are blindly placed above or posterior to the larynx to allow rapid ventilation and oxygenation. They are good rescue devices for patients who are difficult or impos-

sible to ventilate and oxygenate with a face mask, especially morbidly obese patients and those with large beards or significant facial trauma. In the emergency setting, EGAs can provide temporary rescue ventilation until tracheal intubation or a surgical airway can be performed. It is important to have at least one of these devices immediately available when managing emergency airways. EGAs can be divided into two groups, LMAs and retroglottic devices.

Laryngeal Mask Airways

The LMA consists of a hollow shaft or airway tube connected to an oval inflatable masklike cuff designed to sit in the hypopharynx facing the glottis, with the tip at the esophageal inlet. The cuffed mask is designed to form a seal around the glottis when the device is placed properly. Some LMAs (LMA Fastrach, Teleflex, Buckinghamshire, UK and LMA Proseal, Teleflex) have handles that allow the operator to increase seal pressure by lifting the entire device toward the ceiling (Review Box 3.3). The first LMA, the LMA Classic (Teleflex) became available in 1988. Since then it has been used more than 200 million times and has been described in more than 2500 academic papers.^{136,140} LMAs are widely considered to be essential adjuncts for rescue ventilation and difficult intubation,¹⁴¹ can be inserted in less than 30 seconds, and provide effective ventilation in more than 98% of patients.¹³⁶ LMAs are primary rescue adjuncts in the difficult airway guidelines put forth by the American Society of Anesthesiologists¹⁴¹ and the Difficult Airway Society in Europe.¹⁴² Advanced Cardiac Life Support guidelines suggest that the LMA is a reasonable alternative to face mask ventilation.¹³⁹ Pediatric Advanced Life Support guidelines acknowledge the LMA as a backup device for difficult pediatric airways.¹⁴³ In anesthesia practice, LMAs are now used for a large percentage of cases in which an ET tube may have been used in the past.

This chapter describes how to insert an intubating LMA (ILMA; LMA Fastrach, Teleflex) and use it for rescue ventilation. Intubation through the Fastrach is described in Chapter 4. The insertion and use of the nonintubating LMA Unique (Teleflex) (the disposable version of the LMA Classic) and LMA Supreme (Teleflex) will also be described because they are cheap, disposable, well tested, and widely available.

Indications

Both LMAs and nonintubating LMAs can be used in the “cannot-intubate/cannot-ventilate” scenario with high success rates, and are very useful when face mask ventilation is difficult because of a beard, massive facial trauma, or obesity (Fig. 3.12).

The ILMA should be the LMA of choice for emergency use. In the cannot-intubate/cannot-ventilate scenario, adequate ventilation with the ILMA is possible in nearly all cases, and is more successful than the LMA.^{5,136,144} In this scenario ventilation with the ILMA is probably superior to bag-mask ventilation.¹⁴⁵ The ILMA can also be used as a primary ventilation and intubation device for patients with difficult airways,¹⁴⁶ and is a reasonable alternative to BMV for reoxygenation after a failed tracheal intubation attempt. Tracheal intubation through the ILMA can be accomplished by using a blind technique, with a lightwand, or under endoscopic guidance (see Chapter 4 for tracheal intubation through the ILMA). Studies of difficult airway management with the ILMA show that almost all patients can be adequately ventilated with the ILMA and 94% to 99%

Laryngeal Mask Airway Insertion

Indications

Failed rapid-sequence intubation
 Difficult bag-mask ventilation
 Difficult intubation
 Facial trauma
 Obesity
 Primary airway in cardiac arrest or use by emergency medical services

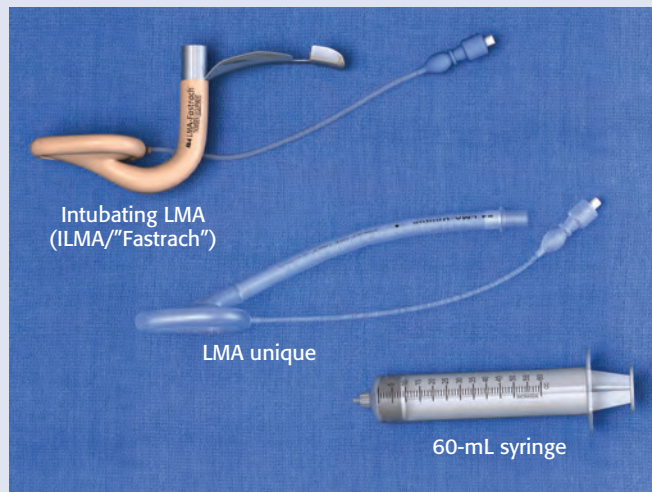

Contraindications

Limited mouth opening (<2 cm)
 High airway pressure
 Inadequate paralysis or sedation

Complications

Inability to ventilate (rare)
 Inability to intubate
 Aspiration (rare)

Equipment

Review Box 3.3 Laryngeal mask airways: indications, contraindications, complications, and equipment.

Figure 3.12 A, This morbidly obese patient was found asystolic by the emergency medical service. She could not be intubated in the field with multiple attempts and did not survive bag-mask resuscitation. This patient is a candidate for a laryngeal mask airway (LMA). B–D, The LMA is inserted by depressing the jaw, introduced, advanced, inflated, and attached to a resuscitation bag. Postmortem ventilation with the LMA was very easy. In retrospect, the LMA device should have been the first airway adjunct chosen by the emergency medical service (and in the emergency department), totally bypassing attempts with other methods likely to fail.

can be intubated through the device.^{5,136,147–154} In addition, for difficult airway management the ILMA is technically easier to use than the LMA. In the emergency setting, where obtaining a definitive airway (i.e., tracheal intubation) is the eventual goal, it is more practical to use an ILMA. In addition, the LMA Fastrach (Teleflex) is the most widely used and well-studied ILMA and is easier to insert than the LMA Classic (Teleflex).^{155–159} Finally, when the head is in the neutral position, the LMA Fastrach (Teleflex) is more likely to allow successful ventilation than the LMA Classic (Teleflex) during in-line stabilization of the cervical spine.^{160–162}

ILMAs are especially useful in patients with difficult bag-mask ventilation caused by a beard, severe facial trauma, or obesity because none of these factors inhibit ILMA placement. When brisk bleeding above the glottis makes ventilation and intubation difficult, the ILMA can reduce aspiration of blood and facilitate blind or fiberoptic intubation. In patients requiring urgent cricothyrotomy or percutaneous needle insertion into

the trachea, the ILMA can be used to counteract anterior neck pressure. In this capacity, the ILMA provides temporary ventilation and stabilizes the cervical spine during the surgical airway procedure.

Newer LMAs (and some ILMAs) feature a channel posterior to the airway that allows an orogastric tube to be placed into the stomach while the device is used for oxygenation and ventilation. This is particularly useful in patients with gastric distension after BMV, or as a primary device (instead of BMV) in neonates, infants, and children, because they are especially prone to gastric distension with face mask ventilation.

The LMA Classic (Teleflex) (or single-use LMA Unique, Teleflex) is the most extensively tested LMA for children. It may provide a more secure and reliable means of ventilation than bag-mask ventilation.⁴ The LMA allows adequate ventilation in 98% of adults with known difficult airways and in 90% to 95% of those with unexpectedly difficult airways.^{136,163–166} It is also useful as a rescue device in difficult pediatric airways.¹³⁶

Two descriptive studies and 86 case reports describe use of the LMA for difficult pediatric airways.^{136,167–173} In these reports, ventilation was adequate with the LMA in nearly all pediatric patients.^{136,171,173,174} Case series and case reports also suggest that the LMA can provide an effective rescue airway during neonatal resuscitation if BMV and ET intubation fail.¹⁷⁵

Contraindications

The ILMA and LMA are contraindicated in patients with less than 2 cm of mouth opening because they require 2 cm of space between the upper and the lower incisors to be inserted. Any LMA is relatively contraindicated in awake patients, especially those with a full stomach, because insertion of an LMA in an awake patient will cause coughing, gagging, or emesis. If an LMA is inserted when the patient is awake and the stomach is full, there is a high likelihood of emesis and aspiration. In the ED, an LMA should be used only if the patient is unconscious or after a paralytic agent has been given. Once an LMA is inserted and ventilation is established, the patient should not be allowed to wake up or gag. Consider giving a long-acting paralytic agent or multiple doses of succinylcholine after an LMA is placed and ventilation is adequate.

Although several studies have shown that the ILMA is safe and effective for ventilation and intubation during in-line cervical spine stabilization, some evidence shows that the ILMA causes posterior pressure on the midportion of the cervical spine.^{150,176–179} The clinical importance of cervical spine pressure caused by the ILMA is unknown, and the device is generally considered safe in patients with an unstable cervical spine injury. Providers should be aware of this concern and make every effort to stabilize the ILMA in these situations.

Types of LMAs

Several manufacturers now make LMAs as the patent on the LMA Classic (Teleflex) expired in 2003. It is important to recognize that all LMAs are not the same.

There are four popular ILMAs. The LMA Fastrach (Teleflex; www.lmaco.com) has the most clinical use and research of all the ILMAs (Fig. 3.13A). Advantages include a handle that makes placement easier and allows the operator to lift up to improve the seal against the laryngeal inlet if needed. There is no gastric port to allow for gastric decompression. Blind intubation rates are significantly higher with the LMA Fastrach (Teleflex) compared to the Cookgas air-Q¹⁸⁰ (CookGas LLC, St Louis, MO; www.cookgas.com); no adequate research has yet been performed comparing blind intubation rates to other devices. The Air-Q intubating laryngeal airway (CookGas LLC) has four different models and is popular with some clinicians (Fig. 3.13B). The i-Gel LMA (Intersurgical, Berkshire, UK; www.i-gel.com) features a thermoplastic elastomer cuff that does not need inflation, so it may be easier to insert than other LMAs (Fig. 3.13C).^{181–190} A gastric channel is present to allow for gastric decompression using an orogastric tube. The Ambu AuraGain (Ambu, Ballerup, Denmark; www.ambu.com) is a newer ILMA with gastric access that seems promising, though little research has been performed on this device to date (Fig. 3.13D).

The nonintubating LMA Supreme (Teleflex) is the latest offering from the Laryngeal Mask Company (Fig. 3.13E); it has a new mask shape that may allow a better mask seal compared to prior models^{191,192} (LMA Classic, Teleflex and LMA Unique, Teleflex) and a gastric evacuation channel. It

features a firm curved shape and a bite block handle, so ease of insertion may be similar to that of the Fastrach (Teleflex), and it is available in all sizes from neonate to large adult.^{193–202} However, it does not facilitate tracheal intubation. The LMA Protector (Teleflex) is an ILMA that has recently been released, which is similar to the LMA Supreme (Teleflex) (with gastric access) and will allow intubation using a flexible endoscope.

Procedure

The insertion and use of the LMA Fastrach (Teleflex) and LMA Classic (Teleflex) will be described. Because insertion of all ILMAs and nonintubating LMAs follow similar steps, the procedure for the LMA Fastrach (Teleflex) will be illustrative of steps for ILMAs and LMAs that have a rigid body or handle, and the LMA Classic (Teleflex) will be illustrative for ILMAs and LMAs that are not rigid and do not utilize a handle.

Intubating LMAs

The first step is to select the appropriate size of ILMA, based on manufacturer's recommendations. The Fastrach ILMA (Teleflex) is available in three sizes: size 3 for children weighing 30 kg to 50 kg, size 4 for small adults weighing 50 kg to 70 kg, and size 5 for adults weighing 70 kg to 100 kg (Table 3.1). When there is doubt about which size is appropriate, it is probably better to use the larger size.

After choosing the correct ILMA, completely deflate the cuff while pushing it posteriorly so that it assumes a smooth wedge shape without any wrinkles (Fig. 3.14, step 1). Place a small amount of water-based lubricant onto the posterior surface of the ILMA just before insertion (Fig. 3.14, step 2). Open the patient's mouth and position the posterior mask tip so that it is flat against the hard palate, immediately posterior to the upper incisors (Fig. 3.14, step 3). Advance the airway straight into the mouth along the hard palate without rotation until the curved part of the airway tube is in contact with the patient's chin. Then rotate the ILMA completely into the hypopharynx by advancing it along its curved axis. Keep the posterior of the mask firmly applied to the soft palate and posterior pharynx until firm resistance is felt (Fig. 3.14, step 4). Cricoid pressure impedes proper placement of the ILMA, so briefly release

TABLE 3.1 Laryngeal Mask Airway, Disposable Laryngeal Mask Airway, and Intubating Laryngeal Mask Airway Size Recommendations Based on Weight^a

WEIGHT (kg)	LMA	DISPOSABLE LMA	ILMA
<5	1	—	—
5–10	1.5	—	—
10–20	2	—	—
20–30	2.5	—	—
30–50	3	3	3
50–70	4	4	4
70–100	5	5	5
>100	6	—	—

^aNote that only a standard LMA is available for patients less than 30 kg. ILMA, Intubating laryngeal mask airway; LMA, laryngeal mask airway.

Figure 3.13 Popular intubating laryngeal mask airways (LMAs) and the LMA Supreme (Teleflex) **A**, LMA Fastrach (Teleflex), which has a handle that makes insertion easier and allows the operator to increase the seal pressure if needed, but has no gastric port. **B**, Air-Q (Cookgas LLC), which has four variations (disposable, reusable, noninflatable cuff, and blocker with gastric port). **C**, I-gel (Intersurgical), features a noninflatable cuff and gastric port. **D**, Ambu AuraGain (Ambu), features a gastric port. **E**, LMA Supreme (Teleflex), a nonintubating LMA with a rigid shape to make insertion easier and a gastric port.

cricoid pressure while the device is rotated into its final position, wedged into the proximal esophagus.^{133,134,203} After insertion, the airway tube should emerge from the mouth directed somewhat caudally. Without holding the tube or handle, inflate the mask cuff (Fig. 3.14, step 5). The entire device will normally slide backward a bit when the cuff is inflated. Frequently, only half the maximum cuff volume is sufficient to obtain a good mask seal. Do not overinflate the cuff because this may make the seal worse. See the instruction manual for maximum cuff volumes. Attach a bag and ventilate the patient while using chest rise, breath sounds, and capnography to confirm adequate gas exchange. If bagging is easy and ventilation is good, the aperture of the ILMA is probably aligned correctly over the vocal cords.

If optimal ILMA placement is not accomplished initially, adjusting maneuvers can be attempted. The purpose of adjusting maneuvers is to align the aperture of the ILMA with the glottic opening. Proper positioning of the ILMA aperture with the

glottic opening allows optimal ventilation and facilitates tracheal intubation. Before adjusting the ILMA, consider the patient's position and degree of relaxation because both may affect ILMA function. The ILMA works best in the neutral or sniffing position; cervical extension may interfere with proper placement. The patient should not react to ILMA placement with coughing or gagging because this may interfere with proper placement. Have a single operator perform the adjustment maneuvers by gripping the ILMA handle with one hand, in a “frying-pan” grip, and providing bag ventilation with the other hand. After each adjustment maneuver, assess the quality of bag ventilation and mask seal. Easy bag ventilation, good chest rise, and absence of an audible mask leak are indications of good ILMA alignment with the glottis (Fig. 3.14, step 6).

To adjust the position of the ILMA, first gently pull the handle toward you without rotation along the ILMA's curvature. Next, gently push the handle toward the patient's feet without rotating it. Finally, try the *Chandy maneuver*, which consists

Intubating Laryngeal Mask Airway Insertion

1 Completely deflate the cuff while pushing it posteriorly, so that it assumes a smooth wedge shape without any wrinkles.

2 Place a small amount of water-based lubricant onto the posterior surface of the ILMA just before insertion.

3 Place the head and neck in a slightly elevated position with minimal extension. Open the mouth widely and place the posterior surface of the device against the hard palate, immediately posterior to the upper incisors.

4 Advance the ILMA straight into the mouth until the curved part of the airway tube contacts the chin. Then, rotate the ILMA into the hypopharynx until firm resistance is felt. Release cricoid pressure during this step.

5 Let go of the handle and inflate the cuff. Initially inflate the cuff with only half of the maximum volume, and increase inflation as needed. Do not overinflate the cuff. (See product manual for maximum volumes.)

6 Attach a bag and ventilate the patient. Use chest rise, breath sounds, and capnography to confirm adequate gas exchange. If bagging is easy and ventilation is good, the LMA is probably correctly aligned over the glottis.

Chandy Maneuver Step 1

7 If adjustment is needed, try the Chandy maneuver. First, gently rotate the ILMA farther into the hypopharynx.

Chandy Maneuver Step 2

8 Next, lift the handle upwards, toward the ceiling above the patient's feet.

This maneuver aligns the mask with the glottis and may provide for better ventilation.

9 If these maneuvers fail, the epiglottis may be folded down over the glottis (*asterisk*).

Perform the "up-down" maneuver, by first rotating the ILMA out of the hypopharynx along its curvature about 5–6 cm.

10 Next, slide the ILMA back into position while pressing it against the posterior pharynx.

(Note, the cuff should remain inflated during this maneuver.)

Figure 3.14 Intubating laryngeal mask airway (ILMA or "Fastrach"; Teleflex) insertion.

of gently rotating the ILMA farther into the hypopharynx and then lifting the handle toward the ceiling above the patient's feet (Fig. 3.14, steps 7 and 8). If these simple maneuvers do not result in adequate ventilation, consider the "up-down maneuver" (Fig. 3.14, steps 9 and 10). This technique is used to correct downfolding of the epiglottis, which is common with insertion of the ILMA and may interfere with ventilation or intubation. The up-down maneuver is accomplished by rotating the ILMA out of the hypopharynx along its curvature approximately 5 cm to 6 cm while the cuff remains inflated, and then sliding it back into position while pressing it against the posterior pharynx. Do not use excessive force when placing or adjusting the ILMA.

If adjusting maneuvers do not result in adequate ventilation, it is likely that the wrong size ILMA has been used. Incorrect ILMA size is more likely to be a problem if the device is too small; attempting insertion of a larger ILMA is a reasonable first approach. If another ILMA size is not available, external anterior neck manipulation or downward pressure may bring the glottis and ILMA cuff into proper alignment. If the size of the ILMA is not in question, consider completely removing and carefully reinserting the device (see Chapter 4 for intubation through the ILMA and ILMA removal).

Nonintubating LMAs

The following steps describe the use of the LMA Classic (Teleflex) (or single-use LMA Unique, Teleflex), though these instructions will be similar for other LMAs that do not have a handle similar to the LMA Fastrach (Teleflex) or LMA Supreme (Teleflex).

The first step is to select the appropriate size LMA. The LMA is available in a wide range of sizes, from size 1 for neonates weighing less than 5 kg to size 6 for adults weighing more than 100 kg. The disposable version is available in sizes 1 through 5, but not size 6. After selecting the proper size, completely deflate the LMA cuff while pushing it posteriorly so that it forms a smooth wedge shape without any wrinkles (Fig. 3.15, step 1). Place a small amount of water-based lubricant onto the posterior surface of the LMA just before insertion (Fig. 3.15, step 2). The best patient position for insertion of the LMA is the sniffing position, with the neck flexed and the head extended. The LMA may be inserted via two different techniques, depending on access to the patient. The most common method is the index finger insertion technique. This is accomplished by holding the LMA like a pen, with the index finger at the junction of the airway tube and the cuff (Fig. 3.15, step 3). Have an assistant open the patient's mouth and insert the LMA with the posterior tip pressed against the hard palate just behind the upper incisors (Fig. 3.15, step 4). Under direct vision, use the index finger to slide the LMA along the hard palate and into the oropharynx (Fig. 3.15, step 5). As the LMA is inserted farther, extend the index finger and push the posterior cuff along the soft palate and posterior pharynx. Exert counterpressure on the back of the patient's head during insertion. Continue to push the LMA into the hypopharynx until resistance is felt. Use the other hand to hold the proximal end of the LMA tube while removing your index finger from the patient's mouth (Fig. 3.15, step 6).

An alternative method is the thumb insertion technique. Use this technique when you have limited access to the patient from behind (see www.lmana.com for details). Hold the LMA with your thumb at the junction of the cuff and the airway tube. Place the mask against the hard palate under direct vision,

as with the index finger technique. Use the thumb to push the LMA into the mouth along the palate and posterior pharynx. Hold the end of the airway tube with the other hand while removing your thumb from the patient's mouth.

After the LMA is fully inserted, let go of the proximal end of the airway tube and inflate the cuff enough to achieve a good seal over the glottis (Fig. 3.15, step 7). This may require only half the maximum cuff volume. Be careful to not overinflate the LMA cuff (see the product packaging for maximal cuff volumes). Attach a bag and ventilate the patient, with chest rise, breath sounds, and capnography used to confirm adequate gas exchange (Fig. 3.15, step 8). If bagging is easy and ventilation is good, the aperture of the LMA is probably aligned correctly over the glottic opening. Proper positioning of the LMA aperture with the glottic opening allows optimal ventilation.

Several tips or techniques should be considered if LMA ventilation is inadequate. The best way to ensure proper ventilation is to optimize the insertion technique by carefully following the aforementioned directions. Position the patient's head and neck properly and ensure that the patient is deeply anesthetized or paralyzed. Listen for an audible cuff leak to make sure that a good mask seal has been achieved. Adjust the cuff volume if necessary to improve the mask seal and ensure optimal ventilation. Simply adding more air to the cuff will not necessarily improve the seal of the mask with the glottis. Cuff overinflation may cause a leak, but deflation and repositioning may improve the seal.

Sometimes adjusting the patient's head and neck position is easier than trying to change the position of the LMA. Move the patient into a better sniffing position or into the chin-to-chest position to see whether this improves the LMA cuff seal. If these positions do not help or are not possible, try a jaw-thrust or a chin-lift maneuver. Apply anterior neck pressure to help manipulate the glottis into improved contact with the LMA mask. This technique can be used in combination with any of the maneuvers just discussed.

If mask seal and ventilation are still not optimal after simple repositioning maneuvers, withdraw, advance, or rotate the LMA cuff. Another alternative is to completely remove and reinsert the LMA while paying careful attention to the details just described. If unsuccessful, change the size of the LMA. A larger LMA will usually improve ventilation even if it is more difficult to insert. It is much more common to need to increase the LMA size than to decrease it. Finally, consider using the ILMA, placing a King LT, or performing a surgical airway when ventilation with the LMA is not adequate.

Aftercare

If the LMA or ILMA will remain in place without tracheal intubation, either one can be secured like an ET tube. Removal of the ILMA after tracheal intubation is easy, but more difficult than insertion of the device (see Chapter 4).

Complications

The most important complications associated with using the LMA are aspiration of gastric contents and hypoxia. The LMA does not protect against aspiration and may actually cause vomiting if the patient gags during placement of the device. In fasted anesthetized patients, the incidence of aspiration is very low, approximately 2 per 10,000 cases.¹³⁶ There are many descriptive studies and case reports of the use of an LMA for difficult airways with no mention of significant aspiration.¹³⁶ Although the risk for aspiration is surely higher than 2 per

Laryngeal Mask Airway Insertion

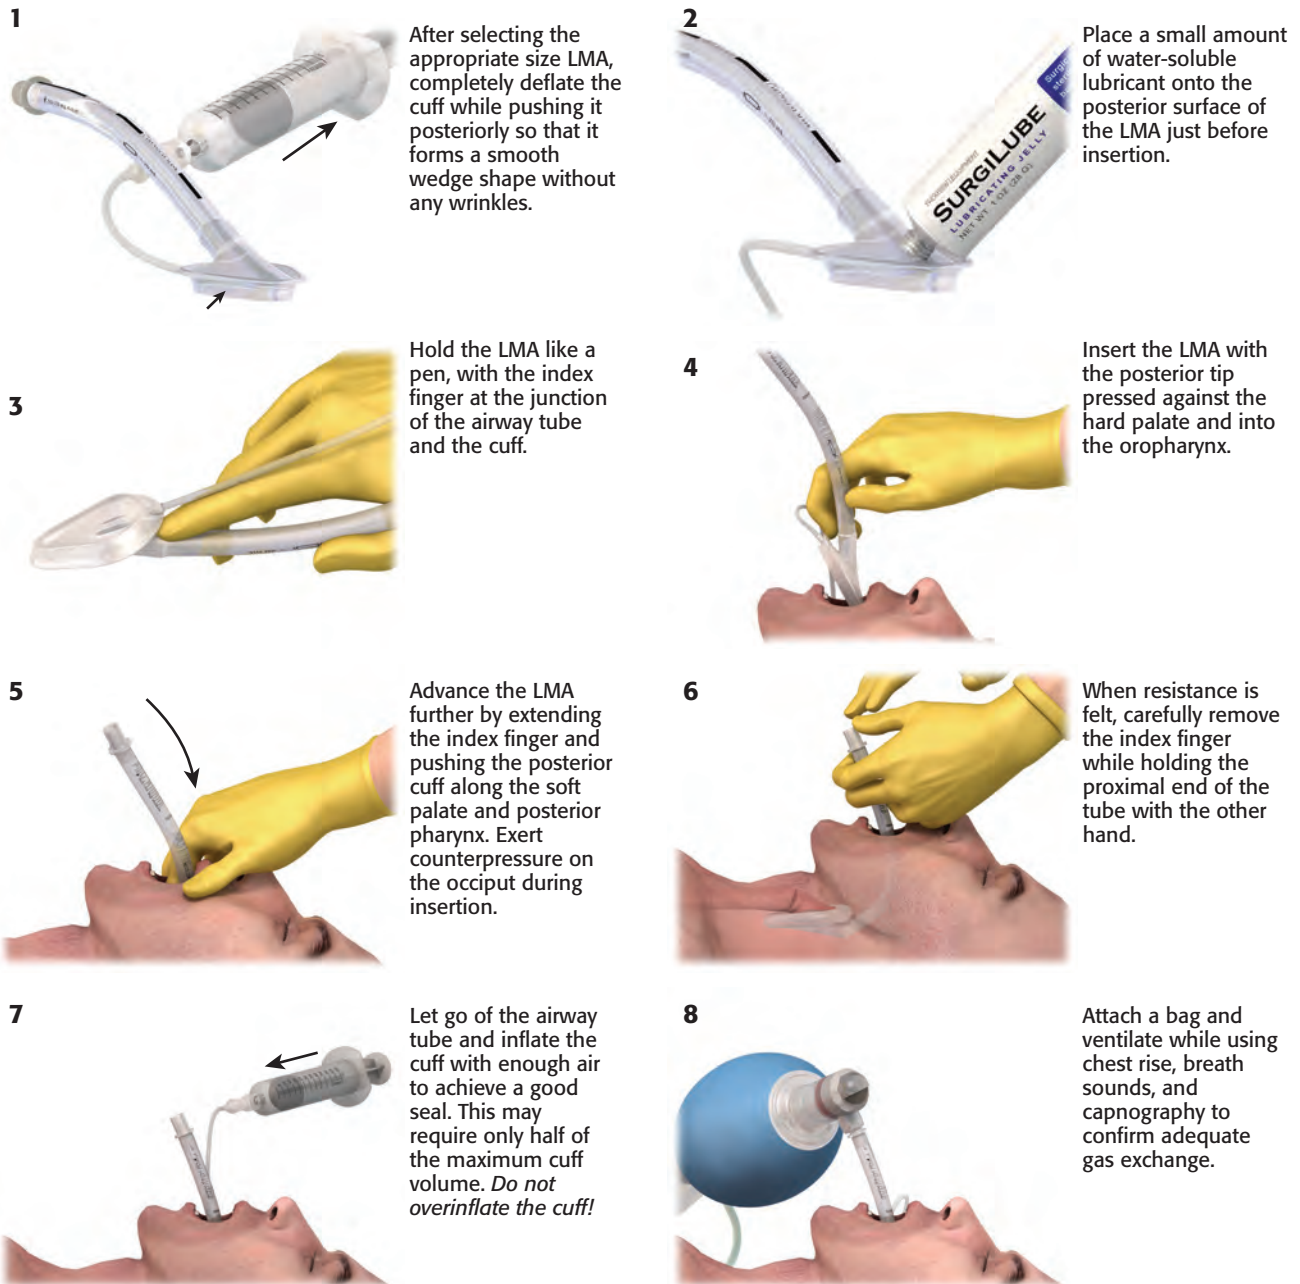

Figure 3.15 Laryngeal mask airway (LMA) insertion. The LMA Unique (Teleflex) is shown in this sequence.

10,000 when using the LMA in the ED, there is evidence that it provides some protection from passive regurgitation and produces less gastric inflation than BMV does.²⁰⁴

Retroglottic Airway Devices

King LT

The King LT (King Airway-LTS-D EMS, King Systems, Noblesville, IN; www.kingsystems.com) is a retroglottic device

that functions similar to the esophageal-tracheal Combitube (see later). Like the Combitube, the LT is designed to isolate the glottic opening between an oropharyngeal cuff and an esophageal cuff (Review Box 3.4). Unlike the Combitube, the King LT has only one airway lumen and a simplified cuff system, so both cuffs can be inflated from a single port. The literature regarding the King LT is confusing because many versions of the device have been clinically tested during the last decade. The latest disposable versions are the LT-D and

Retroglottic Airway Devices

Indications

Primary airway in the emergency medical services setting
 Primary airway in cardiac arrest
 Failed rapid-sequence intubation
 Difficult bag-mask ventilation
 Difficult intubation
 Facial trauma
 Obesity

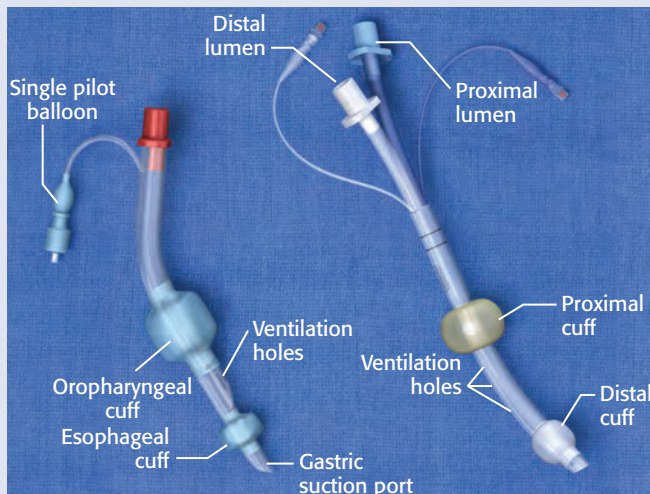

Contraindications

Limited mouth opening
 High airway pressure
 Inadequate paralysis or sedation

Complications

Inability to ventilate
 Aspiration (rare)
Specifically for the King LT device:
 Tracheal placement
 Tongue edema

Equipment

The King LTS-D (left) and the Combitube (right).

Review Box 3.4 Retroglottic airway devices: indications, contraindications, complications, and equipment.

the LTS-D. The LTS-D has an 18-Fr gastric suction port at the tip. The modern LTS-D has been available since 2004 and is also called the LTS II in some literature.^{205,206}

The King LT is designed for blind placement and has a large proximal cuff and small distal cuff. Unlike the Combitube, the tip of the King LT is designed to be placed in the esophagus only. The shape of the King LT and the size of the tip in previous versions made it unlikely to be placed into the trachea.²⁰⁷ However, the latest design of the LTS-D has a narrower tip and in one study had a 10% incidence of tracheal placement.²⁰⁸ Interestingly, most patients with tracheal placement of the LTS-D were still able to be adequately ventilated.²⁰⁸

Popularity of the LTS-D has grown rapidly in EMS systems, and it is now widely used by EMS agencies in the United States. Several studies have shown that the LTS-D has a high rate of successful ventilation in the operating room setting.²⁰⁹⁻²¹¹ In addition, there are several case reports of the LT being used as a rescue device for the cannot-intubate/cannot-ventilate scenario and when placement of an LMA failed.^{212,213} Some data suggest that the LTS-D may be useful in neonates and small infants when direct laryngoscopy fails,²¹⁴ though the smallest LT-D currently available in the United States is size 2 (patients 12 kg to 25 kg), and the smallest LTS-D is size 3 (patients 4 to 5 feet tall). In the EMS setting, the LT-D has a high success rate (95%) when used for ventilation of out-of-hospital cardiac arrest.²¹⁵ One study found a higher first-attempt success rate for paramedics using the King LT in cardiac arrest compared to ET intubation.²¹⁶ In addition, Frascione and colleagues found that the rate of successful insertion and ventilation with the LTS-D is essentially equivalent to that of standard ET intubation in the hands of paramedics.²¹⁷

Indications and Contraindications

In the ED, the King LT is a good choice as a primary airway in patients who are unresponsive or in cardiac arrest, especially in

the uncontrolled prehospital environment. The King LT can be used in any emergency airway setting for rescue ventilation after failed BMV or failed intubation. In cases of failed intubation with an unexpectedly difficult airway, the King LT may be used to provide adequate ventilation and allow time for other methods of intubation or a controlled surgical airway.^{207,218,219}

Because the King LT is a supraglottic airway and is designed to be placed blindly, it is relatively contraindicated in patients with obstruction of the upper airway by a foreign body, and should not be used in patients with an intact gag reflex.

Placement of the King LT

The first step is to choose the proper size King LT. The LTS-D is available only in adolescent and adult sizes in the United States. Size 3 is yellow and designed for patients 4 to 5 feet in height, size 4 is red and designed for patients 5 to 6 feet in height, and size 5 is purple and designed for patients taller than 6 feet. Several pediatric sizes are available in Europe, but not in the United States. The smallest LT-D available in the United States can be placed in patients weighing as little as 12 kg (approximately 18 months old).

After determining the appropriate size King LT, check the cuffs and then completely deflate them before placement. Lubricate the device with a water-based lubricant. The best patient position for insertion of the King LT is the sniffing position, but it can be placed with the head in the neutral position if necessary. Hold the LT at the connector with the dominant hand and hold the mouth open by grasping the chin with the nondominant hand. Introduce the tip of the device into the corner of the mouth while rotating the tube 45 to 90 degrees so that the blue orientation line on the tube is touching the corner of the mouth. Pass the tip of the device into the mouth and under the tongue. As the tip passes under the base of the tongue, rotate the tube back to the midline so that the blue orientation line faces the ceiling. Without exerting force,

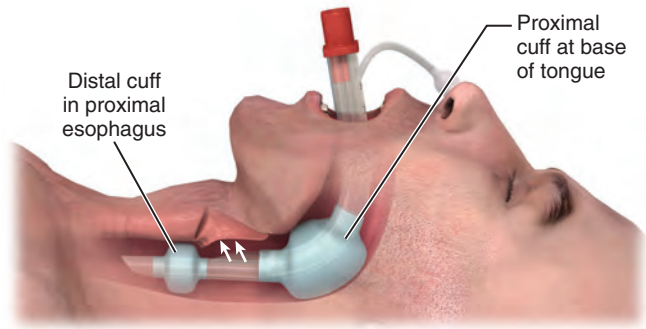

Figure 3.16 King LTS-D. The device is properly placed posterior to the larynx, with the distal end in the proximal esophagus. The distal cuff is inflated in the proximal esophagus and the larger proximal cuff is inflated at the base of the tongue. The proximal portion of the tube is at the lip line and the distal aperture (between the cuffs) is aligned with the glottic opening; oxygen flow from the device to the glottis is depicted by the *white arrows*.

advance the King LT until the connector is aligned with the teeth. Inflate the cuffs with the minimum volume necessary to create a good seal (see the product brochure for maximum cuff volumes). While ventilating with a bag-valve system, gently withdraw the King LT until ventilation becomes easy and free flowing. Confirm placement with chest rise, breath sounds, and capnography (Fig. 3.16).

Complications

It is hard to assess the complication rate of the King LT because the device has been modified several times in the last decade and there is no organized surveillance of out-of-hospital airway devices.²²⁰ The current LT-D and LTS-D devices have been available since 2004. The LTS-D is referred to as the LTS II in some studies. The most serious complication is tracheal placement, which occurred in 10% of cases in one study and is probably significantly underappreciated and underreported.²⁰⁸ Another complication that is not uncommon and certainly underreported is tongue edema. There is one case report of massive tongue edema occurring 3 hours after placement of the King LT,²²¹ and mild tongue edema is relatively common and not reported in the literature. Fig. 3.17 depicts probable pharyngeal or esophageal perforation, with massive subcutaneous neck and face emphysema following prehospital placement of a King LT. Because an autopsy was denied, the exact injury was never confirmed and may have been related to other interventions during resuscitation.

There is some concern that the large oropharyngeal balloon of the King LT might compress the carotid arteries and be detrimental in patients undergoing CPR, but currently this is only suggested in animal models²²²; no high-quality human research has been conducted to date, though one small study that reviewed computed tomography scans of the neck for 17 patients with EGAs in place found no evidence of mechanical compression of the carotid arteries on image review.²²³

Combitube and EasyTube

The esophageal-tracheal Combitube (Nellcor, Pleasanton, CA; www.nellcor.com) is a retroglottic airway device designed as a rescue device for difficult and emergency airways and can be placed blindly and rapidly.^{224,225}

Figure 3.17 Massive neck, periorbital, and facial edema following cardiopulmonary resuscitation with a King LT airway in place. The exact pathology was not determined but was thought to be a pharyngeal or esophageal perforation.

The Combitube (Fig. 3.18) has two parallel lumens, a small distal cuff, and a large proximal cuff. When it is placed blindly the tip will end up in the esophagus in approximately 95% of cases and in the trachea in approximately 5%. The longer lumen or tube is used for ventilation when the tip is in the esophagus. It is perforated at the level of the pharynx and occluded at the distal end. The shorter lumen or tube is used for ventilation when the tip is in the trachea. It is open at the distal end, like a standard ET tube. The large proximal cuff or balloon is designed to occlude the pharynx by filling the space between the base of the tongue and the soft palate. The small distal cuff serves as a seal in either the esophagus or the trachea.²²⁶⁻²³¹

The Combitube provides adequate ventilation in approximately 95% of patients when placed by prehospital providers,^{226,230,231} and in nearly 100% of patients when placed by physicians.²³² It compares favorably with the ET tube with respect to ventilation and oxygenation in cardiac arrest situations.^{224,229} In unconscious patients, the Combitube may provide protection from aspiration.²³³

Indications and contraindications for the Combitube are similar to the King LT airway. Because the King is easier to use and proven to be an effective and reliable primary and rescue airway device, the Combitube is used less frequently than previously.

Placement of the Combitube

The Combitube is available in two sizes. The manufacturer recommends the smaller 37-Fr device for patients from 4 feet to 5 feet 6 inches tall and the larger 41-Fr device for patients taller than 5 feet 6 inches. Studies suggest that the smaller 37-Fr Combitube can be used safely in patients up to approximately 6 feet tall.^{234,235} The larger 41-Fr device is appropriate for patients taller than 6 feet.

To insert the Combitube, hold the device in the dominant hand and gently advance it caudally into the pharynx while grasping the tongue and jaw between the thumb and index finger of the nondominant hand. Pass the tube blindly along the tongue to a depth that places the printed rings on the proximal end of the tube between the patient's teeth and the alveolar ridge.²³⁶ If resistance is met in the hypopharynx, remove

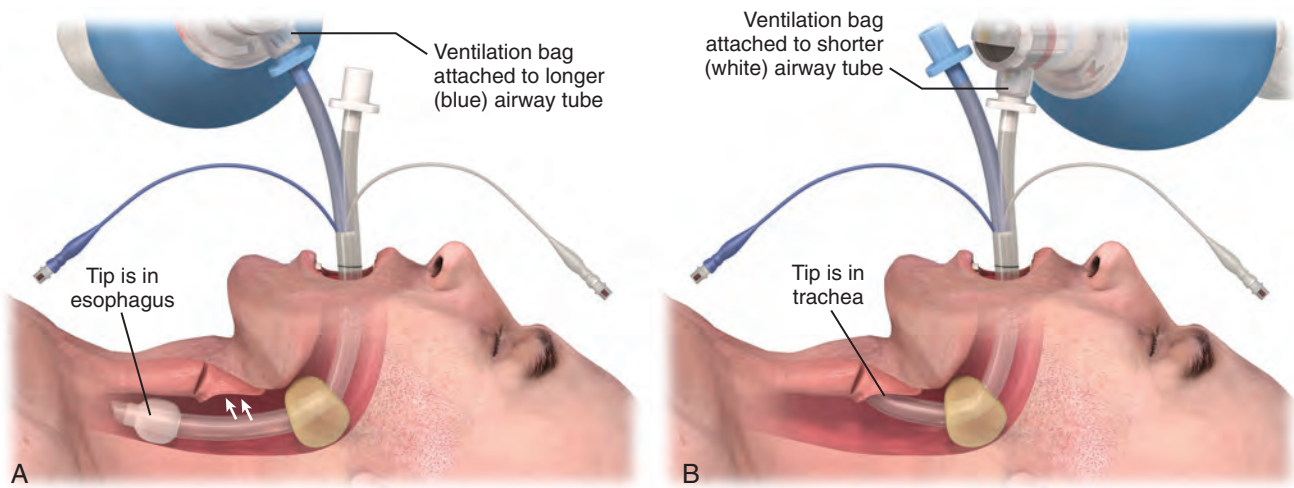

Figure 3.18 Combitube. **A**, Approximately 95% of placements are esophageal, so begin ventilation through the longer (*blue*) airway tube. Use chest rise, breath sounds, and capnography to assess for proper placement. When the distal tip is in the esophagus, ventilation occurs through the vent holes between the distal and proximal cuffs (*white arrows*). **B**, If the tip of the Combitube is in the trachea, ventilation cannot be accomplished via the long (*blue*) airway tube. It is essential to recognize this quickly, and use the short (*white*) tube for ventilations.

the tube and bend it between the balloons for several seconds to facilitate insertion.²³⁶ After insertion, fill the pharyngeal balloon with 100 mL of air and the distal cuff with 10 mL to 15 mL of air. The large pharyngeal balloon serves to securely seat the Combitube in the oropharynx and creates a closed system in the case of esophageal placement. Because approximately 95% of placements are esophageal, begin ventilation through the longer (*blue*) airway tube.²³¹

Use chest rise, good breath sounds, and capnography, without gastric inflation, to confirm proper ventilation. Alternatively, use a Wee-type aspirator device on the shorter (*clear*) lumen to confirm that the tip is in the esophagus before ventilation through the longer (*blue*) lumen.²³⁷ Inability to easily aspirate air confirms esophageal placement. Easy aspiration with the Wee-type device indicates tracheal positioning of the tube and requires changing the ventilation to the shorter (*clear*) tracheal lumen.

Complications

Inappropriate balloon inflation and incorrect Combitube placement can lead to air leaks during ventilation. The most

common placement error is an improper insertion angle. Use a more caudal, longitudinal direction of insertion as opposed to an anteroposterior direction of insertion. The Combitube must also be maintained in the true midline position during insertion to avoid blind pockets in the supraglottic area, which can prevent passage of the tube.²³¹

CONCLUSION

Good basic airway skills and the familiarity with and availability of proven rescue devices are the keys to emergency airway management. There are many techniques and devices that can be used to manage emergency airways. In difficult situations, providers will probably have the best success when basic skills are performed excellently.

Tracheal Intubation

Brian E. Driver and Robert F. Reardon

Intubation is often the pivotal procedure in the emergency management of critically ill patients. There are several new devices that can improve the likelihood of successful intubation, and it is important to put the intubation procedure in perspective, understanding that intubation is just one part of airway management. The primary objective of airway management is to maintain adequate ventilation and oxygenation, and intubation only allows ventilation and oxygenation after the procedure is completed, not during the procedure.¹ It is critical to have good basic airway management skills (see [Chapter 3](#)). It is also important to use intubation techniques that have a high likelihood of first pass success, to have the wisdom to recognize when a given approach has failed, and to quickly move to a different technique. Use of an emergency airway algorithm can help providers make difficult decisions in a timely manner (see later section on [Emergency Airway Algorithm](#)).²

This chapter describes nearly every possible means of tracheal intubation, with emphasis on widely used techniques. The most common means of intubation in the emergency setting is rapid-sequence intubation (RSI), and this approach must be considered very carefully. If a difficult intubation is anticipated, awake intubation may be preferred. Although flexible endoscopic devices are commonly used, with good topical anesthesia, nearly any intubating technique can be used for awake intubation. Because many difficult airways cannot be predicted, it is essential to have a well-defined backup plan and appropriate resources. The intubating laryngeal mask airway (LMA Fastrach, Teleflex, Inc, Wayne, PA) is an ideal backup device for failed RSI because it provides ventilation and oxygenation and facilitates tracheal intubation in a high percentage of patients with failed RSI.²

GENERAL APPROACH TO EMERGENCY INTUBATION

Preplanning is the key to successful emergency airway management. Providers should follow a clear, preconceived, practiced airway algorithm that uses readily available and familiar equipment and techniques. When encountering a difficult airway, it is more important to be comfortable with a few well-proven devices and techniques than to try new or unfamiliar devices.²⁻⁴ It is important to know when to abandon one approach and move on to the next. No single approach is mandated. The best technique is the one chosen by the clinician at the bedside based on one's individual experience and expertise given the specific clinical scenario.

A critical aspect of preparation is making sure that all essential equipment required to perform the airway maneuvers is immediately available and within easy access. This may be accomplished by wall-mounting essential equipment in the emergency department (ED) resuscitation room.⁵ Alternatively,

equipment can be placed in dedicated adult and pediatric airway carts or tackle boxes in an open, organized, and labeled manner, with the carts and boxes checked and stocked regularly ([Fig. 4.1](#)).⁶ Essential equipment that is seldom used but is potentially lifesaving should be clearly identified and placed in an easily accessible location such as a dedicated difficult airway cart. The importance of this concept cannot be overstated. Technical expertise cannot substitute for the lack of essential equipment. In airway management, failure has ominous consequences. Mental, physical, and equipment preparation maximizes the chance of success.

AIRWAY ANATOMY

An understanding of airway anatomy and its terminology is requisite for any discussion of airway management procedures ([Fig. 4.2](#)). The following terms are used frequently in this chapter:

Pharynx: the upper part of the throat posterior to the nasal cavity, mouth, and larynx

1. *Nasopharynx*: base of the skull to the soft palate
2. *Oropharynx*: soft palate to the epiglottis
3. *Hypopharynx*: epiglottis to the cricoid ring (posteriorly), including the piriform sinus/recess/fossa

Piriform sinus/recess/fossa: the pockets on both sides of the laryngeal inlet separated from the larynx by the aryepiglottic folds

Larynx: the anterior structures of the throat (commonly called the voice box) from the tip of the epiglottis to the inferior border of the cricoid cartilage, including the laryngeal inlet

Laryngeal inlet: the opening to the larynx bounded anterosuperiorly by the epiglottis, laterally by the aryepiglottic folds, and posteriorly by the arytenoid cartilage

Arytenoid/posterior cartilage: the posterior aspect of the laryngeal inlet separating the glottis (anterior) from the esophagus (posterior)

1. *Corniculate cartilage*: the medial portion of the arytenoid/posterior cartilage
2. *Cuneiform cartilage*: the lateral prominence of the arytenoid/posterior cartilage
3. *Interarytenoid notch*: the notch between the posterior cartilage

Glottis: the vocal apparatus, including the true and false cords and the glottic opening

Vallecula: the space between the base of the tongue and the epiglottis

Hyoepiglottic ligament: anterior midline ligament connecting the epiglottis to the hyoid bone

PREPARATION

Intubation is best accomplished with two operators, one to perform the intubation and the other to handle equipment, help with positioning, observe the patient and monitor, and keep track of time. Unfortunately, the ideal scenario and adequate time for preparation are not always available to the clinician, who has to make calculated adjustments based on the situation at hand. Before intubating, it is preferable to take the following steps in chronologic order: (1) attach the necessary monitoring devices and administer oxygen, (2) establish intravenous

Figure 4.1 **A**, Adult airway cart. Equipment and materials are visible, labeled, and accessible. **B**, Labeling is especially important because it lets you know what is missing. (Concept of Dr. Ernest Ruiz, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

Figure 4.2 **A**, Anatomy of the upper airway. **B**, View of the larynx, epiglottis, and vocal cords seen with a laryngoscope. The key to a successful intubation is identification of the vocal cords. (A, Netter illustration used with permission of Elsevier, Inc. All rights reserved.)

access, (3) draw up essential medications and label them if time permits, (4) confirm that the intubation equipment is available and functioning, (5) reassess oxygenation and maximize preoxygenation, (6) position the patient correctly, and (7) make sure that all team members are aware of the primary procedural approach and the most likely backup plan. In the haste of the moment, it is a common error to forget to preoxygenate or to position the patient optimally. Simple omissions, such as failing to restrain the patient's hands or remove the patient's dentures or misplacing the suction tip, can seriously hamper the success of the procedure. Utilize universal precautions by wearing gloves, a gown, and eye and mouth protection.

The concept of using checklists to decrease medical errors and improve patient care has grown since a landmark article demonstrated decreased complications and mortality in surgical patients when checklists were utilized.⁷ Timely and successful tracheal intubation, while minimizing hypoxemia and other complications, is paramount when caring for ill and injured patients who require intubation. Pre-intubation checklists can reduce cognitive load for the intubating physician by creating a framework for approaching all emergency intubations. Checklists prompt clinicians to verify that all necessary equipment is available and functioning, to perform a standardized airway assessment, to execute optimal preoxygenation, and to develop an airway plan with patient-specific backups. The use of pre-intubation checklists has been shown to reduce peri-intubation complications in trauma patients.⁸ Example checklists are seen in [Box 4.1](#).

BOX 4.1 Preintubation Checklists

PRE-ARRIVAL

1. Bag mask ventilation setup with oxygen running at >15 L/min
2. Suction connected and running
3. Laryngoscope functioning and ready
4. Ready an endotracheal tube: check cuff, insert stylet, and have a “straight to cuff” shape with a 35-degree distal bend
5. Back-up devices such as laryngeal mask airway or King LT airway available and ready
6. Cricothyrotomy set located
7. End-tidal CO₂ detector ready

PRE-INTUBATION

1. Assess the airway: open mouth, examine neck mobility, palpate anterior neck
2. Decide best approach: awake, sedated, or RSI
3. Communicate intubation medication orders to nurses, including post-intubation medications
4. Optimally position patient
5. Preoxygenate patient (usually with face mask oxygen at 60 L/min)
6. Apply nasal cannula at 10–15 L/min in preparation for apneic oxygenation
7. Discuss airway plan with entire team
8. Ensure functioning pulse oximeter
9. Ensure patient intravenous catheter
10. Ensure assistants are ready (nurses, respiratory therapists)

RSI, *Rapid-sequence intubation*.

PREOXYGENATION

Preoxygenation is one of the most important aspects of emergency airway management. The goal of preoxygenation is to replace all the nitrogen in the lungs with oxygen prior to the start of intubation attempts. This allows the lungs to act as an oxygen reservoir during the apneic period of RSI. This provides the intubator with additional time before the onset of hypoxemia, and significantly increases the chance for successful intubation on the first attempt. It is not enough to achieve a peripheral oxygen saturation (SpO₂) value of 100% prior to intubation, because an SpO₂ of 100% does not necessarily correspond with denitrogenation of the lungs; furthermore, partial pressure of arterial oxygen (PaO₂) at 100% SpO₂ can range from approximately 100 mm Hg to 600 mm Hg. Failure to preoxygenate before RSI is often a critical factor when a straightforward emergency airway becomes an unexpected airway problem. Those at greatest risk for rapid desaturation include obese, pregnant, critically ill, and pediatric patients; these populations will benefit most from optimal preoxygenation.

Preoxygenate by providing the maximal fraction of inspired oxygen (FiO₂) with a simple face mask or non-rebreather mask for 3 to 5 minutes before intubation.^{9,10} The type of mask is less important than the oxygen flow rate¹¹; at very high flow rates the FiO₂ for any device usually exceeds 90%. At lower flow rates (< 30 L/min) the FiO₂ will not be high enough for adequate preoxygenation,¹² so the oxygen flow rate should be at least 30 L/min. When using a standard oxygen flow meter this requires turning it up as high as possible, beyond the marked maximum of 15 L/min, to the “flush” rate. The flush rate is usually marked on each flowmeter and is typically greater than 40 L/min. Oxygen flowmeters that can measure up to 70 L/min, with flush rates up to 90 L/min, are available (see [Fig. 3.7](#) in [Chapter 3](#)); however, a flush rate greater than 40 L/min is probably sufficient for maximal preoxygenation. Providing high flow oxygen washes out expired CO₂, fills the dead space of the nasopharynx and upper airway with oxygen, compensates for any leak between the mask and the patient to avoid entrainment of room air during inspiration, and may provide low levels (1 to 2 cm H₂O) of positive airway pressure.¹³ The importance of very high flow oxygen administration during preoxygenation cannot be overemphasized. If possible, instruct the patient to exhale maximally before beginning preoxygenation.¹⁴

Alternatively, if it is not possible to perform preoxygenation for 3 to 5 minutes prior to intubation, instruct the patient to take eight vital capacity breaths while delivering very high flow oxygen, to provide nearly the same result.^{9,15} Many critically ill patients will not be able to take vital capacity breaths; therefore with time permitting, the preferred method is 3 to 5 minutes of tidal breathing.

Unlike face masks, bag-mask ventilation (BMV) requires proper equipment and good technique to achieve adequate preoxygenation. Bags without one-way valves for inhalation and exhalation will not function properly during spontaneous ventilation, and will provide only room air.¹⁶ Furthermore, unless flow rates are very high (>40 L/min), the mask must be sealed perfectly to the patient's face (see [Chapter 3](#) for proper technique).¹⁷ If the seal is imperfect, room air will be entrained and FiO₂ will be close to that of room air. This is analogous to holding a mask above a patient's face, which likewise provides oxygen content near that of room air. In spontaneously breathing patients, face masks (with a very

high flow rate) are the preferred oxygen delivery device for preoxygenation.

To augment oxygen delivery and prepare for apneic oxygenation (see next section), apply a nasal cannula (at 15 L/min) to the patient during preoxygenation, simultaneously with other preoxygenation efforts.¹⁸ High flow nasal cannula (see Chapter 3 for details), if available, may also improve preoxygenation,¹⁹ though this has never been studied in combination with a high-flow face mask.

The preferred position for preoxygenation is head elevation of 20 to 25 degrees. This position minimizes atelectasis, decreases the pressure of the abdominal contents against the diaphragm, and allows the patient to continue taking deep breaths. In both obese^{20,21} and non-obese adults^{22,23} this position has been demonstrated to be advantageous for preoxygenation. For patients with spinal immobilization, the bed can be placed in 25 degrees of reverse Trendelenburg (head up) to achieve the same effect.²⁴

If SpO₂ cannot be increased above 93% to 95% after optimal preoxygenation, the addition of positive pressure using non-invasive positive pressure ventilation (NPPV) or mask ventilation with a positive end-expiratory pressure valve may improve oxygenation prior to intubation attempts.²⁵

Sometimes patients who will benefit the most from preoxygenation are uncooperative because of delirium from hypoxia, hypercapnia, or other factors. Application of a face mask or NPPV may be difficult or impossible. These patients may benefit from careful sedation without suppression of respirations, allowing for oxygenation with a face mask or NPPV for 2 to 3 minutes before administration of a paralytic agent (also known as *delayed sequence intubation*). Ketamine (1 to 1.5 mg/kg by slow intravenous push) has been suggested for this technique.²⁵ Weingart and colleagues performed sedation for preoxygenation in 62 adults, and demonstrated an increase in SpO₂ for most patients without any adverse events.²⁶ Because of the small sample size and because these patients were managed by experts in airway management and sedation, this technique is not necessarily generalizable to everyday clinical practice. If a patient is sedated for preoxygenation, the clinician should be vigilant for respiratory depression, apnea, and airway obstruction, and have all airway equipment available in case emergency control of the airway or breathing becomes necessary. In many cases, it may be safer to restrain the patient without sedation to facilitate preoxygenation.

Apneic Oxygenation During Intubation

Another method to delay desaturation during RSI is nasopharyngeal oxygen insufflation without ventilation, termed apneic oxygenation. Even in the absence of ventilation, oxygen is able to travel down the tracheobronchial tree to the alveoli and diffuse into the bloodstream, where it is consumed and converted into carbon dioxide. Because oxygen diffuses across the alveoli much more readily than carbon dioxide, because oxygen and carbon dioxide have differences in gas solubility in blood, and because of the high affinity of hemoglobin for oxygen, more oxygen leaves the alveoli than carbon dioxide enters. This creates a pressure gradient that causes oxygen to travel from the nasopharynx to the alveoli and into the bloodstream.²⁵

Studies have shown that providing oxygen therapy during apnea is much more beneficial than one might anticipate.^{27–29} Multiple studies conducted in the operating room, in normal

and morbidly obese patients, have shown that nasopharyngeal oxygen insufflation results in a significant delay in desaturation after the onset of apnea, with many subjects never developing hypoxemia even after six minutes of apnea.^{27,29–31}

A 2016 randomized trial in an intensive care unit (ICU) found no difference in the oxygen saturation nadir between patients who received and did not receive apneic oxygenation during intubation.³² Because ED patients are often intubated within minutes of arrival despite limited history and sometimes limited preoxygenation, and because, contrary to ICU patients, ED patients generally have not been on supplemental oxygen for the several hours preceding intubation, the results of this study should not be generalized to ED care.

Perform apneic oxygenation with every tracheal intubation to decrease the chance of severe hypoxemia. Place a standard nasal cannula beneath the main preoxygenation device (face mask or bag-valve mask). If the patient is awake, limit the flow rate to 5 to 15 L/min during the preoxygenation phase because higher flow rates can be uncomfortable. If the patient is comatose or unresponsive, set the nasal cannula to 15 L/min or higher when initially placed. When the preoxygenation device is removed for intubation, keep the nasal cannula in place. During intubation attempts, set the nasal cannula to at least 15 L/min. It may be beneficial to turn the oxygen flowmeter up as high as possible because higher flow rates have been shown to provide higher FiO₂.³³ If there is nasal obstruction, place a nasopharyngeal airway in one or both nares to facilitate oxygen delivery to the posterior nasopharynx. To optimize gas flow past the upper airway, position the patient for tracheal intubation, and perform maneuvers to ensure upper airway patency (i.e., jaw thrust, head tilt/chin lift). Because conventional nasal cannula oxygen delivery is not humidified, apneic oxygenation at high flow rates will cause some desiccation of the nasopharynx, but this should not cause significant harm because of the short duration of this oxygen supplementation.

High-flow nasal cannula systems may be an even better method of apneic oxygenation, and have been shown in an ICU study to be superior to simple nasal cannula, though both groups had low rates of hypoxemia.¹⁹

ASSESSING FOR A DIFFICULT AIRWAY

When trying to predict whether there will be difficulty during emergency intubation, it is important to understand that most of the literature on prediction of difficult laryngoscopy does not apply very well in the emergency setting. A study by Levitan and colleagues in 2004 showed that two-thirds of patients who were intubated in their ED via RSI could not be assessed with the most common difficult airway prediction tests (Mallampati scoring, measurement of thyromental distance, and neck mobility testing) because of altered mental status or cervical spine immobilization.³⁴ Even in the best circumstances, only approximately half the cases of difficult laryngoscopy can be predicted.³⁵ Many factors such as Mallampati scoring and measurement of the thyromental distance have not been found to accurately predict difficult laryngoscopy, especially in the emergency setting.^{34–37} Only obvious anatomic and pathologic abnormalities and a history of difficult intubation are accurate predictors of difficult laryngoscopy.³⁴ The American Society of Anesthesiology Difficult Airway Guidelines state that “in patients with no gross upper airway pathology or anatomic anomaly, there is insufficient published evidence to evaluate

the effect of a physical examination on predicting the presence of a difficult airway.^{38,39} This does not mean that emergency providers should ignore factors that are known to be associated with difficult laryngoscopy, but these must be placed in perspective.

No examination finding alone can predict difficult laryngoscopy, and a combination of multiple factors makes difficulty more likely. The classic predictors of difficult intubation include a history of previous difficult intubation, prominent upper incisors, limited ability to extend at the atlanto-occipital joint,⁴⁰ poor visibility of pharyngeal structures when the patient extends the tongue (Mallampati classification or the tongue-pharyngeal ratio) (Fig. 4.3A),⁴¹ limited ability to open the mouth (suggested by a space less than three fingerbreadths between the upper and lower incisors),⁴² short thyromental distance (< 6 cm from the thyroid notch to the chin with the neck in extension) (see Fig. 4.3B),⁴³ and a limited direct laryngoscopic view of the laryngeal inlet (Fig. 4.4).⁴² A relatively new test is the upper lip bite test, which has been shown in some studies to be more accurate and specific than older tests.^{44–48} It is essentially a test of anterior mandibular mobility, and the less mobility the more difficult it is to intubate the patient. Upper lip bite criteria are as follows: class I, the lower incisors can bite the upper lip above the vermilion line; class II, the lower incisors can bite the upper lip below the vermilion line; and class III, the lower incisors cannot bite the upper lip.

Many of these predictors cannot be assessed in the emergency setting.³⁴ Some of the key predictors are apparent simply by observing the external appearance of the patient's head and neck. Patients with neck tumors, thermal or chemical burns, traumatic injuries involving the face and anterior aspect of the neck, angioedema, infection of pharyngeal and laryngeal soft tissues, or previous operations in or around the airway suggest a difficult intubation because distorted anatomy or secretions may compromise visualization of the vocal cords. Facial or skull fractures may further limit airway options by precluding nasotracheal (NT) intubation. Patients with ankylosing arthritis or developmental abnormalities such as a hypoplastic mandible or the large tongue of Down's syndrome are difficult to intubate because neck rigidity and problems of tongue displacement can obscure visualization of the glottis.

Besides these obvious congenital and pathologic conditions, the presence of a short, thick neck is one of the more common predictors of a difficult airway. Such individuals are easily identifiable by observing the head and neck in profile. Obesity alone may not be an independent predictor of difficult intubation, but obese patients with large-circumference necks are likely to be difficult to intubate.⁴⁷ Facial hair can complicate a difficult airway by rendering BMV ineffective because of the lack of a good mask seal. One patient type that does not immediately stand out as a difficult intubation, but can be surprisingly so, is a patient with an unusually long mandibulo-hyoid distance (the thyroid prominence appearing low in the neck) and a short mandibular ramus.⁴⁹ Visualization of the larynx is difficult because of the distance to the larynx and the relative hypopharyngeal location of the tongue.

Knowledge of the poor performance of difficult airway predictors should not make emergency providers more cavalier about using RSI; rather, it should create more concern. The solution is not to avoid RSI because lack of paralysis makes every intubation more difficult. Even though predicting a difficult airway is challenging, and even though a comprehensive airway assessment may not be possible because of patient

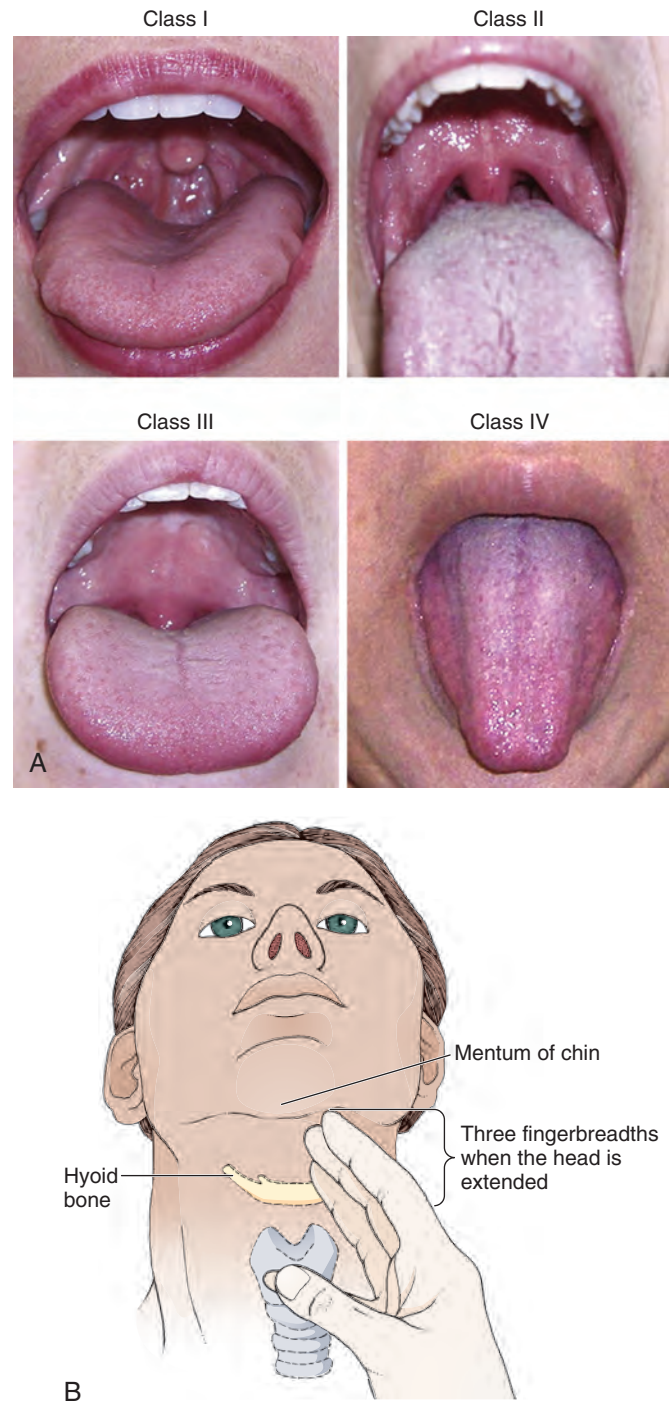

Figure 4.3 A, The Mallampati classification predicts intubation difficulty based on the visibility of intraoral structures. Classes III and IV predict difficult intubation. B, A short thyromental distance (less than 6 cm or 3 fingerbreadths) when the head is extended predicts difficult intubation. (A, From Kryger MH: Sleep breathing disorders: examination of the patient with suspected sleep apnea. In Kryger MH, editor: *Kryger Atlas of Clinical Sleep Medicine*. Philadelphia, 2010, Elsevier.)

behavior or clinical circumstances, performing an assessment of the airway is important and serves as a cognitive forcing strategy⁵⁰ that guides the physician to plan and prepare for the airway intervention. It is essential to appreciate the critical importance of having a clear backup plan when intubation

Figure 4.4 Cormack and Lehane grading of laryngeal views during laryngoscopy. **A**, Grade I. Most of the glottis is visible. **B**, Grade II. The posterior aspect of the glottis is visible. **C**, Grade III. Only the epiglottis is seen; no part of the laryngeal inlet is visible. **D**, Grade IV. The epiglottis is not visible. Patients with grades I and II are usually easy to intubate with direct laryngoscopy, whereas those with grades III and IV are often difficult; the ability to see the arytenoid cartilage is the important difference.

Direct Laryngoscopy

Indications

Routine emergency intubation
Difficult airways

Contraindications

Limited mouth opening
Upper airway distortion or swelling
Kyphosis (extreme curvature of the upper back)
Copious blood or secretions

Complications

Hypoxic brain injury
Cardiac arrest
Aspiration
Upper airway trauma
Dental trauma

Equipment

Review Box 4.1 Direct laryngoscopy: indications, contraindications, complications, and equipment.

with RSI fails.^{34,51} This situation mandates the need for a preconceived algorithm that uses proven rescue techniques applicable to a broad range of clinical scenarios, such as the bougie (flexible intubating stylet) and the intubating LMA Fastrach (Teleflex).² The value of the bougie is indisputable, and it is clear that using the intubating LMA Fastrach after failed RSI has decreased the frequency of failed airways and the need for surgical intervention.^{2,4,52–58} Because RSI is the “go-to” method for emergency intubation, providers must be prepared to perform a surgical airway when laryngoscopy, BMV, and backup devices fail.^{2,59}

EMERGENCY AIRWAY DECISION MAKING

The airway provider must have many tools readily available to deal with an acutely compromised airway. It is important to be proficient in a number of different techniques and to tailor their use to the needs of the individual patient. Rescuers should practice potential scenarios before facing patients with a compromised airway. Failure to do so may lead to unnecessarily

aggressive management in some situations or to irreversible hypoxic injury as a result of hesitation in others. Deciding who requires a definitive airway and who needs only supportive measures is a formidable task for even the most skilled clinician.

The following parameters should be assessed before the decision is made to establish a definitive airway:

- Adequacy of current ventilation
- Potential for hypoxia
- Airway patency
- Need for neuromuscular blockade (uncooperative, full stomach, teeth clenching)
- Cervical spine stability
- Safety of the technique and skill of the operator

Consideration of these factors should guide the clinician in deciding if tracheal intubation is necessary, and in selecting the optimal technique. Choosing the initial approach is often straightforward. Difficulty arises precipitously when the initial approach fails. Time becomes critical as the risk for irreversible hypoxic injury and cardiac arrest rises. Anxiety then increases the potential for error. Forethought and practice are invaluable when managing these situations.

Clinicians who perform emergency intubation, especially RSI, must understand that oxygenation and ventilation, not tracheal intubation, are paramount when caring for critically ill patients. Patients who are hypoxic on arrival and those who develop hypoxia after a failed first intubation attempt need good BMV to restore oxygenation and keep them stable enough for further intubation attempts. The importance of BMV skills cannot be overstated (see [Chapter 3](#)), and mastery of this skill alleviates much of the anxiety associated with difficult emergency airways and improves the chance for successful RSI.³ It is critically important to have an extraglottic airway (EGA) device immediately available during every RSI in the event that BMV is difficult or impossible. All clinicians who perform emergency intubation should be prepared to perform a surgical airway when intubation methods and backup ventilation techniques fail.

Decision to Perform Rapid-Sequence Intubation (RSI)

RSI in anesthesia has evolved since the introduction of succinylcholine in 1951. RSI was initially used as an abbreviation for rapid-sequence induction but is now synonymous with rapid-sequence intubation. Initially, the main purpose of RSI was to decrease the risk for aspiration in patients with full stomachs who needed emergency intubation. RSI has now become the most common method of emergency airway management because paralysis facilitates optimal intubating conditions in critically ill patients.⁶⁰⁻⁶⁴

Emergency providers should be very careful to not use RSI in a cavalier manner. When giving a paralytic agent, the provider takes complete responsibility for airway maintenance, ventilation, and oxygenation of the patient. Consider one of many awake intubation (i.e., intubation without paralysis) options in patients with known or anticipated difficult airways ([Box 4.2](#)). In the emergency setting it is useful to think of difficult airways as situations in which our usual methods of intubation and backup ventilation/oxygenation techniques fail. The goal should be to avoid RSI in patients who cannot be easily intubated via the common techniques (direct or video laryngoscopy) and cannot be ventilated with a bag-mask device. Risk factors for difficult or impossible BMV have been well studied and include the presence of a beard, obesity, lack of teeth, age older than 55 years, a history of snoring, short thyromental distance, and limited mandibular protrusion (see [Box 3.2](#) in [Chapter 3](#)). It is also prudent to consider whether an EGA device will be difficult to place because this is often the primary backup plan. RSI is contraindicated in patients who cannot be orally intubated and it should usually be avoided

in patients with laryngotracheal abnormalities caused by tumors, infection, edema, or a history of cervical radiation therapy.

If the clinician decides that RSI is not appropriate for a patient, there are many options that can be performed without paralysis (see [Box 4.2](#)). Flexible endoscopic intubation is the go-to procedure for most anesthesiologists and is described later in the chapter. Direct and video laryngoscopy can also be performed without paralysis. If excellent topical anesthesia is achieved, some patients can be intubated without any sedation.

Ideal Versus Emergency Technique

The intubation plan that would be best in the ideal/elective situation is often not the best plan in the emergency setting. Consider the patient with rapidly increasing upper airway swelling due to angioedema or anaphylaxis, causing impending complete airway obstruction. Because of predicted difficulty with direct and video laryngoscopy, some providers would not consider this patient a candidate for RSI. Other intubation strategies might have a higher chance of success if time was not a factor. The patient will likely develop complete airway obstruction, critical hypoxia, and death in the time required to set up and perform endoscopic nasal intubation. In this situation the emergency provider is “forced to act”⁶⁵ to complete timely tracheal intubation. The best course for this patient is likely RSI with modern video laryngoscopy equipment and a good backup plan, such as the LMA Fastrach (Teleflex), followed by a cricothyrotomy. There are many other scenarios in which the emergency airway plan is much different than the ideal/elective airway plan, such as patients with severe trauma who have multiple different life-threats. In these patients, intubation often needs to be expedited so that other life threats can be addressed in a timely manner.

Failed Airways

A failed airway should be differentiated from a known or anticipated difficult airway. A patient is considered to have a failed airway in the following situations⁶⁶: (1) inability to maintain oxygenation by BMV or EGA device; (2) failure of three or more intubation attempts by an experienced operator; (3) failure of the first attempt in a “forced to act” situation.

If a patient has a failed airway, and oxygenation can be maintained, the clinician should attempt intubation by another method (e.g., flexible endoscopy, intubating LMA [ILMA], video laryngoscopy, surgical airway, and others); if a more experienced provider is not already present then one should be called for. This could be an anesthesiologist, emergency physician, paramedic, or any other clinician with significant airway expertise. If at any point there is failure of oxygenation, an EGA device should be placed while preparing for a cricothyrotomy. If the EGA device cannot oxygenate, a cricothyrotomy should be performed.

Emergency Airway Algorithm

The realization that one cannot predict all cases of failed BMV and failed laryngoscopy mandates the need for a simple pre-conceived algorithm that uses proven rescue techniques that are applicable to a broad range of clinical scenarios, such as the bougie and the LMA Fastrach (Teleflex). The value of the bougie is indisputable, and it is clear that use of the LMA

Fastrach after failed RSI has decreased the frequency of failed airways and the need for surgical airways.^{1,2,4,53–58}

One of the most important concepts to appreciate when using RSI is that of optimal laryngoscopy to maximize first-pass success.^{51,66} Preparation, preoxygenation, proper patient positioning, anterior neck maneuvers, and good laryngoscopy skills are all important components of optimal laryngoscopy. Just as important as optimal laryngoscopy is the ability to recognize when laryngoscopy (or any technique) has failed and when it is time to move on to a different approach. Patient safety during RSI depends on the provider's ability to maintain ventilation and oxygenation if the first attempt at intubation fails.⁵¹ Critical decisions about how to maintain ventilation and oxygenation and when to use a different intubation approach are much easier when using a simple preconceived algorithm. The algorithm presented here summarizes the general approach used in the Department of Emergency Medicine at Hennepin County Medical Center (Fig. 4.5). This algorithm is presented as an example. Individual providers and institutions should determine their own algorithms based on the availability of skills and resources. There are many similarities between this algorithm and those put forth by the American Society of Anesthesiologists and the Difficult Airway Society; however, our algorithm is simpler and more applicable to emergency airway management.^{39,67} Most published airway algorithms are not ideal for emergency airway management because they do not account for the conditions that are commonly encountered: patients with full stomachs who are critically ill and often uncooperative, and intubations that cannot be canceled if the airway is too difficult. Many algorithms resemble wish lists of equipment and skills that are simply not available to many emergency airway providers. Our algorithm is based on the concept that oxygenation, not intubation, is the key.¹ It stresses well-proven concepts, procedures, and devices, and it is modeled after a simple algorithm developed by Combes and colleagues that was validated in a large prospective study.^{2,53,58}

Figure 4.5 Emergency airway management algorithm used at Hennepin County Medical Center. The end point of the algorithm is successful tracheal intubation. This algorithm is presented as an example. Individuals and institutions should formulate their own algorithms based on technical skills and the availability of resources. *ILMA*, Intubating laryngeal mask airway.

DIRECT LARYNGOSCOPY (DL)

Despite the proliferation of approaches and devices designed to secure a definitive airway, DL remains the mainstay of tracheal intubation. DL is a crucial skill even in the era of video laryngoscopy, and is less prone to problems such as device failure or blood and secretions covering the video lens.⁶⁸ Visual confirmation of the tube going through the vocal cords is usually possible.

Indications and Contraindications

DL is indicated in any clinical situation in which a definitive emergency airway is necessary, including routine and difficult airways. Relative contraindications to DL include limited mouth opening, upper airway distortion or swelling, severe kyphosis, or copious blood or secretions.

Equipment

Laryngoscope

There are two basic blade designs for DL, curved (Macintosh) and straight (Miller) (Fig. 4.6). Each comes in various adult and pediatric blade sizes. Slight variations in laryngoscopic technique follow from the choice of blade design, and it is often a matter of personal preference. The tip of the straight blade goes under the epiglottis and lifts it directly, whereas the curved blade fits into the vallecula and indirectly lifts the epiglottis via engagement of the hyoepiglottic ligament to expose the larynx.

Each blade type has advantages and disadvantages. The straight blade is often a better choice in pediatric patients, in patients with an anterior larynx or a long floppy epiglottis, and in individuals whose larynx is fixed by scar tissue. It is less effective, however, in patients with prominent upper teeth, and it is more likely to damage dentition. Use of the straight blade is also more often associated with laryngospasm because it stimulates the superior laryngeal nerve, which innervates the undersurface of the epiglottis. A straight blade may inadvertently be advanced into the esophagus and initially reveal unfamiliar anatomy until it is withdrawn. The blade has a lightbulb at the tip, which may slightly hamper vision. The wider, curved blades are helpful in keeping the tongue retracted from the field of vision and allowing more room for passing the tube through the oropharynx, and they are generally preferred for uncomplicated adult intubations. Aside from

Figure 4.6 A, Macintosh (curved) and B, Miller (straight) laryngoscope blades.

patient considerations, some clinicians prefer the curved blade because they find that it requires less forearm strength than the straight blade.

The illumination provided by the laryngoscope can make a big difference in the ability to visualize the laryngeal inlet. The importance of these factors is underappreciated, as demonstrated by Levitan⁶⁹ in a survey of the Macintosh blades used in 17 Philadelphia EDs. It was found that only 24% of all blades provided the brightness necessary for fine inspection. This finding was largely explained by the fact that the majority of EDs used the A-Mac (American) as opposed to the clearly superior brightness design of the G-Mac (German) or the intermediate brightness of the E-Mac (English).

Tracheal Tubes

The standard adult endotracheal (ET) tube measures approximately 30 cm in length. Tube size is typically printed prominently on the tube and is based on the internal diameter (ID) and measured in millimeters. The range is 2.0 to 10.0 mm in increments of 0.5 mm. The outer tube diameter is 2 to 4 mm larger than the ID.⁷⁰ Tubes are also imprinted with a scale in centimeters that indicates the distance from a tube's distal tip.

Adult men can generally accept a 7.5- to 9.0-mm orotracheal tube, and women can usually be intubated with a 7.0- to 8.0-mm tube. Larger tubes are theoretically desirable because airway resistance increases as tube size decreases, but in practice, a 7.5-mm tube is adequate for almost all patients. In emergency intubations, particularly if a difficult intubation is anticipated, many clinicians choose a smaller tube and change to a larger tube later if necessary. Though generally an acceptable practice, this should be avoided in burn patients because swelling may prohibit subsequent tube placement. For nasal intubation, a slightly smaller (by 0.5 to 1.0 mm) tube may be easier to advance through the nasal passages.

Correct tube size is important in the pediatric population. It is especially important when using an uncuffed tube because a good seal is needed between the ET tube and the upper part of the trachea (Table 4.1). As tube size is based on the ID, a cuffed tube should generally be a half size (0.5 mm) smaller than an uncuffed tube. The smaller ID of an appropriately sized, small cuffed tube could theoretically make it more prone to plugging from secretions. Cuffed tubes are available down as small as 3 mm ID, although indications for these tubes in neonates and infants are rare. A cuffed tube is used in children with decreased lung compliance who may require prolonged mechanical ventilation. In a child, the smallest airway diameter is at the cricoid ring rather than at the vocal cords, as in adults. Hence, a tube may pass the cords but go no farther. If this should occur, the next smaller size tube should be passed. The American Heart Association (AHA) states that both cuffed and uncuffed tubes are acceptable for infants and children who are tracheally intubated.⁷¹ If a cuffed tube is placed, careful attention must be paid to cuff pressures.

In children 2 years or older, the following formula is a highly accurate method for determining correct uncuffed and cuffed ET tube size:

$$\text{Uncuffed tube size (mm)} = [\text{Age (yr)} / 4] + 4$$

$$\text{Cuffed tube size (mm)} = [\text{Age (yr)} / 4] + 3$$

For most clinical situations, using the width of the nail of the patient's little (fifth) finger as a guide is sufficiently accurate and has been shown to be more precise than finger diameter

TABLE 4.1 Tracheal Tube Sizes for Average Patients

AGE	CUFFED ETT SIZE (INTERNAL DIAMETER, mm)	EQUIVALENT TRACHEOTOMY TUBE SIZE
Children		
Preterm	2.5	00
Term	3.0	00
6 months	3.0–3.5	00–0
1–2 years	4.0	0–1
3–4 years	4.5	1–2
5–6 years	5.0	2
10 years	6.0	3
12 years	7.0	4
14 years	See adult sizing	
Adults		
Female	7.0–8.0	5
Male	7.5–9.0	6

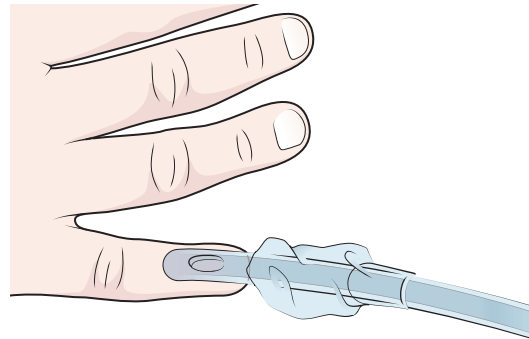

Figure 4.7 Pediatric endotracheal (ET) tube size estimation using the fingernail width of the patient's little finger. In children, a cuffed or uncuffed ET tube may be used.

(Fig. 4.7).⁷² In order to reduce cognitive load during emergency situations,⁷³ it may be best to use a length-based tool to determine the appropriate size ET tube, tube depth, and other resuscitation measures.

A standard tracheal tube uses a high-volume, low-pressure cuff to avoid pressure necrosis of the tracheal lining. A clinical test for determining correct cuff inflation is to slowly inject air until no air leak is audible while the patient is receiving bag-tube ventilation. This usually occurs with 5 to 8 mL of air if the proper size tracheal tube has been selected. Many clinicians use the tension of the pilot balloon as a guide to cuff inflation. Slight compressibility with gentle external pressure indicates adequate inflation for most clinical situations. For long-term use, measure and maintain cuff pressure at 20 to 25 mm Hg. Capillary blood flow is compromised in the tracheal mucosa when cuff pressure exceeds 30 mm Hg. In emergency situations, simply inflate the balloon with 10 mL of air and adjust it when the patient's condition has stabilized.

Figure 4.8 Comparison of the standard tracheal tube tip with the Parker Flex-Tip Tracheal Tube (Parker Medical, Englewood, CO). *Note:* When a standard tube is inserted in the normal fashion, the bevel is oriented vertically and toward the patient's left. The Parker tube tip bevel faces posteriorly and may avoid getting caught on laryngeal structures. The flexible tip of the Parker tube also provides a closer fit on an introducer.

Interest in design of the tip of the tracheal tube has grown as the Seldinger technique is increasingly being applied to intubation. When a tracheal tube is passed over a smaller-caliber introducer (Seldinger technique), regardless of whether it is a tracheal tube introducer or an endoscope, there is a reasonable chance that the tube will get hung up on the laryngeal soft tissue.⁷⁴ A tracheal tube that has been designed to overcome this problem has a bevel oriented posteriorly and a flexible tip that decreases the distance between the tube and whatever it is being passed over (Fig. 4.8).

Check the ET tube cuff for leaks by inflating the pilot balloon before attempting intubation. Prepare the tube for placement by passing a malleable stylet down the tube to increase its stiffness and enhance control of the tip of the tube. Do not extend the stylet beyond the eyelet of the tube. Bend the tube and stylet to create a “straight-to-cuff” shape with a 35-degree distal bend. Lubricate the tip and cuff of the tube with viscous lidocaine or a water-soluble gel.

Optimal Patient Positioning for DL

The sniffing position, with the patient's head extended on the neck and the neck flexed relative to the torso, has traditionally been considered the best head position for DL.^{75,76} This position aligns the oral, pharyngeal, and laryngeal axes (Fig. 4.9A–C).

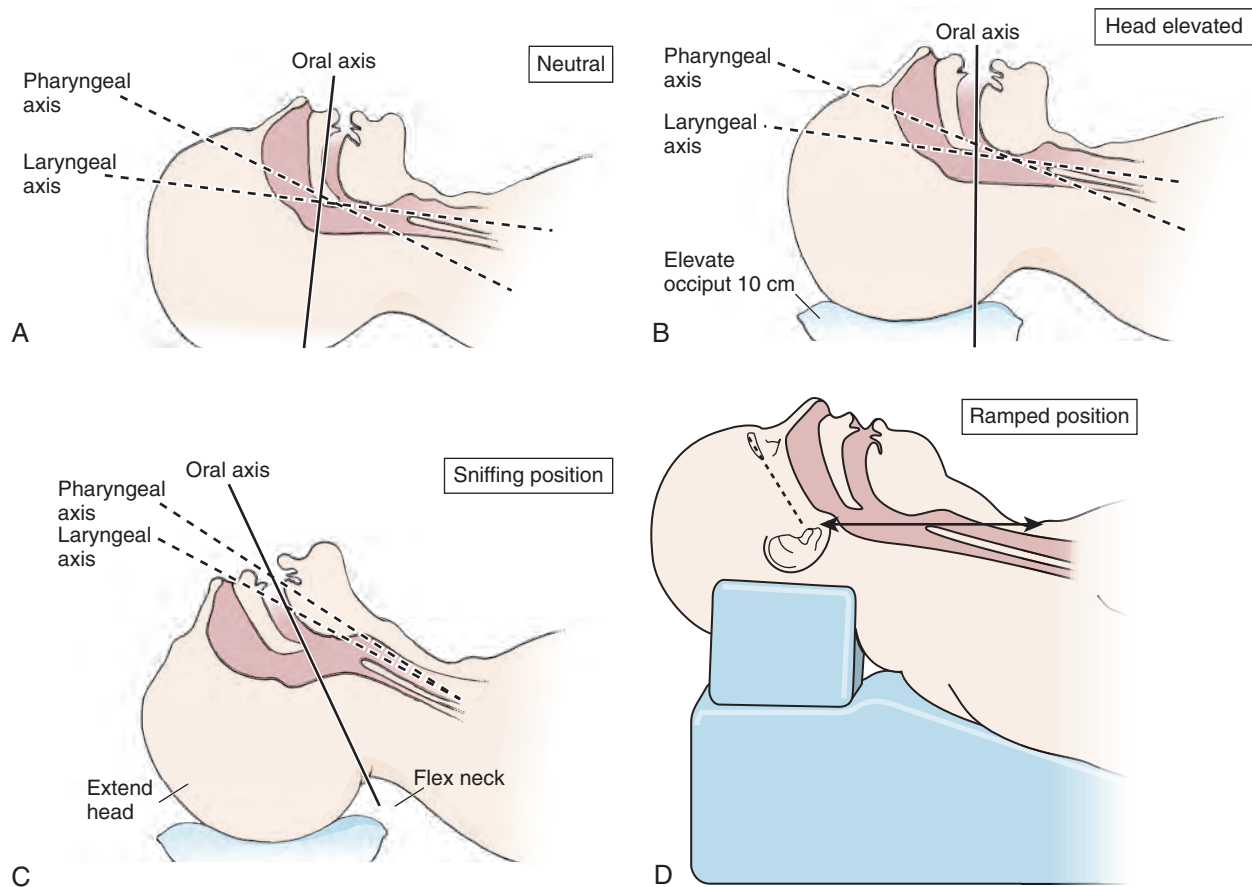

Figure 4.9 Head positioning for tracheal intubation. **A**, Neutral position. **B**, Head elevated. **C**, “Sniffing” position with a flexed neck and extended head. Note that flexing the neck while extending the head lines up the various axes and allows direct laryngoscopy. **D**, Morbidly obese patients are best intubated in a ramped position with elevation of the upper part of the back, neck, and head; the ideal position aligns the external auditory canal and the sternum.

Horton and colleagues described the ideal sniffing position for normal patients as neck flexion of 35 degrees and atlanto-occipital extension such that the plane of the face is -15 degrees to the horizontal position.⁷⁷ In supine patients, neck flexion is achieved by head elevation. Depending on the size and shape of the patient, the amount of head elevation may differ significantly, and the end point should be horizontal alignment of the external auditory meatus with the sternum.^{75,78–80} In normal-size adults it is usually possible to achieve the sniffing position with 7 to 10 cm of head elevation.^{81,82} Morbidly obese patients require much more head elevation to achieve the proper sniffing position. In these patients, aligning the external auditory meatus with the sternum requires elevation of the head and neck, as well as the upper part of the back (see Fig. 4.9D).^{3,79,70,83} This can be accomplished by building a ramp of towels and pillows under the upper torso, head, and neck or by using a Troop Elevation Pillow (Mercury Medical, Clearwater, FL) or similar device. Alternatively, elevating the head to a 25-degree back-up position (keeping the patient supine while placing the bed in 25-degree reverse Trendelenburg) may achieve the same purpose.⁸⁴

Two studies have shown that elevating the head (flexing the neck) beyond the sniffing position often improves visualization of the glottis.^{79,85} Because the amount of head elevation needed for optimal laryngoscopy varies depending on individual patient anatomy, it is important to make laryngoscopy a dynamic procedure. This is best accomplished by putting your right hand behind the patient's head to lift, flex, and extend the head as needed to bring the glottis into view.⁸⁶ Optimal positioning of the head and neck is not possible in trauma patients who require in-line stabilization of the cervical spine. This is one of the aspects that makes trauma airways so challenging and makes other maneuvers, such as external laryngeal manipulation (ELM), even more important in these patients.⁸⁶ It should also be noted that some patients, especially those who are obese, are in neck extension when lying supine because of upper dorsal fat deposition. If this is noted, the head can be raised until the head and neck are in neutral position.

Procedure and Technique of DL

Learning DL

Existing data suggests that novices who learn tracheal intubation skills with video laryngoscopy have higher success rates at DL compared to novices who learn tracheal intubation skills with DL.^{87,88} When utilizing DL alone, it is estimated that at least 50 intubations need to be performed to achieve greater than 90% success.⁸⁹ Using a video laryngoscopy system that allows both direct and video laryngoscopy (video systems with a Macintosh blade) may be ideal for learning DL skills.

Adults

Place the patient in the supine position with the head at the level of the lower part of the intubator's sternum (Fig. 4.10, step 2). To maintain the best mechanical advantage, keep your back straight and do not hunch over the patient. Bend only at the knees (Fig. 4.11). Keep the left elbow relatively close to the body and flex it slightly to provide better support. In a severely dyspneic patient who cannot tolerate lying down, perform DL with the patient seated semi-erect and the clinician on a stepstool behind the patient.⁹⁰

Grasp the laryngoscope in the left hand with the back end of the blade pressed into the hypothenar aspect of your hand.

Draw the patient's lower lip down with your right thumb, and introduce the tip of the laryngoscope into the right side of the patient's mouth (see Fig. 4.10, step 3). Slide the blade along the right side of the tongue while gradually displacing the tongue toward the left as you move the blade to the center of the mouth (see Fig. 4.10, step 4). If you initially place the blade in the middle of the tongue, it will fold over the lateral edge of the blade and obscure visualization of the airway. Placing the blade in the middle of the tongue and failing to move the tongue to the left are two common errors that prevent visualization of the vocal cords (Fig. 4.12).

As you move the tip of the blade toward the base of the tongue, exert force along the axis of the laryngoscope handle by lifting upward and forward at a 45-degree angle (see Fig. 4.10, step 6). The direction of this force is critical because if the force is too horizontal or too vertical, poor visualization will result. Avoid bending the wrist because it can result in dental injury if the teeth are used as a fulcrum for the blade. Slowly advance the blade down the tongue, searching for the epiglottis. It may help to have an assistant retract the cheek laterally to further expose the laryngeal structures. Locating the epiglottis is a crucial step in laryngoscopy, and has been termed *epiglottoscopy*.⁹¹ The laryngeal inlet lies just distal and below the epiglottis.

The step after visualization of the epiglottis depends on which laryngoscope blade is being used. With the curved blade, place the tip into the vallecula, the space between the base of the tongue and the epiglottis (see Fig. 4.12D). Continued anterior elevation of the base of the tongue will partially lift the epiglottis. With the blade in the midline of the vallecula, engage the hyoepiglottic ligament with the tip of the blade to indirectly lift the epiglottis and expose the laryngeal inlet. If the tip of the blade is inserted too deeply into the vallecula, the epiglottis may be pushed down and obscure the glottis.⁴¹ When using the straight blade, insert the tip under and slightly beyond the epiglottis and directly lift it up (see Fig. 4.12E). If the straight blade is placed too deeply, the entire larynx may be elevated anteriorly and out of the field of vision. Gradually withdraw the blade to allow the laryngeal inlet to drop down into view. If the blade is deep and posterior, the lack of recognizable structures indicates esophageal passage; gradually withdraw the blade to permit the laryngeal inlet to come into view.

Infants and Children

It is helpful to appreciate the anatomic differences between children and adults when intubating pediatric patients (Fig. 4.13 and Table 4.2). Children's proportionately larger heads naturally place them in the sniffing position, so a towel under the occiput is rarely necessary (Fig. 4.14). The large head of newborns can result in a posterior positioning of the larynx that prevents visualization of the vocal cords. A small towel under the infant's shoulders should correct this problem. This is not necessary in all children; rather, the goal of any positioning maneuvers should be alignment of the tragus with the anterior shoulder.

The head may also be floppy and may benefit from stabilization by an assistant. The child's increased tongue-to-oropharynx ratio and shorter neck hinder forward displacement of the tongue and, when coupled with a U-shaped epiglottis, can make visualization of the glottis difficult. DL in infants and young children is generally best performed with a straight blade: Miller size 0 for premature infants, size 1 for normal-sized infants, and size 2 for older children. The infant's larynx lies

Direct Laryngoscopy

1 Check all equipment, including the light on the laryngoscope and the cuff on the endotracheal tube.

Ensure that suction and difficult airway devices are within reach.

2 Place patient in the sniffing position, elevate the bed so that the patient's head is at the level of the lower part of your sternum, and preoxygenate.

3 Hold laryngoscope with your left hand. Open patient's mouth with your right hand and introduce the laryngoscope into the right side of the patient's mouth.

4 Push the tongue to the left side of the mouth, slowly advance the blade, and progressively identify the base of the tongue, the epiglottis, and the posterior cartilages.

5 Place the Macintosh blade in the vallecula, or the Miller blade under the epiglottis (E), and visualize the vocal cords (VC) and arytenoid cartilages (A).

Do not take your eyes off of the cords once they are identified.

6 Lift in the direction of the laryngoscope handle.

Manipulate the thyroid cartilage to achieve optimal laryngeal exposure. Have an assistant maintain that position during intubation.

7 Instruct an assistant to retract the right cheek for better visualization. Pass the tube on the right side of the patient's mouth. *Do not allow the tube to obstruct your view of the vocal cords during advancement.*

8 Under direct visualization, pass the tube 3–4 cm beyond the vocal cords.

9 Remove the stylet and inflate the pilot balloon.

10 Confirm proper placement with end-tidal CO₂ detection, auscultation, and a chest radiograph.

Figure 4.10 Direct laryngoscopy.

Figure 4.11 Proper positioning of the clinician, patient, and assistant for tracheal intubation. The following points are demonstrated: the difficult airway cart is adjacent to the patient, the suction device is at the head of the bed, the patient is in the “sniffing position” with the occiput elevated and the clinician’s right hand ready for additional adjustment if necessary, the bed is elevated and the clinician is at the appropriate distance from the patient, and the laryngoscope handle is angled at 45 degrees.

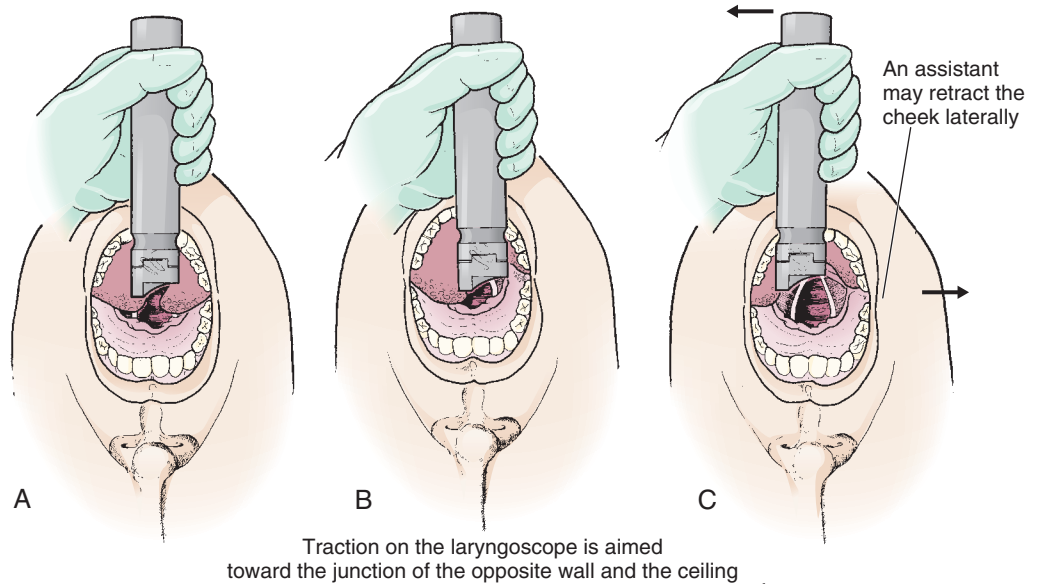

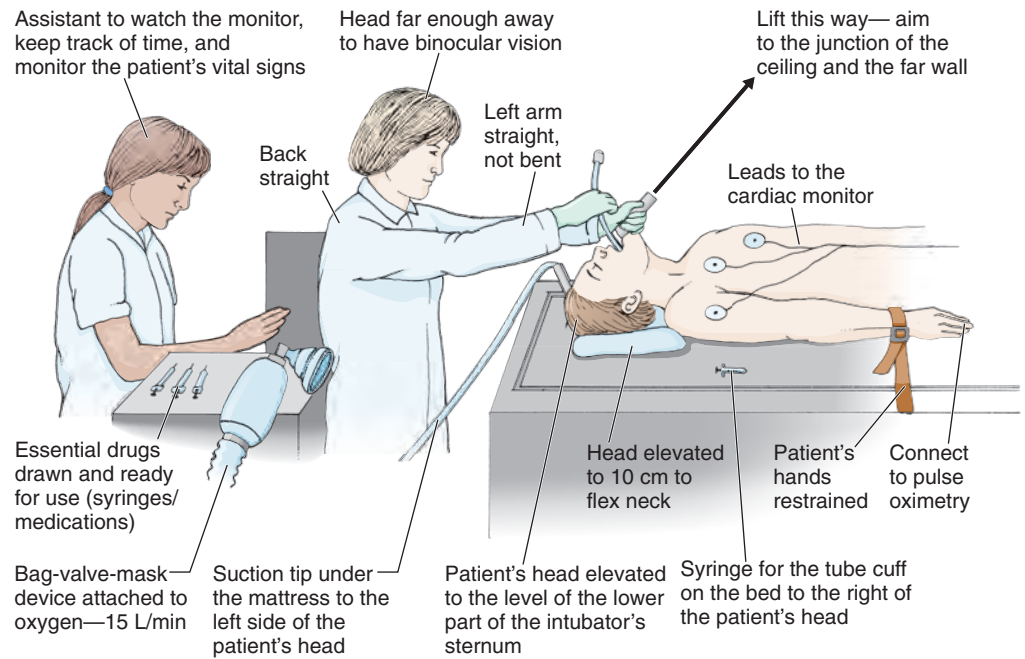

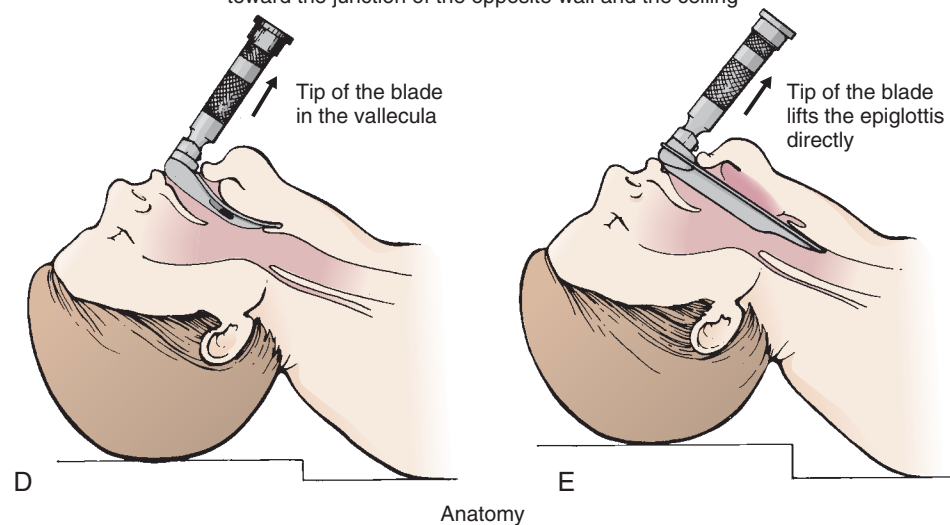

Figure 4.12 Common problems encountered when using a laryngoscope. **A**, The laryngoscope blade is under the middle of the tongue, with the sides of the tongue hanging down and obscuring the glottis. **B**, The tongue is not pushed far enough to the left and is obscuring the glottis. **C**, Correct blade position with the tongue elevated and to the left. **D**, Use of the curved (Macintosh) laryngoscope blade. **E**, Use of the straight (Miller) blade.

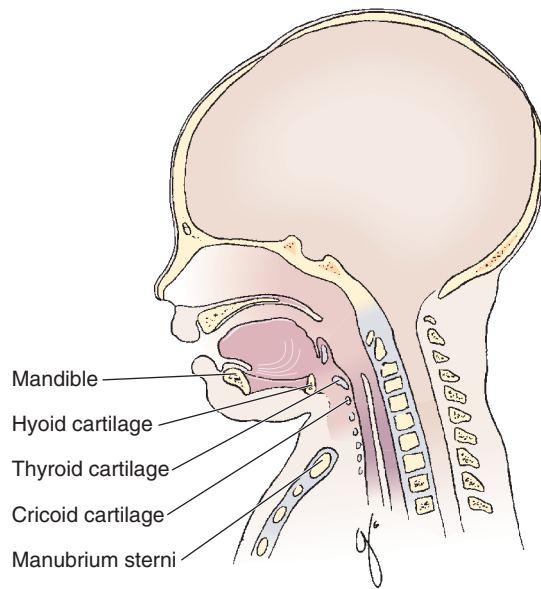

Figure 4.13 Sagittal section of the neck of an infant. Note that in small children, the neck is shorter and the larynx is located more cephalad. (From Snell RS, Smith MS, editors: *Clinical Anatomy for Emergency Medicine*. St Louis, 1993, Mosby-Year Book, p 16.)

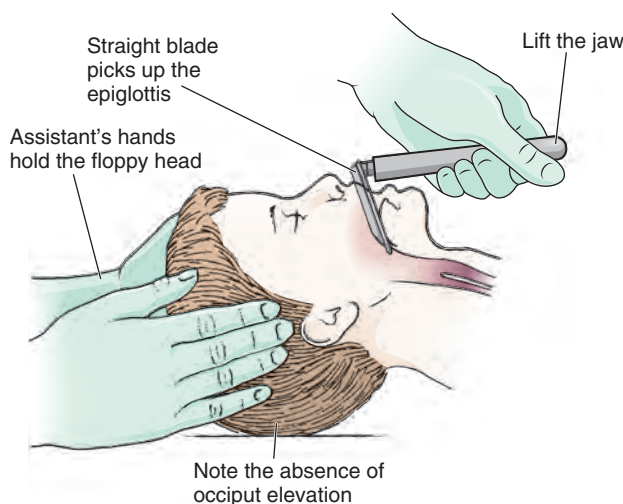

Figure 4.14 Oral intubation in a child with a straight blade. The proportionately large floppy head of a child may present some difficulty, and an assistant may be required to hold the child's head straight.

higher and relatively more anterior. If no laryngeal structures are visible after laryngeal pressure, gradually withdraw the blade. Inadvertent advancement of the blade into the esophagus is a common error.

Cricoid Pressure, ELM, Bimanual Laryngoscopy, and BURP

The differences between cricoid pressure, ELM, and backward, upward, rightward pressure (BURP) are often misunderstood. Cricoid pressure is the application of pressure at the anterior cricoid ring to displace it posteriorly to attempt to occlude the esophagus, with the intent of preventing regurgitation and aspiration; cricoid pressure is not intended to improve visualiza-

tion during laryngoscopy. ELM is the application of pressure on the thyroid cartilage during laryngoscopy to help optimize visualization of the glottis. BURP is often the best combination of forces that need to be applied to the thyroid cartilage during ELM. Bimanual laryngoscopy refers to use of the right hand to perform ELM.

Cricoid Pressure

There is some good evidence that cricoid pressure (Sellick's maneuver) helps prevent gastric inflation during BMV,⁹²⁻⁹⁷ though cricoid pressure during BMV reduces tidal volume, increases peak inspiratory pressure, and prevents good air exchange.^{93,95,96,98-105}

The only evidence suggesting that cricoid pressure prevents regurgitation during intubation consists of five cadaver studies,^{97,106-109} one human study,¹¹⁰ and some case reports,¹¹¹ which is poor evidence by today's standards of evidence-based medical practice.^{92,112} There are mixed data about the effects of cricoid pressure and laryngoscopic view,¹¹³ and several studies have shown that it worsens visualization of the larynx.¹¹⁴⁻¹¹⁶ A Cochrane review found insufficient evidence to support or refute the use of cricoid pressure during intubation.¹¹⁷ There are many reports of significant regurgitation and aspiration regardless of the application of cricoid pressure.¹¹⁸⁻¹²¹ Cricoid pressure also decreases successful insertion of and intubation through LMAs.¹²²⁻¹²⁹ Despite the lack of evidence, many experts believe that Sellick's maneuver is critical during RSI.¹³⁰⁻¹³³

Because aspiration has dire consequences and because cricoid pressure has traditionally been considered integral to patient safety during emergency airway management,¹¹² it is reasonable to apply cricoid pressure as long as it does not interfere with ventilation and intubation. There is significant evidence that it can interfere with ventilation and intubation, so it is best to apply cricoid pressure on a case-by-case basis with a full understanding of the benefits and drawbacks of cricoid pressure.¹¹² If cricoid pressure is utilized, it should be released immediately if there is any difficulty either intubating or ventilating a patient in an emergency setting.^{101,112,121,134,135} Routine use of cricoid pressure during BMV of patients in cardiac arrest is not currently recommended in the AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care.¹³⁶ It is reasonable to release or relax cricoid pressure during insertion of an LMA, during intubation with an ILMA, or if ventilation with the LMA is difficult.^{92,112,128}

Some authors believe that improper technique is to blame for the many reported failures of Sellick's maneuver.⁹² The proper technique for applying Sellick's maneuver is to place the thumb and middle finger on either side of the cricoid cartilage and the index finger in the center anteriorly.⁹⁷ Apply 30 N (6.7 lb.) of force to the cricoid cartilage in the posterior direction.^{92,136} As a reference, approximately 40 N of digital force on the bridge of the nose will usually cause pain.⁹²

ELM, Bimanual Laryngoscopy, and BURP

ELM is the application of pressure on the thyroid cartilage in an attempt to improve the view of the larynx during laryngoscopy. Multiple studies have shown that ELM performed by the laryngoscopist (bimanual laryngoscopy) is superior to having an assistant apply anterior neck pressure.^{115,137} Bimanual laryngoscopy is best because the direction and amount of force that will optimize laryngeal exposure is variable. BURP is sometimes optimal, and it often worsens the laryngoscopic view,¹¹⁵ so it is best to move the larynx in a variety of directions

TABLE 4.2 Comparison of the Airway in Adults and Children

COMPARISON	CHILD	ADULT	CLINICAL CONSEQUENCES OR ADJUSTMENTS FOR CHILDREN
Head	Proportionately larger (up to approximately age 10 yr)	Proportionately smaller	A child is naturally in the sniffing position when supine. Do not place a towel under the occiput; a child may benefit from elevation of the shoulders. The large head may be “floppy” and require the assistant to hold the head still during intubation.
Teeth	Easily knocked out	Stable unless decay or trauma is a factor	Teeth may be knocked out and aspirated or forced into trachea.
Tonsils or adenoids	Large and friable	Generally not a problem	Nasotracheal intubation in a child may cause excessive bleeding and is not recommended. Adenoid or tonsil tissue may plug the endotracheal tube or cause airway obstruction from aspiration.
Tongue	Relatively larger	Relatively smaller	The tongue is difficult to displace anteriorly in a child. Consider using a straight blade.
Larynx	Opposite C2-C3	Opposite C4-C6	A more superiorly located larynx or an “anterior” larynx is more difficult to visualize. Consider using a straight blade.
Epiglottis	U shaped, shorter, stiffer	Flatter, more flexible	The epiglottis is more difficult to manipulate in a child; it may fold down and obstruct the view with use of a curved blade. Consider using a straight blade.
Vocal cords	Concave upward; anterior attachment of the cords lower than posterior, thereby creating a slant	Horizontal	A concave shape does not affect intubation, but it may affect ventilation. For partial airway obstruction or to break laryngospasm, consider positive pressure ventilation with a jaw-lift maneuver to open the arytenoids. The anterior superior slant of the vocal cords may cause the endotracheal tube to hang up on the anterior commissure as it passes into the larynx. Rotate the tube 90 degrees counterclockwise. Overextension of the neck may cause partial airway obstruction as a result of airway collapse.
Length of the trachea	Relatively shorter	Relatively longer	A short trachea increases the likelihood of main stem bronchus intubation. Follow the formula for correct depth of placement (cm depth = $0.5 \times \text{age [yr]} + 12$) measured from the corner of the mouth. The double black line on the endotracheal tube should pass just beyond the cords.
Airway diameter	Relatively smaller; smallest diameter at the cricoid ring	Relatively larger; smallest diameter between the vocal cords	Laryngoscope-induced trauma, edema, and foreign material will significantly alter the diameter of the airway. Be gentle. Extremes of flexion or extension may kink the airway. If trouble with bag-valve-mask ventilation occurs, reassess the degree of head flexion or extension. Cricoid pressure may cause complete airway obstruction. The endotracheal tube may pass through the cords but be too large to pass through the cricoid ring. If unable to pass into the trachea, use the next smaller tube.
Residual lung capacity	Relatively smaller	Relatively larger	A child becomes hypoxic more quickly than an adult does. Closely monitor O ₂ saturation and avoid prolonged periods without ventilation.

to determine the optimal ELM. The best way to quickly apply a variety of different forces to the larynx to determine the optimal ELM is by manipulation of the larynx with the laryngoscopist's right hand (Fig. 4.15).¹³⁷

Operator-directed posterior displacement of the larynx during laryngoscopy was described by Brunnings in 1912.¹³⁸ After Sellick described the use of cricoid pressure to avoid

regurgitation in 1961, it became common to have an assistant apply anterior neck pressure during laryngoscopy.⁹⁷ In 1993, Knill reported that having an assistant apply BURP to the cricoid or thyroid cartilage improved visualization of the glottis during two cases of difficult laryngoscopy.¹³⁹ In 1993, Takahata and coworkers performed a prospective study of 630 intubations and found that BURP produced better laryngeal exposure than

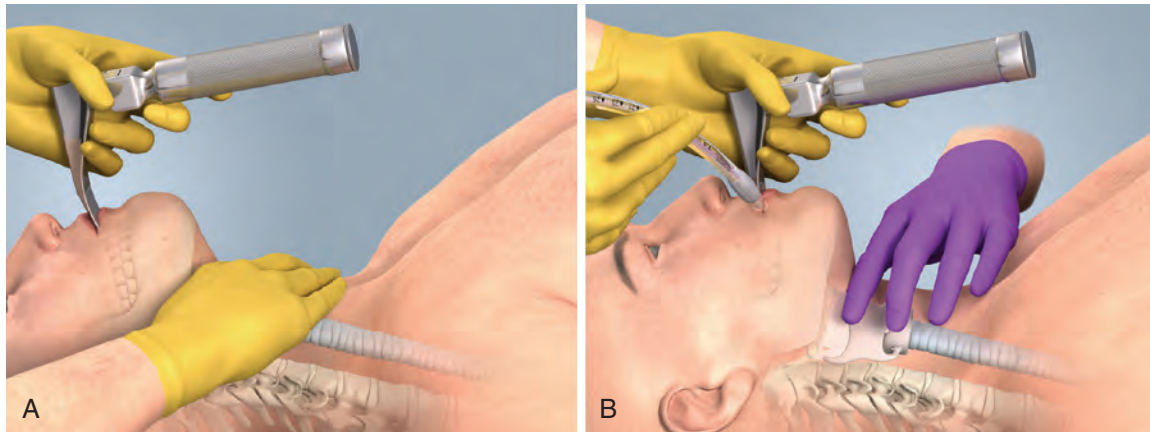

Figure 4.15 External laryngeal manipulation (ELM) (or bimanual laryngoscopy). **A**, ELM step 1. The laryngoscopist optimizes view of the larynx by reaching around to the patient's neck with the right hand and manipulating the thyroid cartilage while performing laryngoscopy. **B**, ELM step 2. The assistant's hand replaces the laryngoscopist's hand on the anterior aspect of the neck and maintains the position of the larynx while the laryngoscopist places the tracheal tube.

Figure 4.16 The epiglottis is elevated and visualization of the vocal cords is improved by applying pressure on the hyoepiglottic ligament and external laryngeal manipulation. (Courtesy Richard M. Levitan, MD, Airway Cam Technologies, Inc., Wayne, PA. Used with permission.)

Figure 4.17 Note the assistant manipulating the anterior part of the neck and retracting the cheek for better visualization.

just backward pressure in patients with difficult laryngoscopy.¹⁴⁰ A 2005 prospective crossover trial by Snider and colleagues found no benefit with routine application of the BURP maneuver.¹⁴¹

Studies by Benumof, Levitan, and colleagues have demonstrated that it is best to apply pressure on the thyroid cartilage (not the cricoid cartilage) and suggested that ELM should be applied by the laryngoscopist's right hand, not by an assistant.^{115,137,142} They also found that the direction of force required for optimal ELM was not always upward and rightward and that the amount of backward pressure was variable.¹¹⁵ In a 1996 study of 181 patients, Benumof and Cooper found that external manipulation was optimal when applied to the thyroid cartilage in 88% of patients and to the cricoid cartilage in only 11% of patients.¹³⁷ In a 2006 cadaveric study of 1530 laryngoscopies by 104 laryngoscopists, Levitan and associates found that bimanual laryngoscopy was more effective than both BURP and cricoid pressure for optimizing laryngeal exposure (Figs. 4.16 and 4.17; see also Fig. 4.15).¹¹⁵ In addition, they found that cricoid pressure worsened the view of the larynx in 29% of cases and BURP worsened it in 35%.¹¹⁵ In a 2002 study of

eight first-year emergency medicine residents performing 271 intubations in an operating room setting, Levitan and colleagues found that bimanual laryngoscopy (ELM performed by the laryngoscopist) consistently improved laryngeal exposure by novice intubators.¹⁴²

Bimanual laryngoscopy with ELM should be performed whenever the laryngeal view is not optimal after good laryngoscopic technique. To perform this procedure, the intubator applies posterior pressure on the thyroid cartilage. The force vector (right or left, upwards or downwards, and amount of posterior pressure) will vary patient to patient, and the intubator should find the force vector that provides the best laryngeal view. Once this is established, an assistant applies the same force vector to the thyroid cartilage as the intubator removes pressure to free the hand in order to pass the tracheal tube. The assistant holds pressure while the intubator completes tracheal intubation.

Passing the Tube

Once the vocal cords have been visualized, the final step is to pass the tube through the vocal cords and into the trachea

under direct vision. It is best to use a malleable stylet for all emergency intubations. The best stylet shape is straight with a 35-degree hockey-stick bend at the proximal cuff (“straight-to-cuff”). In a 2006 study, Levitan and colleagues showed that stylet bend angles greater than 35 degrees made ET tube passage more difficult.¹⁴³

Hold the tube in your right hand and introduce it from the right side of the patient’s mouth. Lateral retraction of the cheek by an assistant may greatly aid overall visualization (see Fig. 4.17). Advance the tube toward the patient’s larynx below the line of sight with the bend facing upward. When advanced in this manner, the tube does not obstruct the view of the larynx until the last possible moment before the tube enters the larynx. If the patient is not chemically paralyzed, pass the tube during inspiration, when the vocal cords are maximally open. It enters the trachea when the cuff disappears through the vocal cords. Advance the tube 3 to 4 cm beyond this point. It is not enough to see the tube approach the cords; watch the tube pass through the vocal cords to ensure tracheal placement. Directly observing the tube pass through the cords is the best way to immediately confirm correct placement. If part of the glottis is visualized and it is difficult to pass the tube, consider using a bougie (tracheal tube introducer).

Tracheal Tube Introducer (Bougie)

If DL does not bring the vocal cords fully into view, a tracheal tube introducer may be used to facilitate intubation. This adjunct is a long, thin, semirigid introducer that, with the aid of a laryngoscope, is passed through the laryngeal inlet and over which an ET tube is advanced through the cords and into the trachea. The technique, originally described more than 60 years ago by Macintosh,¹⁴⁴ was recommended for patients in whom visualizing the vocal cords was difficult. It has also been shown to be effective when the laryngeal inlet cannot be visualized at all.¹⁴⁵ It is the most common airway adjunct used in British EDs for complicated intubations.¹⁴⁶ Its efficacy has been demonstrated prospectively during difficult intubations in the operating room, as a pivotal component of a difficult airway algorithm in the operating room, and when compared with conventional laryngoscopy in the ED.^{53,147,148}

A variety of tracheal tube introducers are available today (Fig. 4.18). The original adjunct was called the gum elastic bougie, or simply “the bougie,” and is currently available in a reusable form for both adult and pediatric patients (Eschmann Tracheal Tube Introducer, Portex Sims, Kent, UK). The adult

Figure 4.18 Several types of tracheal tube introducers. The classic introducer, the gum elastic bougie, **A**, is reusable and comes in curved- and straight-tipped adult forms and a straight pediatric form. The straight bougies, **B**, are 70 cm long and the curved-tipped bougies are 60 cm long. The blue introducer, **C**, (Flextrach ET Tube Guide, Greenfield Med., Austin, TX) is polyethylene and designed for single use and comes only in a curved-tipped adult form (60 cm). **D**, Create a 60-degree bend in the distal portion of the introducer if the laryngeal inlet cannot be seen on laryngoscopy.

size comes in two forms: a 60-cm (15-Fr) version with a short, 40-degree hockey-stick curve at the end, and a straight one that is 70 cm. The adult version can accommodate a 5.5-mm ET tube. The pediatric version is 70 cm (10-Fr) and straight and can accommodate a 4.0-mm tube. A polyethylene introducer designed for single use is also available and comes only in the 60-cm version (Flextrach ET Tube Guide, Greenfield Medical Sourcing, Austin, TX). A variation of this concept is the FROVA Introducer (Cook Critical Care, Bloomington, IN), a plastic introducer with a similar profile to the others except that it has a hollow lumen through which the patient can be ventilated when an accompanying adapter is attached.

Consider using a tracheal tube introducer when a difficult airway is anticipated; it can also be helpful in all intubations when visualization of the laryngeal inlet is limited. A trauma patient with cervical spine precautions is a typical example. The presence of blood and vomitus rarely prevents placement of the bougie into the trachea. Its safety record is impressive despite decades of use, and reports of complications are rare.¹⁴⁹

Shaping the introducer may not be necessary in many cases, but with difficult laryngeal views, create a 60-degree bend in the distal introducer (see Fig. 4.18D).¹⁵⁰ Ideally, tracheal tube introducer-assisted intubation is a two-person procedure (Fig. 4.19). As laryngoscopy begins, the assistant has both a styletted ET tube and bougie prepared and available. The intubator performs laryngoscopy in the normal fashion to obtain the best possible view of the larynx. If the cords are in full view, proceed with intubation using a styletted ET tube. If the view is suboptimal, an assistant can pass the tracheal tube introducer to the operator for placement anterior to the arytenoids and into the larynx. If only the epiglottis is visible, place the introducer, with a 60-degree distal bend, just under the epiglottis and direct it anteriorly. With the laryngoscope still in place and the introducer stabilized by the operator, the assistant slides the ET tube over the introducer. Pass the tube through the larynx. Just before entering the larynx, rotate the tube 90 degrees counterclockwise to avoid having the tip of the ET tube get caught on the laryngeal structures (Fig. 4.20).⁷⁴ Withdraw the laryngoscope and confirm proper tube placement. While securing the ET tube, ask the assistant to remove the introducer.

There are a number of findings that confirm successful introducer placement. If any portion of the arytenoids is visible and the introducer was seen to pass anterior to them without resistance, the introducer is in the airway. Unlike seeing an ET tube “go through the cords” when in fact the laryngeal inlet may have been momentarily obscured by the tube or balloon, the smaller-caliber introducer does not obscure the view of the glottis and thus avoids this potential pitfall. In addition to better visual confirmation, successful passage is indicated, up to 90% of the time, by feeling clicks produced by the angled tip of the introducer as it strikes against the tracheal rings.¹⁵¹ An assistant will also usually feel confirmatory movement in the airway if the anterior aspect of the neck is palpated. If there is still any question whether the introducer is in the airway, gently advance it at least 40 cm, at which point resistance should be felt as the introducer passes the carina and stops inside a main bronchus. If the bougie does not stop when advanced approximately 40 cm, the introducer is most likely in the esophagus. Withdraw it and reattempt placement.

Several technical points should be emphasized. The first is that it is important to create a curve in the distal portion of

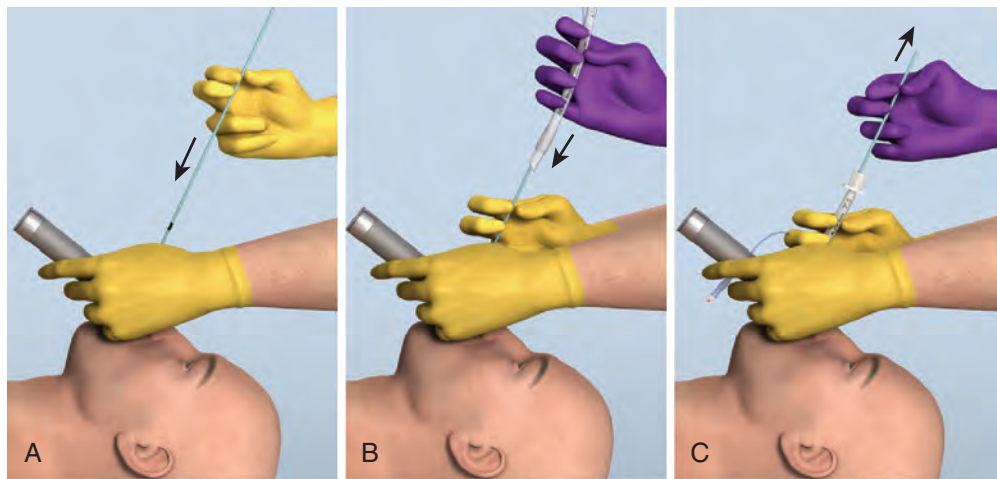

Figure 4.19 Two-person tracheal tube introducer technique. The introducer is handed to the clinician after the best glottic view has been obtained. **A**, The clinician places the introducer (the *black line* positioned at the teeth indicates the proper introducer depth to ensure stable positioning within the trachea while providing enough length to grasp the end of the introducer before passing the tube). **B**, An assistant passes the tracheal tube over the introducer as the clinician holds the introducer steady. **C**, The clinician passes the tracheal tube with a 90-degree counterclockwise rotation as the tube approaches the glottis, and the assistant withdraws the introducer.

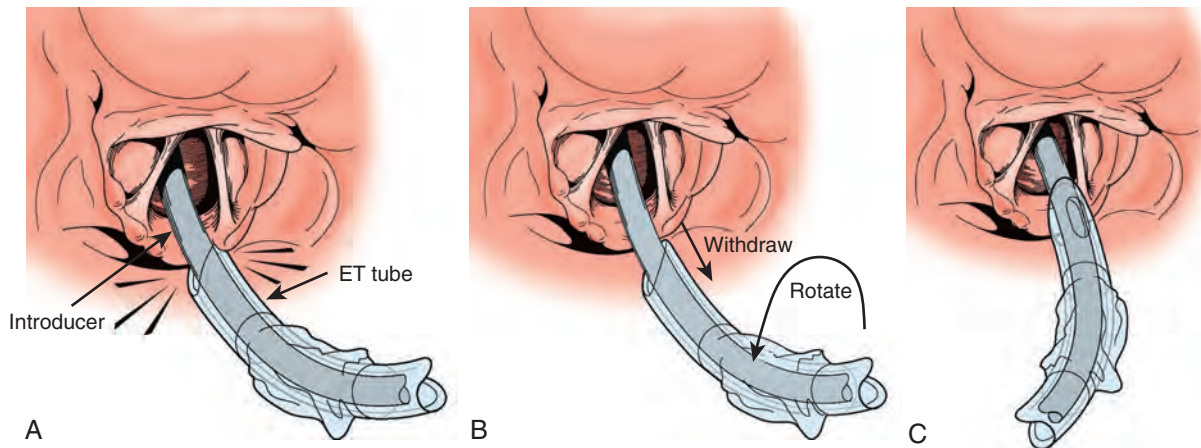

Figure 4.20 A common cause of difficulty when railroaded an endotracheal (ET) tube over a tracheal tube introducer. **A**, The tip of the ET tube is caught on the right arytenoid as it is being railroaded over the introducer. **B**, Corrective maneuvers: (1) withdrawal of the ET tube 2 cm to disengage the arytenoids and (2) counterclockwise 90-degree rotation of the ET tube to orient the bevel posteriorly. **C**, The bevel of the ET tube is facing posteriorly and allows smooth passage through the glottis. (A–C, Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

the introducer when the laryngeal inlet is not visible. This is not uniformly appreciated, even in England where the bougie is used commonly.¹⁴⁷ It is a mistake to think that the factory-formed curve at the tip will be sufficient to access the glottis in these situations. Second, in some cases the bougie will pass through the cords but will become lodged in the anterior trachea and not be able to be advanced further. If this happens, withdraw slightly and rotate the bougie 90 degrees clockwise to move the curved tip to the patient's right. This will prevent the tip from striking the anterior trachea and allow the bougie to pass to the carina. Third, if there is difficulty passing an ET tube into the laryngeal inlet, this is most likely because the tip of the tube is caught on the right arytenoid cartilage. In this case, withdraw the tube 2 cm, rotate it 90 degrees

counterclockwise, and advance it again (see Fig. 4.20). Fourth, although there may be some benefit to lubricating the distal end of the introducer, in emergency intubations, lubricating the full length of the introducer makes it slippery and hard to handle without conferring any obvious advantage. Lubricating the ET tube, conversely, remains critical for smooth passage through the vocal cords. Fifth, a common error when first using the tracheal tube introducer is to remove the laryngoscope before passing the ET tube over the introducer. This often results in difficulty placing the tube because it is displaced posteriorly by the weight of the pharyngeal soft tissues and gets hung up on the laryngeal structures. Reinsert the laryngoscope. Pull the tube back 2 cm to disengage the soft tissue. Rotate the tube 90 degrees counterclockwise and then readvance

it. Sixth, in instances in which it is difficult to get the introducer sufficiently anterior to access the laryngeal inlet, make sure that the introducer lines up with the operator's line of vision. If the introducer enters the mouth at a significant angle above this line, most often when the clinician is too close to the patient, it may be deflected posteriorly by the lip or intraoral structures and escape the attention of the operator. This creates the impression that the introducer is "too floppy."

In the prehospital setting, where assistance might not be available, the laryngoscope should be removed to mount the ET tube onto the introducer. Once the tube is on the introducer, reinsert the laryngoscope and advance the introducer through the glottic opening. Advance the ET tube while rotating it 90 degrees counterclockwise to ensure successful passage into the trachea. Mounting the tube onto the introducer to insert them as a unit is not advised because it is often difficult to direct the introducer into the laryngeal inlet as it moves within the ET tube.

Laryngospasm

If the patient is not paralyzed, laryngospasm, or persistent contraction of the adductor muscles of the vocal cords, may prevent passage of the tube. Pretreatment with topical lidocaine may decrease the likelihood of laryngospasm, though this is not routinely performed. After laryngospasm is noted, one option is to spray lidocaine (2% or 4%) directly onto the vocal cords. An infrequent but effective means of achieving tracheal anesthesia is transtracheal puncture and injection of 3 to 4 mL of lidocaine through the cricothyroid membrane. Laryngospasm is usually brief and often followed by a gasp. Be ready to pass the tube at this moment. Occasionally, the spasm is prolonged and needs to be disrupted with sustained anterior traction applied at the angles of the mandible, as in the jaw-thrust maneuver. Do not force the tube at any time because it could cause permanent damage to the vocal cords. Consider using a smaller tube. Prolonged, intense spasm may ultimately require muscle relaxation with a paralyzing drug (see [Chapter 5](#)). Pediatric patients are far more prone to laryngospasm than adults.¹⁵² In a child, if vocal cord spasm prevents passage of the tube, a chest-thrust maneuver may momentarily open the passage and permit intubation.¹⁵³

Positioning and Securing the Tube

Secure the ET tube in a position that minimizes both the chance of inadvertent, main stem endobronchial intubation and the risk for extubation. The tip should lie in the midtrachea with room to accommodate neck movement. Because tube movement with both neck flexion and extension averages 2 cm,¹⁵⁴ the desired range of tip location is between 3 and 7 cm above the carina.

The average tracheal length is between 10 and 13 cm. On a radiograph, the tip of the tube should ideally be 5 ± 2 cm above the carina when the head and neck are in a neutral position. On a portable radiograph, the adult carina overlies the fifth, sixth, or seventh thoracic vertebral body. If the carina is not visible, it can be assumed that the tip of the tube is properly positioned if it is aligned with the third or fourth thoracic vertebra. In children, the carina is more cephalad than in adults, and it is consistently situated between T3 and T5. In children, T1 is the reference point for the tip of the ET tube.¹⁵⁵

Estimate the proper depth of tube placement before radiographic confirmation by using the following formulas, in

which length represents the distance from the tip of the tube to the upper incisors in children^{156,157} and from the upper incisors¹⁵⁸ or the corner of the mouth¹⁵⁹ in adults:

Children: Tracheal tube depth (cm) = [age (yr) / 2] + 12
(or use length-based aid such as a Broselow tape)

Adults: Women: Tracheal tube depth (cm) = 21 cm

Med: Tracheal tube depth (cm) = 23 cm

In adults, this method has been shown to be more reliable than auscultation in determining the correct depth of placement.¹⁵⁸ One can anticipate that tall male patients will often require deeper placement, to 24 or 25 cm, and that short women will often require a shallower placement of 19 or 20 cm.

Inflate the cuff to the point of minimal air leak with positive pressure ventilation. In an emergency intubation, inflate with 10 mL of air and adjust the inflation volume after the patient is stabilized.

After placement of the tracheal tube, auscultate both lungs under positive pressure ventilation. Take care to auscultate posterolaterally because auscultation anteriorly can reveal sounds that mimic breath sounds and arise from the stomach. With the tube in position and the cuff inflated, secure the tube in place. Attach commercial ET tube holders, adhesive tape, or umbilical (nonadhesive cloth) tape securely to the tube and around the patient's head ([Figs. 4.21](#) and [4.22](#)). Position the tube at the corner of the mouth, where the tongue is less likely to expel it. This position is also more comfortable for the patient and allows suctioning. A bite block or oral airway to prevent crimping of the ET tube or damage from biting is commonly incorporated into the system used to secure the tube.

Unintentional extubation can have disastrous consequences, particularly if the patient was difficult to intubate initially. Secure the ET tube immediately after correct placement has been confirmed. Orotracheal intubation is associated with a higher rate of unplanned extubation than NT intubation.¹⁶⁰ During transport, moving the intubated patient, or obtaining radiographs, designate one person to tend to the ET tube to avoid unplanned extubation. Inadequate sedation is another risk factor for unplanned extubation.¹⁶⁰ If long-acting paralytics have not been administered, consider sedation or physical restraints to prevent self-extubation by an agitated or confused patient.

Confirmation of Tracheal Tube Placement Clinical Assessment

Confirm tracheal placement clinically by seeing the tube pass through the vocal cords ([Table 4.3](#)). If any question remains, apply posterior pressure on the ET tube while the laryngoscope is still in place and expose the tube by altering the angle as it passes between the cords.¹⁶¹ Absent or diminished breath sounds, any sound or vocalization, increased abdominal size, and gurgling sounds during ventilation are clinical signs of esophageal placement. If the patient can moan or groan, the tube is not in the trachea! Critically, esophageal placement is not always obvious. One may hear "normal" breath sounds if only the midline of the thorax is auscultated. The presence of condensation of the ET tube as a means of confirming tracheal placement may also be misleading. Blinded observers noted condensation of the ET tube during ventilation in 23 of 27 esophageal intubations in an animal model.¹⁶² One way to clinically assess tracheal placement after several ventilations

Taping an Endotracheal Tube

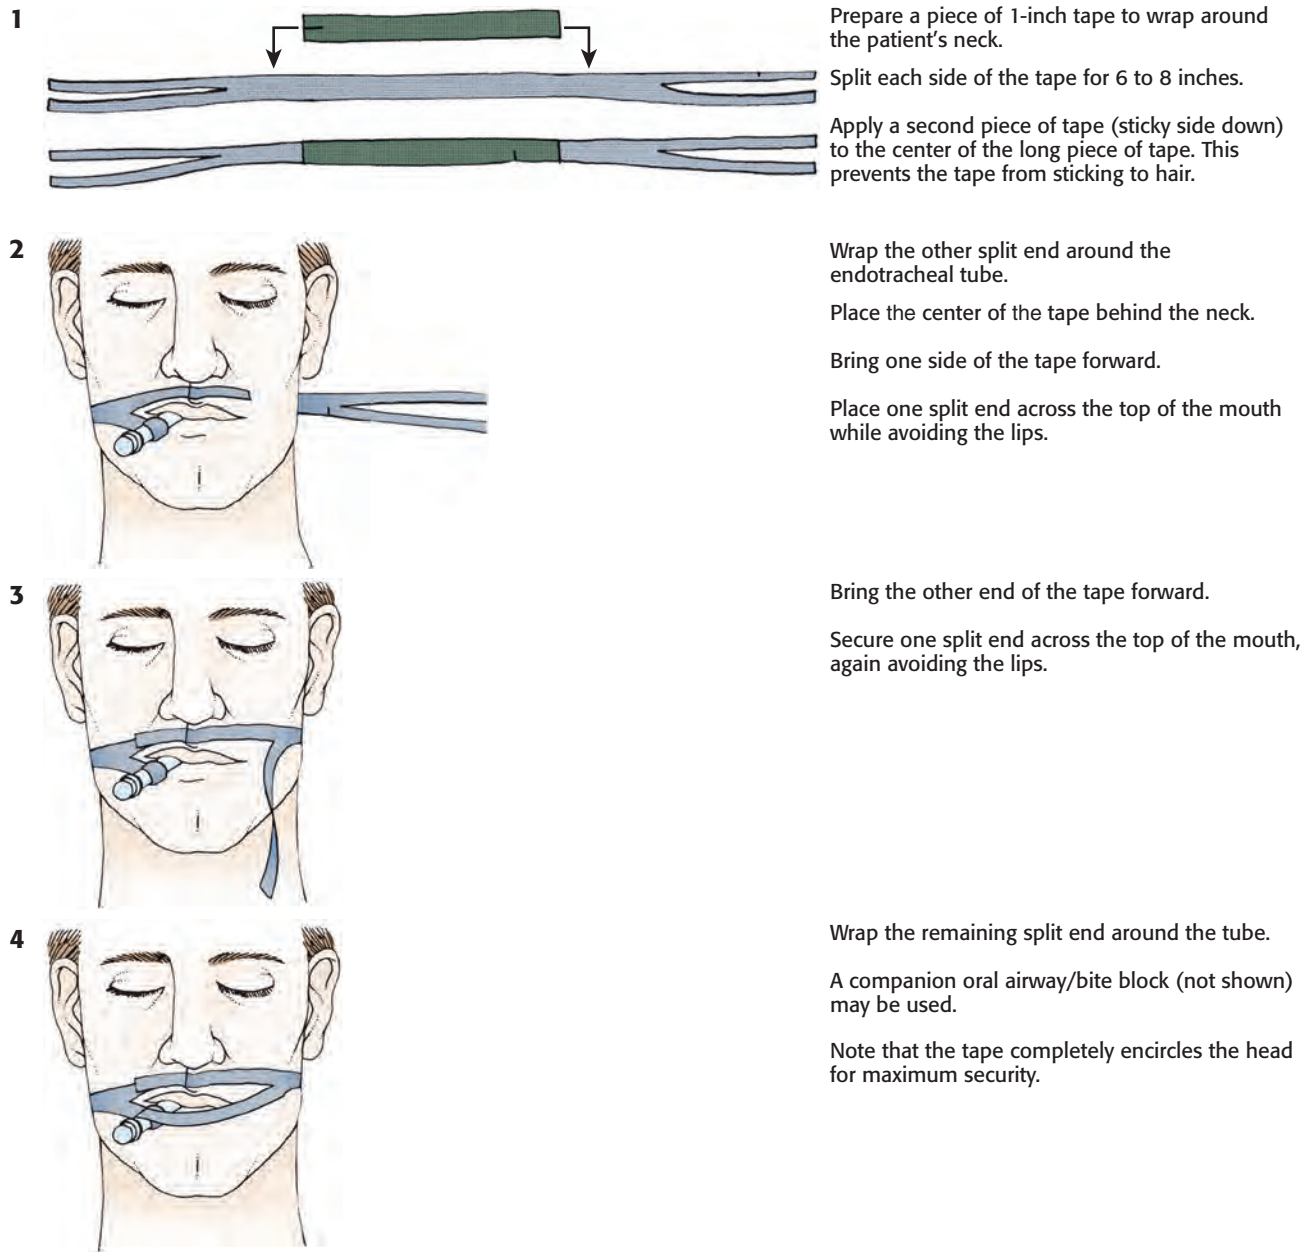

Figure 4.21 Technique for taping an endotracheal tube. The method illustrated can be replaced by using a commercial holder or tracheostomy cloth tie. Avoid taping the lips.

or during spontaneous respiration is to note whether air is felt or heard to exit through the tube after cuff inflation. If tidal volume is adequate, the exit of air should be obvious.

Asymmetric breath sounds indicate probable main stem bronchus intubation. Because of the angles of takeoff of the main bronchi and the fact that the carina lies to the left of midline in adults, right main stem intubation is most common and is indicated by decreased breath sounds on the left side. When asymmetric sounds are heard, deflate the cuff and withdraw the tube until equal breath sounds are present. Bloch and coworkers¹⁶³ reported accurate pediatric tracheal positioning

if after noting asymmetric breath sounds the tube is withdrawn a defined distance beyond the point at which equal breath sounds are first heard: 2 cm in children younger than 5 years and 3 cm in older children.

Esophageal Detector Device

An aspiration technique used to determine ET tube location was first described by Wee in 1988.¹⁶⁴ The technique takes advantage of the difference in tracheal and esophageal resistance to collapse during aspiration to locate the tip of the tracheal tube. After intubation, attach a large syringe (Positube esophageal

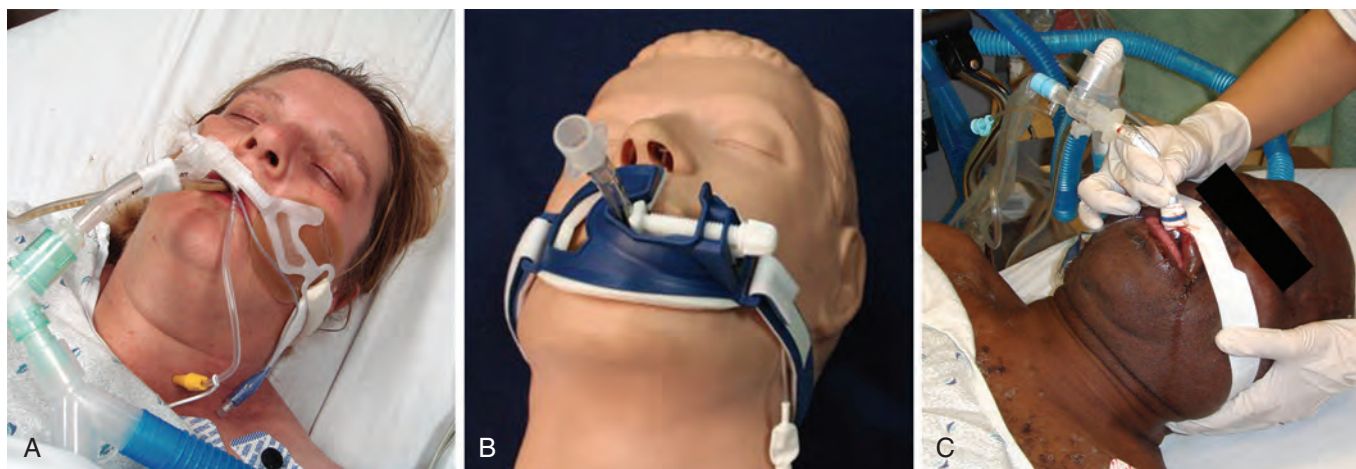

Figure 4.22 **A**, A commercial disposable tube holder is ideal and preferred to secure an endotracheal (ET) tube without the use of messy tape. **B**, A plastic disposable ET holder firmly secures the ET tube with a small clamp. **C**, When positioning a patient for transfer to another bed or for a chest radiograph, ensure the integrity of the ET tube by placing the right hand firmly against the right side of the face while holding the tube securely with the same hand. The other hand immobilizes the neck. (**B**, Courtesy Laerdal Medical, Wappingers Falls, NY.)

TABLE 4.3 Assessing Proper Tube Placement

TEST	INTERPRETATION
Observe the tube pass through the vocal cords	Accurate way to ensure placement; if in doubt, look again after intubation
End-tidal CO ₂ measurements	Reliable if a good persistent waveform is present; can be misleading with nasotracheal intubation if the tip is curled supraglottically: it will give a positive CO ₂ reading
Auscultation of breath sounds over the chest	May be misleading, especially if only the midline is examined; listen in both axillae
Auscultation over the stomach	Gurgling indicates esophageal placement
Condensation (fog) forms inside the tube with each breath	Not reliable to confirm tracheal placement
Observe the chest rise with positive pressure and fall with release	Generally reliable if good chest rise is present; may be absent in patients with a small tidal volume or severe bronchospasm
Feel air exiting from the end of the tube after inflation	Reliable
Air remains in the lung after the end of the tube is occluded and exits when the occlusion is removed	Reliable, but one may “ventilate” a closed area of the esophagus
Ask the patient to speak; listen for moaning or other sounds	If the tube is in proper place, no sound is possible
Chest radiograph	Cannot always differentiate between tracheal and esophageal placement. If known to be in the trachea by other measures, radiography can assess for proper depth of tube insertion.
Aspiration technique	Tracheal location is confirmed (assuming patient ET tube) if 30–40 mL of air is aspirated without resistance; probable esophageal location if unable to aspirate the syringe easily or delayed bulb refill occurs; can be misleading with nasotracheal intubation if the tube has curled supraglottically
Fiberoptic bronchoscope	Reliable if tracheal rings are seen down the endotracheal tube
Lighted stylet down the endotracheal tube	Reliable if transillumination seen in the low midline portion of the neck
Ultrasound detection of tracheal tube location	Appears to be reliable but not extensively studied

detector, Flotec, Indianapolis, IN) to the end of the ET tube and withdraw the plunger of the syringe. If the tube is placed in the trachea correctly, the plunger will pull back without resistance as air is aspirated from the lungs. If the tracheal tube is in the esophagus, resistance is felt when the plunger is withdrawn because the pliable walls of the esophagus collapse under the negative pressure and occlude the end of the tube. Another device that uses the same principle as syringe aspiration is the self-inflating bulb (e.g., Ellick device).

In the initial study conducted in an operating room, tube placement was identified correctly in 99 of 100 cases (51 esophageal, 48 tracheal).¹⁶⁴ The result was considered equivocal in the remaining case. That tube was removed and found to be nearly totally occluded with purulent secretions. Slight resistance was noted in one patient with right main stem intubation; the resistance decreased when the tube was pulled back. Before use, always check the esophageal detector device for air leaks. If any connections are loose, the leak may allow the syringe to be withdrawn easily, thereby mimicking tracheal location of the tube.

When using the aspiration technique, apply constant, slow aspiration to avoid occlusion of the tube from tracheal mucosa drawn up under the high negative pressure. If the tracheal tube is placed correctly, 30 to 40 mL of air can be aspirated without resistance. If air was initially aspirated and some resistance is then encountered, the tracheal tube should be pulled back between 0.5 and 1.0 cm and rotated 45 degrees. This takes the tube out of the bronchus if it has been placed too deeply and changes the orientation of the bevel if the tube has been temporarily occluded with tracheal mucosa. Air is easily aspirated if the tube was in the trachea, but repositioning it will make no difference if the tube was in the esophagus. The syringe aspiration technique can be used before or after ventilation of the patient. Inflation of the tube cuff has no effect on the reliability of the test.¹⁶⁵ This device is reliable, rapid, inexpensive, and easy to use.¹⁶⁵

A squeeze-bulb aspirator is an alternative to the syringe technique. Attach the bulb to the ET tube and squeeze; if the tube is in the esophagus, it is accompanied by a flatus-like sound followed by absent or markedly delayed refilling. Insufflation of a tube in the trachea is silent with instantaneous refill. An early study with the Ellick evacuator bulb device reported that 82% of esophageal intubations were identified.¹⁶⁶ A later study using a slightly different bulb device (Respironics, Murrysville, PA) found that all 45 esophageal intubations were detected.¹⁶⁷ The device is cheap, easy to use, and operated single-handedly in less than 5 seconds.¹⁶⁶ The bulb should not be used in freezing temperatures because of loss of elasticity. Confusion may occur if the esophageal tube is tested more than once because subsequent inflations may be silent. With repeated assessments, false-positive refilling of the bulb may occur as a result of instillation of air during the first attempt. This observation has led to a recommendation that the bulb be compressed before it is attached to the ET tube. Delayed, though complete refilling of the bulb may occur with bronchial tube placement or placement in the more pliable pediatric airway. The bulb suction modification of the aspiration technique has not been studied as thoroughly as the syringe technique.

A significant number of false positives occur with esophageal detection devices (the tube is correctly placed in the trachea, but the device suggests that it is in the esophagus). These patients are almost uniformly obese. Endoscopic evaluation

found that the tracheal wall was invaginated into the ET tube because of the negative pressure.¹⁶⁸ In such circumstances, if the intubation was felt to be successful, visually re-confirm that the ET tube is through the cords before removing the ET tube. Alternatively, if the patient has a perfusing rhythm and an expired CO₂ device is available, it should be used. To date, there has been one reported case of unrecognized esophageal intubation undetected by the syringe aspiration technique.¹⁶⁹ In this case there was marked gastric distention from forceful BMV. The esophageal detection device is not reliable in confirming tracheal tube depth and position after intubation because easy aspiration of air will occur if the tip of the tube is located supraglottically (expired CO₂ will also be misleading).

End-Tidal CO₂

End-Tidal CO₂ detection is probably the best technique, apart from visualizing the tube pass through the cords, to confirm tracheal placement of the ET tube. A high level of CO₂ in exhaled air is the physiologic basis for capnography and the principle on which end-tidal CO₂ pressure (PETCO₂) detectors were developed (see Chapter 2). Continuous waveform capnography is recommended by the AHA guidelines as the most reliable method of confirming and monitoring correct placement of an ET tube (class I, level of evidence [LOE]). This recommendation is based on multiple studies showing 100% accuracy of waveform capnography for detecting correct ET tube placement.¹³⁶ Continuous waveform capnography is accurate even in cardiac arrest. Patients with prolonged cardiac arrest will still have a typical square waveform but a low PETCO₂ value.

When waveform capnography is not available, emergency providers may have to rely on colorimetric CO₂ indicators, which correspond to CO₂ levels flowing through the device when placed on the tracheal tube adapter (see Fig. 4.10, *step 10*). The typical device displays opposite colors (e.g., yellow and purple) to indicate low levels of CO₂ in esophageal gas versus the high levels of CO₂ exhaled from the respiratory tree. Handheld quantitative or semiquantitative electronic CO₂ monitors are also available. Eventually, all prehospital defibrillators will have advanced monitoring capability that includes capnography.

A multicenter study of a colorimetric device demonstrated an overall sensitivity of 80% and a specificity of 96%.¹⁷⁰ In patients with spontaneous circulation and an inflated tracheal tube cuff, the sensitivity and specificity were 100%. The poor sensitivity (69%) noted in patients in cardiac arrest was due to the fact that low exhaled CO₂ levels were seen with both very-low-flow states and esophageal intubation. The device must be used with caution in cardiac arrest victims. CO₂ levels return to normal after return of spontaneous circulation. Colorimetric changes may be difficult to discern in situations with reduced lighting, and secretions can interfere with the change in color. Regardless of the monitoring device, patients should be ventilated for a minimum of six breaths before taking a reading. Recent ingestion of carbonated beverages can result in spuriously high CO₂ levels with esophageal intubation.¹⁷¹ Colorimetric changes do not exclude supraglottic positioning of the tip of the ET tube. Adequate ventilation and oxygenation may be achieved in the supraglottic position, but there is still a risk for aspiration in the absence of a protected airway and the potential for further tube dislodgment. Glottic positioning may be difficult to detect clinically. The only signs may be

persistent cuff leak or diminished chest rise with ventilation. Radiographic evidence or direct visualization confirms the diagnosis.¹⁷²

Ultrasound Detection of Tracheal Tube Location

Some data suggest that transtracheal ultrasound may play a future role in confirming tracheal location of the ET tube location after intubation. All studies are small, and sensitivity ranges from 96% to 100% for confirming tracheal placement, whereas specificity (detecting esophageal intubation) ranges from 88% to 100%.^{173–178} If the ET tube is in the trachea, acoustic shadowing is seen posterior to the anterior tracheal rings only. If the ET is in the esophagus, the esophagus is opened by the ET tube and shadowing is seen posterior to the anterior esophageal wall (as well as the trachea). This method relies on the esophagus being located in the paratracheal position; if the esophagus is directly posterior to the trachea, then detecting esophageal intubation is very difficult.

Sonographic sliding signs can also be used immediately after tracheal intubation is confirmed by waveform capnography to evaluate for main stem intubation prior to obtaining a chest radiograph.^{179,180} Assuming there is no other underlying lung pathology, absence of sliding on the left after intubation indicates probable right main stem intubation. The ET tube can be withdrawn 2 cm, and sliding signs reassessed.

Comparison of Detector Devices

In the setting of spontaneous circulation, both syringe aspiration and PETCO₂ detection are highly reliable means of excluding esophageal intubation. An animal study comparing these techniques with clinical assessment and measuring the speed and accuracy of determining tube placement demonstrated that both the syringe esophageal detector device and PETCO₂ detection were highly accurate, approaching 100%.¹⁸¹ The esophageal detector device was more rapid, with determination in 13.8 seconds versus 31.5 seconds for PETCO₂ detection. The detector device remained accurate when air was insufflated into the esophagus for 1 minute, thus simulating unrecognized esophageal placement. Clinical assessment alone yielded an alarming 30% rate of failure to identify esophageal intubation. In the setting of cardiac arrest, the aspiration method is more reliable than colorimetric CO₂ detection, although waveform capnography remains reliable even in low flow states.

An unequivocal method for determining tracheal tube location uses the endoscope. Passage of the scope through the tube with visualization of the tracheal rings confirms ET placement and position within the trachea. Placement of a lighted stylet down the tracheal tube and successful transtracheal illumination can also be used to determine correct ET placement.¹⁸²

At present, there is no perfect device for confirmation of ET tube placement in all situations. Be aware of the limitations of each device; it is ideal to use multiple means of confirmation to ensure tracheal placement of the ET tube.

Complications of Intubation

Failure to achieve adequate ventilation and oxygenation is the most serious complication of tracheal intubation. The potential for hypoxia exists just before intubation as more conservative oxygenation methods are attempted and then fail, during difficult intubation when ventilation is halted for an attempt at intubation, and after intubation when esophageal intubation goes undetected. Because irreversible cerebral anoxia occurs within minutes, conservative airway management maneuvers

should be limited to 2 to 3 minutes; failure to achieve adequate oxygenation should lead to a quick decision to intubate.

As a guide, limit intubation attempts to the amount of time that a single deep breath can be held by the patient. This is especially important in a child because the functional residual capacity of a child's lungs is less than that of an adult. Historically, the maximum recommended duration of an intubation attempt in an apneic patient has been 30 seconds, followed by a period of BMV before intubation is attempted again. Longer attempts at intubation are permissible when guided by accurate data from an oxygen saturation monitor because oxygen saturation may remain in the normal range for much longer in patients who have been preoxygenated. As a general rule, intubation attempts may continue if oxygen saturation is above 90% and should be interrupted for BMV when oxygen saturation drops below 90%.

Assessment of tube location is the top priority immediately after placement. The best assurance of tracheal placement is to see the tube pass through the vocal cords. Techniques to assess tube placement were discussed earlier. If esophageal intubation is discovered, removal of the tube may be followed by emesis. Apply cricoid pressure during tube removal and maintain it until the intubation is successful. Keep a large-bore suction tip catheter readily available should vomiting occur. Alternatively, leave the first tube in the esophagus to serve as a temporary gastric-venting device and as a guide to intubation until tracheal intubation is achieved.

Though seldom associated with serious complications, unrecognized placement of the tip of the ET tube in the right main stem bronchus may cause hypoxia, atelectasis, pneumothorax, and unilateral pulmonary edema.¹⁸³ Obtain a chest radiograph soon after intubation to confirm tube positioning. Endobronchial intubation was clinically unrecognized without a chest film in 7% of prehospital intubations in one study.¹⁸⁴ Persistent asymmetric breath sounds after correct tube positioning suggests unilateral pulmonary pathology (e.g., main stem bronchus obstruction, pneumothorax, hemothorax).

Prolonged efforts to intubate can also cause cardiac decompensation. Pharyngeal stimulation can produce profound bradycardia or asystole, thereby confirming the need for an assistant to monitor cardiac rhythm throughout the intubation. Keep atropine available to reverse the vagal-induced bradycardia that may occur secondary to suctioning or laryngoscopy. Prolonged pharyngeal stimulation may also result in laryngospasm, bronchospasm, and apnea. Hypotension requiring intervention in the peri-intubation period occurs in approximately 1.5% of intubations.⁶⁴ If a patient is profoundly hypovolemic and does not need immediate intubation, it may be best to resuscitate with intravenous fluids prior to intubation to avoid worsening hypotension.

Generally, dentures are removed for intubation but kept in place for BMV. Check for loose or missing teeth before and after orotracheal intubation. Look for any avulsed teeth not found in the oral cavity on the postintubation chest film. Dental injury occurs in approximately 0.5% of intubations.⁶⁴ Laceration of the mucosa of the lips, especially the lower lip, may occur. Tracheal or bronchial injuries are rare, but serious and usually occur in infants and the elderly as a result of their decreased tissue elasticity.¹⁸⁵

Emesis with aspiration of gastric contents is another serious complication that can occur during intubation. Avoiding BMV when possible may help reduce the risk of this adverse event. Case reports of adult respiratory distress syndrome and chronic

lung disease are thought to be due to aspiration of activated charcoal.^{185,186} In patients who are obtunded or who are at high risk for seizures or vomiting, consider tracheal intubation before the administration of activated charcoal.

There are ongoing concerns that DL may cause or worsen spinal cord injury in a patient with an unstable cervical spine injury. These concerns are essentially theoretical, with no credible data to prove or disprove a true effect. Many anesthesiologists prefer awake endoscopic intubation in this setting, but no data support one approach over another. A cadaveric study of intubation during fluoroscopy showed that DL with in-line immobilization in the setting of complete C4-5 ligamentous instability did not result in clinically significant movement.¹⁸⁷ The greatest degree of motion occurs at the atlanto-occipital junction and decreases with each sequential interspace, and studies of cervical spine instability at these higher levels have not been performed.¹⁸⁸ It can also be argued that cadaveric studies do not accurately depict the trauma setting, and yet this model is probably going to remain the best one available. Unless new information emerges regarding the risks of orotracheal intubation with DL, it appears to be a safe approach when performed in conjunction with in-line immobilization. The cervical collar should be removed for intubation, and cervical immobilization held manually by an assistant.

Intubation can be complicated by a persistent air leak. This is generally caused by failure of either the cuff or the pilot balloon or by positioning the cuff balloon between the vocal cords. If the cuff balloon is leaking, replace the tracheal tube (see later section on [Changing Tracheal Tubes](#)). If the pilot balloon is determined to be leaking, this can usually be remedied without changing the tube.¹⁸⁹ An incompetent one-way balloon valve can be fixed by placing a stopcock in the inflating valve. Reinflate the cuff and shut off the stopcock to solve the problem. If the leak involves the pilot balloon or if the distal inflation tube has been inadvertently severed, cut off the defective part and slide a 20-gauge catheter into the inflation tube. Then connect the stopcock to the catheter, inflate the cuff, and close the stopcock.

Tracheal stricture used to be a significant late complication of long-term intubation with low-volume, high-pressure cuffs. The use of high-volume, low-pressure cuffs has markedly decreased the incidence of this complication.¹⁹⁰ Tubes with high-pressure cuffs are obsolete and should be avoided.

Conclusion

DL is the most common means of securing a definitive airway. With adequate preparation and emphasis on preoxygenation and positioning, it is usually successful. RSI has rendered patients much more amenable to DL for emergency airway management (see [Chapter 5](#)). Once the patient is paralyzed, it becomes the clinician's supreme responsibility to ventilate, oxygenate, and protect the patient's airway. Mastery of DL fulfills part of this obligation. Being prepared for failure and having a successful backup plan fulfills the remainder of this responsibility. The remainder of this chapter is devoted to adjuncts and alternatives to DL.

VIDEO AND OPTICAL LARYNGOSCOPES

Video and optical laryngoscopes continue to transform airway management. These devices are all somewhat similar in that

they use video, fiberoptics, or mirrors to visualize the larynx. They provide a better view of the glottis with less effort and have a shorter learning curve than DL. Only the Macintosh shaped video laryngoscopes are designed to sweep the tongue aside and allow either a direct or video view of the larynx. The other devices are made to look around the curve of the tongue rather than lifting it or pushing it aside, so they are more angulated. The drawback of more angulated devices is that getting an excellent view of the vocal cords does not always correlate with easy intubation^{191,192} because it can be difficult to manipulate the ET tube around the sharp curve of the blade. Adding a tube channel to the blade obviates the need to manipulate the ET tube around the sharp curve but may add other complexities.¹⁹¹ Because expense is a major impediment to the widespread use of video laryngoscopy, the relatively inexpensive Airtraq device (see Category 3 later) may be a good choice in settings in which difficult intubation is rare and funding is limited.⁴ Video laryngoscopy is associated with higher first pass success rates compared to DL, especially in patients with known or suspected difficult airways. Some experts recommend that video laryngoscopy be used for all emergency intubations.¹⁹³

Video and optical laryngoscopes can be divided into three broad categories:

1. Video laryngoscopes with standard Macintosh blades (Storz C-MAC, GlideScope Titanium MAC, McGrath MAC, Venner A.P. Advance Mac Blade).
2. Video laryngoscopes with angulated blades (GlideScope, McGrath Series 5, Storz D-Blade).
3. Video or optical laryngoscopes with a tube channel (Airtraq, Pentax AWS, KingVISION). (See the following sections for pictures and manufacturers of each device.)

Video Laryngoscopes With Standard Macintosh Blades

These devices have blades that are exactly the same or very similar to a standard English or German Macintosh direct laryngoscope. They all have a digital camera adjacent to the light source a few centimeters proximal to the tip. Each of these devices can be used for either conventional DL or video laryngoscopy. The Storz C-MAC (Karl Storz, Tuttlingen, Germany) is the only device in this group that has been sufficiently tested ([Fig. 4.23](#)).¹⁹⁴⁻²⁰² The laryngeal view obtained on the video monitor is better than the direct view in most patients.^{195,197} The improved laryngeal view provided by the camera is especially helpful in morbidly obese patients and in trauma patients who require cervical spine immobilization.^{194,201}

Unlike other video laryngoscopy systems, those with Macintosh blades still allow direct visualization of airway structures even if blood or secretions obscure the camera view, or if there are any other camera malfunctions.⁶⁸ This may help avoid the need to change equipment during the intubation process. The use of a video laryngoscopy system that still allows the ability to perform DL may be ideal for learning DL skills, as novices who learn intubation on a video laryngoscope system have higher success rates when performing DL.⁸⁷

Background

The Storz Video Macintosh Laryngoscope was introduced into clinical practice by Kaplan, Ward, and Berci, and in 2002.²⁰⁰ The latest version of this device, the Storz C-MAC, is smaller,

more portable, and cheaper.¹⁹² The C-MAC consists of a one-piece blade, a cable, and a monitor. It can record digital video or still images onto a Secure Digital memory card. This section will discuss the use of the Storz C-MAC because it is the most used and most tested video laryngoscopy system with a Macintosh blade. The procedure will be similar for other video laryngoscopy systems with a Macintosh blade. The GlideScope Titanium MAC (Verathon Medical, Bothell, WA), McGrath MAC (Medtronic, Minneapolis, MN), and A.P. Advance Mac Blade (Venner Medical, Singapore) appear similar in design, but they are all newer and less tested.

Indications

The C-MAC can be used for almost any orotracheal intubation attempt in an emergency setting. If laryngoscopy is not predicted to be difficult, the operator can intubate using DL, with video

laryngoscopy immediately available if the airway proves to be difficult or if there is difficulty passing the tracheal tube introducer or ET tube. However, many experts feel that all emergency intubations should be performed with video laryngoscopy,¹⁹³ though DL skills remain crucial.⁶⁸ The C-MAC allows both direct and video laryngoscopy.

The C-MAC can be used when DL is difficult. In 2006, Kaplan and coauthors published a prospective multicenter trial in which the DL view was compared with the video view during 865 intubations with the Storz Video Macintosh system.¹⁹⁸ They reported 7 cases in which the direct view of the larynx was easy and the video view was difficult and 100 cases in which the direct view was difficult and the video view was easy. In 2009, Jungbauer and colleagues studied 200 patients with Mallampati class III or IV anatomy.¹⁹⁷ They randomized patients to intubation with DL or with the Storz Video Macintosh system. The success rate with DL was 92% and the success rate with the Storz Video Macintosh system was 99%. Other studies also demonstrate that the C-MAC is superior to DL for difficult airways.^{203,204} The C-MAC is also superior to DL after a failed first attempt,²⁰⁵ though sometimes DL is used as a rescue device when video laryngoscopy fails.

The Storz C-MAC may be a good option for routine intubations at academic institutions that are teaching novice intubators. By viewing the video screen, the senior physician can teach laryngoscopy skills in real time while the learner performs DL. In 2008, Howard-Quijano and coauthors published a prospective, randomized, crossover study of 37 novice intubators (medical students and residents) who performed 222 intubations with the Storz Video Macintosh system.¹⁹⁶ The novice intubators performed only DL and were not allowed to see the video monitor in any case. Intubations were randomized so that either the instructors could see the video monitor or it was covered by a drape. Novice intubators were given 2 minutes to intubate before the instructor took over. When instructors were allowed to see the video monitor,

Figure 4.23 The Storz C-MAC (Karl Storz, Tuttlingen, Germany) video laryngoscope system.

Video and Optical Laryngoscopy

Indications

- Routine emergency intubation
- Teaching of direct laryngoscopy skills to novices
- Difficult airways
- Failed direct laryngoscopy
- Morbid obesity
- Trauma patients with cervical spine immobilization

Contraindications

- Limited mouth opening
- Severe kyphosis
- Copious blood or secretions

Complications

- Dental trauma
- Oropharyngeal trauma

Equipment

Ancillary equipment (endotracheal tubes, etc) not depicted

Review Box 4.2 Video laryngoscopy: indications, contraindications, complications, and equipment.

the novice intubators had a 69% success rate and a 3% rate of esophageal intubation. When instructors were blinded to the video monitor, the novice intubators had a 55% success rate and a 17% rate of esophageal intubation.

Two studies compared the Storz C-MAC with the GlideScope and McGrath systems. A 2009 study of 450 patients with normal airways by van Zundert and colleagues showed that those intubated with the Storz C-MAC were intubated more quickly and had a higher first-pass success rate than did those intubated with the GlideScope or McGrath MAC.²⁰² Another study compared the C-MAC with the GlideScope and McGrath in 150 morbidly obese patients and found that those intubated with the C-MAC had significantly fewer intubation attempts and a shorter intubation time.²⁰¹ The C-MAC is more successful in trauma patients with cervical spine immobilization.^{206,207}

Contraindications

Contraindications to use of the C-MAC are rare. Like other video laryngoscopes, the lens on the video camera is susceptible to obscuration by secretions or blood. Unlike other video devices, the C-MAC facilitates direct visualization of anatomic structures.

Procedure

Much of the procedure for laryngoscopy with the C-MAC is similar to that for DL. When the tip of the Storz C-MAC is advanced into the vallecula, it gives an 80-degree-wide field of view and offers a panoramic view of the glottis. Moving slowly and using a progressive visualization technique to find the tongue, epiglottis, posterior cartilages, and vocal cords (as with DL) is the best approach to performing laryngoscopy with the C-MAC. Keep in mind that although the tip of the C-MAC is usually placed in the vallecula, it may help to directly lift the epiglottis with the tip of the blade if laryngoscopy is difficult; this is known as the *straight-blade technique*.²⁰⁸

Complications

A complication that may be encountered is blind passage of the ET tube into the mouth while fixating on the video monitor. This can result in damage to oral and pharyngeal structures. It is less common with the C-MAC than with the GlideScope and McGrath MAC.

Video Laryngoscopes With Angulated Blades

The GlideScope (Verathon, Bothell, WA), McGrath Series 5 (Teleflex, Buckinghamshire, UK), and Storz D-Blade (Karl Storz, Tuttlingen, Germany) video laryngoscopes are similarly shaped devices that have sharply angulated, nonchanneled, and narrow-flanged blades.^{191,192,209,210} All these devices have a distal angulation of approximately 60 degrees and a digital camera a few centimeters proximal to the tip. These blades do not allow laryngoscopy by direct visualization. They are designed to follow the natural curvature of the upper airway and look around the tongue rather than displace it. Excellent visualization of the glottis is nearly always achieved when the distal tip of the blade is in or near the vallecula. Because the point of reference is from the location of the camera near the distal tip of these devices, they reliably provide a panoramic view of the larynx that cannot be achieved with DL. Both the GlideScope and the McGrath allow easy visualization of the larynx, even with inexperienced providers or difficult airway

anatomy.^{201,202,209,211–216} Maneuvering the ET tube around the severe angle of the blade and into the trachea is more difficult compared to systems with a Macintosh blade, and this is where problems can occur.¹⁹¹ In one large trial involving inexperienced GlideScope operators, the device was abandoned in 3.7% of intubations despite the fact that an excellent view of the glottis was achieved in most of these cases.²⁰⁹

Background

In 2001, the original GlideScope video laryngoscope became the first commercially available video laryngoscope. The first report of its use was in a case report of the management of a difficult airway.²¹⁷ Three GlideScope models are now available: the Titanium (Fig. 4.24), which is the newest version that features reusable titanium blades or disposable plastic blades of a similar shape; the AVL, which has both single-use and reusable plastic blades to cover a reusable video baton with a mountable monitor; and the Ranger, which has a small portable monitor and the choice of a reusable blade or a video baton with disposable blades (Ranger Single Use). All GlideScope models have a lens antifog mechanism and digital recording capability. Though this section will discuss hyperangulated blades, the Titanium system also offers blades with a Macintosh shape.

The McGrath portable video laryngoscope is another device with similar characteristics but is more compact. It became available in 2005, and the current model is called the McGrath Series 5 (Fig. 4.25). The shape of the blade is very similar to that of the GlideScope, but it has a small video monitor (1.7 inches diagonally) on the end of the handle. It also has an adjustable-length, detachable metal blade (camera stick) that is covered by a disposable plastic blade during use, so no part of the handle or metal blade makes contact with the patient. It has no recording capability.

The Storz D-Blade became available in 2010 and also has a blade shape similar to that of the GlideScope. It is an optional blade for use with the Storz C-MAC system and has the same functionality as the other C-MAC blades but does not allow the option of direct visualization of the larynx. It was designed specifically for difficult intubations.

The GlideScope and its use are discussed as representative of this class of indirect video-assisted laryngoscopes with thin, sharply angulated and unchanneled blades.

Indications

Like the C-MAC, video laryngoscopy systems with hyperangulated blades can also be used for routine intubations and

Figure 4.24 The GlideScope Titanium (Verathon Medical, Bothell, WA) video laryngoscope system.

Figure 4.25 The McGrath Series 5 (Teleflex, Buckinghamshire, UK) video laryngoscope.

have higher success rates than DL.^{218,219} The GlideScope, McGrath Series 5, and Storz D-Blade may be especially useful when DL is difficult or fails. In 2010, Noppens and coauthors reported a series of 61 patients with failed DL, all with Cormack-Lehane grade III and IV views, who subsequently had good laryngoscopic views and 95% were successfully intubated with a McGrath video laryngoscope.²²⁰ In 2011, Cavus and colleagues published a very similar series of 20 patients with grade III and IV views who had failed DL but subsequently had good laryngoscopic views and were all successfully intubated with the Storz D-Blade.²²¹ There are many case reports of easy intubations with the GlideScope and McGrath video laryngoscopes after failed DL.^{217,222} In addition, several case reports show that the GlideScope and McGrath can facilitate successful awake intubation in patients with known or suspected difficult airways.^{223–225}

A significant advantage of the more angulated video laryngoscopes is that they can provide a good view of the larynx when the neck is in the neutral position. Not surprisingly, there are several small studies and case reports demonstrating that the GlideScope and McGrath provide good laryngoscopic views and a high rate of successful intubation in patients with cervical spine immobilization.^{226–228} There is also a case report of a patient with severe ankylosing spondylitis who was easily intubated on the first attempt with the McGrath.²²⁹

There may be patients in whom the larynx is so anterior that devices with a Macintosh blade are unable to adequately visualize the airway structures; hyperangulated blades may be especially useful in this situation.

Finally, the GlideScope is useful for routine intubations by inexperienced or novice intubators, because it takes more than 50 intubations with DL to become proficient.⁸⁹ In a 2009 study by Nouruzi-Sedeh and coworkers, 20 novices each intubated five patients with DL and five patients with the GlideScope. They had a 51% success rate with DL and a 93% success rate with the GlideScope.²¹⁴

Contraindications

Contraindications to using angulated video laryngoscopes are not well described in the literature. As with any video or

optical device, blood or secretions on the lens may decrease visualization of the larynx. Fogging was a problem with older endoscopic devices, but this problem is rare with the newer video devices. Limited mouth opening (< 2 cm) can make insertion of these devices more challenging, though they require less mouth opening than devices with Macintosh blades.¹⁹¹ The biggest contraindication is probably lack of experience or absence of a rigid stylet or tracheal tube introducer to allow the operator to maneuver the ET tube around the sharp angle of the blade.¹⁹¹

Procedure and Technique

Grasp the video laryngoscope in the left hand and place it in the patient's mouth with the scissor technique. Under direct vision, not by viewing the screen, advance the blade through the oropharynx along the midline of the tongue (Fig. 4.26, step 4). Then look up at the monitor while continuing to advance the blade down the midline of the tongue, progressively identifying the base of the tongue and the epiglottis. With a gentle lifting motion, place the tip of the blade in the vallecula. Elevate the epiglottis and expose the laryngeal inlet (see Fig. 4.26, step 5). If the glottis is not well visualized, tilt the handle back slightly to enhance exposure. If needed, manipulate the neck externally to enhance visualization. If more exposure is required, place the tip of the blade under the epiglottis and gently lift and tilt back. While attempting to optimize the laryngeal view, be careful to not place the blade too close to the laryngeal inlet because it may tip the larynx anteriorly and inferiorly, thus making it more difficult to access the laryngeal inlet and pass the tube through it.

Use a rigid steel GlideRite (Verathon Medical) stylet, which has the same 60-degree curve as the blade of the GlideScope, McGrath, and D-Blade. Alternatively, a malleable stylet with a 60-degree distal bend or a bougie may be acceptable, but these devices may fail if tube passage is challenging. Pass the ET tube through the oropharynx under direct vision until it passes under the curve of the blade, and then look for it on the monitor (see Fig. 4.26, step 6). Decrease the chance of soft tissue injury by carefully passing the ET tube along the side of the GlideScope.²³⁰ When the tip of the ET tube comes into view, direct it into the glottis and advance it to the appropriate depth (see Fig. 4.26, step 8). If a malleable stylet or bougie is used, it may be difficult to get the tube to go anterior enough. If a malleable stylet must be used, try introducing the tube from the right side of the patient and rotating it 90 degrees and vertically into a midline position behind the tongue. This will help the tip of the stylet maintain its shape as it passes through the oropharynx. Another option is to use a Parker Flex-It (Parker Medical, Engelwood, CO) intubation stylet to direct the tip of the ET tube anteriorly.²⁰⁹ It is important to realize that the fixed steel (GlideRite) stylet needs to be withdrawn as the ET tube is passed through the vocal cords because the tip of the stylet will be essentially pointing toward the ceiling as it approaches the laryngeal inlet (see Fig. 4.26, step 9). The large knob on the proximal end of the GlideRite stylet is designed to be pushed up by the tip of the intubator's thumb, thus making ET tube advancement and stylet withdrawal a one-handed procedure.

Complications

Several relatively minor complications have been reported with use of the GlideScope. There are case reports of injury to the soft palate and tonsillar pillars, as well as two cases of puncture

Video Laryngoscopy (GlideScope)

1 Prepare the endotracheal tube.
Depending on the system that you are using, insert a rigid stylet or preload the tube onto the device.

2 Check the rest of your equipment, including the light source and video monitor.

3 Preoxygenate and premedicate the patient as clinically indicated.

4 Place the blade into the mouth under direct visualization (don't look at the video monitor yet).

Keep the blade in the midline of the tongue throughout the procedure.

5 Slowly advance the blade while watching the video monitor. Progressively identify the tongue and epiglottis.

Place the blade in the vallecula or under the epiglottis, gently lift, and identify the vocal cords.

6 Under direct visualization (don't look at the monitor), pass the styleted tube through the mouth and into the posterior pharynx.

Look up at the video monitor and watch for the tip of the tube to appear.

8 Direct the tube through the vocal cords under direct visualization on the video monitor.

9 While the operator firmly secures the endotracheal tube, an assistant removes the stylet as the tube is passed through the vocal cords.

NOTE: This image sequence depicts video laryngoscopy using the GlideScope. The procedure sequence may vary with the use of other devices. Refer to text for additional information.

Be familiar with the equipment used at your institution prior to use.

Figure 4.26 Video laryngoscopy (GlideScope, Verathon Medical, Bothell, WA). Note that there are times when the operator *does not* look at the screen but rather uses direct vision (*steps 4 and 6*).

of the right palatopharyngeal arch, one requiring surgical repair.^{230–232}

Summary

Video-assisted laryngoscopy is a major advancement in visualization of the laryngeal inlet. Hyperangulated blades are very promising because they provide an improved laryngeal view and have a shorter learning curve than DL. The majority of intubation failures are due to an inability to pass the tube through the larynx despite excellent glottic views.²⁰⁹ Using a fixed steel stylet (GlideRite stylet) helps, and does not eliminate this problem.¹⁹¹ Advancements need to be made in achieving tracheal intubation once the glottis is seen. The addition of a tube channel obviates the need to maneuver the ET tube around the sharp angle of the blade; channeled devices are described in the next section.

Video and Optical Laryngoscopes With a Tube Channel

Four devices allow indirect video or optical visualization of the larynx and also provide a channeled blade to guide the ET tube through the vocal cords. The Airtraq (Fig. 4.27) (Prodol Meditec S.A., Vizcaya, Spain) and Pentax AirWay Scope (Fig. 4.28) (AWS) (Pentax, Tokyo) are the only devices in this group that have been sufficiently tested. The King Vision aBlade (Ambu, Ballerup, Denmark) and Venner A.P. Advance Difficult Airway Blade (DAB) (Venner Medical, Singapore) are newer and less tested. The ET tube is inserted into the channel before the device is placed in the airway, and the channel guides the ET tube into the trachea once the glottis is visualized. This design helps alleviate the most common problem associated with video and optical laryngoscopy: difficulty placing the ET tube despite an excellent view of the glottis.

All the channel-guided devices have the same curvature as the normal upper airway. They allow visualization of the glottis by looking around the tongue instead of trying to straighten the airway and push the tongue out of the way. They consistently provide a better view of the glottis and may lead to less airway trauma and hemodynamic stimulation than occurs with DL.^{233–235} The concept of a laryngoscope shaped like the natural curvature

Figure 4.27 The Airtraq (Prodol Meditec S.A., Vizcaya, Spain) intubation device. The device pictured uses prisms and mirrors so that the larynx can be visualized via the eyepiece. A newer model features a video system with video out capability.

of the upper airway and containing a channel to guide the ET tube is not new, but the addition of optics and video just recently made this concept a reality.^{235–238} The advantage of these devices is that they provide an excellent view of the glottis with little need for maneuvering and they eliminate the requirement for the hand-eye coordination needed to pass the ET tube around an acute curve.^{239–241}

Indications

Difficult intubation with DL is an indication for using a channel-guided optical or video device. The Airtraq and Pentax AWS have a high rate of success in patients with known or predicted difficult airways.^{213,233,234} In 2009, a study by Asai and colleagues reported 270 patients with difficult airways by DL (grade III and IV views) and found that 268 of these patients (99.3%) had good glottic visualization and were easily intubated with the Pentax AWS.²³⁴ In a 2009 trial of patients with expected difficult airways, Malik and coworkers randomized 75 patients to DL, the Pentax AWS, or the GlideScope.²¹³ The rate of successful intubation was 84% with DL, 96% with the GlideScope, and 100% with the Pentax AWS.

The Airtraq and Pentax AWS are particularly useful for difficult airways because of cervical spine immobilization and morbid obesity.^{242–245} In 2007, Ndolo and coauthors published a study of 106 morbidly obese patients who were randomized to intubation with DL or the Airtraq.²⁴⁶ All patients randomized to the Airtraq were successfully intubated, and six patients in the DL group required rescue intubation with the Airtraq. In 2007, Maharaj published a study of 40 patients with cervical spine immobilization who were randomized to DL or the Airtraq.²⁴⁴ All patients randomized to the Airtraq group were intubated on the first attempt and were intubated faster and with less difficulty than the DL group.

In 2008, Enomoto and associates studied 203 patients with manual in-line neck stabilization who required intubation.²⁴³ They randomized these patients to intubation with DL or the Pentax AWS. The intubation success rate with DL was 89% versus 100% with the Pentax AWS. A similar study by Liu

Figure 4.28 The Pentax AWS (Air Way Scope) (Pentax, Tokyo).

and coworkers in 2009 included 70 patients with manual in-line stabilization of the cervical spine and randomized them to intubation with the Pentax AWS or the GlideScope.²¹¹ They reported a 100% rate of successful intubation with the Pentax AWS and 89% with the GlideScope. In addition, two studies used fluoroscopy to compare cervical spine motion during intubation with DL versus intubation with the Pentax AWS.^{247,248} Both studies found that intubation with the Pentax AWS caused less movement of the upper cervical spine than DL.

The Airtraq is generally used during RSI but may also be used for awake intubation of patients with difficult airways.^{249,250} When compared with DL, both the AirTraq and Pentax AWS consistently provide better visualization of the glottis and have a higher rate of successful intubation.^{213,233,234,237,243} Two small studies and one large trial have shown that the Airtraq has a very high rate of success after failed DL.^{4,233,237} In 2011, Amathieu and coauthors reported the results of a large prospective trial in which they used an algorithm that specified use of the Airtraq as a backup for all cases of failed RSI with DL.⁴ They had 28 patients who could not be intubated with DL after multiple attempts, including the use of a bougie. Intubation with the Airtraq was successful in 27 of 28 of these patients (97%), and the other patient was intubated with an ILMA.⁴

Contraindications

The greatest drawback of channeled video and optical devices is that copious amounts of blood or secretions can obscure the view. Because they do not allow a direct line of sight to the larynx, visualization and intubation are dependent on the video or optical image. If blood or fluid covers the tip of the lens, the image is obscured. This problem can be minimized by aggressively suctioning the hypopharynx before placing the device in the mouth.

Inability to open the mouth or severely limited mouth opening is a contraindication to using the channel-guided devices just described. If the patient's mouth opening is at least 2 cm, these devices can succeed in cases in which DL would be impossible. The normal adult-size Airtraq requires 18 mm of mouth opening, and the pediatric and infant sizes require 12.5 mm. The Pentax AWS requires approximately 20 mm of mouth opening.

Procedure

Before beginning the procedure check that you are using the correct size device, ensure that it is functioning properly, and choose the correct size ET tube for the device and the patient. Insert the ET tube into the channel of the device and advance it to the end of the channel while ensuring it is not advanced so far that it obscures the video or optical lens. Insert the tip of the blade into the mouth vertically so that the handle of the device is pointed toward the patient's feet. Rotate it into the pharynx and hypopharynx along the midline of the tongue until the tip is in the vallecula. If the glottis is not visualized immediately, try backing the blade out 1 to 2 cm and lift the device gently in the direction of the handle (toward the ceiling). A common mistake is to insert the blade too deep initially, which offers a narrower view of the glottis and may make intubation difficult. When the vocal cords are well visualized in the center of the video or optical image, advance the ET tube through the cords by sliding it forward within the channel. If the ET tube does not go through the cords, pull it back and realize that you need to adjust the position of the entire device to change the trajectory of the tube. If the tube tends to go

posterior to the vocal cords, lift the device toward the ceiling and tip the handle back slightly (while avoiding contact with the upper teeth), and then advance the tube again. Alternatively, pass a bougie through the ET tube (or in the channel without an ET tube) and direct the curved tip up and through the vocal cords.

When using the Pentax AWS, it is important to know that the ET tube leaves the channel in line with the tip of the blade (more anterior than the Airtraq). Therefore when the tip of the AWS blade is in the vallecula, the tube often strikes the epiglottis when it is advanced. To avoid this problem, advance the tip of the AWS blade posterior to the epiglottis (as with straight-blade laryngoscopy), and lift the epiglottis out of the way before advancing the ET tube.

Dhonneur, Ndoko, and colleagues described alternative techniques for insertion of the Airtraq in morbidly obese patients.^{245,246} They rotate the device 90 to 180 degrees for initial insertion of the distal tip into the patient's mouth and then rotate it into the normal orientation (handle toward the patient's feet) before advancing it into the hypopharynx. This helps alleviate problems with the handle of the device striking the patient's chest during insertion.

Aftercare

A common mistake when using laryngoscopes with a tube channel is to quickly remove the laryngoscope after the ET tube is advanced into the trachea. Because the ET tube is already inside the trachea, it is best to attach a resuscitation bag and ventilate the patient. After giving several breaths, stabilizing oxygenation, and confirming tracheal placement with capnography, slowly and carefully remove the device while providing ongoing ventilation. It is appropriate to leave the laryngoscope in place for a few minutes after intubation to allow visual reconfirmation of proper tracheal placement, particularly if there is a problem with ventilation or oxygenation immediately following intubation. To remove the tube from the channel of these devices, hold the end of the ET tube firmly in the right hand and carefully wiggle the device to the left. When the tube slides out of the channel, slowly rotate the laryngoscope out of the patient's mouth. Reconfirm tracheal placement with capnography and adjust the depth of the ET tube as needed.

Complications

No significant complications have been reported with the tube channel video and optical devices. Because the blades of these devices are rigid and cannot be directly visualized after entering the mouth, they have potential for soft tissue damage. Complications of other video laryngoscopes are primarily a result of blind ET tube placement through the mouth and pharynx, and the tube channel devices eliminate this problem.

Intubating Laryngeal Mask Airways

ILMAs are unique devices because they are easy to insert, provide excellent ventilation and oxygenation (better than BMV), and also provide a reliable means of tracheal intubation.^{55,251–254} Many clinicians who have used the Fastrach ILMA in an emergency setting insist on having this device in their difficult airway tool kit.^{2,53,57,253,255,256} It is impossible to overstate the value of this device for failed emergency RSI, and unlike other rescue devices, a large volume of data support its use in general and in the setting of failed RSI.^{2,53,56–58,256–260} It has become the primary rescue device for failed RSI in many EDs.

Intubating Laryngeal Mask Airway

Indications

Failed rapid-sequence intubation
 Cannot-intubate/cannot-ventilate scenario
 Difficult mask ventilation
 Expected difficult intubation
 Refractory hypoxemia despite preoxygenation

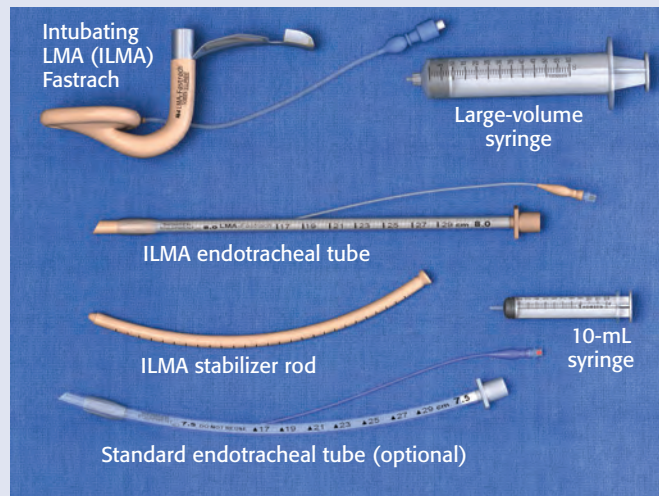

Contraindications

Unable to open mouth
 Awake patient

Complications

Laryngeal or esophageal injury from blind intubation
 Aspiration (rare)

Equipment

Review Box 4.3 Intubating laryngeal mask airway: indications, contraindications, complications, and equipment.

There are many different LMAs and other extraglottic devices on the market, and this can cause confusion. Although several extraglottic devices (see [Chapter 3](#)) can be used for rescue ventilation or oxygenation, only the devices discussed here can also provide a reliable means of tracheal intubation. The Fastrach is the only device in this group that has been extensively tested and the only ILMA that can reliably facilitate blind intubation (without endoscopic guidance).^{2,53,55,252–254,261–264}

Types of ILMAs

There are four popular ILMAs currently available (see [Chapter 3](#), [Fig. 3.12](#)). The LMA Fastrach (Teleflex; <http://www.lmaco.com>) has, by far, been the most used and most studied ILMA. It has excellent blind intubation rates, much higher than the Air-Q (Cookgas LLC, St. Louis, MO)^{261,262} or i-Gel (Intersurgical, Berkshire, UK),^{264,265} and there are numerous investigations detailing its success as a rescue device in difficult and failed airways. A unique feature of the Fastrach is the metal handle that makes insertion easier and enables lifting of the device to create a better seal against the glottis. There are also newer ILMA devices that show promise: the Air-Q, i-Gel, and Auragain (Ambu, Ballerup, Denmark). Whereas the smallest Fastrach is size 3 (for children 30 to 50 kg), the other ILMAs are available in all sizes, including neonates less than 5 kg. The LMA Protector (Teleflex; <http://www.lmaco.com>) is an ILMA that will soon be released, and is similar to the LMA Supreme (with gastric access) but will allow intubation using a flexible endoscope.

An important feature of newer ILMAs is gastric access channels, allowing placement of an orogastric tube through the gastric port and into the stomach with the ILMA in place. This is particularly useful in patients with distended stomachs after prolonged BMV, and in children who are more prone to gastric insufflation even with shorter BMV times. The Air-Q

is available in four versions, one of which has a gastric port (Air-Q Blocker). The i-Gel and Auragain both have gastric ports. The LMA Fastrach does not have gastric access.

Indications

ILMAs are indicated as an alternative to BMV or as a conduit for intubation of difficult airways.²⁵⁸ In the cannot-intubate/cannot-ventilate scenario, it is a reliable rescue device. In this situation, adequate ventilation with the ILMA is possible in nearly all cases.^{2,4,128} The ILMA is more successful for ventilation and intubation of difficult airways than the LMA Classic.¹²⁸ For inexperienced providers, ventilation with the ILMA is usually superior to face mask ventilation.²⁶⁶

The ILMA can also be used as a primary ventilation and intubation device in patients with difficult airways.²⁵⁸ Studies of difficult airway management with the ILMA show that almost all patients can be adequately ventilated with the ILMA and 94% to 99% can be intubated through the device.* Patients who are difficult to intubate by DL are often easy to intubate with the ILMA because many anatomic factors that cause difficult DL do not affect placement or function of the LMA Fastrach.^{55,56}

The LMA Fastrach is especially useful in patients with difficult face mask ventilation because of a beard, severe facial trauma, or obesity because none of these factors inhibit Fastrach placement. When brisk bleeding above the glottis makes ventilation and intubation difficult, the Fastrach can prevent aspiration of blood and facilitate blind or endoscopic intubation. In patients requiring urgent cricothyrotomy or percutaneous needle insertion into the trachea, the ILMA can be used to counteract anterior neck pressure. In this capacity, the Fastrach provides temporary ventilation and aids in stabilization of the cervical spine during the surgical airway procedure.

*References 2, 53, 55, 57, 128, 252–254, 258, 267, 268.

Contraindications

One limitation of the LMA Fastrach is that it cannot be used in infants and small children because the smallest size, a No. 3, is not suitable for patients smaller than 30 kg. Other ILMAs (or nonintubating LMAs) should be used in patients less than 30 kg. Other ILMAs require flexible endoscopic guidance for reliable tracheal intubation.

LMAs are contraindicated in patients with less than 2 cm of mouth opening. They are unlikely to be successful in patients with grossly distorted supraglottic anatomy from disease processes or postradiation scarring. They are also relatively contraindicated in awake patients because of the high risk for emesis when the gag and airway reflexes are intact.

Intubation through the LMA Fastrach

The majority of intubations through the ILMA are performed blindly by using either the designated LMA ET tube or a standard ET tube. Regardless of the tube used, it is critical that the ILMA be optimally adjusted before attempting blind or flexible endoscopic intubation through the device.

The LMA ET tube, also known as the LMA Fastrach, is designed specifically for the ILMA. There are two versions of the LMA ET tube: a reusable and a single-use disposable. The reusable version is made of silicone and the single-use version is made of polyvinyl chloride (PVC). The specialized LMA ET tubes are soft and straight and have a midline-beveled tip. These features are designed to allow the LMA ET tubes to emerge from the ILMA mask at an acute angle and to minimize potential injury to the vocal cords and esophagus. The drawback of the specialized Fastrach ET tubes is that they have low-volume high-pressure cuffs, which could potentially cause ischemic damage to the trachea, and there are no clinical data on how long these tubes can remain in place.²⁶⁹ Use of a standard ET tube for intubation through the LMA Fastrach has been well studied and is the current practice in many EDs.²⁷⁰⁻²⁷² Another option is to use a Parker Flex-Tip ET tube (Parker Medical) (see Fig. 4.8).²⁷³

Procedure and Technique for Blind Intubation

The LMA Fastrach is the only device that enables reliable tracheal intubation without the use of a flexible endoscope. If another ILMA is used, tracheal intubation has much lower success rates and, in general, blind intubation should not be attempted.

Before intubation through the LMA Fastrach, make sure that the patient is ventilating optimally through the device. Determine this by manually ventilating the patient while holding the ILMA handle with a “frying-pan” grip. If any resistance is felt, adjust the handle by slight rotation in the sagittal plane and then lift the entire device toward the ceiling (see the “Chandy maneuver,” Fig. 4.29, step 3).

Before inserting the ET tube, lubricate it generously. Advance the ET tube with the curve opposite that of the LMA Fastrach curve (Fig. 4.29, step 5). When the tube has advanced to 15 cm, the tip will start to emerge from the LMA Fastrach mask. Just before advancing the tube, use the frying-pan grip and apply a slight anterior lift (not a tilt) to further align the aperture of the ILMA with the glottis (see second part of the Chandy maneuver, Fig. 4.29, step 6). Do not use a levering action. While holding the handle in this position, gently pass

the tracheal tube to approximately 16.5 cm. In this position, the ET tube will push the epiglottic elevating bar up and may now come in contact with the larynx or esophagus. If cricoid pressure is being applied, decrease it because it may interfere with passage of the ET tube through the glottis. If no resistance is encountered, advance the tube into the trachea until the tracheal tube adapter comes in contact with the proximal end of the ILMA tube (see Fig. 4.29, step 7). Do not use force when advancing the tube.

If the ET tube does not pass into the trachea easily, withdraw the ET tube to the 15-cm mark and readjust the position of the LMA Fastrach. If the tube meets resistance at approximately 17 cm, this may indicate a fully down-folded epiglottis or impaction of the tip of the tube against the anterior laryngeal wall. Rotating the tube may overcome impaction of the tip. To correct a down-folded epiglottis, remove the ET tube and perform the “up-down maneuver” by rotating the ILMA outward 5 to 6 cm without deflating the mask and then sliding it back into the hypopharynx (see Chapter 3, Fig. 3.13, steps 9 and 10). If these maneuvers are unsuccessful, it is likely that the wrong size LMA Fastrach is being used. Consider using a flexible endoscope to guide intubation (also see the “Insertion Technique and Maneuvers Guide,” on the company website: <http://www.lmana.com>).

Once the LMA ET tube has passed into the trachea, inflate the tube cuff and attempt to ventilate the patient. Check for proper tube placement with a PETCO₂ detector. If the tube is in the trachea, deflate the cuff of the ILMA. There is no rush to remove the ILMA; it can remain in place for an hour or longer if more pressing patient care issues need to be addressed first.

Using a Standard ET Tube

Use of a standard ET tube is not recommended by the manufacturer, but it is a well-studied and common practice.^{271,274-276} The manufacturer warns that using a standard ET tube may be associated with a greater likelihood of laryngeal trauma, but there are no reports of such trauma in the literature. The only report of significant trauma with blind intubation through the LMA Fastrach is a case report of esophageal perforation and subsequent death caused by use of the specialized LMA ET tube.²⁷⁷ A laboratory study showed that a standard PVC ET tube exerts 7 to 10 times more pressure on distal structures than the silicone LMA ET tube, and the clinical relevance of this finding is unknown.^{270,278} Some experts suggest warming the tip of a standard PVC ET tube (to soften it) before insertion through the LMA Fastrach.^{271,274,276}

Because of the potential for injury with blind intubation through the ILMA, use endoscopic guidance if there is any difficulty. If using a standard ET tube, insert the ET tube with its curvature opposite the curvature of the LMA Fastrach tube (see Fig. 4.29, step 5). This allows the ET tube to exit the Fastrach at a less acute angle and then to advance into the trachea more easily.^{259,276}

If intubation through the LMA Fastrach fails, the device can still be used to provide ventilation and oxygenation during more invasive airway procedures, such as retrograde intubation or cricothyrotomy.²⁷⁹

Flexible Endoscopic Intubation through ILMAs

A flexible bronchoscope can be used to verify the position of the larynx either before or during intubation. When intubating

Endotracheal Intubation With the ILMA (Fastrach)

1 Insert the ILMA by sliding the posterior surface of the mask along the palate and posterior pharynx until firm resistance is felt (see Chapter 3).

2 Inflate the ILMA cuff and begin ventilations through the device as you prepare for intubation.

3 **CHANDY MANEUVER**
Step 1

Rotate handle in the sagittal plane to move the cuff forward against the larynx.

This maneuver provides a good seal and optimal ventilations.

4

Insert the LMA Fastrach ET tube to the 15-cm mark.

At this point, the tip of the tube will begin to emerge from the LMA.

5 **Correct**

Incorrect

If using a standard ET tube, align the curve so that it is opposite of the LMA curve.

This allows the tube to exit the mask at an angle more conducive to tracheal entry.

6

CHANDY MANEUVER
Step 2

Prior to passing the tracheal tube, lift the handle anteriorly (not tilted) to better align the cuff and larynx for smooth ET tube passage.

Tip of tube

7

Adapter

If no resistance is felt, advance the tube into the trachea until the adapter comes into contact with the ILMA airway tube.

Do not use force.

8

Inflate the ET tube cuff, ventilate, and check tube position with PETCO₂.

If the tube is properly positioned, deflate the LMA cuff.

9

Adapter

Stabilizer rod

To remove the LMA, deflate the LMA cuff and remove the adapter from the tube.

Rotate the LMA out of the mouth while using the stabilizer rod to keep the tube in place.

10

Remove the stabilizing rod when the mask is clear of the mouth, and complete removal of the LMA.

Reattach the adapter and resume ventilation.

Figure 4.29 Endotracheal (ET) intubation with the intubating laryngeal mask airway (ILMA) (Fastrach, Teleflex, Buckinghamshire, UK).

through the ILMA over an endoscope, a standard ET tube is sufficient and there is no reason to use the specialized LMA ET tube.

To use a flexible endoscope to intubate through the LMA Fastrach, first advance the ET tube through the ILMA Fastrach to 15 cm. At a 15-cm depth the view through the endoscope should show the glottis beyond the epiglottic elevating bar. Advance the ET tube 1.5 cm before advancing the endoscope. This protects the camera elements from being damaged by the epiglottic elevating bar. The view at 16.5 cm should show the vocal cords and trachea. Advance the endoscope into the trachea and then pass the ET tube over the endoscope. If the vocal cords are not visualized immediately, see the LMA Insertion Technique and Maneuvers Guide, described in Chapter 3.

To use a flexible endoscope to intubate through other LMAs, the procedure is similar. First, place the ET tube approximately halfway to the opening in the laryngeal mask bowl. At this point, it may be useful to connect a swivel adapter to the ET tube adapter (see Fig. 4.29) that will allow ongoing ventilation with the ability to place the flexible endoscope through the other port. If this step is performed, the cuff of the ET tube should be inflated during endoscopic intubation to minimize the air leak during ventilation. After the ET tube is placed halfway to the opening of the laryngeal mask bowl, the endoscope is introduced into the ET tube and advanced until the laryngeal inlet is visualized. Advance the endoscope into the trachea and then pass the ET tube over the endoscope. If the laryngeal inlet is not immediately visualized, the laryngeal mask should be repositioned before attempting intubation.

For children, the most common flexible bronchoscope has an outer diameter of 3.6 to 3.8 mm, which enables intubation of a 4.5 ET tube or larger. This allows intubation through an ILMA for children as small as 2 to 3 years old. Children younger than this should not be intubated through an ILMA, unless a smaller endoscope is used.

ILMA Removal After Intubation

To remove the ILMA, first deflate the cuff, if present (see Fig. 4.29, *step 8*), and be careful to not deflate the ET tube cuff. Start by removing the ET tube adapter. Then hold the proximal end of the ET tube in place while rotating the ILMA out of the hypopharynx. As the ILMA passes over the ET tube and out of the mouth, hold the ET tube in place with a stabilizer rod (see Fig. 4.29, *step 9*), without advancing the tube farther. If a stabilizer rod is not available, a second ET tube can also be used to aid in ILMA removal. When the ET tube pilot balloon comes in contact with the stabilizer rod, remove the stabilizer rod to allow the pilot balloon to travel through the ILMA tube. Then reattach the ET adapter and resume ventilation. Adjust the depth of the ET tube as needed.

Intubation through the LMA Classic

The recommended technique for tracheal intubation through the LMA Classic uses an endoscope and has a high success rate but requires a smaller ET tube and some adjustments.^{280,281} Blind intubation through a nonintubating LMA (LMA Classic or LMA Unique) has a poor success rate and is not recommended.^{282–284} Using a tracheal tube introducer as a guide through the LMA is unlikely to be successful and is not recommended.^{285,286}

After ensuring that the LMA is ventilating properly, place a well-lubricated ET tube into the LMA tube and advance it to a depth of 24 cm (No. 5 LMA), so that the tip of the ET tube has just passed the fenestrations. Pass a lubricated endoscope through the ET tube and advance it through the vocal cords. If the epiglottis is deflected downward, manipulate the tip of the endoscope under the epiglottis until the vocal cords come into view. Pass the ET tube over the endoscope and into the trachea, and then inflate the ET tube cuff and ventilate the patient. Check for correct ET tube placement with a PETCO₂ detector. Cricoid pressure may impede placement and intubation through the LMA.^{125,126} Release cricoid pressure, if necessary, to accomplish these procedures.

Complications When Intubating through LMAs

Although most patients can be safely intubated blindly through the ILMA, there is a small chance of injury to the larynx or esophagus, especially with multiple blind attempts. There is one case report of a death caused by esophageal perforation during blind intubation through the ILMA. Consider using endoscopic guidance if blind intubation is difficult or if the clinician is inexperienced. Intubation through a nonintubating LMA is not recommended unless facilitated by an endoscope.

Summary

LMAs provide an excellent means of oxygenation and ventilation when face mask ventilation is difficult or impossible. In addition, LMAs are particularly useful when managing patients who are difficult to intubate with DL. By facilitating the management of difficult or failed ventilation and difficult or failed intubation, LMAs are an indispensable component of the difficult airway algorithm.

FLEXIBLE ENDOSCOPIC INTUBATION

Flexible endoscopic intubation is the most common technique used by anesthesiologists for known difficult airways. Physicians who perform endoscopic intubations daily have a success rate of nearly 100% when using this technique for difficult intubations.²⁸⁷ In the ED, with more difficult intubating conditions and less experienced fiberopticists, the success rate is 50% to 90%.^{288–291} The most common reason cited for failure of flexible endoscopic intubation in the operating room is clinician inexperience.²⁹² In the ED, failure is most often attributed to poor visibility from blood, vomitus, and other secretions.^{288–290} Mlinik and colleagues²⁹⁰ found that successful ED endoscopic intubations averaged 2 minutes whereas failures averaged 8 minutes. They recommended consideration of alternative approaches if intubation attempts take more than 3 minutes.

Flexible endoscopic intubation is often the best method for intubating awake patients with a known difficult airway. It can be accomplished via the nasal or oral route and is better tolerated than DL. It usually provides excellent visualization of the airway and permits evaluation of the airway before placement of the tube. The expense of the equipment, its fragility, and the length of time required to both achieve and maintain technical proficiency are drawbacks. Because intubation with a flexible endoscope is performed much less commonly than other methods,⁶⁴ clinicians are encouraged to learn and maintain

Flexible Fiberoptic Intubation

Indications

Known or suspected difficult airway
 Distorted airway anatomy
 Swelling
 Abscess/infection
 Morbid obesity
 Trauma
 Tumors/previous radiation therapy

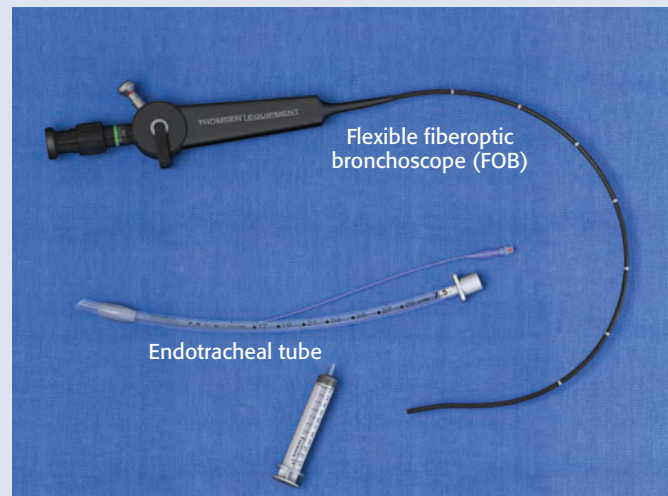

Contraindications

Nasal approach
 Severe midface trauma
 Coagulopathy
Relative
 Active airway bleeding
 Vomiting

Complications

Hypoxia from prolonged intubation attempts
 Vomiting
 Laryngospasm
 Soft tissue trauma

Equipment

Review Box 4.4 Flexible endoscopic intubation: indications, contraindications, complications, and equipment.

this skill when performing bedside nasopharyngoscopy for patients with severe sore throat, new hoarseness, suspected foreign body, possible laryngeal injury after neck trauma, and in other cases when upper airway edema, obstruction, or pathology is suspected. All clinicians who perform airway management should also perform nasopharyngoscopy with laryngoscopy on a regular basis. Expense has become less of an issue in recent years with the introduction of disposable endoscopes like the Ambu aScope (Ambu, Ballerup, Denmark).

Endoscopes are graded according to their external diameter, measured in millimeters. Endoscopes specifically designed for ET intubations are available from several companies (Pentax, Olympus, Machida, Storz, and Fujinon). A practical size for an intubating scope is approximately 4 to 5 mm. Although it is physically possible to pass an ET tube sized 0.5 mm larger over an endoscope, the fit is tight. As a rule, the ET tube should be approximately 1 mm larger than the intubating scope. The size of the working channel, the port that allows suction, administration of oxygen, and passage of fluid or catheters, are also important when evaluating endoscopes. A working channel of approximately 2 mm is desirable to allow adequate suction of secretions, though working channels are not strictly necessary for endoscopic intubation.

Older fiberoptic systems required the intubator to look into an eyepiece when performing intubation. Newer flexible endoscopic systems plug into a video monitor, enabling assistants and learners to visualize the airway anatomy; newer systems enable the intubator to maintain a more comfortable position while holding the endoscope and sheath properly.

Indications and Contraindications

Patients with known or suspected difficult airways are good candidates for awake or semi-awake endoscopic intubation.

Patients with distorted airway anatomy, including swelling of the mouth or tongue, upper airway abscess or infection, morbid obesity, cervical spine injury, trismus, and penetrating and blunt neck trauma, are all good candidates for awake endoscopic intubation. Patients with laryngeal tumors, especially those with a history of radiation therapy encompassing the cervical region, may be impossible to intubate by any other nonsurgical method. An endoscope can also be helpful when assessing and intubating patients with airway obstruction from presumed foreign body aspiration. Flexible endoscopic intubation is best used as the initial approach to tracheal intubation, and it may also be used as a rescue device when other methods fail.²⁹³ Flexible endoscopic intubation can also be performed through an ILMA or LMA after difficult ventilation or failed intubation.

Contraindications to the nasal approach are severe midface trauma and coagulopathy. Patients who are likely to receive thrombolytics should also be excluded. Although there are no clear contraindications to endoscopic orotracheal intubation, active airway bleeding, excessive oral secretions, and vomiting are relative contraindications because successful endoscopic intubation is rarely achieved in these settings. Because of the time that must be expended preparing for and performing flexible endoscopic intubation, patients with impending airway closure from a dynamic process that is causing severe upper airway obstruction or swelling should have their airway secured by other means. Hypoxia despite good attempts at oxygenation is another relative contraindication, especially if the intubator is inexperienced in flexible endoscopic intubation.

Procedure and Technique

Preparation

Proper preparation of the upper airway is crucial for successful awake or semi-awake endoscopic intubation. If time permits,

administration of a drying agent such as glycopyrrolate 10 to 20 minutes before the procedure will reduce oral secretions and increase effectiveness of topical anesthesia. Topical anesthesia should be applied to the posterior oropharynx, hypopharynx, and larynx for all endoscopic intubations. If nasal intubation is planned, administer topical anesthesia to the selected naris; application of a vasoconstrictor such as oxymetazoline (Afrin, Bayer, Whippany, NJ) or phenylephrine is recommended to increase the caliber of the nasal passage and reduce the chance of epistaxis.

Deliver local anesthetic to the upper airway by one of several methods. Application of 4% or 5% lidocaine cream by “buttering” the base of the tongue is an effective technique to anesthetize the posterior tongue, vallecula, epiglottis, and laryngeal structures. The tongue is held in protrusion as the base of the tongue is buttered with 4% or 5% lidocaine cream using a tongue depressor. Because the patient is unable to swallow with a protruded tongue, the ointment warms, liquefies, and moves posteriorly and inferiorly to anesthetize the laryngeal structures. It is contended that the ointment also penetrates the mucosa to anesthetize the glossopharyngeal and superior laryngeal nerves.²⁹⁴ Nebulized lidocaine (4 to 6 mL of a 4% solution) can be used to anesthetize the entire upper airway if time permits. Lidocaine (3 mL of a 4% solution) can be injected percutaneously through the cricothyroid membrane via a 20-gauge needle, thereby providing anesthesia to the larynx and trachea. A flexible atomizer device that attaches to a standard syringe (Fig. 4.30) (LMA MADgic, Teleflex) can be used to accurately apply atomized 4% aqueous lidocaine to the posterior oropharynx and upper laryngeal structures; tracheal anesthesia can be accomplished by having the patient inspire as the medication is sprayed. Some laryngeal and tracheal anesthesia can be achieved by oral spray with a laryngeal tracheal anesthetic set, but this is probably less effective than other methods. Finally, 4% aqueous lidocaine can be sprayed through the working channel of the endoscopic scope during the procedure via the “spray as you go” technique.

Nasal anesthesia can be accomplished by several methods. A flexible atomizer (Fig. 4.31) can be passed to the posterior nasopharynx, and then 4% aqueous lidocaine is sprayed as

the patient sniffs. This is repeated several times as the flexible atomizer is slowly withdrawn. Nebulized 4% lidocaine can anesthetize the nasal passage, assuming the patient is not mouth breathing. Viscous lidocaine gel can be injected with a syringe into the nasal passage as the patient sniffs; absorption into the mucous membranes is probably enhanced if a nasal airway is placed after application. This has the added benefit of further dilating the nasal passage. Some clinicians use topical cocaine 4% to anesthetize the nose because of excellent tissue penetration.

The maximum dose of lidocaine for airway anesthesia is approximately 4 mg/kg (approximately 250–300 mg in an adult). Sedation for endoscopic intubation can be accomplished with ketamine, etomidate, propofol, fentanyl, alfentanil, or midazolam (see Chapter 5). The goal of sedation is to preserve spontaneous respiration, but limit patient movement and reaction to the procedure. A combination of good topical anesthesia and mild sedation allows the best chance for successful intubation. If excellent topical anesthesia is achieved, parenteral sedation is sometimes unnecessary.

Figure 4.30 This malleable atomizer (LMA MADgic device; Teleflex, Buckinghamshire, UK) allows topical anesthesia to be applied accurately to multiple areas.

Figure 4.31 Attaching a standard swivel adapter (A) to the end of the ET tube during endoscopic intubation through the intubating laryngeal mask airway (ILMA) allows the patient to be ventilated during the entire procedure (B). *BVM*, Bag-valve-mask; *ETT*, endotracheal tube; *FO*, flexible fiberoptic scope; *SC*, stopcock.

The optimal position of the neck is extension, as opposed to the slight cervical flexion desired when using DL. Extension allows better visualization of the glottis by elevating the epiglottis off the posterior pharyngeal wall. This is especially pertinent in a comatose patient who lacks the muscle tone necessary to maintain an open airway. If problems arise with the tongue and soft tissues falling back and obscuring the view of the endoscope, apply a jaw-lift maneuver or grasp the tongue and pull it forward and away from the soft palate and posterior pharyngeal wall. This also moves the epiglottis away from the posterior pharyngeal wall and facilitates exposure of the cords. Extend the head to accomplish the same objective.

Endoscopic intubation may be performed with the patient in the upright, semi-upright, or supine position. Stand facing the patient or at the patient's head, depending on personal preference. The upright and semi-upright positions help keep pharyngeal soft tissue from obstructing the airway. The upright position may be more familiar to emergency clinicians who are skilled at diagnostic nasopharyngoscopy.

The greatest impediment to successful endoscopic intubation is an inability to visualize the larynx because blood or secretions have covered the optical element and cannot be removed. Suction actively just before introduction of the endoscope. Application of a small amount of soap to the lens may decrease fogging. If the endoscope has a working channel, suction minor secretions through the suction port during the procedure. The camera can also be cleaned by pressing the lens against a moist mucosal surface or having the patient swallow. Whereas some advocate oxygen insufflation through the suction port to blow away secretions, defog the tip, and increase the inspired oxygen content, there are case reports of gastric insufflation causing gastric rupture,²⁹⁵⁻²⁹⁷ as well as pulmonary barotrauma.^{298,299} If oxygen insufflation is used to clear secretions, it should be used for a few seconds at a time. Supplemental oxygen can be administered separately, through the nose or mouth.

Once the scope has entered the trachea, difficulty advancing the ET tube may be encountered. The tip of the tube most commonly catches on the right arytenoid cartilage or vocal cord. To fix this, withdraw the tube 2 cm, rotate it counterclockwise 90 degrees, and readvance the tube to remedy the problem (see Fig. 4.20).

Nasal Approach

The nasal approach is technically easier than the oral approach because the angle of insertion allows better visualization of the larynx with minimal manipulation of the endoscope. Patient cooperation is also less critical with this approach. In an unconscious patient, the tip of the scope is also less likely to impinge on the base of the tongue with a nasal approach. In some patients the mouth is not accessible at all because of trismus, swelling, or trauma (e.g., angioedema caused by an angiotensin-converting enzyme [ACE] inhibitor), so the nasal route is the only option for endoscopic intubation (Fig. 4.32).

If conditions permit, choose the most patent nostril. In a cooperative patient, determine this by simply occluding each nostril and asking the patient to identify the nostril that is easiest to breathe through. Identify the most patent nostril by direct vision or by gently inserting a gloved finger that is lubricated with viscous lidocaine into the nostrils. If time is not an issue, an effective method to dilate the nasal cavity and administer an anesthetic is to pass a lidocaine gel-lubricated nasopharyngeal airway (nasal trumpet) into the selected nostril.

Leave this airway in place for several minutes, and introduce progressively larger trumpets.

First, place a well-lubricated ET tube in the nostril to a depth of approximately 10 cm before passing the scope through it. Alternatively, mount the ET tube over the scope and first pass the scope through the nostril (Fig. 4.33). Either sequence is acceptable. The advantage of first passing the tracheal tube through the nose is that it avoids the possibility of secretions covering the scope and positions the scope just above the laryngeal inlet. One disadvantage is that it may cause epistaxis, and, in some patients, the tube may not pass easily into the nasopharynx. However, if the tube will not pass into the nasopharynx it is best to discover this at the beginning of the procedure rather than after the trachea has been intubated with the endoscope.

At an insertion depth of 10 cm, the ET tube should have advanced around the bend into the nasopharynx. If negotiating this bend is difficult, place a well-lubricated endoscope through the tube and into the oropharynx to serve as a guide for the ET tube. Once the tracheal tube is in the oropharynx, perform thorough oropharyngeal suctioning before introducing the scope into the ET tube. Advance the endoscope toward the larynx. The epiglottis and vocal cords are seen with little or no manipulation of the tip of the endoscope in 90% of patients.²⁸³ Advance the scope and keep the cords in view by making frequent minor adjustments of the tip of the scope.

In a comatose or obtunded patient, the tongue and other soft tissues may obscure the view of the larynx. This can be alleviated by asking an assistant to pull the tongue forward or to apply a chin- or jaw-lift maneuver. Advance the scope through the larynx to the carina and pass the ET tube over the firmly held endoscope into the trachea. Remember that in adults, the average distance from the naris to the epiglottis is 16 to 17 cm. If the scope has been advanced much beyond this distance and the glottis is still not seen, the scope is probably in the esophagus.³⁰⁰ If the scope meets resistance at approximately this same level and only a pink blur is visible, the tip of the scope is probably in a piriform sinus. Transillumination of the soft tissues may confirm this and indicate the necessary corrective maneuvers.

Oral Approach

Oral endoscopic intubation is indicated when nasal intubation is contraindicated, most commonly because of severe midface trauma or clinician inexperience. Skilled endoscopists often find the oral approach just as easy as the nasal approach. For the less experienced, the oral approach may be more difficult because the path of the scope is less defined by the surrounding soft tissue and the tip of the scope is more likely to impinge on the base of the tongue or vallecula. Keeping the scope in the midline and elevating the soft tissue by pulling the tongue forward or applying the jaw-lift maneuver will minimize this difficulty. Because the oropharyngeal axis is not as well aligned with the larynx as the nasopharyngeal axis, more scope manipulation is required when using the oral approach.

Difficulty with the oral approach can be minimized by using an oral intubating airway (Fig. 4.34). This adjunct resembles an oropharyngeal airway but is longer and has a cylindrical passage through which the endoscope and tracheal tube are passed. The tip of this airway lies just above the laryngeal inlet and ensures midline positioning. Make sure that the patient is either adequately anesthetized or obtunded before the oral airway is placed to minimize gagging or emesis. The ET tube

Figure 4.32 **A**, This patient with life-threatening angiotensin-converting enzyme inhibitor-induced angioedema is in severe distress, and oral intubation is impossible. This can be a lethal condition. **B**, Endoscopic nasotracheal intubation is a good choice, but it is very difficult, if not impossible, in a struggling patient. Ketamine anesthesia is ideal, does not depress respirations, and allows easy administration of supplemental oxygen. A less ideal option is blind nasotracheal intubation. A surgical airway may be required. *Note*: In this case the tracheal tube was premounted on the scope before the scope was passed into the patient's nose. Alternatively, the tube may be first passed approximately 10 cm through the nose, and then the scope passed through the tube and into the trachea.

Figure 4.33 Flexible endoscopic intubation. Note that the tracheal tube is first premounted on the scope. The fiberoptic scope enters the trachea and then serves as a guide over which the tracheal tube is passed. *Larger image*, The nasal approach. *Inset*, Use of an oral intubating airway via the oral approach. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

Figure 4.34 Examples of oral intubating airways. The Williams Airway Intubator (SunMed, Grand Rapids, MI) (*left*) cradles the endotracheal (ET) tube in an open, curved guide, whereas the Ovassapian Fiberoptic Intubating Airway (Teleflex, Buckinghamshire, UK) (*right*) positions the ET tube on the posterior surface of the intubation airway.

can be placed to the tip of the oral airway before the oral airway is inserted, and then the scope passed through the ET tube. Alternatively, place a well-lubricated endoscope, pre-mounted with an ET tube, through the well-positioned oral intubating airway. An assistant holds the oral airway and can make minor adjustments to place the tip of the oral airway just above the laryngeal inlet. This is made easier if an endoscopic system with a video screen is used, so that the intubator and assistant can both observe the camera image. Once the airway structures are visualized, intubate the trachea with the scope (see Fig. 4.33, *inset*). Advance the ET tube over

the scope and into the trachea. This may require the same counterclockwise maneuver as described with the nasal approach. After successful intubation, the oral airway can be left in place as a bite block or may be removed over the ET tube after removal of the tube adapter. Some oral intubating airways can be removed from the mouth without disconnecting the ET tube adapter.

An alternative, albeit less practical, approach to the traditional oral endoscopic intubation for an anticipated difficult airway requires two clinicians. One performs DL, places the tip of the endoscope under the epiglottis, and blindly advances it while the second clinician, holding the body of the scope, directs the tip of the scope through the cords (Fig. 4.35). Most patients who could be intubated with this technique can probably be intubated using video laryngoscopy with a well-curved bougie.

Figure 4.35 Two-person fiberoptic intubation for difficult intubation. The laryngoscopist obtains the best hypopharyngeal exposure and directs the fiberoptic tip in the direction of the glottis. The second clinician, who manipulates the tip of the fiberoptic scope, directs the laryngoscopist to slowly advance the tip until it has successfully passed through the cords.

Endoscope Technique

Flexible endoscopic intubation will be more successful if proper technique is maintained. The scope body and endoscope controls are held in one hand while the other hand stabilizes the sheath as it enters the ET tube or patient. The intubator directs motion in one plane with the endoscope controls; to move perpendicular to the plane under direct control the tip of the scope must be rotated. This is best accomplished by keeping the endoscopic sheath taut between the scope body and the point of entry into the patient, and performing rotation of the scope body to affect rotation at the tip of the scope. If the sheath is not held taut, rotation of the scope body will not cause rotation at the tip because of excessive slack in the sheath. The intubator can attempt to rotate the tip by twisting the sheath with the stabilizing hand, but this is technically more difficult and usually less effective. Newer endoscope systems with video monitors make it easier to hold the endoscope and sheath properly (Fig. 4.36).

Complications

Complications of endoscopic orotracheal intubation include hypoxia from prolonged intubation attempts, emesis, and laryngospasm. Oxygen saturation monitoring should alert the clinician to hypoxia. Most complications seen with endoscopically guided NT intubation are associated with passing the ET tube through the nasopharynx. Epistaxis is the most common, followed by other nasopharyngeal injuries. A rare but potentially significant complication may result if, on blind advancement of the endoscope through the ET tube, the tip of the scope exits through Murphy's eye (the distal side port of the ET tube).³⁰¹ Attempts at passing the ET tube through the larynx will fail because the tip of the tube, now extending off the midline, will catch on the laryngeal structures.

Summary

The primary advantages of endoscopic intubation are the ability to visualize upper airway abnormalities, to negotiate difficult airway anatomy, and to carefully perform tracheal intubation under visual guidance. Endoscopic intubation is noninvasive and well tolerated if meticulous attention is paid to topical anesthesia. Its major limitation is poor visibility

Figure 4.36 The endoscopic sheath must be kept taut in order successfully rotate the tip of the device. **A**, This technique is difficult on older scopes that utilize an eyepiece. **B**, Newer systems with a video monitor make it easier to manipulate the endoscope properly.

because of blood and secretions. If drying agents and suction cannot mitigate excessive secretions or blood, it is best to avoid endoscopic intubation. Procedural time can be another limitation. Endoscopic intubation requires more practice than many other methods of airway management, and considerable experience should be obtained before using the endoscope in an airway emergency. Endoscopic intubation is more likely to be successful if used early in the management of a difficult airway rather than as a last resort after repeated failure with DL.

OPTICAL AND VIDEO INTUBATING STYLETS

A class of devices that incorporates optics or video into a semirigid metal or metal-reinforced stylet was introduced in the late 1990s. Intubating stylets are different from other video laryngoscopy devices in two important ways. First, they do not create potential space for tube passage like devices with blades. Second, they intubate the trachea directly. Intubating stylets remain popular with some anesthesiologists, but are rarely used in emergency airway management with so many video laryngoscopy devices available.⁶⁴

Intubating stylets can be used in conjunction with DL or as stand-alone devices. They require laryngoscopic assistance in 8% to 20% of cases and in general are more successful when used in this way.^{302,303} Visibility can be hampered by blood and secretions, but less so than with flexible endoscopy.³⁰⁴ These devices are more intuitive and require less practice than flexible endoscopy. The Clarus Video System, Shikani Optical Stylet and Levitan FPS Scope (Clarus Medical, Minneapolis) are examples of these malleable optical stylets (Fig. 4.37). The Bonfils Retromolar Intubation Fiberscope (Karl Storz Endoscopy, Tuttlingen, Germany) is rigid but otherwise structurally and functionally similar to the Shikani. The distal end of the Bonfils has a fixed curve of 40 degrees, whereas the other scopes are malleable up to 120 degrees. The intubator can look through an eyepiece or a video screen, depending on the model used.

Indications and Contraindications

Semirigid fiberoptic stylets are useful when the glottis cannot be seen readily, and may be a useful adjunct for any difficult

Figure 4.37 Examples of semirigid fiberoptic stylets: the Levitan (Clarus Medical, LLC., Minneapolis) (top) and Shikani (Clarus Medical) (bottom).

airway, especially if mouth opening is limited. A relative contraindication is the presence of significant blood or oral secretions.

Procedure and Technique

The semirigid fiberoptic stylet can be used with or without DL. In either case, place the patient in the sniffing position. Load an ET tube onto a lightly lubricated stylet so that the ET tube extends 1 to 2 cm beyond the end of the stylet.

If the device is used alone, create an accentuated curve of between 70 and 80 degrees at the proximal aspect of the cuff of the tube so that it can negotiate the oropharynx. Suction the oropharynx well before attempting intubation. Grasp the mandible with the left hand. Next, raise the jaw to lift the tongue and epiglottis off the posterior hypopharyngeal wall. Ask an assistant to apply a jaw-thrust maneuver or grasp the tongue with gauze and retract it anteriorly. Place the device into the mouth, and while following the curve of the tongue, bring it up under the epiglottis with fiberoptic or video guidance. When the laryngeal inlet is visualized, direct the tip into the larynx. Advance the ET tube as you withdraw the stylet. If resistance is met while advancing the tube, the tip may be catching on the anterior larynx or trachea. Rotate the tube clockwise 120 degrees at the proximal end, which will result in a 90-degree rotation at the tip. With the bevel now anterior, allow the tube to advance without catching. It is important to remember that the direction of rotation of the ET tube is *clockwise* if resistance is encountered *after* going through the cords. For resistance encountered *before* the cords, such as occurs with tracheal tube introducers, fiberoptic scopes, and NT intubation, rotate the tube *counterclockwise*.

Semirigid optical stylets can be used with DL, either primarily or after encountering difficulty while using the device alone. With this approach, make the angle of the distal stylet less acute, at approximately 35 degrees, and introduce the device only after obtaining maximal visualization with the laryngoscope. If the epiglottis can be seen, advance the tip of the stylet just underneath it via direct vision. Be careful to not embed the tip of the ET tube in the supraglottic soft tissue because it will obscure visibility. At this point, guide the stylet–ET tube unit into the glottis and advance the tube off the stylet.

There have been no reported complications with semirigid fiberoptic stylets other than the failures or prolonged attempts usually related to poor visibility from blood and secretions.³⁰²

Summary

Semirigid fiberoptic stylets combine the features of direct and indirect laryngoscopy and provide a valuable tool when approaching a difficult airway. They can be used alone or in conjunction with a laryngoscope.

OROTRACHEAL INTUBATION WITH A KING LARYNGEAL TUBE (LT) OR COMBITUBE IN PLACE

King LT (Ambu, Ballerup, Denmark) airways are used extensively in the prehospital setting because they can be placed quickly and provide reliable oxygenation and ventilation in the vast majority of patients. It is common for patients to arrive to the ED with a King LT (or Combitube [Covidien/

Medtronic, Minneapolis, MN]) in place; almost all will need to have it replaced with an ET tube at some point. Intubation through the King LT devices is technically possible with fiberoptics or a bougie, but many who have tried this maneuver in clinical practice have been disappointed. The reason is that the aperture does not necessarily directly align with the glottis, even when the device is ventilating properly.³⁰⁵ In one study the glottis was visualized in only 51% of patients when a fiberoptic was passed through the King LT.³⁰⁶ The clinician has the choice of whether to remove the functioning retroglottic airway before attempting intubation, or to leave the device in place during intubation. An advantage of leaving the device in place is the maintenance of oxygenation and ventilation until just before the attempt begins, and the ability to reinflate the balloons and resume oxygenation immediately after a failed attempt, without having to replace the laryngeal tube.

DL with the King LT in place is difficult. In contrast, video laryngoscopy usually allows excellent visualization of the glottis and placement of an ET tube while the King LT remains in place (with the balloons deflated), and is a reliable method of securing the airway with a laryngeal tube in place.^{307,308} This approach allows providers to avoid the risk of removing a functional airway in a patient who may be difficult to intubate (Fig. 4.38).

To perform this procedure, use a video laryngoscope to obtain a view of the large proximal balloon. Deflate the balloons. The glottis will usually come immediately into view. If it does not, optimize the view using the laryngoscope; small adjustments (rotation or slight retraction) of the laryngeal tube may also be needed. Pass a bougie into the airway, and then have an assistant place an ET tube onto the bougie; intubate the trachea as described previously. Inflate the ET tube and confirm placement. After the tube is known to be in the trachea and patient is stable, remove the laryngeal tube.

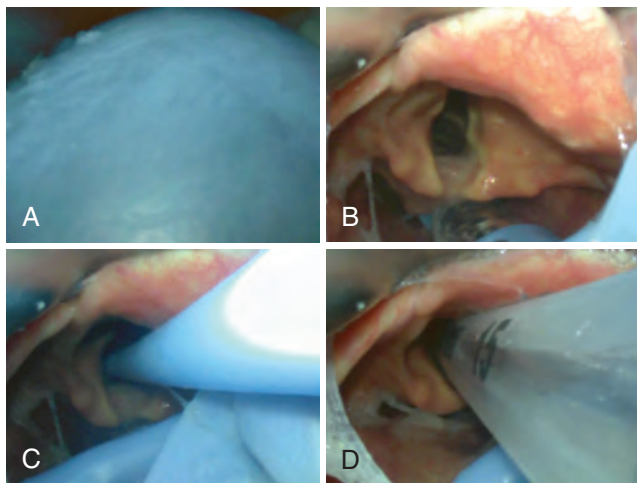

Figure 4.38 Tracheal intubation around a King LT (Ambu, Ballerup, Denmark) airway using video laryngoscopy. **A**, The laryngoscope is placed in the mouth and advanced until the large balloon comes into view. **B**, The balloon is deflated. Usually the glottis will immediately appear. If it does not, optimize the view by ensuring the laryngoscope blade is in the vallecula and engaged in the midline hyoepiglottic ligament. **C**, Pass a bougie into the trachea. **D**, The tube is passed over the bougie. After confirmation that the endotracheal tube is in the trachea, the King LT airway can be removed. If there is difficulty during the procedure, or if intubation is unsuccessful, inflate the King LT balloons and resume ventilation.

BLIND NASOTRACHEAL (NT) INTUBATION

Blind NT intubation can be one of the more technically demanding airway approaches, with the outcome being heavily dependent on the skill and experience of the clinician and a certain amount of luck. The primary advantage of the blind technique is that it minimizes neck movement and does not require mouth opening. In extenuating circumstances, it can be accomplished without an intravenous line.

NT intubation is technically more difficult than oral intubation, and it has definite advantages. Blind NT intubation is possible with the patient in the sitting position, a distinct advantage when intubating a patient with congestive heart failure who cannot tolerate lying flat. In fact, patients in respiratory distress are the easiest to intubate blindly because their air hunger results in increased abduction of the vocal cords, which facilitates entry of the tube into the trachea. Danzl and Thomas³⁰⁹ reported a success rate of 92% in a large series of ED patients, but success rates are highly dependent on clinician skill, and success is probably significantly lower in current practice because this technique is used less frequently than in decades past.

An NT tube has advantages that extend beyond the immediate difficulties of airway control. The patient cannot bite the tube or manipulate it with the tongue. Oral injuries may be cared for without interference from the tube. An NT tube is more easily stabilized and generally easier to care for than an orotracheal tube. It is better tolerated by the patient, permits easier movement in bed, and produces less reflex salivation than an orotracheal tube.

Indications and Contraindications

Patients requiring airway control who have spontaneous respirations can be considered for blind NT intubation. The typical patient is one with an anticipated difficult airway and persistently low oxygen saturation despite preoxygenation. Patients with severe chronic obstructive pulmonary disease (COPD) or asthma who have high airway pressures and may be difficult to ventilate with a face mask are another group to consider for NT intubation. Some other common examples of a difficult airway to consider for NT intubation are patients with short thick necks, trismus, neck immobility, and oral injuries. Other conditions that preclude successful orotracheal intubation include severe arthritis, fixed deformities of the cervical spine, or ACE inhibitor-induced angioedema.

Apnea is the major contraindication to blind NT intubation because attempts to place the tube without respirations as a guide are futile. Avoid nasal intubation in patients with severe nasal or midface trauma. In the presence of a basilar skull fracture, an NT tube may inadvertently enter the cranial cavity.^{310,311} Nasal intubation is also relatively contraindicated if the patient is taking anticoagulants, has a known coagulopathy, or has recently been or soon will be administered thrombolytics. Blind NT intubation should be avoided in patients with expanding neck hematomas and oropharyngeal trauma. If the patient has known abnormal glottic anatomy that would impede blind tube passage, other methods will probably be more successful. Patient combativeness, if not controlled with sedation, makes blind intubation difficult. Inability to open the mouth (such as a wired jaw) is a relative contraindication because emesis may be induced and it may be impossible to clear the vomitus; endoscopic guidance may be preferred to reduce the

risk of emesis. Exercise judgment in each individual case and be prepared to use neuromuscular blocking agents or to bypass the upper airway with a surgical technique if such a complication develops.

Procedure and Technique

Place the patient in the sniffing position with the proximal part of the neck slightly flexed and the head extended on the neck. Like endoscopic NT intubation, patient preparation is important. Apply phenylephrine drops, oxymetazoline (Afrin) spray, or 4% cocaine spray to both nares to dilate the nasal passages and reduce the risk of epistaxis. Topical anesthesia of the nares, oropharynx, hypopharynx, and larynx with lidocaine spray (4%) is also indicated if time permits (as described previously). If available, cocaine is ideal because it is both a vasoconstrictor and an anesthetic, but caution is necessary in hypertensive patients. Choose the most patent nostril. In a cooperative patient, simply occlude each nostril and ask the patient which naris is easier to breathe through. The most patent nostril can also be identified by direct vision or by gently inserting a gloved finger lubricated with viscous lidocaine into the nostrils. If time permits, pass a nasal airway first and allow it to remain in place to physically dilate the passage.

After preparation of the nostril, insert a well-lubricated 7.0- or 7.5-mm ET tube along the floor of the nasal cavity. Do not direct the tube cephalad, as one might expect from the external nasal anatomy, but rather direct it straight backward toward the occiput and along the nasal floor. Twist the tube gently to bypass any soft tissue obstruction in the nasal cavity. It is sometimes recommended that the tube's bevel be oriented toward the septum to avoid injury to the inferior turbinate. At 6 to 7 cm, one usually feels a "give" as the tube passes the nasal choana and negotiates the abrupt 90-degree curve required to enter the nasopharynx. This is the most painful and traumatic part of the procedure and must be done gently. If resistance persists despite continued gentle pressure and twisting of the tube, pass a suction catheter or endoscope down the tube and into the oropharynx to allow successful passage of the tube over the catheter.³¹² If this attempt fails, try the other nostril. To avoid this difficulty from the outset, use a controllable-tip tracheal tube (Endotrol, Mallinckrodt Medical, Inc., St. Louis). The tube allows you to increase the flexion of the tube, thereby facilitating passage beyond this tight curve. One study found that the Endotrol tube enhanced first-attempt success with blind NT intubation.³¹³ A study of paramedic-performed blind NT intubation reported success rates of 58% with standard ET tubes versus 72% with ET tubes with a directional controllable tip.³¹⁴

As the tube advances through the oropharynx and hypopharynx, it approaches the vocal cords, and breath sounds from the tube typically become louder. Fogging of the tube may also occur. At the point of maximal breath sounds, the tube is lying immediately in front of the laryngeal inlet. The tube is most easily advanced into the trachea during inspiration, when the vocal cords are maximally open. As the patient begins to breathe in, advance the tube in one smooth motion. If a cough reflex is present, the patient usually coughs and becomes stridorous during this maneuver, which suggests successful tracheal intubation. The absence of such a response should alert the clinician to probable esophageal passage. Remember that in adults, the average distance from the naris to the epiglottis is 16 to 17 cm; if the scope is advanced past this distance

and is not in the trachea, it is probably in the esophagus. If there is a delay in advancing the tube, consider adding oxygen to the end of the tube or providing supplemental oxygen to the mouth or other naris to increase the inspired oxygen concentration. Once the tube is in the trachea, vocalization should cease. Persistent vocalizations suggest esophageal intubation. Breath sounds coming from the tube and tube fogging are other signs of correct ET tube placement. Reflex swallowing during blind NT intubation may direct the tube posteriorly toward the esophagus. If this occurs, direct conscious patients to stick out their tongue to inhibit swallowing and prevent consequent movement of the larynx. Application of laryngeal pressure may also help avoid esophageal passage.

After intubation, auscultate over both lungs while applying positive pressure ventilation. If only one lung is being ventilated, withdraw the tube until breath sounds are heard bilaterally. The optimum distance from the external nares to the tip of the tube is approximately 28 cm in males and 26 cm in females.³¹⁵ After verification of tracheal placement, inflate the cuff and secure the tube.

Technical Difficulties

The NT tube may slide smoothly through the hypopharynx and into the trachea on the first pass. Unfortunately, such is not always the case; in an operating room series, the first attempt was successful in less than 50% of instances.³¹⁶ When the initial pass is unsuccessful, there are four potential locations of the tip of the tube: anterior to the epiglottis in the vallecula, on the arytenoids or vocal cords, in a piriform sinus, or in the esophagus.

Observation and palpation of the soft tissues of the neck during attempted passage of the NT tube are helpful in finding the misplaced tube. Before reattempting placement, withdraw the tube slightly. Do not remove it from the nose because this will create additional trauma to the nasal soft tissues. If cervical spine injury is suspected, avoid any cervical maneuver that moves the neck significantly. To move the ET tube in relation to the laryngeal inlet, it is important to know how the tip of the ET tube responds to head movements. Flexion of the neck will move the tip posteriorly; extension of the neck will move the tip anteriorly; rotation of the neck to the right and left will move the tip of the tube contralateral to the direction of rotation. Based on the suspected location of the tip of the tube, the following methods will help achieve success when difficulties with tube placement are encountered.

Anterior to the Epiglottis

Difficulty advancing the tube beyond 15 cm or palpation of the tip of the tube anteriorly at the level of the hyoid bone suggests an impasse anterior to the epiglottis in the vallecula. Withdraw the tube 2 cm, decrease the degree of neck extension, and readvance the tube.

Arytenoid Cartilage and Vocal Cord

Contrary to the classic teaching,³¹⁷ studies have demonstrated a propensity for an NT tube, when placed through the right nares, to lie posteriorly and to the right as it approaches the larynx.^{318,319} It is not surprising that the most common obstacles to advancement of the NT tube are the right arytenoid and the vocal cords. No data are available on common obstacles encountered if the tube is placed in the left nares. If the tube appears to be hanging up on firm cartilaginous tissue, withdraw

Figure 4.39 A common problem with blind tracheal tube passage through the larynx. **A**, The tip of the tube is caught on the arytenoid cartilage. **B**, Rotation of tube 90 degrees counterclockwise orients the bevel of the tip posteriorly and allows passage into the larynx. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

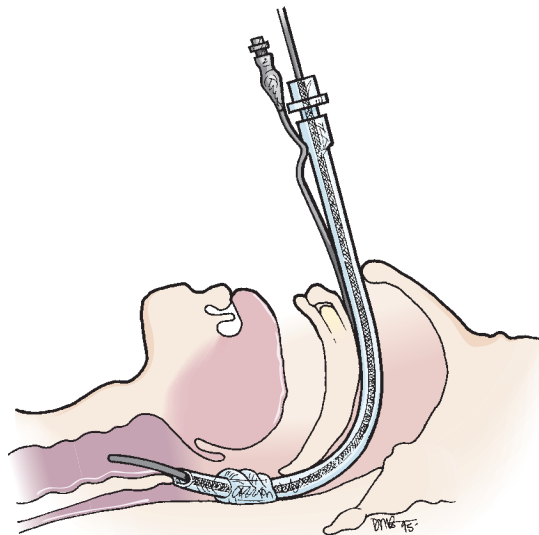

Figure 4.40 Use of suction catheter to aid in passage of a nasotracheal tube caught at the laryngeal inlet. The suction catheter is passed down the tracheal tube and into the trachea. The tracheal tube is then passed over the suction catheter, and the catheter is removed. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

the tube 2 cm, rotate it 90 degrees counterclockwise, and readvance it. This maneuver orients the bevel of the tube posteriorly and frequently results in successful passage (Fig. 4.39). When evaluated in the ED, this maneuver was successful 73% of the time.³²⁰ Another technique is to pass a suction catheter down the tube. It will often pass through the larynx without difficulty, and the tube can then be advanced over the catheter (Fig. 4.40).^{321,322}

Piriform Sinus

Bulging of the neck lateral and superior to the larynx indicates tube location in a piriform sinus. Withdraw the tube 2 cm, rotate it slightly away from the bulge, and then readvance it.

An alternative method is to tilt the patient's head toward the side of the misplacement and then reattempt placement.³²³

Esophageal Placement

Esophageal placement is indicated by a smooth passage of the tube and the loss of breath sounds through the tube. The larynx may be seen or felt to elevate as the tube passes under it. Assisted ventilation will usually produce gurgling sounds when the epigastrium is auscultated. Withdraw the tube until breath sounds are clearly heard, and reattempt passage while applying pressure to the cricoid. Increase extension of the head on the neck during placement. If attempts continue to result in esophageal misplacement, the following maneuver may result in successful tracheal intubation. From the precise point at which breath sounds are lost, withdraw the ET tube 1 cm and inflate the cuff with 15 mL of air, which results in elevation of the tube off the posterior pharyngeal wall, and can help angle the tube toward the larynx. Advance the tube 2 cm. Continued breath sounds indicate a probable intralaryngeal location. At this point, deflate the cuff and advance the ET tube into the trachea (Fig. 4.41). This technique may be particularly useful in patients with cervical spine injury because it requires no manipulation of the head or neck.³²⁴ This maneuver, when used on the first pass in 20 patients in the operating room, was successful in 75% of cases.³¹⁶ This maneuver can also be combined with the passage of a suction catheter after inflation of the ET tube cuff. The suction catheter will often pass easily into the trachea; the cuff can be deflated and the tube advanced into the trachea.

If a controllable-tip ET tube (Endotrol) is used, flex the tip anteriorly to help avoid esophageal placement.³¹³ Remember that the tip is very responsive to pulling on the ring. A common mistake is exerting too much force on the ring, which can result in the tube curling up before the larynx and preventing advancement. There has been a case report of an Endotrol tube “kinking” at the point of sharpest curvature and causing difficulty with suctioning but no problems with ventilation.³²⁵ Another device that allows flexion of the distal ET tube is the Parker Flex-Tip stylet (Parker Medical).

Laryngospasm

Laryngospasm is a common problem that arises when NT intubation is attempted. It is usually transient. Withdraw the tube slightly and wait for the patient's first gasp to advance the tube. This is frequently successful because the vocal cords are widely abducted during inhalation. Assess laryngeal anesthesia, and if topical and nebulized lidocaine has already been administered without success, consider transcricothyroid anesthesia (e.g., 2 mL of 4% lidocaine).³²⁶ Occasionally, a jaw lift is necessary to break prolonged spasm. Another option is to use a smaller tube.

Complications

Epistaxis is the most common complication of blind NT intubation. Severe epistaxis was encountered in only 5 of 300 cases reported by Danzl and Thomas.³⁰⁹ Tintinalli and Claffey³²⁷ reported severe bleeding in 1 of 71 patients and less serious bleeding in 12 others. Bleeding is not usually a problem unless it provokes vomiting or aspiration, which is a serious potential problem in obtunded patients with trismus or a decreased gag reflex. Other immediate complications include turbinate fracture, intracranial placement through a basilar skull fracture,

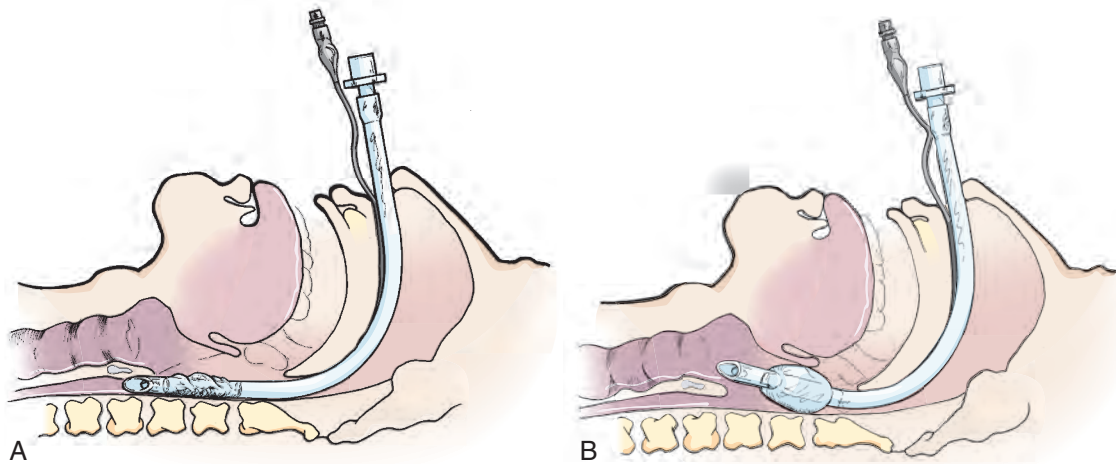

Figure 4.41 Much skill and a lot of luck are involved in successful blind nasotracheal intubation. Use of tracheal tube cuff inflation may aid in nasotracheal intubation. **A**, The tracheal tube is pulled back after passage through the esophagus. **B**, Once breath sounds are heard, the cuff is inflated with 15 mL of air and readvanced into the laryngeal inlet. Once seated in the inlet, the cuff is deflated and the tube advanced into the trachea. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

retropharyngeal laceration or dissection, and delayed or unsuccessful placement.^{310,328,329} Complications may be minimized by selecting a smaller tube and using a gentle technique.

Sinusitis in patients with an NT tube is common and can be an unrecognized cause of sepsis.³³⁰ Rare but potentially fatal delayed complications include mediastinitis after retropharyngeal abscess³³¹ and massive pneumocephalus.³³²

Because most complications occur during tube advancement through the nasal passage and proximal nasopharynx, the complications of blind NT intubation and placement under direct vision are largely the same. Retropharyngeal laceration and esophageal intubation are more of a threat with blind placement techniques because they are more likely to go unrecognized.³²⁷

Summary

Blind NT intubation is being used less frequently than in the past because clinicians are increasingly becoming comfortable performing oral intubation in patients with potential cervical spine injuries. In addition, emergency physicians frequently use paralytics to facilitate orotracheal intubation. Nevertheless, blind NT intubation remains an effective and potentially lifesaving approach to a difficult airway.

DIGITAL INTUBATION

Digital intubation uses the index and middle fingers to blindly direct the ET tube into the larynx. It is particularly well suited to the prehospital situation, such as when a trapped victim cannot be positioned for intubation. A prehospital series of 66 digitally intubated patients demonstrated an 89% success rate.³³³

Indications and Contraindications

Digital intubation is indicated in a deeply comatose patient whose larynx cannot be visualized and who has a contraindica-

tion to NT intubation. Digital intubation could be particularly helpful in situations with poor lighting, abnormal patient positioning (e.g., in an extrication situation), or when standard intubation equipment is unavailable or malfunctioning, and no other approaches are possible. Advantages include speed and ease of placement, immunity to constraints visualizing the larynx, and little neck movement. Contraindications are primarily precautions to protect the clinician. Digital intubation should not be attempted in any patient with a significant risk of biting. This includes calm, awake patients and agitated patients.

Procedure and Technique

Place the patient's head and neck in the neutral position. Stand at the patient's right side, facing the patient. Introduce your left index and middle fingers into the right angle of the patient's mouth and slide them along the surface of the tongue until the epiglottis is felt. The tip of the epiglottis should be palpated 8 to 10 cm from the corner of the mouth in average adults. Use of a stylet in the tube is optional, but the largest reported series had good success without a stylet.³³³ For a clinician with short fingers or a patient with an anterior larynx, a stylet is advantageous. If a stylet is used, place it in the tube and bend it into the form of an open J with the distal end terminating in a gentle hook. Introduce a lubricated tube from the patient's left side between the tongue and the rescuer's two fingers (Fig. 4.42). Cradle the tube between two fingers and guide the tip beneath the epiglottis. Apply gentle anterior pressure to direct the tube into the larynx. If the clinician has sufficiently long fingers, place them posterior to the arytenoids to act as a "backstop" for the tube, to both avoid esophageal passage and assist in laryngeal placement.³³⁴ If a stylet has been used, withdraw it at this time while simultaneously advancing the tube. An alternative to using a stylet for directing the tube anteriorly is to select an ET tube with a controllable tip (Endotrol, Mallinckrodt Medical, Inc., St. Louis).

A variation of the technique of digital intubation has been described for intubating a newborn.³³⁵ In this technique, only

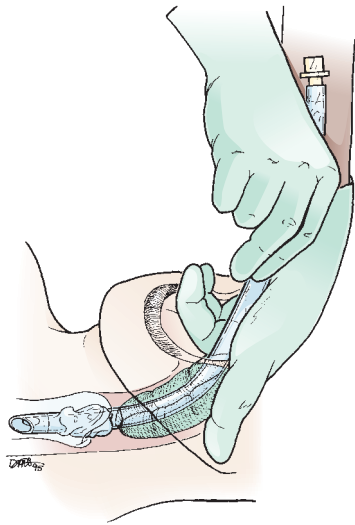

Figure 4.42 Digital intubation. The tracheal tube is cradled between the index and middle fingers and guided into the glottic opening. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

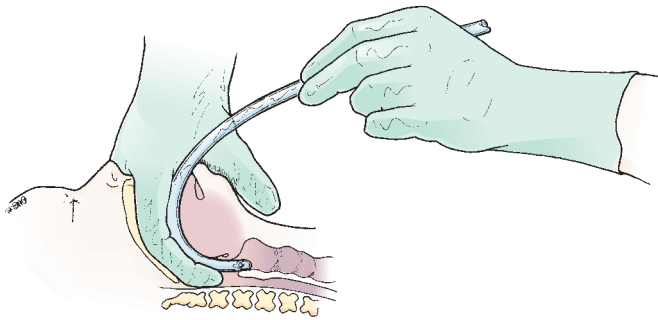

Figure 4.43 Digital intubation in a neonate. The tube is guided by using only the index finger to palpate the epiglottis and laryngeal inlet. A stylet is optional. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

the index finger is used to guide the tube into the larynx. Bend the end of the tube and moisten both the tube and the finger with sterile water. Use the index finger of the nondominant hand to follow the tongue posteriorly and palpate the epiglottis and paired arytenoids. Use the thumb of the same hand to apply cricoid pressure and steady the larynx. Hold the ET tube in the dominant hand and advance it with the nondominant index finger used as a guide (Fig. 4.43). The tube will encounter subtle resistance as it enters the trachea, and palpation of the tube through the trachea provides further confirmation of correct placement. A styletted tube, shaped in the form of a J, is usually desired until familiarity with the procedure is achieved.

Complications

The risk associated with esophageal intubation is always present, and the potential for esophageal misplacement is increased in comatose or cardiac-arrest patients. If used in patients with a gag reflex, induction of emesis with aspiration is a risk. A high incidence of left main stem intubation was noted in a cadaveric study,³³⁶ but clinical confirmation is lacking. The greatest risk seems to be to the clinician, whose fingers may be bitten.

Summary

Although the most recent experience with digital intubation in adults has been prehospital use, there is no reason why it should be confined to this setting. The majority of moribund ED patients who defy orotracheal intubation are never given a trial of digital intubation. This omission likely deprives some patients of expeditious airway management.

RETROGRADE INTUBATION

Retrograde orotracheal intubation is a technique of guided ET intubation that involves the use of a wire or catheter placed percutaneously through the cricothyroid membrane or high trachea and exiting through the mouth or nose. An ET tube is then passed over this guide and advanced through the vocal cords into the trachea. Introduced by Butler and Cirillo in 1960,³³⁷ the technique has undergone several recent modifications that have enhanced its value as a means of establishing a definitive airway when more conventional techniques have failed.

Indications and Contraindications

Retrograde intubation is indicated when definitive airway control is required and less invasive methods have failed. Indications include trismus, ankylosis of the jaw or cervical spine, upper airway masses or swelling, unstable cervical spine injuries, and maxillofacial trauma. It can be used to convert transtracheal needle ventilation (see Chapter 6) into a definitive airway. It was used successfully in a 1-month-old with developmental abnormalities.³³⁸ It can be particularly helpful in trauma patients with airway bleeding that prevents visualization of the glottis.³³⁹

Contraindications to retrograde intubation include the availability of a less invasive means of airway control and inability to open the mouth. If rapid control of the airway is needed, consider other alternate strategies including a cricothyrotomy because retrograde intubation takes several minutes to set up and perform. A relative contraindication is an apneic patient who cannot be effectively ventilated with a bag-valve-mask device. In this setting, it is advisable to first establish transtracheal needle ventilation (see Chapter 6) before attempting retrograde intubation or proceed directly to cricothyrotomy.

Equipment

Materials include (1) local anesthetic and skin preparation material, (2) an 18-gauge needle, (3) a 60-cm epidural catheter-needle combination or an 80-cm (0.88-mm diameter) spring guidewire (J tip preferred), (4) a hemostat, (5) long forceps (e.g., Magill) for grasping the wire in the pharynx, (6) an ET tube of appropriate size, (7) a syringe for the tube cuff, and (8) material for securing the tube. A prepackaged alternative is the Cook Retrograde Intubation Set (Cook Critical Care, Bloomington, IN), which also contains a sheath.

Procedure and Technique

Locate the three important anatomic landmarks by palpation: hyoid bone, thyroid cartilage, and cricoid cartilage. Prepare the skin overlying the cricothyroid membrane and anesthetize it. Maintain a cephalad orientation of the needle bevel, and

Retrograde Intubation

Indications

Need for a definitive airway when other methods have failed
Trismus
Ankylosis of the jaw or cervical spine
Upper airway masses
Unstable cervical spine fractures
Maxillofacial trauma

Contraindications

Availability of less invasive means of airway control
Inability to open the mouth
Need for rapid airway control

Complications

Hemorrhage
Subcutaneous emphysema
Soft tissue infection
Failure to achieve intubation

Equipment

Review Box 4.5 Retrograde intubation: indications, contraindications, complications, and equipment.

puncture the lower half of the cricothyroid membrane (Fig. 4.44). Direct the needle slightly cephalad. Aspirate air to confirm position of the tip of the needle within the lumen of the larynx. An alternative entry point is the high trachea, usually through the subcricoid space, with the same steps being used as described for the cricothyroid membrane.

Remove the syringe and pass the wire through the needle. Advance it until it is seen in the patient's mouth or until it exits the nose. A laryngoscope may facilitate this process. If the wire is found in the hypopharynx, grasp it with the Magill forceps and draw it out through the mouth. Remove the needle from the neck and secure the end of the wire at the puncture site with a hemostat. The next steps will depend on whether a plastic sheath, also referred to as an *obturator*, is available.

If no sheath is available, thread the oral end of the wire in through the ET tube side port (not the end of the tube), and advance it up the tube until it can be grasped with a second hemostat. Threading the wire through the side port allows the tip of the tube to protrude 1 cm beyond the point at which the wire enters the larynx. Pull the wire taut and move it back and forth to ensure that no slack remains. Advance the ET tube over the wire until resistance is met. This is the most critical point in the procedure. Because retrograde intubation is a blind technique, it may be difficult to determine whether the tube has entered the trachea or is impeded by more proximal structures. If the ET tube has successfully passed through the vocal cords and is being restricted by the guidewire as it traverses the anterior laryngeal wall, the clinician should feel some caudally directed tension on the wire at its laryngeal insertion point. If this does not occur, the tip of the ET tube may be proximal to the vocal cords, in the vallecula, in a piriform sinus, or abutting the narrow anterior aspect of the vocal cords. If in doubt, pull the tube back 2 cm, rotate it 90 degrees counterclockwise, and then readvance the tube. This will usually

result in successful passage through the larynx.³⁰⁰ When satisfied that the tube has entered the trachea, stabilize the tube and pull the guidewire out through the mouth. Then advance the tube farther into the trachea.

The classic method of retrograde intubation, as just described, has undergone modifications that facilitate passage of the ET tube through the glottis. A significant advance has been the addition of a plastic sheath that is passed antegrade over the wire until it meets resistance where the wire penetrates the laryngeal mucosa (see Fig. 4.42).³⁴⁰ This sheath needs to be stiff enough to effectively guide an ET tube, yet small enough to easily pass through the vocal cords without impinging on any supraglottic or glottic structures.

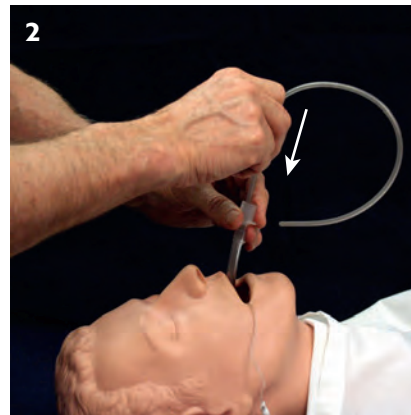

If a sheath is available, after grasping the wire from the mouth, thread the plastic sheath over the wire until it comes to rest against the anterior laryngeal wall. Withdraw the wire from the mouth and advance the sheath. Once the sheath is well within the trachea, pass the ET tube over the sheath. If any resistance at the arytenoids or vocal cords is encountered, pull the tube back 1 to 2 cm and rotate it 90 degrees counterclockwise. One advantage of the antegrade sheath is that it lies freely in the larynx, allowing more posterior passage through the widest distance between the cords. In contrast, the wire pulls the ET tube anteriorly toward the narrow commissure of the vocal cords and is more likely to result in impingement of the tube on the cords. In addition, use of the sheath permits unrestricted advancement of the ET tube, but a wire entering the larynx 1.0 to 1.5 cm below the vocal cords prevents the tube from advancing more than this distance before removal of the wire.

If no sheath is available, consider placing the needle inferiorly in the trachea, thereby increasing the distance that the ET tube can be advanced before being stopped by the wire.³⁴¹ This will decrease the likelihood of dislodging the tip of the ET tube when the guidewire is withdrawn.

Replacing a Malfunctioning Endotracheal Tube

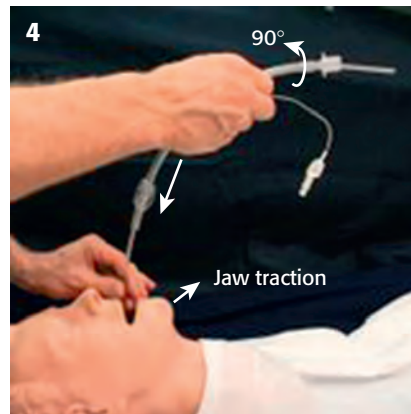

1 Preoxygenate and sedate the patient as clinically indicated. The procedure here is demonstrated with an 80-mm TTX tube exchanger (Hudson Respiratory Care).

2 Pass the tube exchanger through the defective ET tube deep into the airway.

3 Remove the defective tube and leave the tube exchanger in place as a guiding stylet.

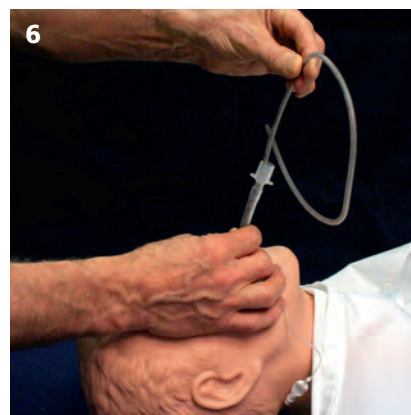

4 Pass a new ET tube over the tube exchanger and into the airway.

A 90° counterclockwise tube rotation and jaw traction will help the tube pass into the laryngeal inlet.

Use a laryngoscope to elevate soft tissues if necessary.

5 Place the ET tube into the trachea to the desired depth.

6 Remove the tube exchanger.

Confirm ET tube position.

Figure 4.44 Replacing a malfunctioning endotracheal tube

Complications

The complications of retrograde intubation are largely related to puncture of the cricothyroid membrane (see [Chapter 6](#)). The potential for hemorrhage is minimized by taking care to puncture the cricothyroid membrane in its lower half to avoid the cricothyroid artery. Subcutaneous emphysema may occur, but it is of no clinical significance because no air is insufflated during this technique. A small incidence of soft tissue infection is reported with translaryngeal needle procedures, and ensuring that the wire is withdrawn from the mouth rather than the neck can minimize this problem. The final complication, failure

to achieve intubation, has been mitigated by addition of the antegrade sheath over the wire.

Summary

Retrograde intubation is an underused technique for achieving tracheal intubation in a patient who cannot be intubated by less aggressive means. It is more invasive than fiberoptic intubation but requires less skill. Retrograde intubation usually takes several minutes to complete,³³⁴ and the patient can undergo BMV throughout much of the procedure. Recent modifications in the technique guarantee this method a prominent place in

the management of difficult airways, particularly when active bleeding compromises the airway.

CHANGING TRACHEAL TUBES

A tracheal tube with a leaking cuff is a vexing problem, especially if the original intubation was difficult. A method of replacing

the tube without losing control of the tracheal lumen is preferred. This can be achieved by passing a guide down the defective tube, withdrawing the tube while leaving the guide in place, and introducing a new tube over the guide and into the trachea (Fig. 4.45).

A number of different guides have been described (e.g., simple nasogastric tubes, 18-Fr Salem sump tubes, feeding tubes), and they are poor substitutes for a bougie. Tracheal

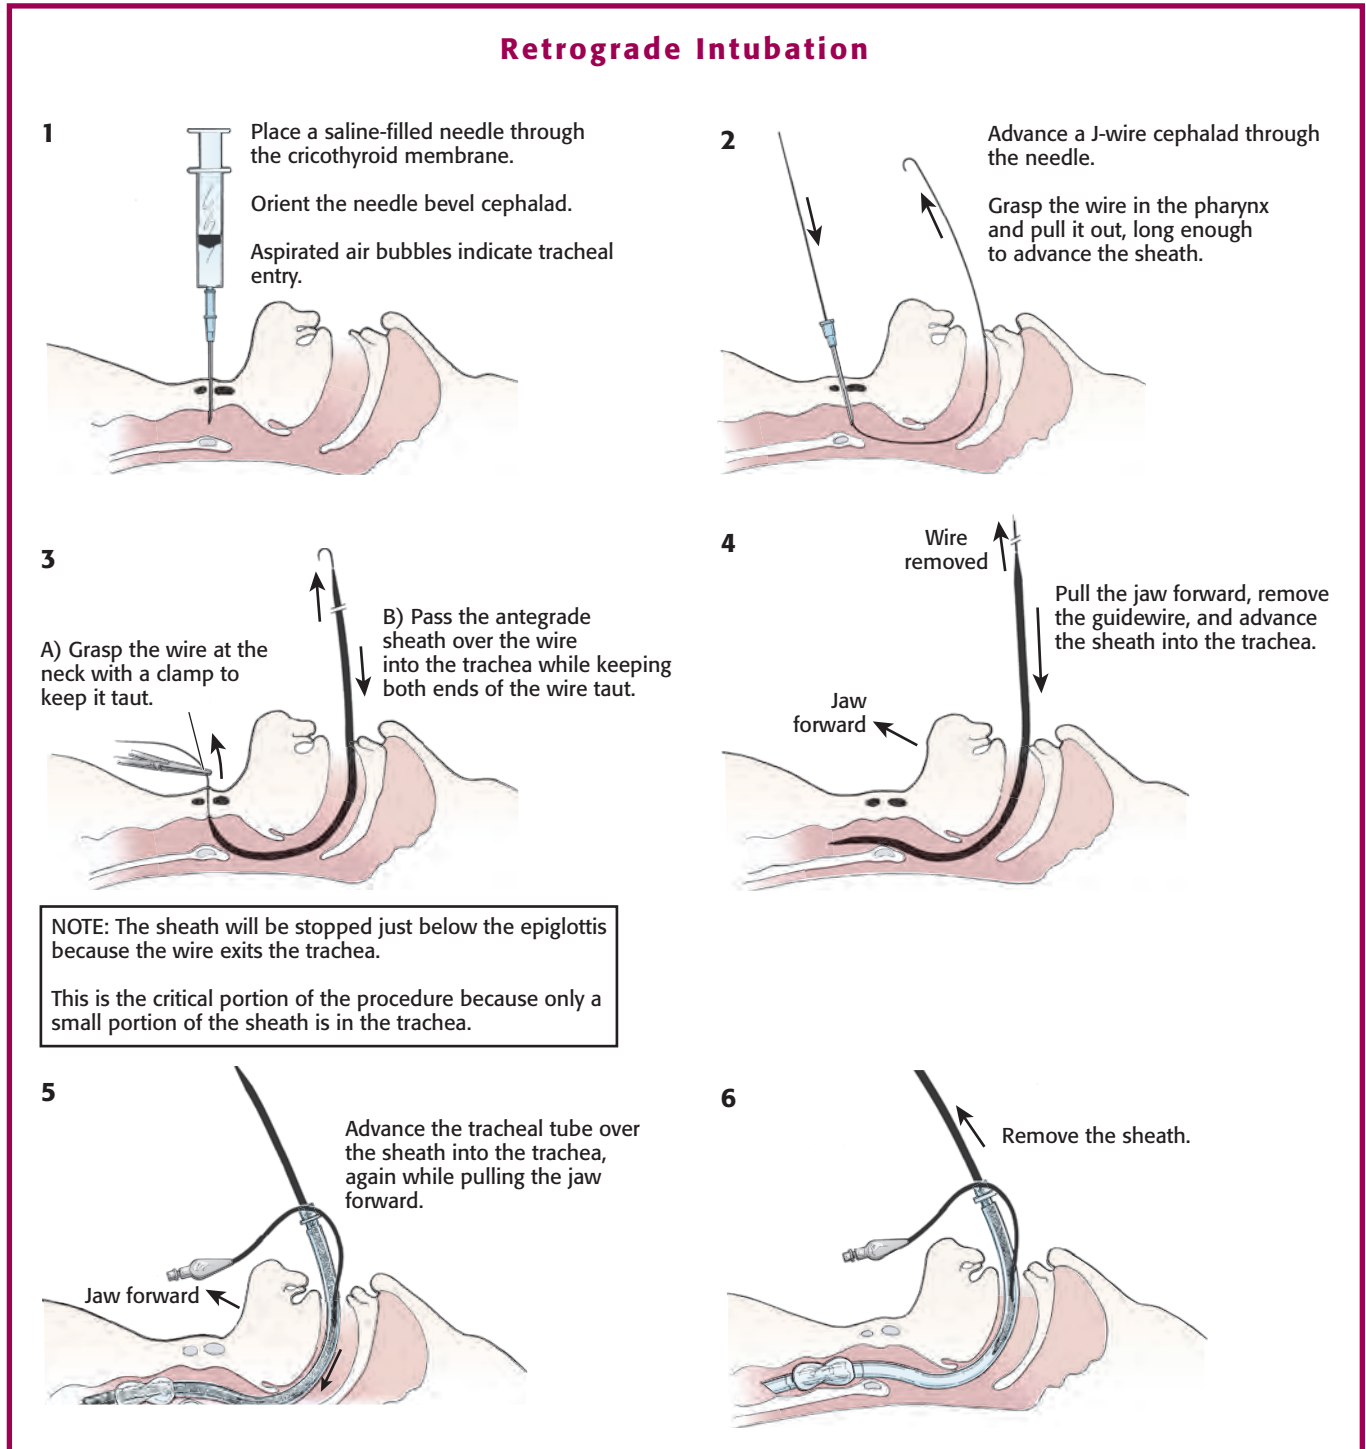

Figure 4.45 Retrograde intubation using a guidewire and antegrade sheath. (Courtesy Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis.)

tube exchangers are also available and can be used successfully for tube exchange, but are less stiff than a bougie. Bougies are generally easier to locate in the airway cart and intubators are more familiar with their use.

Advantages of using a bougie or tube exchanger include the following: they are long enough to allow deep placement within the airway while allowing easy exchange of the ET tubes, stiff enough to prevent dislodgment when the ET tube is introduced, and ready to use without modification.

Procedure and Technique

Before the procedure, sedate and restrain the patient properly. Preoxygenate the patient before placing the guide through the existing tube. Lubricate the guide and advance it into the defective tube so that it is well within the tracheal lumen (for adults, approximately 30 cm). While applying cricoid pressure, withdraw the defective tube over the guide, and take care to not dislodge the guide when removing the tube. Slide the replacement tube over the guide and gently advance it into the trachea. At this juncture, it may be helpful to perform a jaw-thrust or chin-lift maneuver to facilitate passage through the pharynx. Resistance may be encountered at the laryngeal inlet or vocal cords. If this occurs, withdraw the tube 1 to 2 cm, rotate it 90 degrees counterclockwise, and then readvance it. It may help to perform this step under direct vision with a video laryngoscope. After the tube is visualized clearly in the trachea, remove the guide, inflate the cuff, and ventilate the patient. After correct placement has been verified, secure the new tube.

Complications are related to the time required to change the tube. A successfully performed procedure can be accomplished within 30 seconds. Laryngeal injury from forcing the exchange guide or the new ET tube can occur, but this can be mitigated by not using excessive force during the procedure.

PREVENTING UNPLANNED EXTUBATION

Unplanned extubation is undesirable and can be medically disastrous if unrecognized or if the medical condition requires immediate reintubation. Not all extubations can be prevented. They most often occur when patients suddenly pull out their own tube or during transport. It is not uncommon for a deceased patient to arrive at the medical examiner with a tube in an incorrect position that was dislodged during transit. Unplanned extubation is best prevented with the use of physical and chemical restraints, aggressive sedation of intubated patients, and careful attention to the integrity of the ET tube during procedures, such as positioning for postresuscitation chest radiographs or transfer to another bed.

CONCLUSION

Emergency airway management in critically ill or injured patients with acute airway compromise is one of the greatest challenges for clinicians. Although the definition of a difficult airway will change as our ability to visualize the laryngeal inlet continues to improve, the challenge of emergency airways will persist. Mastery of the basics of airway management and DL, competency in a number of guided or indirect intubation techniques, and the ability to perform a surgical airway are all necessary skills for emergency airway management. Mastery of technique, advance preparation of equipment, and experience in clinical decision-making are essential. Scenario visualization and advanced simulation models can provide an excellent means of practicing the difficult decision making and technical maneuvers necessary for effective emergency airway management.

See Videos 4.1 to 4.21 for airway management procedures using various devices.

Pharmacologic Adjuncts to Intubation

Richard B. Schwartz and Daniel McCollum

Endotracheal (ET) intubation in the emergency setting presents a challenge distinct from that associated with intubation of fasted, premedicated patients in the operating room (OR). Patients in the emergency department (ED) are frequently uncooperative and unstable and may have medical problems or anatomic abnormalities that are completely unknown to the treating clinician. It is challenging that within a matter of minutes and with scant data the clinician must assess and control the airway while diagnosing and managing the patient's other life-threatening problems.

In 1979, Taryle and colleagues¹ reported that complications occurred in more than half the patients intubated in a university hospital ED. They called for improved house officer training in ET intubation, including “more liberal use of the procedures and agents used in the OR, including sedatives and muscle relaxers.”¹ Since this report, the use of neuromuscular blockade and rapid-sequence intubation (RSI) have become the standard for emergency medicine practice.^{2,3}

In addition to RSI, emergency physicians now use airway devices such as videoscopes and flexible fiberoptic bronchoscopes to manage difficult and complex airways. In high-risk patients it is increasingly common for awake intubation techniques to be utilized.⁴ This allows for the safe management of an emergent airway without the risk of completely eliminating the patient's airway reflexes. A related approach that has been described as *delayed-sequence intubation* has emerged in recent years.^{5,6} This technique may be considered as procedural sedation to allow preoxygenation prior to intubation. Both awake intubation and delayed-sequence intubation techniques have their own unique pharmacologic considerations. Clinicians must concentrate not only on the manual skills of airway management, but also on selection of the appropriate drugs to achieve specific objectives. These objectives include: (1) immediate airway control, including induction of unconsciousness and muscle paralysis; (2) analgesia and sedation in awake patients; (3) minimization of the adverse physiologic effects of intubation, including systemic and intracranial hypertension; and (4) prevention of harm during the postintubation period, including inadequate sedation, hemodynamic instability, or oversedation.

This chapter reviews the mechanisms and strategic use of the drugs that are currently available to facilitate intubation in the ED.

OVERVIEW OF RSI

The sequential process for quickly intubating a patient in an emergency situation is referred to as *rapid-sequence intubation*. The steps in performing RSI are often described by the six “P’s”: preparation, preoxygenation, pretreatment, paralysis and induction, placement of the tube, and postintubation manage-

ment (Fig. 5.1). This sequential technique of rapidly inducing unconsciousness (induction) combined with muscular paralysis to create optimal conditions for intubation has gained broad acceptance among ED clinicians. Many patients do not afford the clinician the time or opportunity to comply with the ideal scenario of tracheal intubation described in this chapter. RSI, as described in this chapter, is the ideal method of emergency airway management for intubations that are not anticipated to be difficult. Consider awake techniques of intubation in high-risk patients with airways that are anticipated to be difficult.

Preparation occurs before and during preoxygenation. Assess the airway to determine the likelihood of a difficult intubation. Simultaneously, establish an intravenous (IV) line and connect the patient to cardiac, pulse oximetry, and end-tidal CO₂ monitors when available. Assemble all necessary drugs and equipment for oral intubation and the desired backup equipment for airway management.

Begin RSI preoxygenation as soon as possible by administering 100% oxygen. The intent is to displace nitrogen from the lungs and replace it with an oxygen reserve that will last several minutes. Under optimal conditions, breathing 100% oxygen for 3 minutes has been demonstrated to maintain acceptable oxygen saturation for up to 8 minutes in previously healthy apneic individuals.⁷ Another method is to give four vital capacity (maximal) breaths of 100% oxygen from a face mask, which can also maintain acceptable saturation for 6 minutes.⁷ Comparable results may not be extrapolated to the ED setting because of differences in the underlying health and cooperation of the patient population.

A recent advance in preoxygenation of patients prior to intubation is the Nasal Oxygenation During Efforts Securing A Tube (NO DESAT) technique.⁸ In the NO DESAT technique a nasal cannula is placed underneath the non-rebreather face mask. In awake patients, the nasal cannula can be comfortably set to 5 L/min of oxygen. After induction agents are given, this can be safely increased to 15 L/min of oxygen. The nasal cannula may be left on throughout the attempt to intubate, as it will not interfere with the ability to place an orotracheal tube. This has the potential to prolong the time to desaturation, but clinical studies of this technique's application in the ED are currently lacking.

Pretreatment consists of the administration of medications to mitigate the potential untoward responses to intubation. Pretreatment during RSI usually occurs 2 to 5 minutes before induction of unconsciousness or muscular paralysis. Although preoxygenation should be maintained for as long as practical before beginning intubation, the ideal situation and circumstances are not always present, and clinical judgment is the deciding factor for this portion of RSI. The clinical utility of routine pretreatment to improve patient-oriented outcomes in ED RSI has been challenged.⁹

Paralysis and induction involve the induction of a state of unconsciousness with a sedative agent, followed immediately by muscle paralysis. A protocol for ED-based RSI is summarized in Box 5.1.

ET intubation and RSI have also expanded beyond the ED into the prehospital setting. Prehospital RSI protocols use a sedative plus a paralytic for patients not in cardiac arrest, with success rates as high as 92% to 98%.¹⁰⁻¹⁴ Without a full complement of medications, prehospital intubation becomes significantly more difficult, and success rates drop to approximately 60%.¹⁵ Rates of misplaced ET tubes and complications by

Rapid-Sequence Intubation: The 6 “P’s”

1 Preparation

Preparation occurs prior to and during oxygenation. Assess the airway for difficulty. Establish an IV line, place the patient on the monitors, and assemble all required medications and equipment.

2 Preoxygenation

Begin RSI preoxygenation as soon as possible by placing the patient on 100% oxygen. Oxygen will displace nitrogen from the lungs and provide an oxygen reserve that will last several minutes.

3 Pretreatment

Consider pretreating with medications such as lidocaine, atropine, and/or fentanyl (depending on the clinical scenario) 2 to 3 minutes prior to induction and paralysis.

4 Paralysis and induction

Administer a sedative agent to induce loss of consciousness (induction). After induction, administer a paralytic agent to achieve muscle relaxation, which greatly facilitates intubation.

5 Placement of the tube

Once the patient is sedated and paralyzed, place the endotracheal tube. Intubation techniques are reviewed in Chapter 2.

6 Postintubation management

Confirm proper tube position with an end tidal CO₂ detector, auscultation, and chest radiograph. Assess for adequate tissue oxygenation and response to previously administered drugs.

Figure 5.1 The 6 “P’s” of rapid-sequence intubation. *IV*, Intravenous; *RSI*, rapid-sequence intubation.

BOX 5.1 Rapid-Sequence Intubation Protocol

1. Preoxygenate (denitrogenate) the lungs by providing 100% oxygen by mask. Apply nasal cannula at high flow at this time if using nasal cannula for apneic oxygenation.
2. Assemble the equipment required:
 - Bag-valve-mask device connected to an oxygen delivery system.
 - Suction with a Yankauer tip.
 - ET tube with an intact cuff, stylet, syringe, and tape.
 - Laryngoscope and blades, in working order.
 - Backup airway equipment.
3. Check to be sure that a functioning, secure intravenous line is in place.
4. Continuously monitor cardiac rhythm and oxygen saturation.
5. Premedicate as appropriate:
 - Fentanyl: 2 to 3 $\mu\text{g}/\text{kg}$ given at a rate of 1 to 2 $\mu\text{g}/\text{kg}$ per min intravenously.
 - Atropine: 0.01 mg/kg by intravenous push for children or adolescents.
 - Lidocaine: 1.5 to 2 mg/kg intravenously over a period of 30 to 60 seconds.
6. Induce anesthesia with one of the following agents administered intravenously: ketamine, etomidate, fentanyl, midazolam, or propofol.
7. Give succinylcholine, 1.5 mg/kg by intravenous push (use 2 mg/kg for infants and small children) or rocuronium 1.2 mg/kg.
8. Apnea, jaw relaxation, and/or decreased resistance to bag-mask ventilation (use only when oxygenation before rapid-sequence intubation cannot be optimized by spontaneous ventilation) indicates that the patient is sufficiently relaxed to proceed with intubation.
9. Perform ET intubation. If unable to intubate during the first 20-second attempt, stop and ventilate the patient with the bag-mask device for 30 to 60 seconds. Monitor pulse oximetry readings as a guide.
10. Treat bradycardia occurring during intubation with atropine, 0.5 mg by intravenous push (smaller dose for children; see item 5).
11. Once intubation is completed, inflate the cuff and confirm ET tube placement by auscultating for bilateral breath sounds and checking the pulse oximetry and capnography readings. Ultrasound for lung sliding on both sides may be a useful adjunct.
12. Secure the ET tube.

ET, Endotracheal.

paramedics may be much higher than previously reported.^{16,17} Studies indicate that outcomes may be worse for patients with traumatic brain injury intubated in the prehospital setting than in the ED.¹⁸ For these reasons many prehospital systems have moved away from the use of RSI.

The technique for proper ET tube placement is discussed in Chapter 4. Postintubation monitoring should assess for proper tube placement, adequate tissue oxygenation, and response to previously administered drugs. After laryngoscopy, ensure ongoing analgesic and anxiolytic therapy.

PRETREATMENT: PREVENTING THE COMPLICATIONS OF INTUBATION

Numerous reports have highlighted the physiologic responses to tracheal intubation and attempted to define their immediate or long-term adverse effects and to offer interventions to ameliorate potential organ injury. It is certain that intubation and adjunctive medications have the potential to alter reflexes, intracranial pressure (ICP), blood pressure, and pulse rate, and may induce disturbances in cardiac rhythms, but the actual clinical consequences of these commonly observed changes are largely unknown. Clinical experience suggests that most transient alterations in physiology occurring with ED intubation produce no specific or readily documented long-term sequelae, or are often consequences that cannot easily be monitored or prevented. Prudent clinicians are aware of the potential adverse effects of intubation and are cognizant of potential methods to minimize them. Careful monitoring of the postintubation condition will guide specific interventions.

Overzealous attempts to suppress the physiologic responses that normally accompany airway manipulation may be counterproductive. It would be desirable to provide airway control under the best of circumstances and with the least amount of injury to the patient, but the ideal approach to the physiologic responses to intubation is simply unknown. Most information has been extrapolated from experimental animal models or from the anesthesia experience and similar issues may not apply to the milieu of the ED experience. It is critical to prevent hypotension and hypoxia during intubation, particularly in those with neurologic injury.¹⁹ Patients that theoretically would benefit the most from pretreatment medications are those that may be least able to tolerate any delay in obtaining a definitive airway. The following discussion serves as a general clinical guide to alterations in the physiologic response to intubation.

The Pressor Response

In addition to the ubiquitous sinus tachycardia, a number of dysrhythmias have been reported after intubation. They are primarily ventricular in origin and include ectopic beats, bigeminy, and short runs of ventricular tachycardia. No studies have established a direct relationship between the response and subsequent clinical deterioration in a large patient population. It is also unclear whether attenuation of the pressor response prevents dysrhythmias or electrocardiographic evidence of ischemia. Ideally, it would be desirable to avoid sudden increases in blood pressure in unstable patients with acute cardiac or vascular disease. Unfortunately, it is unclear if outcomes are improved by attempting to mitigate the pressor response.²⁰

Multiple medications have been evaluated to attempt to reduce the pressor response. Lidocaine has been the most extensively evaluated, but it has not been shown to improve outcomes.²⁰ A dose of 1.5 to 2 mg/kg may slightly reduce the heart rate or blood pressure increase caused by intubation.²¹ One small trial demonstrated that nebulized tetracaine reduced increases in heart rate during intubation, but this is not commonly done in emergency practice.²² Fentanyl dosed at 2 to 5 $\mu\text{g}/\text{kg}$ is likely to be more effective at blunting the pressor response than lidocaine.^{23,24} Fentanyl will be discussed in more detail later, in relation to its possible benefit in preventing increases in ICP.

Lidocaine and fentanyl are the drugs with the largest evidence base supporting their use to decrease the pressor response. Other drugs, including thiopental, sodium nitropruside, labetalol, nitroglycerin, verapamil, nifedipine, clonidine, fentanyl, sufentanil, etomidate, and magnesium, have shown variable responses.^{25–28} In light of the uncertainty of the benefit of any premedication in improving patient outcomes, these other medications cannot be recommended for routine use. In patients at very high risk for harm by transient increases in heart rate or hypertension (such as those experiencing hypertensive emergency or having an active myocardial infarction), it would be reasonable to consider fentanyl or lidocaine. Given the lack of patient-oriented outcomes in the available literature, it is also very reasonable to not premedicate these patients and proceed with intubation without delay.

Hypotension

A more pressing concern for the majority of patients intubated in the ED is the importance of avoiding hypotension. Post-intubation hemodynamic instability occurs in over 10% of emergency intubations.²⁹ Unlike the uncertainty regarding patient harm as a result of transient hypertension, transient hypotension is associated with poor patient outcomes.³⁰ This is of even higher concern in patients with known or suspected traumatic brain injury.³¹

Avoid hypotension by initiating adequate resuscitation prior to attempts at intubation. If the patient's clinical condition permits, pursue appropriate volume resuscitation with blood in actively bleeding patients and fluids in hypovolemic patients prior to intubation. Even relatively hemodynamically stable drugs, such as etomidate, may contribute to hypotension in critically ill patients by reducing the endogenous catecholamine response.^{32,33} The physiologic changes that contribute to hypotension following intubation include both the reduced venous return from positive pressure ventilation and the effects of medications given during intubation. It is a challenge to balance the need for airway control and the need to adequately resuscitate prior to intubation.

Once hypotension has occurred during or after intubation, the fastest way to correct this is with the use of vasopressors. If time permits clinically, it is advisable to start vasopressors prior to attempting to intubate if a patient is already hypotensive. Due to the necessary delays in setting up a vasopressor through a pump, there has been recent increased attention to the use of push-dose vasopressors to treat peri-intubation hypotension (Box 5.2 and Fig. 5.2).^{34–36} Further details about how to mix a dilute solution of vasopressor for this purpose will be provided later. It is certainly reasonable to administer temporary vasopressors for this purpose through a peripheral IV line to avoid further delays in intubation to place a central line.³⁶ Although currently we lack patient-oriented data on whether push-dose pressors improve outcomes in hypotensive patients, the clear harm of even transient hypotension makes the use of these agents a reasonable approach until additional data is generated.

Intracranial Hypertension

Stimulation of the respiratory tract by maneuvers such as laryngoscopy, tracheal intubation, and ET suctioning is commonly associated with a brief rise in ICP. The exact mechanism responsible for this rise is unknown. One potential mechanism is the coughing and gagging that frequently follow manipulation

BOX 5.2 How to Make Push-Dose Epinephrine

1. Gather materials: 10 mL saline flush, blunt-tip needle, and 10-mL syringe of 1:10,000 epinephrine from code cart (Fig. 5.2A).
2. Waste 1 mL of saline flush into sink (Fig. 5.2B).
3. Draw up 1 mL of epinephrine into flush syringe using the blunt tip. This creates a 1:100,000 mixture of epinephrine (Fig. 5.2C).
4. Shake vigorously after drawing a little air into syringe to evenly mix (Fig. 5.2D).
5. Clearly label syringe as 1:100,000 epinephrine. This syringe must be clearly labeled to avoid unintentional bolus of 0.1 mg of epinephrine if someone mistook it for a regular saline flush (Fig. 5.2E).
6. Administer 1 mL to 2 mL of this 1:100,000 epinephrine every 2 to 5 minutes IV as needed for hypotension. This medication is dilute enough to be reasonably safe even if it extravasates, as this is the same concentration of epinephrine found in standard lidocaine with epinephrine syringes.

of the upper airway and subsequent transmission of intrathoracic pressure to the cerebral circulation. An alternative explanation is the release of catecholamines that accompanies laryngoscopy, which causes a rise in mean arterial pressure and cerebral perfusion pressure. A small rise in ICP has been reported after the administration of succinylcholine. The value of pretreatment with defasciculating doses of neuromuscular blockers (NMBs) to prevent rises in ICP is unknown.³⁷

Although the exact significance of a transient rise in ICP is not known, it is possible that it may be detrimental in patients with head trauma or intracranial hypertension. This theoretical harm comes from a possible reduction in cerebral blood flow if a rise in intracranial hypertension is not compensated for by a rise in systemic blood pressure. A number of drugs, including lidocaine, succinylcholine, and the majority of anesthesia induction agents, have been studied to determine whether their use prevents this response. Many of the existing clinical data are not particularly relevant to the ED setting because they are derived from patients in various stages of general anesthesia, during which a wide variety of drug combinations and doses are utilized.

Good evidence suggests that deep general anesthesia prevents the rise in ICP associated with intubation. Depending on the drug used, anesthesia may compromise cardiovascular performance and critically reduce cerebral blood flow.³⁸ The ideal anesthetic agents to facilitate intubation of patients with acute intracranial pathology may be those that have minimal effects on cardiovascular performance, such as etomidate or fentanyl. Etomidate has been demonstrated to prevent changes in both cerebral perfusion pressure and ICP after tracheal intubation of patients with space-occupying intracranial lesions.³⁹

Fentanyl is perhaps the agent with the best evidence supporting its use in prevention of increased ICP during intubation.^{19,23,24} The dose is 2 to 5 µg/kg, and is higher than dosages typically used for other indications of fentanyl. To be effective, this dose must be given well before intubation, preferably at least 3 minutes prior to intubation.⁴⁰

Ketamine is traditionally contraindicated in patients with head injuries, but this has come into question.³² Whereas there may be minimal increases in ICP with ketamine, this effect is

Figure 5.2 How to make push-dose epinephrine (see Box 5.2).

offset by a rise in systemic blood pressure. This appears to preserve cerebral blood flow and may in fact be cerebroprotective.⁴¹ There are no current studies that have demonstrated poor patient outcomes due to the use of ketamine in critically ill patients.⁴²

Atropine for Prevention of Bradycardia

Bradycardia is not infrequent during intubation, especially in young children and neonates. Traditionally, premedication with atropine has been advocated to reduce the incidence of bradycardia.⁴³ A dose of 0.01 mg/kg given intravenously is the standard dose for premedication. While there may be a slight decrease in the incidence of bradycardia with this medication,

patient-oriented outcomes have not been proven to benefit.^{40,43} It is not unreasonable to use atropine only in response to bradycardia, as opposed to using it as a premedication.

Bronchospasm

Patients with reactive airway disease may have further bronchospasm during the process of intubation. Lidocaine has traditionally been used to decrease the incidence of bronchospasm in asthma patients who require intubation. A dose of 1.5 to 3 mg/kg given intravenously has been advocated.²⁰ This medication has not been proven to reduce the incidence of bronchospasm, but nebulized albuterol has been shown to be of benefit.⁴⁴

At the present time, the clinical consequences of intubation-induced physiologic changes are not thoroughly understood. The role of drugs in preventing these changes is equally unclear. Despite this lack of data, it may be intuitively reasonable to attempt to protect patients at theoretical risk. The approach outlined in [Box 5.3](#) is recommended.

INDUCTION AGENTS

After premedication, a sedative agent is used to induce loss of consciousness. A number of diverse drugs are available in the

BOX 5.3 Sample Protocol for Intubation of a Head-Injured Adult Patient

1. Preoxygenate with 100% O₂ for 2 to 3 minutes.
2. Administer lidocaine, 1.5 to 2 mg/kg intravenously.
3. Sedate with fentanyl, 3 to 5 µg/kg.
4. Induce anesthesia with etomidate, 0.3 mg/kg.
5. Paralyze with succinylcholine, 1.5 mg/kg or rocuronium 1.2 mg/kg.
6. Perform intubation.
7. Maintain postintubation analgesia and sedation.
8. Maintain paralysis if indicated (vecuronium, 0.1 mg/kg).

"The benefit of this traditional protocol is unproved but can be supported if contraindications do not exist.

BOX 5.4 Recommendations for Sedation of Patients Undergoing Rapid-Sequence Intubation in Specific Circumstances

The most appropriate medications for sedation before rapid-sequence intubation are based on evaluation of the clinical scenario, and no specific recommendations are appropriate for all circumstances. Different situations, too complex to list here, lend themselves to the use of certain agents (see text). There are no specific standards that must be followed, and the medical literature can be confusing, contradictory, or inadequate. The following conditions and sedation agent recommendations may guide the clinician. Note that appropriate paralytic drugs should also be used.

HEAD INJURY OR POTENTIALLY ELEVATED INTRACRANIAL PRESSURE

Pretreatment with the various medications described in the text are appropriate but of unproven value. Adequate cerebral perfusion pressure should be maintained to prevent secondary brain injury. Etomidate is suggested for induction of these patients, but ketamine is also likely to be safe in this population. For hypotensive patients, etomidate or ketamine may be used.

STATUS EPILEPTICUS

Midazolam or thiopental may be used for induction. Reduced doses should be used in the unusual circumstance of seizure with hypotension. Midazolam may be used for induction in those with adequate blood pressures. Ketamine and propofol may also be used for induction as they may have some antiepileptic properties.

ED to induce unconsciousness before intubation, including barbiturates, benzodiazepines, etomidate, ketamine, opiates, and propofol. The choice of a particular induction agent depends on the experience and training of the clinician, the patient's clinical status, drug characteristics, and institutional protocols ([Box 5.4](#)). Considerable evidence indicates that the selected sedative agent influences the quality of intubation conditions and the rapidity of their attainment. These effects persist even when paralytic agents are used. Commonly used drugs and their doses are summarized in [Table 5.1](#).

Etomidate

Etomidate is an ultrashort-acting nonbarbiturate hypnotic agent that has been used successfully as an anesthesia induction agent in Europe since the mid-1970s and in the United States since 1983. A significant benefit of etomidate in the emergency setting is its lack of cardiodepressant effects.^{45,46} Several case series have now demonstrated its safety and effective use in ED RSI.^{47,48} Extensive experience with this agent now exists in both pediatric⁴⁹ and adult patients, and it is an agent of choice for most ED intubations.

Etomidate is a carboxylated imidazole that is both water and lipid soluble. The drug reaches peak brain concentrations within 1 minute of IV infusion⁵⁰ and induces unconsciousness within 30 seconds of administration. Its effects last less than 10 minutes after a single bolus dose.¹⁵ Redistribution of the drug is quite rapid, which accounts for its short duration of action. Etomidate is rapidly hydrolyzed in the liver and plasma and forms an inactive metabolite excreted primarily in urine.⁵⁰

HEMODYNAMICALLY STABLE PATIENT WITH SEVERE BRONCHOSPASM

Induction with ketamine or propofol is suggested. Etomidate and midazolam are acceptable alternatives. In hemodynamically unstable patients with severe bronchospasm, ketamine is suggested. Thiopental should not be used in these patients because it provokes release of histamine and can induce or exacerbate bronchospasm.

PATIENTS WITH CARDIOVASCULAR COMPROMISE

Etomidate is suggested because of the hemodynamic stability that it provides. If the patient is in shock or severely hypotensive, ketamine and/or etomidate are suggested. If etomidate is used in a patient with sepsis who has associated hypotension refractory to treatment with fluid resuscitation and a vasopressor, a single dose of hydrocortisone (100 mg intravenously) may be given (value unproven).

FOR AN "AWAKE LOOK" BEFORE INTUBATION OR DELAYED-SEQUENCE INTUBATION

Ketamine is suggested, but it may not be appropriate when these patients have cardiovascular disease or hypertension.

Adapted from Caro D, Walls RM, Grayzel J: Sedation or induction agents for rapid sequence intubation in adults. <https://www.scribd.com/document/72424186/Sedation-or-Induction-Agents-for-Rapid-Sequence-intubation-in-Adults>.

TABLE 5.1 Recommended Anesthetic Dosing for Rapid-Sequence Intubation and Clinical Considerations

DRUG ^a	DOSE	PREFERRED IN	AVOID IN
Thiopental	3–5 mg/kg IV	↑ ICP, SE	Hypotension, RAD
Methohexital	1–1.5 mg/kg IV	↑ ICP, SE	Hypotension, RAD
Fentanyl	5–15 µg/kg IV		
Midazolam	0.1–0.3 mg/kg IV	SE	Hypotension
Ketamine	1–2 mg/kg IV	RAD, Hypotension	
Etomidate	0.3 mg/kg IV	Hypotension	Sepsis (unclear)
Propofol	2 mg/kg IV	↑ ICP, SE	Hypotension

^aAny of these can drugs be used before the administration of a neuromuscular blocking agent to induce anesthesia (see text).

ICP, Intracranial pressure; IV, intravenous; RAD, reactive airway disease; SE, status epilepticus.

The recommended dose is 0.3 mg/kg via rapid IV bolus. There is virtually no accumulation of the drug, and anesthesia may be maintained through repeated doses; however, etomidate should not be used as an infusion or in repeated bolus doses for maintenance of sedation after intubation in the ED.⁵¹

Etomidate acts on the central nervous system (CNS) by stimulating γ -aminobutyric acid (GABA) receptors and depressing the reticular activating system. It produces electroencephalographic changes similar to those produced by barbiturates as patients pass rapidly through light to deep levels of surgical anesthesia. Because etomidate has no analgesic activity,⁵⁰ it should be used in conjunction with a parenteral analgesic when painful conditions are being treated, although it is most commonly used as a sole induction agent for intubation. Etomidate decreases cerebral oxygen consumption, cerebral blood flow, and ICP but appears to have minimal effects on cerebral perfusion pressure.³⁹ Etomidate is characterized by hemodynamic stability without significant changes in mean arterial pressure,^{46–48} although a slightly increased heart rate may be observed.⁵¹ Etomidate is suggested for induction of patients with significant cardiovascular disease requiring RSI. The hemodynamic stability that it provides and the absence of induced hypertension make it preferable to other sedatives. This hemodynamic stability persists even in patients with preexisting hypotension.⁵² The most common immediate side effects of etomidate are pain at the site of injection, nausea, vomiting, and rather common myoclonic jerks.⁵³ Pain on injection is reported in up to two thirds of patients, although the clinical significance of this transient discomfort immediately prior to intubation is unclear. Use of a large vein, simultaneous saline infusion, and opioid premedication can reduce the discomfort in appropriate situations.⁵⁴ Myoclonic activity has been reported in approximately one third of cases and is believed to be caused by disinhibition of subcortical activity rather than CNS stimulation and does not represent seizure activity.⁵⁰ This

sometimes dramatic effect can be avoided through the use of NMBs and is rarely seen in the ED, where paralytic agents are regularly used with RSI. No treatment of myoclonus is necessary, and it is of no clinical significance. If persistent, an IV benzodiazepine may be administered. Etomidate need not be avoided in patients with seizure disorders, status epilepticus, head injury, or stroke.

Some degree of altered adrenal function has been demonstrated even after a single dose of etomidate.^{55,56} The true clinical effect is unknown, and because the alteration in adrenal function appears to persist for 12 to 24 hours, there is theoretical concern about potential clinical consequences. Etomidate is a reversible inhibitor of 11 β -hydroxylase, the enzyme that converts 11-deoxycortisol to cortisol. Although cortisol levels do not fall below the normal physiologic range, even a single induction dose of etomidate causes a measurable decrease in the level of circulating cortisol that occurs in response to the administration of exogenous adrenocorticotropic hormone (ACTH).

A substudy of the Corticosteroid Therapy of Septic Shock (CORTICUS) trial evaluating the use of hydrocortisone in septic shock provided further evidence about the safety of the use of etomidate in patients with sepsis. There was a statistically significant increase in mortality (42.7% versus 30.5%) for those that received etomidate.⁵⁷ Unfortunately, this effect was not diminished by the administration of hydrocortisone. In a separate study that compared etomidate with ketamine, a multicenter randomized trial of critically ill patients requiring emergency intubation found no significant difference in organ failure score, 28-day mortality, or intubating conditions between patients given etomidate for induction and those given ketamine.⁵⁸ No serious, drug-related adverse events were reported with either medication. Even though adrenal insufficiency occurred at a higher rate in the etomidate group (86%), it also developed in approximately 48% of patients receiving ketamine. A Cochrane metaanalysis that reviewed eight studies found no conclusive evidence that a single dose of etomidate negatively impacted patient-oriented outcomes.⁵⁹

Clinicians performing postintubation ACTH stimulation testing should be aware that the results may be affected by prior administration of etomidate. The empirical administration of glucocorticoids for the first 24 hours after a dose of etomidate has been given to patients with sepsis is not supported by outcome studies.

The debate over the use of etomidate as an induction agent in those with known sepsis is unlikely to be definitively answered in the near future. Despite numerous studies with conflicting results, there is no clear evidence that patients are harmed by a single dose of this drug. It is not always immediately clear on arrival in the ED if patients who require intubation have sepsis. It is the recommendation of the authors that ketamine be considered in patients requiring intubation who have known sepsis. While the use of etomidate is not a violation of the standard of care, the favorable pharmacologic properties of ketamine make it an ideal induction agent for those with known sepsis.

Ketamine

Unique among anesthetic agents, ketamine produces a dissociative anesthesia characterized by excellent analgesia and amnesia despite the appearance of wakefulness. As a drug that is potent and relatively safe with a rapid onset and brief duration of action, ketamine fits the profile of an agent that could be used

effectively to facilitate intubation. Ketamine has been advocated for pharmacologic control of undifferentiated agitated and violent patients with excited delirium. It does possess some pharmacologic properties that theoretically limit its use in selected circumstances.

Ketamine is a water- and lipid-soluble drug that rapidly penetrates the CNS. Like the barbiturates, ketamine accumulates rapidly and then undergoes redistribution with subsequent degradation in the liver.⁶⁰ The recommended dose of ketamine before intubation is 1 to 2 mg/kg administered intravenously over a 1-minute period. Anesthesia occurs within 1 minute of completing the infusion and lasts 5 to 10 minutes. A smaller additional dose (0.5 to 1 mg/kg) may be given 5 minutes after the initial dose if needed to maintain anesthesia. The intramuscular dose for intubation has not been well studied, and a suggested dose is 4 to 5 mg/kg. Onset of action occurs within 2 to 3 minutes. Because of its good vascularity, the anterior thigh muscle is theoretically the preferred site for administration. Unlike other anesthetic agents that depress the reticular activating system, ketamine acts by interrupting association pathways between the thalamocortical and limbic systems. Characteristically, the eyes remain open and patients exhibit spontaneous, though not purposeful, movements. Increases in blood pressure, heart rate, cardiac output, and myocardial oxygen consumption are seen and are most likely mediated through the CNS. In vitro studies indicate that ketamine is a myocardial depressant, and the CNS-mediated pressor effects generally mask the direct cardiac effects,^{61,62} making it potentially useful in patients with hemorrhagic shock or hypotension. Respirations are initially rapid and shallow after ketamine administration, but they soon return to normal.⁴⁰

Other features of ketamine anesthesia include increased skeletal muscle tone, preservation of the laryngeal and pharyngeal reflexes, hypersalivation, and relaxation of bronchial smooth muscle. Discussions exist regarding the use of ketamine in patients with head injury or potentially elevated ICP. Ketamine can potentially cause a rise in ICP through sympathetic stimulation, theoretically exacerbating the condition of patients with elevated ICP. Recent literature questions the degree to which ketamine raises ICP,⁶³ with some studies actually showing decreased ICP with the administration of ketamine.⁶⁴ A 2009 trial demonstrated the safety of ketamine compared to etomidate in critically ill patients.⁵⁸ Ketamine may benefit patients with a neurologic injury by increasing cerebral perfusion.

Other studies suggest that ketamine does not interfere with cerebral metabolism or increase cerebral oxygen consumption and does not reduce regional glucose metabolism.⁶⁵ Ketamine can also offset any decrease in mean arterial pressure caused by fentanyl, a drug commonly used as part of RSI in patients with a head injury.⁶³ For similar reasons, some have advocated the addition of ketamine if propofol is to be used for induction. The resultant “ketofol” mixture is less likely to cause hypotension than propofol monotherapy.⁶⁶ A prospective randomized controlled trial is underway to provide additional information about the performance of ketofol as an induction agent.⁶⁷

Overall, evidence suggesting that ketamine elevates ICP to any significant clinical extent is weak, and evidence that harm might ensue is weaker. Based on current evidence it is reasonable to conclude that ketamine is an appropriate induction agent for RSI in patients with suspected ICP elevation and normal blood pressure or hypotension. In patients with hypertension and suspected ICP elevation, ketamine should be used with

caution because of its tendency to further increase blood pressure. Patients with severe hypertension may be better served by using etomidate or propofol for induction.

The most promising use of ketamine as an intubation adjunct has been in the setting of acute bronchospastic disease. Ketamine relaxes bronchial smooth muscle either directly through enhancement of sympathomimetic effects or indirectly through inhibition of vagal effects. Ketamine also increases bronchial secretions and may decrease the incidence of mucous plugging that is commonly seen in decompensating asthmatic patients.⁶⁸ Clinical reports have demonstrated a reduction in airway resistance and an increase in pulmonary compliance within minutes of ketamine administration.⁶⁰ Bronchospastic patients struggling to breathe and unable to tolerate oxygen masks or bronchodilators because of hypoxic encephalopathy will continue to breathe deeply and rapidly with ketamine anesthesia, thereby allowing the maximum delivery of oxygen before a more elective intubation (Fig. 5.3).

A potential side effect that has raised some concern about the use of ketamine for RSI is its tendency to produce post-anesthesia emergence reactions, a characteristic that it shares with the structurally similar drug phencyclidine. The reemergence phenomenon, such as disturbing dreams as patients emerge from ketamine-induced anesthesia, is much less of a concern when the drug is used for RSI. In fact, there are no convincing data indicating that, when used for RSI, ketamine produces unpleasant reemergence reactions that are significant or common enough to limit its use for this purpose. One study found that although dreams occurred frequently following sedative doses of ketamine, they were generally pleasant and the frequency of reemergence phenomena and delirium was markedly reduced by the concomitant use of a benzodiazepine.⁶⁹ Rarely, reactions may be marked and distressing, with symptoms including floating sensations, dizziness, blurred vision, out-of-body experiences, and vivid dreams or nightmares. The true incidence of emergence reactions following RSI is unknown,

Figure 5.3 This asthmatic is diaphoretic, confused, and agitated and cannot tolerate inhaled bronchodilators. He is about to suffer respiratory arrest and cannot be preoxygenated before intubation. Pulse oximetry shows an oxygen saturation of 82% to 84%. Ketamine is an ideal agent under these circumstances. Keeping him on the stretcher was difficult but within 60 seconds following intravenous administration of ketamine (100 mg), he stopped fighting but kept breathing rapidly. A non-rebreathing oxygen mask was tolerated and oxygen saturation rose to 98%, after which he was electively intubated under controlled preoxygenated conditions. A ketamine infusion (1 mg/kg per hr) was maintained for a few hours.

and clinical experience suggests that it is not an issue for RSI in the ED. Such reactions are less common in children than in adults and may be suppressed with benzodiazepines. Both diazepam and lorazepam appear to be useful in adults and the latter is more effective, most likely because of its enhanced amnestic effect. Midazolam is effective in adult patients at doses of 0.07 mg/kg⁷⁰ and may be the preferred agent because it has potent amnestic effects and a short duration of action. Studies in children have failed to show a reduction in the rate of emergence reactions in those treated with both ketamine and midazolam.^{71,72}

Despite preservation of pharyngeal and laryngeal reflexes in patients sedated with ketamine, aspiration can still occur.⁷³ Ketamine does not relax skeletal muscles, and production of the desired intubating conditions requires the simultaneous administration of a paralytic agent, thereby removing all upper airway reflexes. Despite the possibility of aspiration, the use of ketamine is associated with very few airway complications. A study of over 1000 uses of ketamine for pediatric sedation revealed no cases of aspiration.⁷⁴

Ketamine's excellent safety profile and preservation of respiratory drive make it an excellent agent for awake intubations or delayed-sequence intubation.⁶ This will be discussed further in later sections.

Propofol

Propofol is a popular drug among anesthesiologists for OR-based induction and is ideal for ED use. Multiple reports have demonstrated the safety and efficacy of propofol for ED procedural sedation.^{75,76} Although some ED clinicians now routinely intubate with propofol, its role as an adjunct to intubation in the ED is undergoing evolution.⁷⁷ Propofol is an alkylphenol sedative-hypnotic used for induction and maintenance of general anesthesia. The drug has no analgesic activity and it exerts a powerful amnestic effect. Propofol tends to decrease vomiting through an unknown antiemetic effect. It produces dose-dependent depression of consciousness ranging from light sedation to coma. Propofol is a highly lipophilic, water-insoluble compound that undergoes rapid uptake by vascular tissues, including the brain, followed soon afterward by redistribution to muscle and fat. The drug is metabolized by the liver and excreted in urine.⁷⁸ After an induction dose of 2 mg/kg intravenously, unconsciousness occurs within 1 minute and lasts for 5 to 10 minutes. A smaller dose (1 to 1.5 mg/kg) is recommended in the elderly and when simultaneously administering other CNS depressants. Because propofol has a short duration of action and patients rapidly regain consciousness, repeat boluses are not a practical way to maintain a desired level of sedation after intubation has been completed.⁷⁸ Therefore a slow drip infusion of 50 to 200 µg/kg per min IV titrated to effect is preferred.

Propofol reduces airway resistance, making it a useful induction agent for patients with bronchospasm. Its neuroinhibitory effects make propofol a possible induction agent for patients with intracranial pathology, provided that they are hemodynamically stable. The propofol-induced decrease in mean arterial pressure, generally approximately 10 mm Hg, can reduce cerebral perfusion pressure, thereby theoretically exacerbating CNS injury. As even transient hypotension has been associated with poor outcomes in critically ill patients, propofol should not be used if the patient is hypotensive or at high risk for hypotension.³⁰

Propofol does not prolong the QT interval. Although the manufacturer lists egg or soybean allergy as a contraindication to the use of propofol, significant allergic reactions to the newer preparation of the drug are extremely rare. Evidence from 2016 suggests that there is no connection between propofol and egg, soy, or peanut allergy.⁷⁹

Propofol suppresses sympathetic activity, thereby causing myocardial depression and peripheral vasodilation, particularly in the elderly or hypovolemic patients and when administered simultaneously with opioids. Hypotension can be minimized with appropriate fluid loading or reversal with pulse dosing IV ephedrine. Propofol reduces cerebral blood flow and may cause mild CNS excitatory activity (e.g., myoclonus, tremors, hiccups) during induction. Propofol has been used in the treatment of status epilepticus,⁸⁰ but more data is needed on its safety as an induction agent for this purpose. Pain on injection occurs commonly, even when the drug is infused slowly.⁷⁸ Pretreating the infusing vein with 3 mL of 1% lidocaine (30 mg) injected over a 30-second period or choosing a large antecubital vein will ameliorate this pain. It is unclear if this transient pain is meaningful in patients being induced for intubation due to the likely amnesia caused by drug administration.

Propofol is a reasonable induction agent for RSI in the ED, especially if the patient is hypertensive or in status epilepticus. The safety of etomidate and ketamine are the main challenges to the routine use of propofol for intubation. Whereas propofol has an excellent record for stable patients in the OR and for procedural sedation,⁴⁰ the common side effect of hypotension precludes its use in many critically ill patients. Its short duration of action and ease of titration make it a more attractive agent for postintubation sedation than as a routine agent for induction.

Benzodiazepines (Midazolam)

The benzodiazepines are a class of drugs characterized by anxiolytic, hypnotic, sedative, anticonvulsant, muscle relaxant, and amnestic effects. Several of these properties make the benzodiazepines appealing adjuvant agents for intubation, particularly when used in combination with opioids. It is important to remember that benzodiazepines do not have analgesic effects. Although they may produce excellent sedation and impair the patient's memory of an unpleasant experience, they will not prevent the pain associated with intubation. The high risk of hypotension in critically ill patients who receive both benzodiazepines and opiates limit this drug class's use for induction in the ED.

Midazolam has replaced diazepam as a preoperative sedative agent, even in elderly patients.^{81,82} When compared with diazepam, the primary advantages of midazolam include a twofold increase in potency, shorter half-life, and decreased potential for cardiorespiratory depression. Midazolam is water soluble in an acid medium and does not require suspension in propylene glycol like other benzodiazepines. It is rarely associated with phlebitis and can be given intramuscularly when a very rapid onset of action is not required. At physiologic pH, midazolam is lipophilic and rapidly accumulates in the CNS, with onset of sedation occurring in as little as 1 to 2 minutes. Outside the CNS it accumulates in fatty tissue and extensively binds to plasma, which accounts for the paucity of non-CNS side effects. Its half-life of elimination is 1 to 4 hours and is dependent on release of the drug from adipose tissue and protein-binding sites. The period of sedation after a single IV

dose is considerably shorter. Emergence from a 0.15-mg/kg dose occurs in 15 to 20 minutes.⁸²

Clinical experience using midazolam with or without fentanyl for procedural sedation is considerable, and it is considered both safe and effective in the ED setting. The recommended dose for moderate sedation with midazolam is 0.05 to 0.1 mg/kg given in 1-mg boluses and not exceeding 2.5 mg over a period of 2 minutes. Doses upward of 0.1 mg/kg are often needed to produce good conditions for intubation.^{83,84}

The potential for adverse effects with midazolam is similar to that with other benzodiazepines. A small increase in heart rate is seen frequently, as is a small decrease in systolic blood pressure.⁸⁵ Changes in blood pressure may be exaggerated in the presence of hypovolemia.⁸⁶ An ED-based study reported a mean 10% decrease in systolic blood pressure, with 19% of intubated patients having systolic blood pressure lower than 90 mm Hg.⁸⁵ The cardiac index and coronary artery blood flow are not generally affected. In the prehospital setting, hypotension with midazolam was found to be dose related,⁸⁷ and it should be used cautiously in patients with hypovolemia or traumatic brain injury. Respiratory depression may occur even at standard doses, but it most often follows rapid administration of an excessive dose. Respiratory depression is also more likely to occur in debilitated or elderly patients and in those simultaneously receiving opioids. The effects of midazolam are rapidly reversed by administration of the benzodiazepine antagonist flumazenil. A study of various induction agents for ET intubation suggested that the use of midazolam alone for RSI may be associated with suboptimal intubating conditions and increased difficulty.⁸⁸ Other induction agents may be preferred over midazolam alone during RSI.

Whereas once a common agent for induction, midazolam cannot be recommended as a routine induction agent for intubation in the ED. At the doses required for consistent sedation, hypotension is very common. One study showed that 19% of those intubated with the drug had hypotension.⁸⁸ The association of hypotension with poor outcomes³⁰ precludes the routine use of this medication. A possible exception to this is for patients in status epilepticus, and additional research is needed in this area. Midazolam is a common agent for post-intubation sedation, and it is more appropriate for this use than as an induction agent.

Opioids (Fentanyl)

Although any of several opioids administered intravenously could be used to induce unconsciousness, fentanyl has significant advantages over other opioid agents. A synthetic opioid, it has been widely used since its introduction in 1968. Its favorable pharmacologic properties include rapid serum clearance, high potency, and minimal release of histamine.⁸⁹⁻⁹¹ Fentanyl quickly crosses the blood-brain barrier and produces analgesia in as little as 1 to 2 minutes. Serum levels decline rapidly from peak concentrations because of extensive tissue uptake.^{92,93} Unlike morphine, the brain concentration of fentanyl falls in conjunction with the serum level. The duration of analgesic action is 30 to 40 minutes, although at high doses a second peak of activity may be seen several hours later because of release of the bound drug from tissue stores. Fentanyl is approximately 50 to 100 times as potent as morphine.⁹⁴ This unique combination of potency and short half-life permits the administration of numerous small doses that can be titrated to the desired clinical effect. Similar to other opioids, fentanyl is competitively

reversed with naloxone. Related agents include remifentanyl and sufentanil, but these synthetic opioids are not generally available in the ED setting.

The relative safety of fentanyl permits considerable latitude in dosing. When used as a primary anesthetic agent for major surgical procedures, doses ranging from 50 to 100 µg/kg produce minimal side effects.⁹⁵ Comparatively tiny doses produce sedation, and 3 to 5 µg/kg, given at a rate of 1 to 2 µg/kg per min, is generally an effective analgesic dose. More rapid administration will cause greater depression of the level of consciousness. Mostert and colleagues⁹⁶ reported successful awake intubation in 99 of 103 patients who were administered an average cumulative dose of 3.7 µg/kg. Most of these patients were able to follow commands, and many recalled events surrounding the intubation. A small percentage could not be intubated, even after receiving 500 µg of fentanyl.

Larger doses, perhaps up to 25 µg/kg, may be needed to produce ideal intubating conditions, although if given rapidly, 10 µg/kg is usually adequate. Even this lower dose is more likely to produce unconsciousness than a lesser depth of sedation and it may cause a longer period of unresponsiveness than is desirable. It is preferable to use a low dose of fentanyl (2 to 3 µg/kg) for analgesia combined with a paralytic agent (e.g., succinylcholine) to produce adequate muscle relaxation and a sedative (e.g., midazolam) to reduce anxiety and produce amnesia for the event.

Unlike other opioids, fentanyl causes little or no release of histamine, and its use is seldom associated with emesis or hypotension. It is probably safer than morphine and hydromorphone in hypovolemic patients. Fentanyl also has significantly fewer emetic effects than other opioids do. Adverse effects that have been reported with fentanyl are few and primarily follow the rapid IV infusion of very large doses. Like other opioids, fentanyl may cause rigidity of the skeletal musculature, including the chest wall and diaphragm. Rigidity occurs with doses in excess of 15 µg/kg, but it has also been reported with doses as low as 10 µg/kg and may also be related to rapid administration.^{96,97} The muscular rigidity may be prevented or treated with standard doses of succinylcholine or naloxone.⁹⁸ This rigidity is generally not a major concern during RSI due to the use of paralytics, but may be observed during procedural sedations. The most common significant complication with fentanyl is respiratory depression, and it generally occurs when fentanyl is given in combination with other CNS depressants or in excessive amounts.^{99,100}

Whereas fentanyl appears to be a safe agent for use in the ED, its main limitation as an induction agent is the variable patient response to the drug. Unlike ketamine and etomidate, the effect of a standard dose of fentanyl is unpredictable. This is especially true in patients that are not opioid naïve. As mentioned previously, a small percentage of patients did not have adequate sedation despite doses of 500 µg, limiting its use as a sole induction agent. The main use of fentanyl in current practice is as a pretreatment drug to prevent increased ICP or elevated blood pressure.

NEUROMUSCULAR BLOCKING AGENTS

NMBs are used to achieve muscle relaxation for intubation. They permit complete airway control and greatly simplify visualization of the vocal cords. This is particularly important when intubation must be performed quickly under less than

TABLE 5.2 Commonly Used Neuromuscular Blocking Agents

AGENT	DOSE (mg/kg)	ONSET (min)	DURATION (min)
Succinylcholine	1.5	1	3–5
Pancuronium	0.1	2–5	40–60
Vecuronium	0.1	3	30–35
	0.25	1	60–120
Atracurium	0.5	3	25–35
Mivacurium	0.15	2–3	15–20
Rocuronium	1.2	1–1.5	30–110

ideal circumstances. Sedatives may provide some muscle relaxation, but this requires rapid administration of large doses, which poses a risk for depression of the cardiovascular system. The combination of a paralytic agent and a sedative or analgesic agent is generally superior to the use of either agent alone. A 1999 report showed an 18% failure-to-intubate rate with a sedative alone versus a 0% failure rate for sedatives plus paralytics.¹⁰¹ Procedural complication rates such as significant airway trauma and aspiration were also markedly higher in the group receiving sedation alone.

The only absolute contraindication to the use of NMBs is the inability to manage the airway once the patient becomes apneic. Though not absolutely contraindicated, it is considered inhumane to paralyze and intubate an alert patient. A sedative or an analgesic agent should always be administered simultaneously if the patient is able to perceive pain.

NMBs are classified as either depolarizing or nondepolarizing. Depolarizing agents mimic the action of acetylcholine (ACh) and produce sustained depolarization of the neuromuscular junction, during which time muscle contractions cannot occur. Nondepolarizing agents competitively block the action of ACh at the neuromuscular junction and prevent depolarization and therefore muscle contractions. Commonly used NMBs and their dosages and characteristics are listed in Table 5.2.

Succinylcholine

The standard depolarizing agent currently in use is succinylcholine.¹⁰² It has a chemical structure similar to that of ACh and depolarizes the postjunctional neuromuscular membrane. Administration is followed by a brief period of muscle fasciculations that correspond to the initial membrane depolarization and muscle fiber activation. Unlike ACh, which is released in minute amounts and hydrolyzed in milliseconds, succinylcholine requires several minutes for breakdown to occur. During this time the neuromuscular junction remains depolarized, but the muscles relax and will not contract again until the neuromuscular end plate and adjacent sarcoplasmic reticulum return to the resting state and are again depolarized. Relaxation proceeds from the small, distal, rapidly moving muscles to the proximal, slowly moving muscles. The diaphragm is one of the last muscles to relax.

Succinylcholine is rapidly degraded in serum by the enzyme pseudocholinesterase, and the duration of action of a single dose is 5 to 10 minutes.¹⁰³ Relaxation may be maintained by repeated IV injections. Prolonged or repeated use of the drug enhances its vagal stimulatory effects, thereby resulting in bradycardia, hypotension, and other muscarinic effects. These effects may be seen even at normal doses, particularly in children.¹⁰⁴ For this reason, atropine pretreatment at a dose of 0.02 mg/kg has been recommended by some experts for small children and for adults receiving multiple doses, although the need and optimal dose are still in question.¹⁰⁴ Repeated dosing with succinylcholine may produce a desensitization blockade and create a scenario in which the neuromuscular membrane returns to the resting state and becomes resistant to further depolarization by succinylcholine.^{105,106} In general, there is little need for repeated doses of succinylcholine if appropriately dosed the first time. If paralysis in excess of 5 to 10 minutes is desired, longer-acting, nondepolarizing agents such as rocuronium should be used.

The recommended dose of succinylcholine is 1 to 1.5 mg/kg given intravenously. Dosages at the upper end of this range are suggested to guarantee complete relaxation and avoid the need for repeated dosing. Dosage calculations should also be based on actual, not lean body mass because of alterations in both volume of distribution and pseudocholinesterase activity.¹⁰⁷ Neonates and infants require a slightly higher dose of succinylcholine (2 mg/kg intravenously) as a result of their higher volume of distribution.^{51,108} It is crucial that succinylcholine be administered as a rapid bolus because slow administration may lead to incomplete relaxation. Use of a rapid 20-mL to 30-mL saline flush after IV administration may enhance its desired effect.

There are a number of potential adverse effects of the use of succinylcholine, ranging from minor to life-threatening. Muscle fasciculations accompany the initial depolarization of the neuromuscular membrane. Fasciculations are most prominent in muscular patients and create deep, aching muscle pain that may last for days.¹⁰⁹ It is unclear whether any regimen will totally prevent the succinylcholine-induced fasciculations (seen in 73% to 100% of patients) and myalgias (seen in 10% to 83% of patients), with varying effects reported after numerous interventions.¹¹⁰ Interestingly, higher doses of succinylcholine may be associated with less myalgia. Traditionally, fasciculations have been prevented by the preadministration of a defasciculating dose (0.01 mg/kg) of pancuronium or vecuronium. The evidence available does not suggest that succinylcholine worsens outcomes in at-risk patients, nor does any evidence suggest that defasciculation improves outcomes in at-risk patients.³⁷

A major consideration in the use of succinylcholine is its propensity to cause hyperkalemia. This electrolyte disturbance is believed to occur secondary to asynchronous depolarization of muscle cells and resulting cellular injury. Elevation in serum potassium occurs in normal patients after standard doses but is typically clinically inconsequential, with increases of less than 0.5 mmol/L (mEq/L).¹¹¹ Increases in potassium are not prevented with defasciculating doses of nondepolarizing agents. Marked hyperkalemia is associated with increased extrajunctional muscle ACh receptors, which develop in patients with prolonged diseases of the neuromuscular system. Susceptibility may occur within as few as 5 to 7 days and persists indefinitely. In these cases, the hyperkalemic response may be as much as 5 mmol/L (mEq/L). Such conditions include late severe burns,¹¹² major muscle trauma,¹¹³ spinal cord injury, muscular dystrophy,

multiple sclerosis, and other upper motor neuron diseases^{114,115} such as amyotrophic lateral sclerosis. These large elevations occur only in patients who have had significant tissue injury or muscle denervation for several days or weeks before the use of succinylcholine. Importantly, succinylcholine is not contraindicated in the initial management of patients with acute injuries, including burns, major crush injuries, and spinal cord injuries. Succinylcholine is also not contraindicated in normokalemic patients with renal failure because the magnitude of the rise in serum potassium is the same as in patients with normally functioning kidneys.¹¹⁶ A retrospective review of the use of succinylcholine in 38 operative cases with moderate pre-RSI hyperkalemia (5.6 to 7.6 mmol/L) suggested that the risk for hyperkalemia-related complications may be lower than feared.¹¹⁷ In a review of more than 41,000 intubations, 38 patients had hyperkalemia with a mean serum potassium level of 5.9 mmol/L, so Schow and colleagues¹¹⁷ concluded that it is safe to administer succinylcholine to patients with a potassium level of 5.5 to 6.0 mEq/L.

Succinylcholine is best avoided (if other equally effective pharmacologic options such as rocuronium exist) in the setting of known or suspected preexisting hyperkalemia (e.g., renal failure patients not receiving regular dialysis or demonstrating a wide QRS complex). There is a higher risk of undiagnosed myopathies in pediatric patients, but succinylcholine remains a safe drug for the majority of pediatric intubations.¹⁰⁸

Malignant hyperthermia is a rare complication with an autosomal dominant inheritance pattern that is triggered by multiple anesthetic agents, including succinylcholine. Most provocative agents, such as halothane, are not used in the ED setting, and it is extremely rare for the ED physician to encounter this complication. It occurs in approximately 1 in 15,000 children and 1 in 50,000 adults.¹¹⁸ The clinical syndrome consists of high fever, tachypnea, tachycardia, cardiac arrhythmias, hypoxia, acidosis, myoglobinuria, and impaired coagulation. Unabated muscle contractions mediated by abnormal calcium channels are the physiologic basis for this condition.¹¹⁹ Treatment includes aggressive cooling measures, volume replacement, and correction of hypoxia as well as acid-base and electrolyte abnormalities. Dantrolene sodium, a direct-acting skeletal muscle relaxant, is thought to be effective in reducing the muscle hypermetabolism that causes the dramatic hyperpyrexia.¹²⁰ An associated abnormal response to succinylcholine is isolated masseter spasm,¹²¹ but it can occur in isolation or portend the subsequent development of malignant hyperthermia. Though rare, it has been reported in the emergency medicine literature.¹²² In this condition, forcible sustained contraction of the masseter muscles occurs and prevents mouth opening and oral intubation. Management is controversial, with recommendations ranging from use of a bag-valve-mask, securing a surgical airway until the contraction abates, to attempting to suppress the contractions through administration of a nondepolarizing NMB. A case report of an ED patient with masseter spasm during RSI described successful management with the use of a nondepolarizing NMB (vecuronium).¹²³ Unlike routine cases in the OR, the vast majority of ED patients require definitive airway management and cannot be allowed to simply have the succinylcholine wear off. With the limited evidence available on the management of this rare condition, it is the author's recommendation that rocuronium be used to treat masseter spasm attributed to succinylcholine.

Prolonged paralysis after the administration of succinylcholine may occur in clinical conditions that result in

decreased pseudocholinesterase levels and subsequent decreased metabolism of succinylcholine. Physiologic states associated with this condition include hepatic disease, anemia, renal failure, organophosphate poisoning, pregnancy, chronic cocaine use, advanced age, bronchogenic carcinoma, and connective tissue disorders. Patients with these conditions experience a twofold to threefold increase in the duration of apnea.¹²⁴ Patients with cocaine intoxication may also experience prolonged muscle relaxation because cocaine is competitively metabolized by the cholinesterases. An inherited deficiency of pseudocholinesterase is also present in approximately 0.03% of the population and can lead to prolonged paralysis from the administration of succinylcholine.¹²⁰ The prolonged duration of paralysis for these patients is likely to be of little clinical significance for the majority of ED patients, as the vast majority of patients intubated in the ED are not ready for extubation shortly afterwards and are unlikely to be harmed by slightly prolonged paralysis.

Succinylcholine can also result in an increase in ICP, but the magnitude and significance of the increase in ICP remains controversial.^{125,126} Several investigators have reported increases in the range of 5 to 10 mm Hg, but other researchers have shown no increase. There is no evidence of neurologic deterioration associated with these transient elevations in ICP. Mechanisms that have been proposed to explain the elevated ICP include: (1) a direct effect of fasciculations, (2) an increase in cortical electrical activity with a resultant increase in cerebral blood flow and blood volume, and (3) sympathetic postganglionic stimulation. Limited studies have been performed to evaluate the significance of this rise in ICP in a brain-injured human patient population. These studies have shown no significant change in electroencephalographic activity or ICP with succinylcholine, but the small size of the studies limits the ability to draw conclusions about clinical outcomes.^{108,127,128}

Questions concerning the safety of succinylcholine in the setting of acute intracranial pathology do not have clear answers. The drug has been used widely and successfully in this setting and its continued use is supported by this experience. The very real risk for airway compromise and secondary cerebral insult because of hypoxia from delayed or failed intubation must always be weighed against the theoretical harmful effects. Succinylcholine, despite its many potential side effects, is currently the most frequently used agent for neuromuscular blockade with RSI because of its rapid onset and offset and reliable muscle relaxation characteristics.

Nondepolarizing Agents

Nondepolarizing agents act in a competitive manner to block the effects of ACh at the neuromuscular junction. Drugs in this class include pancuronium, atracurium, vecuronium, mivacurium, and rocuronium. These drugs, particularly the intermediate-acting agents, have fewer side effects than succinylcholine and they have the potential for reversal. They generally have a longer onset and duration of action than succinylcholine, thus making them less attractive choices for RSI because of the delay in muscle relaxation. In most instances, succinylcholine remains the agent of choice to facilitate emergency intubation, and nondepolarizing agents are indicated to maintain paralysis after intubation. Knowledge of appropriate nondepolarizing NMBs is important for situations when succinylcholine may be contraindicated.

Because nondepolarizing agents act competitively at neuromuscular junction receptors, increasing the concentration of ACh may reverse their effects. Cholinesterase inhibitors such as neostigmine or edrophonium may be used but will not be effective until some spontaneous signs of reversal are seen. The concept of reversal is of limited clinical importance in the ED with rare exceptions, such as performance of a neurologic examination on a previously paralyzed patient. When reversal is required, neostigmine, 0.02 to 0.04 mg/kg, is given by slow IV push. An additional dose of 0.01 to 0.02 mg/kg may be given in 5 minutes if reversal is incomplete, but the total dose should not exceed 5 mg in adults. Atropine, 0.01 mg/kg (with a minimum dose of 0.1 mg in children and a maximum dose of 1 mg in adults), should be given concurrently with neostigmine to block its systemic cholinergic effects.^{129–131}

Another potential reversing agent, sugammadex, binds directly to the aminosteroid NMB rather than to cholinesterases.¹³² For reversal of shallow or profound neuromuscular blockade, 2 mg/kg or 4 mg/kg intravenously, respectively, is recommended. The most concerning risk with this medication is anaphylaxis.¹³³ Unfortunately, no studies other than case reports currently address its use in emergency situations. It is approved for use in Europe, but was only recently approved for use in the United States and is not widely available yet.

A study by Lee and colleagues¹³⁴ demonstrated that rocuronium with sugammadex administration leads to faster recovery than succinylcholine after neuromuscular blockade. Whereas the rocuronium/sugammadex arm recovered faster than the succinylcholine arm, sugammadex still took several minutes to reverse many patients. This may be unacceptable in a “cannot-intubate/cannot-oxygenate” situation. A case report of sugammadex use in a cannot-intubate/cannot-oxygenate situation showed that despite partial reversal of paralysis, a tracheostomy was still required.¹³⁵ The availability of this reversal agent for use in the ED does not change the need to be prepared for a surgical airway if required. The high cost of this medication will also make it cost prohibitive for many EDs.¹³⁶

Long-Acting Agents: Pancuronium

Pancuronium is an aminosteroid that is primarily excreted in urine within 1 hour of IV administration.¹³⁷ Classified as a long-acting agent, its onset and duration of action are dose related. After a typical IV dose of 0.1 mg/kg, paralysis occurs within 2 to 5 minutes and lasts approximately 60 minutes. Paralysis may be maintained safely by repeated bolus or drip infusion. Because the effects of the drug are cumulative, repeating the original dose significantly lengthens the duration of paralysis.

Relatively few adverse effects are associated with the use of pancuronium. Many patients experience an increase in heart rate, blood pressure, and cardiac output because of the vagolytic effects of the drug. Ventricular tachycardia and severe hypertension have been reported but are quite rare.^{137,138} Pancuronium may cause release of histamines, resulting in bronchospasm or anaphylactic reactions.¹³⁹ Prolonged paralysis may occur, primarily in patients with myasthenia gravis or with significant impairment in renal function. One consensus panel recommended pancuronium for maintaining paralysis, except in patients with cardiac disease or hemodynamic instability, for whom they recommended vecuronium.¹²⁵ This may be appropriate for an ED patient requiring prolonged paralysis.

Intermediate-Acting Agents: Vecuronium, Atracurium, Mivacurium, and Rocuronium

Vecuronium and atracurium are intermediate-acting agents with an onset of action of approximately 3 minutes and a duration of action of 30 minutes. Mivacurium has an onset of action of 2 to 3 minutes and a duration of action of 15 to 20 minutes. Rocuronium has an onset of action of 1 to 1.5 minutes and a duration of action of 20 to 75 minutes (longer in geriatric patients). These drugs have minimal cardiovascular effects, cause little release of histamine (with the exception of mivacurium),¹⁰⁸ and lack cumulative effects.¹⁴⁰

The recommended doses of vecuronium, atracurium, mivacurium, and rocuronium are listed in Table 5.2. Use of larger doses hastens the onset of action but greatly prolongs the period of paralysis. For example, vecuronium at a dose of 0.25 mg/kg intravenously will cause paralysis in as little as 1 minute, but the period of paralysis will last 1 to 3 hours.^{141,142} Because a rapid onset of action comparable to that of succinylcholine is achieved at high doses of intermediate-acting agents, they may be used as the sole agents to facilitate intubation, particularly if a long period of paralysis is desired after intubation. The paralysis induced by vecuronium or atracurium may be maintained by repeated boluses or drip infusion. Unlike both pancuronium and succinylcholine, these agents have no side effects specifically related to repeat dosing in the ED. A repeated dose of 0.01 to 0.02 mg/kg of vecuronium will extend the period of paralysis by 12 to 15 minutes.

Rocuronium, a structural analogue of vecuronium, is emerging as a desirable alternative agent for RSI when succinylcholine is contraindicated. At doses of 0.6 to 1.2 mg/kg, rocuronium consistently provides good to excellent intubating conditions within 1 minute of administration. Its duration of action is dose dependent and ranges from 20 to 75 minutes.^{143,144} Smaller anesthesia and ED-based studies have demonstrated its clinical utility and safety in RSI protocols.^{143,145,146} Rocuronium creates appropriate intubating conditions faster than vecuronium,¹⁴⁴ making rocuronium the nondepolarizing agent of choice for RSI in the ED.

A 2015 Cochrane analysis including 37 studies compared rocuronium to succinylcholine for RSI. It revealed slightly superior intubating conditions with succinylcholine when compared to rocuronium. Once limited to studies that only utilized 1.2 mg/kg rocuronium, this difference disappeared. It is the authors' recommendation that 1.2 mg/kg of rocuronium be used as the routine dose of this medication.

There is insufficient information to clearly demonstrate whether succinylcholine or rocuronium is the superior paralytic for RSI in the ED. Succinylcholine has a much shorter duration, and also has a much longer list of contraindications. EDs frequently receive undifferentiated patients in respiratory failure requiring immediate airway management, often before a full medical history can be obtained or initial potassium level has been assessed. As mentioned previously, it is far from clear how harmful the transient elevation in potassium is for patients requiring RSI.¹¹⁷ Rocuronium has much cleaner pharmacology and a much longer duration of action. It is unclear what role sugammadex will play as a potential reversal agent for rocuronium, or how a patient in respiratory failure would be best managed after initially failing RSI.¹³⁵ Both agents have their merits and emergency physicians should become comfortable using both agents.

THE “SEDATED LOOK” EVALUATION OF THE AIRWAY BEFORE RSI

In selected stable patients, conditions may exist that preclude the immediate use of RSI, and the more prudent approach would be to assess the airway and intubation needs or potential complications before using paralytics. Examples are patients with angiotensin-converting enzyme inhibitor-induced angioedema or smoke inhalation, where clinical issues of RSI and intubation can be assessed by directly visualizing the larynx. This approach, referred to as a “sedated look” or “awake look,” is used when the clinician suspects a difficult intubation. This approach allows the clinician to verify that the laryngeal structures are indeed visible and accessible before committing to paralysis. This technique allows the patient to maintain respiratory drive during analysis of the airway. This approach is distinct from the practice of intubation with sedation alone or nonparalytic RSI, in which the patient receives a full induction dose of a sedative agent but no neuromuscular blocking agent. This older practice may create a vulnerable and compromised patient in whom intubating conditions are then problematic.

Traditionally in the OR, topical anesthesia (e.g., nebulized 4% lidocaine) along with moderate sedation has been used to allow a view into the airway while enabling the patient to maintain respiratory drive and protective airway reflexes. Although more research is needed to determine which medications are best for sedated looks in the ED, ketamine may be ideal in this circumstance by allowing the patient to maintain respiratory drive while providing analgesia, amnesia, and sedation. Ketamine’s analgesic properties allow it to be used as the sole agent in patients with a bloody traumatized airway, for which topical anesthesia is unlikely to work effectively. Other options are discussed in the following section.

AWAKE INTUBATION

An alternative to induction of unconsciousness in patients requiring intubation is the use of local anesthetic and sedative agents in conscious patients. The availability of relatively effective and safe induction agents makes this a less attractive alternative than in the past, but these techniques may be desirable in specific patients, such as for fiberoptic intubation of a predicted difficult airway. Awake intubation offers a number of potential advantages over RSI. The natural airway is maintained along with spontaneous respiration and a degree of protection from aspiration. The use of sedative agents to produce a state of mild or moderate sedation and adequate topical anesthesia are the principal components needed for awake intubation.

Thomas¹⁴⁷ likened standard laryngoscopy in an awake patient to the “mouth being held open with a wrench.” Awake nasotracheal intubation and fiberoptic intubation can also be an extremely unpleasant experience. The upper airway is richly innervated by sensory branches of the 5th, 7th, 9th, and 10th cranial nerves. In addition to pain fibers, there are stretch receptors that stimulate the coughing and gagging reflexes with even minor airway manipulation. It is essential that adequate analgesia be provided before intubation in all but the most extreme circumstances. Treatment options include topical application of anesthetic agents to the pharyngeal and tracheal mucosa and IV infusion of analgesic or sedative agents.

Local or topical anesthesia techniques may be used in patients who are awake, either in place of or as a supplement to IV analgesia or sedation. They are particularly useful as adjuncts to nasotracheal and fiberoptic intubation but do not generally provide the degree of analgesia or relaxation desirable for traditional laryngoscopy. In addition, the time required to achieve good topical anesthesia may limit the usefulness of these techniques in emergency situations. Topical anesthesia may be achieved by direct application, by cricothyroid membrane puncture, or by inhalation of a nebulized anesthetic.

Direct Application of Topical Anesthetics

Achieving anesthesia of the oral and pharyngeal mucosa is a relatively simple procedure that involves the use of commonly available agents such as 4% lidocaine or a combination such as 14% benzocaine, 2% butamben, and 2% tetracaine (Cetacaine, Cetylite Inc.). Achieving anesthesia of the hypopharynx is more difficult because optimal results require application of the anesthetic to the epiglottis and vocal cords.

If time allows, administer an anticholinergic agent, such as glycopyrrolate, at a dose of 0.2 mg IV to help reduce airway secretions. Give this medication 15 minutes prior to intubation for maximal effect. It is important to attempt to dry the airway with suction and gauze, as glycopyrrolate will only reduce additional secretions and will not remove existing moisture. A dry airway will make topical anesthetics more effective.

Begin this procedure by spraying the tongue and pharynx with a topical agent. Atomization devices that attach to standard syringes (e.g., Mucosal Atomization Device [MAD]; Wolfe Tory Medical, Inc., Salt Lake City, UT) can provide effective drug dispersal without a forceful spray (Fig. 5.4). The more forceful pressurized canister sprays commonly provoke a cough reflex. After allowing at least 2 to 3 minutes to achieve numbing of the tongue and pharynx, spray the epiglottis and vocal cords with the MAD device. A malleable extension tube allows the tip of the MAD to pass around the base of the tongue, thereby permitting direct spraying of the epiglottis and vocal cords. This is generally well tolerated. An alternative method is to visualize the epiglottis and vocal cords with a laryngoscope and directly spray them with the anesthetic agent. The use of a laryngoscope to visualize the vocal cords, however, is much more stimulating to the patient and often not well tolerated. Another alternative is percutaneous injection of an anesthetic agent into the trachea at the level of the cricothyroid membrane.^{148,149}

Figure 5.4 The Mucosal Atomization Device. (Courtesy Wolfe Tory Medical, Inc., Salt Lake City, UT.)

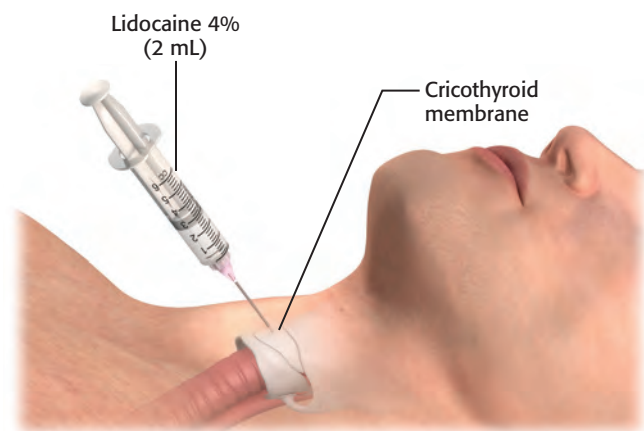

Figure 5.5 Cricothyroid membrane puncture. Prepare the skin with an antiseptic and then puncture the cricothyroid membrane in the midline. Advance the needle until air can be aspirated and then rapidly inject 2 mL of 4% lidocaine. Alternatively, 3 to 4 mL of 2% lidocaine can be used.

Cricothyroid Membrane Puncture

Direct application of topical anesthetics to the subglottic region can also be achieved through cricothyroid membrane puncture (Fig. 5.5). In this procedure, identify the cricothyroid membrane immediately below the thyroid cartilage. After antiseptic skin preparation, puncture the overlying tissue and membrane with a 22-gauge needle in the midline and just above the superior border of the cricoid cartilage. Take care to maintain the needle in the midline at all times to avoid injury to the recurrent laryngeal nerves. Advance the needle until air can be aspirated, which indicates placement of the needle in the trachea. Inject a 2-mL volume of 4% lidocaine rapidly. If the 4% concentration is not available, use 3 to 4 mL of 1% to 2% lidocaine. Typically, this will precipitate a cough and distribute the anesthetic over the upper part of the trachea, vocal cords, and epiglottis. Whereas more invasive than the other described techniques, intratracheal injection may provide superior local anesthesia,^{150,151} but there is limited evidence comparing different techniques.

Nebulized Anesthesia

Nebulized anesthesia is a simple and painless technique that can be used to facilitate awake intubation when the patient's condition is stable enough to permit a several-minute delay. Deliver the anesthetic via a standard nebulizer and face mask connected to an oxygen source that delivers 4 to 8 L/min. It is critical that the oxygen source not be set to the high-flow rate commonly used to nebulize medications such as albuterol. Doing so will anesthetize the lungs without properly anesthetizing the vocal cords. Nebulize a 4-mL volume of a 4% lidocaine solution over a period of approximately 5 minutes. Bourke and colleagues¹⁵² reported achieving consistently good topical anesthesia with this technique, although their patients were often premedicated with combinations of opioids and sedatives. This technique has been successfully used in pediatric patients.¹⁵³ Parkes and colleagues¹⁵⁴ demonstrated that the plasma levels of lidocaine following nebulized lidocaine for awake intubation were detectable, but far below the toxic threshold. Further

evidence of the effectiveness and safety of this procedure has been found through its use in decreasing the pain of placement of nasogastric tubes.¹⁵⁵

Sedation for Awake Intubation

Many patients can be intubated while awake with adequate topical anesthesia, but anxiolysis and mild to moderate sedation may be helpful for selected patients. The use of propofol in low doses (0.2 to 0.3 mg/kg) may be helpful, but exercise caution because propofol can cause hypotension in critically ill patients despite using a low dosage.

A new sedative agent, dexmedetomidine (an α_2 -adrenoreceptor agonist), has been described for use in awake intubation.^{156–158} Dexmedetomidine produces sedation and anxiolysis with minimal respiratory depression. Patients become sleepy but, if stimulated, can easily be aroused and are generally cooperative. These properties make it seem like an ideal agent for awake intubation, but its use is limited in emergencies by a requisite 10-minute loading dose followed by a maintenance infusion. Future studies will be needed before this medication can be recommended for use in the ED.

The sedative that is most conducive to awake intubation is ketamine. It preserves spontaneous respirations, does not generally cause hypotension, and can safely provide a deep level of sedation. Ketamine's tendency to cause increased airway secretions may be partially corrected for with glycopyrrolate or atropine, but there is rather limited data on the need to use an anticholinergic.¹⁵⁹ Ketamine may be used at subdissociative doses (< 0.3 mg/kg) if adequate topical anesthesia has been obtained. It may alternatively be used at dissociative doses (> 1 mg/kg) but theoretically can cause more side effects. An attempt to appropriately anesthetize the airway is important as ketamine preserves airway reflexes. Ketamine's safety profile makes it a good choice for sedation in awake intubations. The clinician should be prepared for possible laryngospasm during the use of a scope with ketamine. Whereas no cases of this have been reported,¹⁵⁸ preparedness for transition to a surgical airway or traditional RSI is essential.

Delayed-Sequence Intubation

Some patients may be unable to tolerate adequate preoxygenation prior to an initial attempt to intubate. Delayed-sequence intubation has been described as procedural sedation for the procedure of preoxygenation.⁶ Ketamine is given at 1 mg/kg IV to provide sedation. This allows the patient to tolerate preoxygenation with any appropriate combination of high-flow nasal cannula, bag-valve-mask (preferably with positive end-expiratory pressure valve), non-rebreather mask, or noninvasive ventilator. Once adequately preoxygenated, the patient's airway may be managed by intubation with a direct laryngoscope, video laryngoscope, or fiberoptic scope.

Conclusion

There have been many major advances in the pharmacologic adjuncts to intubation in the ED. There has been an increasing de-emphasis on the importance of premedications prior to intubation. The importance of avoiding hypotension and hypoxia has caused far less focus on the use of lidocaine, fentanyl, or other medications prior to intubation. Ketamine has now joined etomidate as a first-line induction agent, with many

providers using it almost exclusively. Rocuronium has emerged as the nondepolarizing paralytic of choice in most EDs in recent years. An increased emphasis on awake intubations and the new concept of delayed-sequence intubation has further expanded the use of topical anesthetics and ketamine to assist in difficult airways. A mastery of the pharmacology of drugs used to intubate remains a critical skill for all providers that see critically ill patients.

Cricothyrotomy and Percutaneous Translaryngeal Ventilation

Randy B. Hebert and Daniel Thomas

Few clinical scenarios are as critical as when a patient's airway cannot be controlled with traditional endotracheal (ET) intubation. Although cricothyrotomy is rarely required,¹⁻⁵ the incidence of surgical airways has decreased even further since the advent of adjunctive intubation techniques.^{6,7} The conditions accompanying an airway emergency are often stressful and chaotic and require the emergency department (ED) physician to be intimately familiar with this procedure.

When ET intubation has failed or is contraindicated, cricothyrotomy is often the procedure of last resort. Both surgical cricothyrotomy and needle cricothyrotomy entail puncture of the cricothyroid membrane through the overlying skin to gain access to the airway.

Surgical cricothyrotomy is a procedure in which an incision is made in the cricothyroid membrane and a tracheostomy tube or modified ET tube is placed into the airway to ventilate the patient (Video 6.1). *Tracheostomy* differs from cricothyrotomy in that the incision is made between two of the tracheal rings. *Needle cricothyrotomy* refers to insertion of a catheter via percutaneous needle puncture of the cricothyroid membrane to allow *percutaneous translaryngeal ventilation* (PTLV). The term *transtracheal jet ventilation* is often used interchangeably with PTLV in conjunction with needle cricothyrotomy, but PTLV is more accurate because the cricothyroid membrane is part of the larynx and not the trachea. PTLV is sometimes provided by bag insufflation instead of jet ventilation. The term *jet ventilation* usually refers to low-frequency jet ventilation with oxygen from a wall source as opposed to high-frequency jet ventilation from a dedicated jet ventilator.

ANATOMY

The central structure of importance is the cricothyroid membrane, an elastic membrane located anteriorly and midline in the neck. The membrane is bordered superiorly by the thyroid cartilage and inferiorly by the cricoid cartilage. The lateral aspects of the cricothyroid membrane are partially covered by the cricothyroid muscles, but the central triangular portion is subcutaneous, which makes it an ideal location to access the airway.

Identify the cricothyroid membrane by locating the prominent thyroid cartilage superior to it. The thyroid cartilage consists of two lateral laminae that join at an acute angle in the midline to form the laryngeal prominence. Commonly known as the *Adam's apple*, this structure is more pronounced in males. The internal aspect of the anterior body of the thyroid

cartilage provides the attachment for the vocal ligaments. Superior to the thyroid cartilage and connecting it to the hyoid bone is the thyroid membrane, which allows passage of the superior laryngeal vessels and the internal branch of the superior laryngeal nerve through its laterally located foramina.

The cricoid cartilage forms the inferior border of the cricothyroid membrane and is the only completely circumferential cartilaginous structure of the larynx. It is composed of a broad posterior segment that tapers laterally to form a narrow anterior arch. The tracheal rings descend inferior to the cricoid cartilage.

Identify the cricothyroid membrane between the previously mentioned structures as a shallow depression measuring approximately 9 mm longitudinally and 30 mm transversely. If the depression is obscured by soft tissue swelling, estimate the location of the cricothyroid membrane at approximately 2 to 3 cm inferior to the laryngeal prominence or four fingerbreadths above the sternal notch.⁸⁻¹⁰

The area overlying and immediately adjacent to the cricothyroid membrane is relatively avascular and free of other significant anatomic structures. The cricothyroid arteries branch from the superior thyroid arteries and may form a small anastomotic arch traversing the superior aspect of the cricothyroid membrane. The external branch of the superior laryngeal nerve runs along the lateral aspect of the larynx and innervates the cricothyroid muscles inferior to the membrane. The isthmus of the thyroid gland most often overlies the second and third tracheal rings, although an aberrant pyramidal lobe of the gland may extend just superior to the cricothyroid membrane. The anterior attachments of the vocal cord structures are protected by the thyroid cartilage^{11,12} (Fig. 6.1).

In children, the larynx is positioned more superiorly than in adults.¹³ There is also more overlap between the thyroid cartilage and the cricoid cartilage, thus making the cricoid membrane proportionally smaller¹⁴ (Fig. 6.2).

SURGICAL CRICOTHYROTOMY

Indications and Contraindications

The chief indication for surgical cricothyrotomy is an inability to secure the airway with less invasive techniques in a patient with impending or ongoing hypoxia.¹⁵

Surgical cricothyrotomy, like any invasive procedure, is associated with significant complications and should not be attempted until less invasive measures have failed. No simple algorithm fits all cases. When time and the clinical situation allow, it may be appropriate to attempt to intubate multiple times with traditional laryngoscopy or to try alternative intubation techniques. Emergency decisions are subject to controversy and differ on a case-by-case analysis, but alternatives to cricothyrotomy include bag-valve-mask ventilation, the gum elastic bougie, and laryngeal mask airways. At some point, further attempts at intubation become futile and the benefits of a surgical airway outweigh the risks associated with ongoing hypoxia.¹⁶

When approaching a patient with a compromised airway, the clinician must have a clear potential algorithm in mind with a well-defined plan that shifts the airway approach from laryngoscopy to alternative techniques, and then to cricothyrotomy.¹⁷ The first step in deciding whether cricothyrotomy is indicated is anticipating a possible difficult intubation.¹⁸

Figure 6.1 Normal adult larynx. Note position and configuration of the cricothyroid membrane.

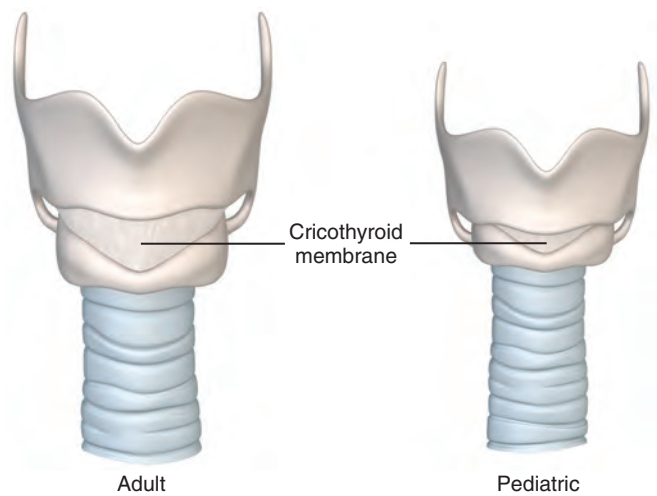

Figure 6.2 Adult larynx compared with a pediatric larynx.

Cricothyrotomy

Indications

Inability to maintain >90% saturation between intubation attempts or after three attempts
 Inability to bag-mask-valve ventilate the patient between intubation attempts or after three attempts
 Multiple attempts at endotracheal intubation fail to secure the airway after failed rescue maneuvers (e.g., gum elastic bougie intubation, intubating laryngeal mask airway)

Contraindications

Age younger than 5–12 years (depending on the source)
 Tracheal transection, fracture, or obstruction below the cricothyroid membrane

Complications

Acute

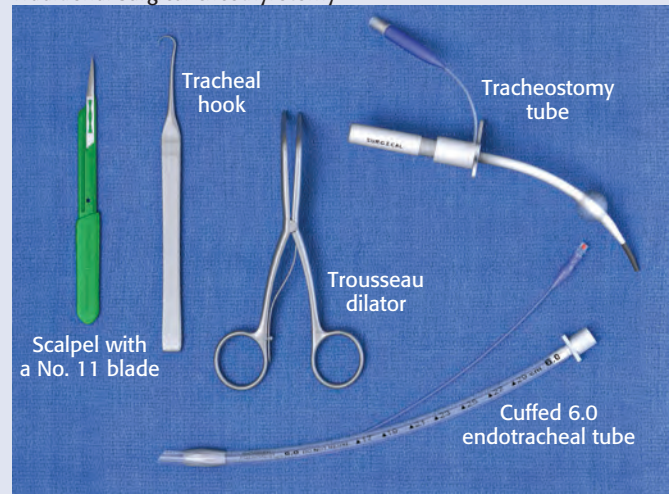

- Bleeding
- Tube malposition
- Bronchial intubation
- Laryngotracheal injury
- Tension pneumothorax
- Tube obstruction

Late

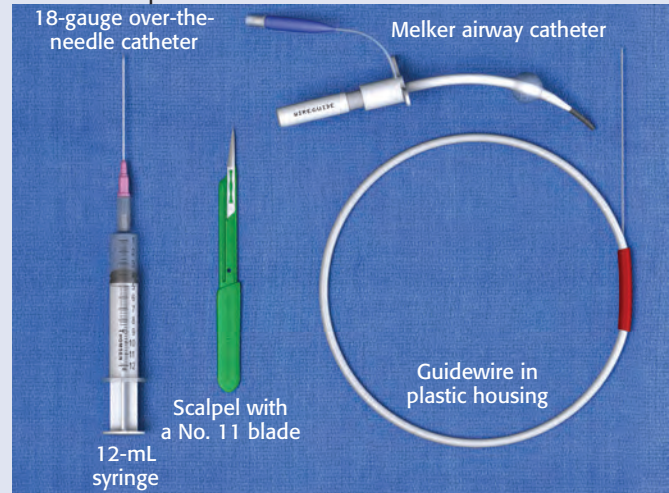

- Subjective voice changes
- Difficulty swallowing
- Infections
- Persistent shortness of breath
- Persistent stoma
- Subglottic or glottic stenosis

Equipment

Traditional surgical cricothyrotomy

Melker technique

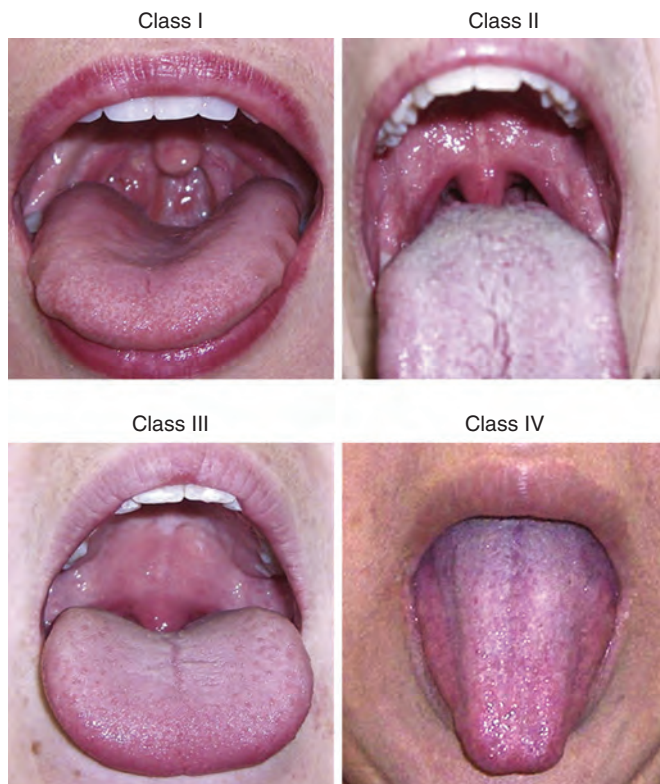

Figure 6.3 Modified Mallampati classes. (From Kryger MH: Sleep breathing disorders: examination of the patient with suspected sleep apnea. In Kryger MH, editor: *Kryger atlas of sleep medicine*, Philadelphia, 2010, Elsevier.)

Several studies in the anesthesia and emergency medicine literature have attempted to identify predictors of a difficult airway. A Mallampati score can be determined in cooperative patients who are able to sit upright. It classifies the degree that the faucial pillars, soft palate, and uvula can be visualized (Fig. 6.3). A higher score predicts a more difficult ET intubation.¹⁹ A Mallampati score can be obtained only in a limited number of ED patients requiring intubation.²⁰ A modified LEMON (Look externally, Evaluate, Mallampati score, Obstruction, Neck mobility) score, when excluding the Mallampati score, is more easily applied to ED patients for prediction of more difficult ET intubation²¹ (Fig. 6.4). Additional indicators of a difficult airway include obesity, oropharyngeal edema, hemorrhage, and laryngospasm^{22–25} (Box 6.1). In anticipation of a failed airway, it may be reasonable to mark the cricothyroid membrane using ultrasound guidance to prepare for the possibility of a cricothyrotomy.²⁶

Cricothyrotomy is indicated when a difficult airway becomes a “failed airway”. Various algorithms have been designed to define a failed airway. The American Society of Anesthesiologists suggests defining a failed airway as an inability to maintain oxygen saturation greater than 90%, signs of inadequate ventilation (cyanosis, absent breath sounds, hemodynamic instability) with positive pressure bag-mask ventilation, or more than three failed attempts at ET intubation or failure to intubate after 10 minutes by an experienced operator.²⁷ As more rescue airway adjunctive devices (such as the laryngeal mask airway, gum elastic bougie, or lighted stylet) become available, it is reasonable to continue beyond three attempts at ET intubation

THE LEMON LAW

EVALUATION CRITERIA	POINTS
L = Look externally	
Facial trauma	1
Large incisors	1
Beard or mustache	1
Large tongue	1
E = Evaluate the 3-3-2 rule	
Incisor distance—3 fingerbreadths	1
Hyoid-mental distance—3 fingerbreadths	1
Thyroid-to-mouth distance—2 fingerbreadths	1
M = Mallampati (Mallampati score >3)	1
O = Obstruction (presence of any condition such as epiglottitis, peritonsillar abscess, trauma)	1
N = Neck mobility (limited neck mobility)	1
Total	10

Figure 6.4 The LEMON law can be used to quickly assess for potentially difficult airways. Higher scores are associated with poor glottic visualization and difficult intubation. (Modified from Soyuncu S: Determination of difficult intubation in the ED, *Ann J Emerg Med* 8:905, 2009).

BOX 6.1 Clinical Indicators of a Difficult Airway

- High Mallampati score
- Thyroid-to-hyoid distance < 2 fingerbreadths
- Obesity
- Large incisors
- Limited neck mobility
- Airway obstruction (partial or complete)
 - Nontraumatic
 - Oropharyngeal edema
 - Laryngospasm
 - Mass effect (cancer, tumor, polyp, web, or other mass)
 - Traumatic
 - Oropharyngeal edema
 - Foreign body obstruction
 - Laryngospasm
 - Obstruction secondary to a mass effect or displacement
 - Stenosis
- Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous (relative)
 - Maxillofacial injuries
 - Cervical spine instability

if adequate ventilation and oxygen saturation greater than 90% can be maintained.^{28,29}

Because of the anatomic differences between children and adults, including a smaller cricothyroid membrane and a rostral, funnel-shaped, and more compliant pediatric larynx, surgical cricothyrotomy has been contraindicated in infants and young children. The exact age at which surgical cricothyrotomy can be performed is controversial and not well defined. Various textbooks list the lower age limit from 5 years³⁰ to 10 years³¹ or 12 years.³² The advanced cardiac life support and pediatric advanced life support define an infant airway as age up to 1 year and a child airway as age 1 to 8 years.

BOX 6.2 Indications for and Contraindications to Surgical Cricothyrotomy

INDICATIONS

Inability to maintain >90% oxygen saturation between intubation attempts or after three attempts
 Inability to ventilate the patient with a bag-valve-mask device between intubation attempts or after three attempts
 Multiple attempts at endotracheal intubation fail to secure the airway

CONTRAINDICATIONS

Age younger than 5–12 years (depending on the source)
 Tracheal transection, fracture, or obstruction below the cricothyroid membrane

Some authors also identify tracheal transection or low tracheal obstruction (below the cricoid) as absolute contraindications to cricothyrotomy because of the need to secure the airway below the injury³³ (Box 6.2).

Equipment

The equipment necessary to perform a traditional surgical cricothyrotomy includes a scalpel with a No. 11 blade, a Trousseau dilator, a tracheal hook, and a tracheostomy tube or modified ET tube (see Review Box 6.1). Bent 18-gauge needles may substitute for tracheal hooks. In addition, the sterile tray may include a syringe and lidocaine with epinephrine for local anesthesia, sterile drapes or towels, antiseptic preparation solution, 4 × 4-cm sterile gauze, scissors, hemostats, and suture material. The average adult's cricothyroid membrane is approximately 9 mm longitudinally and 30 mm horizontally. Familiarity with the dimensions of several standard tracheostomy and ET tubes is essential when selecting the appropriate size for surgical airways. Cuffed tracheostomy tubes are recommended, and they come in various sizes. Shiley tracheostomy tubes are commonly available in most EDs. The No. 4 tube has an inner diameter (ID) of 5.0 mm and an outer diameter (OD) of 9.4 mm, and the No. 6 tube has an ID of 6.4 mm and an OD of 10.8 mm. Shiley tracheostomy tubes have three parts: a cuffed outer cannula, a removable inner cannula, and a removable obturator that is solid and removed after insertion (Fig. 6.5). ET tubes are often used temporarily in place of a tracheostomy tube. With respect to ID, ET tube OD can vary with the manufacturer. As an example, the Mallinckrodt TaperGuard Evac Endotracheal Tube with IDs of 6.0 and 8.0 mm have ODs of 9.0 and 11.8 mm, respectively.³⁴ Although a No. 11 scalpel blade is most commonly used, a No. 20 blade is recommended in some variations of the technique. Commercially available kits include the Melker Cricothyrotomy Kit (Cook Critical Care, Bloomington, IN) for percutaneous cricothyrotomy, which uses the Seldinger technique to insert a cuffed or uncuffed airway catheter.

Procedure

Positioning plays a critical role in success, and the ideal patient position may be impossible because of clinical parameters. For example, hypoxic patients often cannot recline. Ketamine

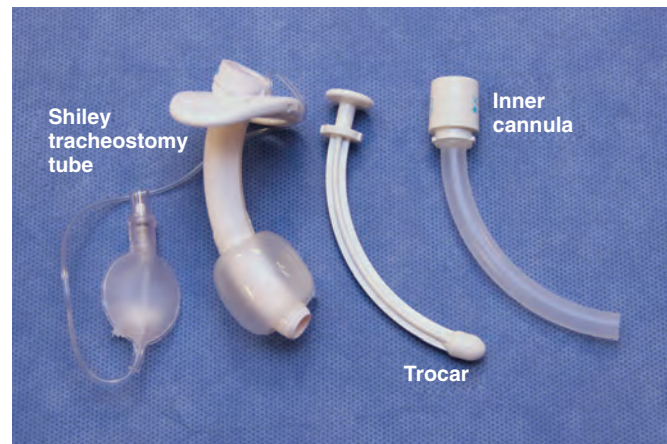

Figure 6.5 Standard Shiley tracheostomy tube with removable trocar and inner cannula.

anesthesia does not suppress the respiratory drive and may aid in patient cooperation and positioning. Ketamine is theoretically the superior agent to facilitate the procedure. When feasible, use the supine position with the neck exposed. Unless the patient has a known or suspected cervical spine injury, hyperextend the neck to more readily identify the landmarks. Surgical cricothyrotomy can safely and successfully be performed with minimal cervical spine movement.³⁵ Preoxygenate the patient by bag-mask ventilation. Prepare the skin of the anterior aspect of the neck with antiseptic solution and create a sterile field with the use of drapes or towels. If the patient is awake or responding to pain, give a subcutaneous and translaryngeal injection of lidocaine with epinephrine as a local anesthetic. Test the integrity of the balloon on the tracheostomy or ET tube by inflating it with 10 mL of air. Wear sterile gloves and take standard precautions by wearing a mask, goggles, and gown. Some preparatory steps may be omitted depending on the urgency of the procedure.

Traditional Technique

The “traditional” (open) cricothyrotomy technique (Fig. 6.6) has changed little since the original description of elective cricothyroidotomy by Brantigan and Grow in 1976.³⁶ McGill and colleagues³⁷ described the addition of a tracheal hook for emergency cricothyrotomy in 1982. In a follow-up report in 1989, Erlandson and colleagues³⁸ emphasized the importance of making an initial vertical skin incision and using a relatively small (No. 4 Shiley) tracheal tube. These modifications have generally been accepted and are commonly described as part of the traditional technique.³⁹

Prepare the tracheostomy tube by testing the balloon, removing the inner cannula, and inserting the solid white obturator. If right hand dominant, stand at the bedside on the patient's right side. Stabilize the larynx with the nondominant hand by grasping both sides of the lateral thyroid cartilage with the thumb and middle finger. Palpate the depression over the cricothyroid membrane with the index finger. Control the larynx throughout the procedure by stabilizing it in this manner (see Fig. 6.6, step 1). In shorter or more obese patients, or in patients with neck swelling, these landmarks may be more difficult to identify by palpation alone.^{40,41} If the laryngeal landmarks are not easily identifiable, bedside ultrasonography

SURGICAL CRICOTHYROTOMY: TRADITIONAL TECHNIQUE

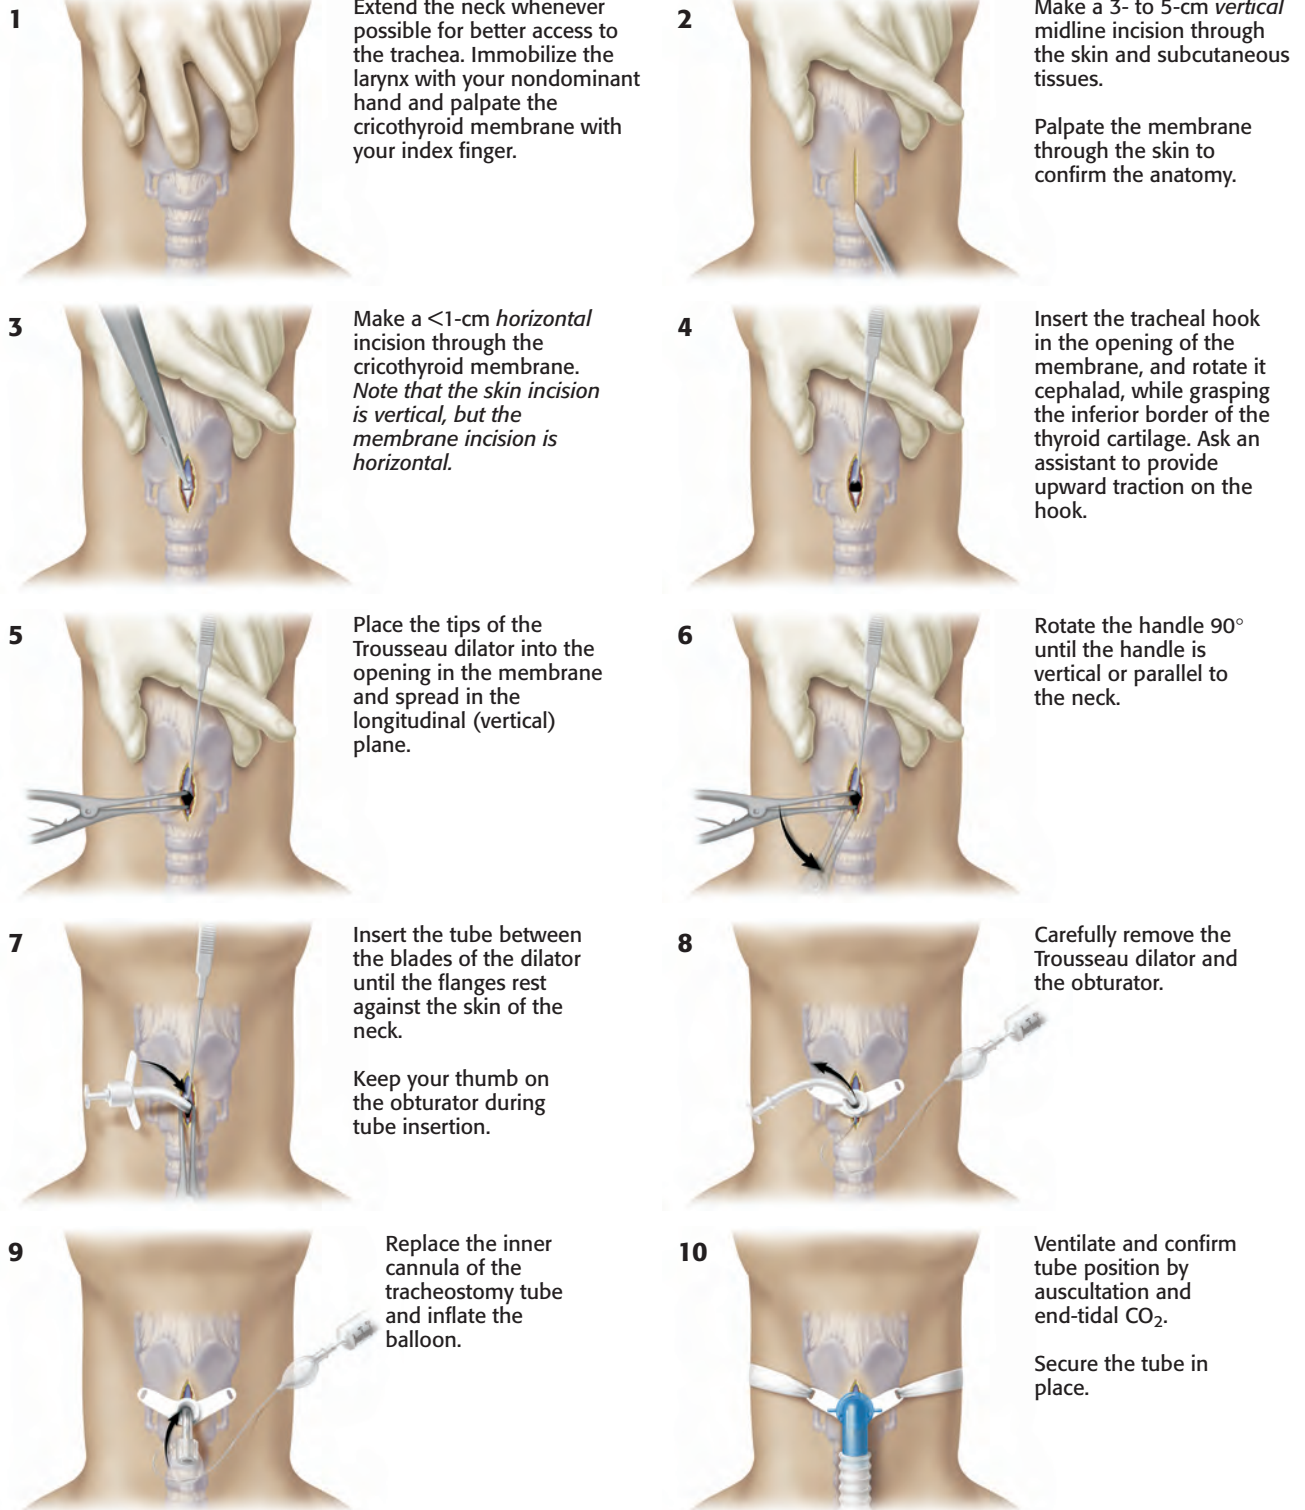

Figure 6.6 Surgical cricothyrotomy: traditional technique. (Adapted from Custalow CB: *Color atlas of emergency department procedures*, Philadelphia, 2005, Saunders.)

Figure 6.7 A, As an option, use the linear ultrasound probe to locate the cricothyroid membrane. B, Ultrasound image of the cricothyroid membrane in the sagittal plane. (B, from Mallin, M, et al: Accuracy of ultrasound-guided marking of the cricothyroid membrane before simulated failed intubation, *Am J Emerg Med* 32:61, 2014).

has been shown to assist in identifying the cricothyroid membrane, as well as decreasing injuries to the larynx and trachea.⁴²⁻⁴⁴ (Fig. 6.7).

While holding the scalpel with a No. 11 blade in the dominant hand, make an approximately 2- to 3-cm *vertical incision* through the skin and subcutaneous tissue (see Fig. 6.6, step 2). With the index finger of the nondominant hand, palpate the cricothyroid membrane through the incision. It is important to understand that the remainder of the procedure should be performed by palpation of the anatomy, not visualization, because bleeding may obscure the field and there is no time to delay while trying to achieve hemostasis. If the cricothyroid membrane cannot be palpated, extend the initial incision superiorly and inferiorly and try to palpate again. Using the stabilizing nondominant index finger as a guide, make a *horizontal* incision of less than 1.0 cm in length through the cricothyroid membrane (see Fig. 6.6, step 3). Note that the skin incision is vertical but the membrane incision is horizontal. Place the nondominant index finger into the stoma momentarily and exchange the scalpel for the tracheal hook.⁴⁵

Using the dominant hand, place the tracheal hook into the opening in the cricothyroid membrane. Rotate the handle cephalad while grasping the inferior border of the thyroid cartilage with it. Ask an assistant to provide upward traction or provide traction yourself by passing the handle of the hook to the nondominant hand (see Fig. 6.6, step 4). Use the tracheal hook to stabilize the larynx and keep it in place throughout the remainder of the procedure.

With the dominant hand, place the tips of the Trousseau dilator into the opening in the membrane with the spreading action oriented initially in the longitudinal or vertical plane so that the handle is facing horizontal or perpendicular to the direction of the neck (see Fig. 6.6, step 5). This instrument works opposite that of most ordinary instruments, such as hemostats. Squeezing the handles opens rather than closes the blades. This can be confusing the first time you use this instrument, and it is worth practicing before you need it in an emergency. If this instrument is not available in an emergency,

Mayo scissors, a hemostat, or even the blunt end of a scalpel handle can be used to dilate the incision in the cricothyroid membrane.⁴⁶

Dilate the incision vertically with the Trousseau dilator. Hold the handles of the Trousseau dilator with the nondominant hand and rotate the handle 90 degrees until the handle is vertical or parallel to the neck (see Fig. 6.6, step 6). If the dilator is left horizontal, the blades of the dilator may impede passage of the tracheostomy tube into the trachea. While holding the dilator with the nondominant hand, take the tube in the dominant hand and insert it between the blades of the dilator until the flanges rest against the skin of the neck (see Fig. 6.6, step 7). Keep the thumb on the obturator throughout the procedure. Carefully remove the Trousseau dilator (see Fig. 6.6, step 8). Remove the obturator and insert the inner cannula. Inflate the balloon (see Fig. 6.6, step 9). Remove the tracheal hook while being especially careful to not puncture the cuff.^{47,48}

If a tracheostomy tube is not available or if there is difficulty placing the tracheostomy tube into the opening in the cricothyroid membrane, try using a 6-0 cuffed ET tube cut to a shorter length. The ID/OD ratios of tracheostomy tubes are comparable to those of ET tubes. Use of a gum elastic bougie (Video 6.2) may facilitate and even hasten placement of an ET tube through the cricothyroid membrane into the trachea.⁴⁹ The advantage of using the bougie is that you can get immediate confirmation that the device is inside the trachea because of the “washboard” vibration that the curved tip makes as it contacts the tracheal rings.⁵⁰ Modify the ET tube by cutting the distal end and replacing the adapter to the cut end (Fig. 6.8). Be careful to not cut the pilot balloon or inflation port. If the ET tube is shortened, it is less likely to kink once it is attached to a ventilator. Advance the ET tube only approximately 5 cm from the tip to avoid main stem intubation. Keep in mind that standard ET tubes do not have centimeter markings at the distal end. Inserting the ET tube so that the distal cuff is approximately 2 cm beyond the cricothyroid membrane usually ensures proper placement.

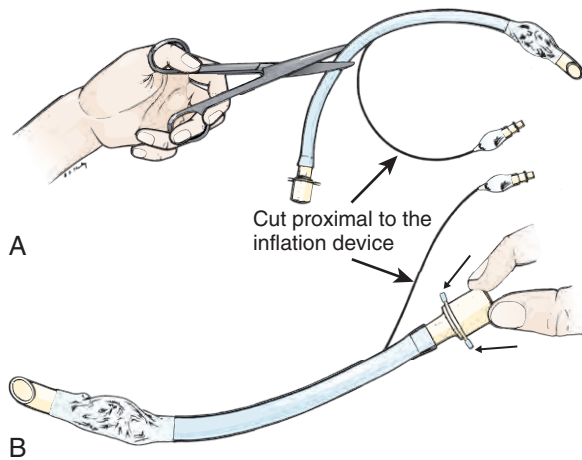

Figure 6.8 **A**, Modify the standard endotracheal (ET) tube for use in surgical cricothyrotomy as a temporary alternative to a tracheostomy tube. Cut the proximal end of the ET tube but be careful to not cut the balloon inflation apparatus. **B**, Replace the adapter on the cut end of the tube.

Confirm proper placement in the same manner as with ET tube placement: end-tidal CO_2 , bilateral chest movement, and breath sounds. Secure the tracheostomy tube with a circumferential tie around the neck or with sutures (see Fig. 6.6, step 10). Verify placement with a post-procedure portable chest radiograph.

Rapid Four-Step Technique (Brofeldt)

Brofeldt and colleagues⁵¹ developed a rapid four-step technique (RFST) to decrease the amount of time required to establish an airway and reduce complications of hypoxia. It combines aspects of traditional cricothyroidotomy and ET intubation. If right handed, stand at the bedside to the patient's left. Palpate the depression over the cricothyroid membrane with the nondominant hand (Fig. 6.9, step 1). With the dominant hand, make a single horizontal stab incision with a No. 20 scalpel blade approximately 1.5 cm in length through the skin, subcutaneous tissue, and cricothyroid membrane (see Fig. 6.9, step 2). With the scalpel blade as a guide, pick up the cricoid cartilage with the tracheal hook and provide traction in the caudal direction to stabilize the trachea (see Fig. 6.9, step 3).

SURGICAL CRICOTHYROTOMY: RAPID FOUR-STEP TECHNIQUE

1

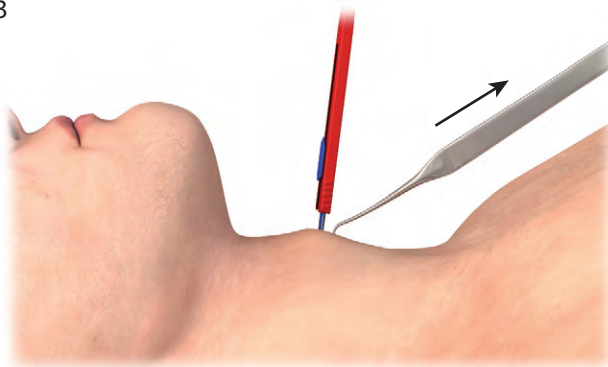

If possible, extend the neck to better expose the trachea. Palpate the depression over the cricothyroid membrane with your nondominant hand.

2

Make a 1.5-cm single horizontal stab incision through the skin, subcutaneous tissue, and cricothyroid membrane.

3

Using the scalpel blade as a guide, pick up the cricoid cartilage with the tracheal hook and provide traction in the caudal direction to stabilize the trachea.

4

Place a No. 4 cuffed tracheostomy tube or a 6.0 cuffed endotracheal tube through the opening.

Figure 6.9 Surgical cricothyrotomy: rapid four-step technique. Extension of the neck (if clinically feasible) facilitates the procedure. (Redrawn from Brofeldt BT, Panacek EA, Richards JR: An easy cricothyrotomy approach: the Rapid Four Step Technique. *Acad Emerg Med* 3:1060, 1996).

Figure 6.10 Bair Claw.

Place a No. 4 cuffed tracheostomy tube or a 6-0 cuffed ET tube through the opening (see Fig. 6.9, step 4).

Because this technique omits dilating the stoma with the Trousseau dilator, it may be more difficult to pass a tracheostomy tube. A gum elastic bougie, using the Seldinger technique, may assist in this step.⁵¹

Bair and colleagues⁵² modified this technique further by introducing a new device called a *Bair Claw* to replace the tracheal hook. The technique is similar to the four-step method except for positioning the operator at the head of the bed instead of the patient's side and the use of a double-hook device rather than a single hook. By replacing the single hook with the double hook, they found a decrease in the incidence of cricoid ring fractures in cadavers (Fig. 6.10).

This method has been further simplified, using ultrasound to localize the cricothyroid membrane. Then, a single horizontal laceration is made, again through the skin, subcutaneous tissue, and cricothyroid membrane. The scalpel is then turned 90 degrees to allow passage of a gum elastic bougie, over which an ET tube is passed.⁵³

Melker Percutaneous Cricothyrotomy Technique

The Melker Cricothyrotomy Kit (Cook Critical Care, Bloomington, IN) is a prepackaged commercial kit that uses the Seldinger technique to place a tracheostomy tube over a guidewire. The kit comes supplied with a 6-mL syringe, an 18-gauge needle with an overlying tetrafluoroethylene (TFE) catheter (the TFE catheter is not included in some kits), a guidewire, a tapered dilator, and a Melker airway catheter in lieu of a tracheostomy tube. Similar to retrograde intubation or needle cricothyrotomy with PTLV, the cricothyroid membrane must be easy to identify because no initial skin incision will be made. Anatomic distortion will make locating the cricothyroid membrane with a needle more difficult.

Preparation for this technique is similar to that for the other techniques. Positioned at the patient's left, palpate the cricothyroid membrane with the nondominant hand. With the dominant hand, attach the needle to the syringe and insert it through the cricothyroid membrane pointing caudally at a 45-degree angle relative to the skin surface (Fig. 6.11, step 1). Be careful not to advance the needle too far because this may result in perforation of the posterior aspect of the trachea. To help recognize when the trachea has been entered, place a small amount of saline in the syringe before the procedure. Apply gentle negative pressure while advancing the syringe. When the membrane is pierced and the trachea is entered, air will be aspirated into the syringe and air bubbles will appear in the saline.

When the needle is in the trachea, pull the syringe and needle back and advance the flexible TFE catheter through

the distal end of the trachea to its hub. If the needle does not have an overlying catheter, leave the needle in place and remove the syringe. Thread the guidewire through the needle or the catheter (see Fig. 6.11, step 2). Once the guidewire is placed securely in the trachea, remove the needle or catheter. With a disposable No. 15 scalpel, make a small incision in the skin at the point of guidewire entry to facilitate passage of the dilator and airway catheter (see Fig. 6.11, step 3).

Place the gray-tipped dilator into the airway catheter and thread it over the wire as one unit (see Fig. 6.11, step 4). Once it is through the skin and into the trachea, advance the airway catheter to its hub until it is flush against the neck. Remove the guidewire and dilator. Confirm placement in the trachea by standard methods. Secure the kit in place with "trach tape."

Melker kits on the market differ with respect to airway catheter ID and whether the airway catheter is cuffed. Some kits do not contain a needle with an overlying catheter.⁵⁴

Complications

Surgical cricothyrotomy is performed infrequently and usually under circumstances that are inherently chaotic. These patients often have confounding medical issues, with high morbidity and mortality rates. Evaluation of short- and long-term complications in this population is difficult.⁵⁵

Surgical cricothyrotomy has been studied to assess the periprocedure and short-term complications that occur with significant frequency. Acute complication rates have been reported to be between 8.7%⁵⁶ and 40%.³⁸ The most frequent complications are uncontrollable bleeding and misplacement of the tube.^{37,57} Most bleeding is from small superficial vessels that can be controlled, but significant bleeding can also occur as a result of the procedure. The cricoid arteries branch from the superior thyroid arteries and anastomose at the anterior superior aspect of the cricothyroid membrane. The laterally running superior thyroid arteries are more often damaged when the initial incision is broad and horizontal. To prevent hemorrhage from these vessels, make the initial skin incision longitudinal as in the traditional technique, and maintain careful awareness of the landmarks.⁵⁸ When making the horizontal incision in the cricothyroid membrane, avoid the cricoid artery by incising the membrane at its inferior aspect. Misplacement of the tracheostomy or ET tube during cricothyrotomy is a concern, just as esophageal intubation is a complication with ET intubation. If the opening in the cricothyroid membrane is not carefully stabilized during the procedure, the tube may inadvertently be inserted into subcutaneous tissue. This complication can be recognized by the presence of subcutaneous emphysema when attempting to ventilate the patient. It is essential to recognize this immediately to prevent the development of hypoxia and obliteration of anatomic landmarks. Failure to detect end-tidal CO₂ and absence of breath sounds by auscultation should alert the physician to a misplaced tube. If suspected, remove the tube and reassess the airway. A misplaced tube can pass into any location other than through the cricothyroid membrane, but the most crucial locations are those that do not enter the airway because this will lead to hypoxia and death if not recognized.

Many other occult complications have been reported less frequently or have been described in case reports, such as main stem bronchial intubation,⁵⁹ laryngotracheal injury,⁶⁰ tension pneumothorax,⁶¹ and obstruction of the tracheostomy tube

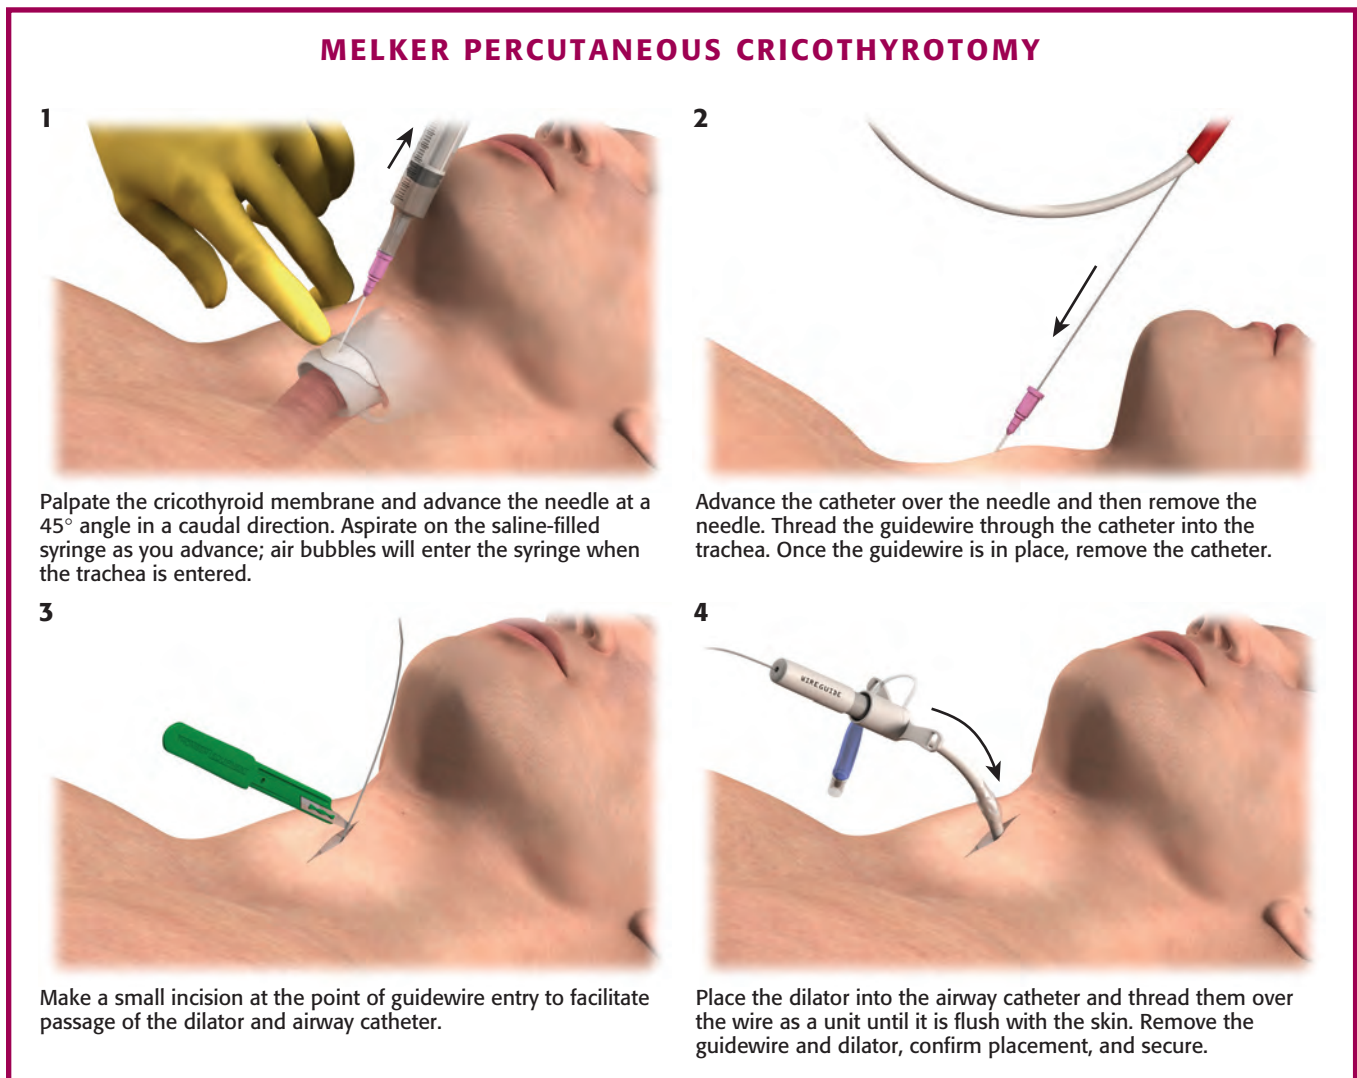

Figure 6.11 Melker percutaneous cricothyrotomy. As with other cricothyrotomy techniques, extension of the neck (if clinically feasible) exposes the trachea and facilitates the procedure.

with blood or secretions.⁶² Slobodkin and colleagues⁶³ reported one case of retrograde pharyngeal intubation (Box 6.3).

Chevalier Jackson's 1921 report⁶⁴ highlighted the concern that subglottic stenosis was a major and frequent complication of cricothyrotomy. It was later refuted by Brantigan and Grow's 1976 study,³⁶ that reported not only an overall complication rate of just 6.1% but also no occurrence of chronic subglottic stenosis as a long-term complication. Since the publication of this latter report, numerous other studies have corroborated their findings that chronic subglottic stenosis is an infrequent long-term complication of surgical cricothyrotomy.⁶⁵⁻⁶⁹ Factors that increase the likelihood of development of subglottic stenosis include concurrent laryngotracheal pathology, prolonged time until decannulation, old age, and diabetes.^{70,71}

Long-term complications resulting in "minor airway problems" have been reported more frequently than subglottic stenosis.⁷² Of these complications, subjective voice change is the most frequently reported.⁷³ Other reported complications include difficulty swallowing, subjective shortness of breath, wound infections, and "noisy breathing."⁷⁴

To decrease the morbidity and mortality associated with prolonged hypoxia and other factors inherent in an airway emergency, attempts have been made to determine whether any technique is superior with regard to complication rate and time needed to secure the airway. When comparing Brofeldt and colleagues' RFST with the traditional five-step technique, Davis and colleagues⁶⁰ found an increased incidence of cricoid ring fracture when the single hook was used for caudal traction on the cricoid cartilage and concluded that the traditional technique produced a lower complication rate. A study by Holmes and colleagues⁴⁵ in which the same two techniques were performed by inexperienced medical students and residents on human cadavers concluded that the single-hook RFST was executed significantly faster than the traditional technique. They noted that there were more complications with the RFST but that the difference in complication rates failed to reach statistical significance. Davis and colleagues⁷⁵ revisited this comparison in a later study and replaced the single hook in the RFST with the double-hooked Bair Claw. The revised study showed that the airway could be secured faster with the

BOX 6.3 Complications of Surgical Cricothyrotomy

ACUTE COMPLICATIONS

More common

- Bleeding
- Malposition of the tube

Less common

- Bronchial intubation
- Laryngotracheal injury
- Tension pneumothorax
- Obstruction of the tube

LATE COMPLICATIONS

More common

- Subjective voice changes
- Difficulty swallowing
- Infections
- Persistent shortness of breath
- Persistent stoma

Infrequent

- Subglottic or glottic stenosis

RFST and that the complication rate was comparable; they also observed that the Bair Claw did not cause any fractures of the cricoid cartilage. Bair and colleagues' retrospective report⁷⁶ of ED cricothyrotomy showed a lower complication rate with the RFST than with the traditional technique.

Consensus cannot be drawn from the literature comparing the traditional method with the percutaneous Seldinger (Melker kit) method. Some studies show no difference in time to ventilation or complication rate when the traditional technique is compared with the Seldinger technique.⁷⁷ Some studies report that the surgical method is faster than the Seldinger method,⁷⁸⁻⁸² whereas others conclude the opposite.^{83,84}

Many complications of cricothyrotomy are relatively minor in comparison to those caused by prolonged hypoxia. Be aware of these potential complications and prepare for them, and do not delay performing the procedure out of fear of them. Reduce complication rates by maintaining a sterile field and being familiar with the techniques and anatomy.

When deciding which surgical cricothyrotomy technique to use, consider the advantages and disadvantages of each technique, the clinical scenario, availability of equipment, and comfort and familiarity with each individual technique.

Success Rates

Success rates for first-attempt ET intubation in the ED are quite high. The reported success rate is 90% for all ED intubations and 98% for attending physician intubations. The "rescue" cricothyrotomy rate is reported to be just 0.7% according to the National Emergency Airway Registry.³ A study including more than 6000 trauma patients reported a 0.3% cricothyrotomy rate in those requiring airway management within the first hour after arrival.⁸⁵ In pediatric patients, the success rate with the first attempt for all ED intubators is slightly less at 85%, with rescue cricothyrotomy performed less than 1% of the time (1 of 156 patients).⁸⁶ As an overview, few emergency physicians have the opportunity to gain extensive

experience with surgical airways, and no standards of care have been developed that define the exact role of cricothyrotomy in clinical practice. It is difficult to successfully perform an emergency surgical airway, and even with proper training and standard experience, not all attempts with this technically difficult procedure will be successful. Although the reported success rate for cricothyrotomy has been quite high (89% to 100%) in most studies,^{25,37,38,55,62,66,76,87} one study found only a 62.5% success rate.⁸⁸ In a community hospital setting, the rather optimistic success rate reported from trauma centers probably cannot be duplicated. In one ED study, the incidence of failed cricothyrotomy (e.g., tube misplacement into the pretracheal space or failed attempts) was 3.6%,⁷⁶ with earlier ED studies being in the 7.9% to 10% range.^{37,38} In the pre-hospital setting, the reported failure rates are 6% to 12% for paramedics,^{25,55,87} 0% for physicians,⁶⁶ and 0% to 38% for air transport medics.^{88,89} In a cadaver model, the first-time performance of cricothyrotomy by intensive care unit clinicians, versus standard surgical cricothyrotomy with the Seldinger technique, resulted in successful tracheal placement in only 70% with the standard technique and 60% with the Seldinger technique.⁷⁷ In an animal model, paramedics had a 90.9% success rate with a percutaneous technique and a 100% success rate with the open surgical technique.⁷⁹

PERCUTANEOUS TRANSLARYNGEAL VENTILATION

PTLV is a procedure in which oxygen is delivered through a 12- to 14-gauge catheter inserted through the cricothyroid membrane via needle cricothyrotomy. Needle cricothyrotomy does not differ greatly from the Seldinger technique variation of surgical cricothyrotomy. Administration of oxygen through the percutaneous translaryngeal catheter is by bag insufflation for pediatric patients younger than 5 years, and by a high-flow source for older children and adults. The methods for controlling jet ventilation have evolved over recent years. The initial use of continuous oxygen flow provided adequate oxygenation but not ventilation.⁹⁰ The technique has evolved so that shorter bursts of oxygen are followed by a longer passive exhalation to resemble a more physiologic respiratory state.

Indications and Contraindications

The indications for and contraindications to needle cricothyrotomy with PTLV are similar to those for surgical cricothyrotomy. Indications include failed attempts at ET intubation, inability to bag-mask ventilate to an oxygen saturation greater than 90%, or airway obstruction above the level of the cricothyroid membrane. Based on the operator's experience, needle cricothyrotomy may be relatively indicated over surgical cricothyrotomy in adult patients. Much of the otolaryngology literature supports the use of PTLV as a means of nonemergency ventilation during head and neck surgery because the smaller ventilation catheter provides a relatively unobstructed field in which to work.⁹¹⁻⁹³ In an emergency airway situation, needle cricothyrotomy may successfully allow time to establish an airway via surgical cricothyrotomy⁹⁴ or the ET route.⁹⁵ Case reports describe PTLV to be relatively indicated over the more invasive surgical cricothyrotomy when ET intubation has failed as a result of copious oropharyngeal secretions. Providing temporary ventilation through the needle catheter may allow

Percutaneous Translaryngeal Ventilation

Indications

Similar to surgical cricothyrotomy
Failed attempts at endotracheal intubation with an inability to bag-mask ventilate to an oxygen saturation >90%
Airway obstruction above the level of the cricothyroid membrane
Preferred method of securing a crash airway in infants and children

Contraindications

Ability to secure the airway through less invasive means
Laryngeal transection or fracture

Complications

Associated with needle placement

- Subcutaneous emphysema
- Kinking of the catheter
- Bleeding
- Malposition of the catheter
- Posterior tracheal wall perforation
- Pneumothorax

Associated with ventilation

- Barotrauma, pneumothorax, pneumomediastinum
- Hypercapnia, respiratory acidosis

Equipment

Review Box 6.2 Percutaneous translaryngeal ventilation: indications, contraindications, complications, and equipment.

sufficient time to clear the upper airway of secretions or obstructions and give the operator more time to establish ET intubation.^{96,97}

Surgical cricothyrotomy is contraindicated in infants and young children. The contraindication arises from the fact that the cricothyroid membrane is too small to insert a tracheostomy tube and there is a significant risk for injury to surrounding structures. Needle cricothyrotomy is the preferred method of securing the airway in crash airway situations in infants and young children.⁹⁸

An absolute contraindication to needle cricothyrotomy is the ability to secure the airway without difficulty through less invasive means.⁹⁹ Similar to surgical cricothyrotomy, needle cricothyrotomy is contraindicated in cases of laryngotracheal transection or fracture because the airway needs to be established below this level.³³ It has been suggested that in cases of complete upper airway obstruction, needle cricothyrotomy is relatively contraindicated in comparison to surgical cricothyrotomy. This concern, which is debatable, is due to the fact that the PTLV

catheter theoretically does not permit adequate expiration volumes and results in hypercapnia and barotrauma.¹⁰⁰

Equipment

The essential material needed for PTLV includes a needle with an overlying catheter, oxygen tubing, an oxygen source with a means of regulating the pressure, and a means to connect them together.

Commercial kits are available, but a standard 12- or 14-gauge Angiocath attached to a 3- or 5-mL syringe can be used to make the puncture through the cricothyroid membrane. The catheter can be left in place to serve as the conduit for oxygen delivery. The larger the diameter of the catheter, the greater the oxygen flow, depending on the method of oxygen delivery.¹⁰¹ Commercial catheters, such as wire-coiled nonkinking catheters and fenestrated catheters, are available as part of prearranged kits (Fig. 6.12). Larger-caliber, 3.0 to 4.0 mm-ID percutaneous tracheal catheter devices are also available.

Figure 6.12 ENK oxygen flow modulator set available as separate kit. (Courtesy Cook Critical Care, Bloomington, IN.)

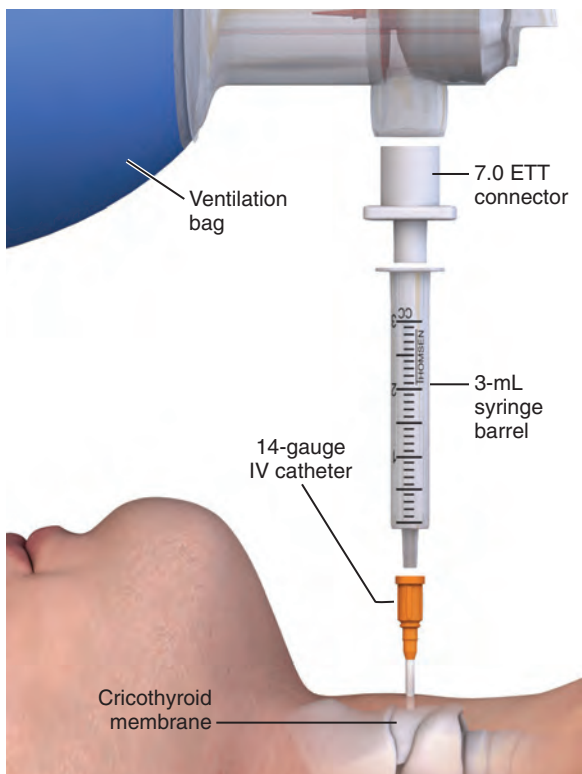

Figure 6.13 Homemade ventilation setup for transtracheal catheter ventilation using a ventilation bag, a standard endotracheal tube adapter, a 3-mL syringe, and a 14-gauge angiocatheter. *ETT*, Endotracheal tube; *IV*, intravenous.

There are two different basic means and therefore armories of equipment to choose from to deliver oxygen through the transtracheal catheter. One method uses a standard ventilation bag to supply oxygen through the catheter. This requires the constant effort of manual bag insufflation as long as the patient is being oxygenated and ventilated. Attach the bag to the adapter of a 7.0-mm ET tube and insert it into the back of a plungerless 3-mL syringe connected to the translaryngeal catheter (Fig. 6.13). Alternatively, attach the bag directly to the catheter with the adapter of a 3.5-mm pediatric ET tube.¹⁰² An inherent problem with this setup is the rigidity of the system. Although

Figure 6.14 Three-way stopcock connecting the oxygen tubing to the hub of the catheter with the third arm open to the atmosphere.

the translaryngeal catheter itself is flexible, there is no flexibility from the hub of the catheter to the bag. Slight movements of the bag relative to the patient may cause dislodgment of the catheter. To ameliorate this obstacle, connect standard intravenous infusion tubing directly to the translaryngeal catheter and attach the distal cut end of a 2.5-mm ET tube to the bag.

In an alternative method, supply oxygen can be supplied from a standard 50 psi wall source, connecting the high-pressure oxygen tubing to the wall source. Then secure the oxygen tubing to a manual on/off valve that is attached to the hub of the catheter. The on/off valve controls the inspiratory-to-expiratory ratio. This valve may be a trigger that is pushed down and released, the third arm of a three-way stopcock open to the atmosphere (Fig. 6.14), or holes placed at the end of the oxygen tubing. A pressure gauge connected to a hand-triggered jet injector may also be used to control the amount of air pressure reaching the catheter¹⁰³ (Fig. 6.15). Commercial kits are available that contain prepackaged systems already assembled. Otherwise, assemble the apparatus in the ED. In an emergency, it is unlikely that one would be able to assemble an apparatus for PTLV from individual components in a timely manner. If a prepackaged PTLV kit is not available, prepare the appropriate components from the ED ahead of time and place them with other airway supplies for easy access.

Assemble additional material such as antiseptic preparation solution, sterile drapes, sterile gauze, and suture material or trach tape in the kit.

Procedure

As with the surgical cricothyrotomy technique, place the patient in the supine position with the neck exposed. Prepare the skin

Figure 6.15 Hand-triggered jet injector. Depressing the lever with the thumb (*arrow*) delivers oxygen to the patient.

of the anterior aspect of the neck. Wear appropriate protective equipment, including sterile gloves, gown, protective eyewear, and a face shield. Hyperextend the patient's neck unless a suspected cervical spine injury prohibits it. Infiltrate the skin with local anesthetic.

Similar to the needle insertion technique used for guidewire-assisted surgical cricothyrotomy, while positioned at the patient's left, locate the cricothyroid membrane with the nondominant hand. Locate the thyroid cartilage and cricoid cartilage and palpate the cricothyroid membrane in the depression between the two while keeping in mind that this depression will be proportionately smaller in children (Fig. 6.16, *step 1*).

Attach a 12- to 14-gauge Angiocath to a 3- or 5-mL syringe filled with 1 to 2 mL of saline or lidocaine. Once the cricothyroid membrane has been located, insert the needle through the overlying skin, subcutaneous tissue, and membrane directed at a 30- to 45-degree angle caudally (see Fig. 6.16, *step 2*). While doing so, aspirate gently with the syringe. The cricothyroid membrane has been pierced and the airway entered when air bubbles are seen in the fluid or there is an increase in the ease of air aspiration (see Fig. 6.16, *step 3*). Once through the membrane, hold the needle in place, advance the catheter to the hub, and then remove the needle (see Fig. 6.16, *steps 4 and 5*). Hold the catheter by hand until the oxygen supply is connected and appropriate placement is confirmed (see Fig. 6.16, *step 6*). Make sure that the hub of the catheter is flush against the skin to avoid an air leak and then secure it with a circumferential tie around the neck. To prevent the tube from being dislodged, keep one hand on the hub of the catheter until the entire procedure is completed and the airway is secured.

Oxygen can be supplied to the catheter through several different conduits. With the resuscitation bag setup, manually ventilate the lungs through the catheter by squeezing and releasing the bag. When coupled with a 14-gauge Angiocath, ventilation with a resuscitation bag produces low maximal tidal volumes, approximately 100 mL per 1 second of inspiratory time in one study.¹⁰⁴ Children, especially those younger than 5 years, have small total lung capacities and need smaller tidal volumes. In these cases, use the bag instead of the jet ventilator. To use this setup, control the volume of air inspired and adjust

it breath by breath based on chest wall motion, pulse oximetry, and capnography. This method is not appropriate for adults because the operator cannot provide adequate tidal volumes and allow enough time for exhalation.^{105,106}

If using high-flow oxygen supplied from a wall source, attach the oxygen tubing to the wall source and secure the distal end of the tubing apparatus to the hub of the translaryngeal catheter. The flow rate recommended for children is 1 L/min per year of age, with titration upward in increments of 1 L/min based on chest wall movement.¹⁰⁷ Most wall-mounted oxygen flowmeters have a maximum flow rate marked at 15 L/min. Pressures generated at this flow rate have been shown to be inadequate to sustain ventilation in adults.^{108,109} To provide the additional pressure necessary to ventilate an adult, open the oxygen flowmeter to full output.¹¹⁰ Ventilate the patient by alternating between allowing and inhibiting airflow through the catheter. This is done by occluding and then releasing the hole or holes if using a stopcock or the ENK oxygen flow modulator (Cook Medical, Bloomington, IN) or by pushing and releasing a trigger if using this type of modulator. Watch for chest wall rise and fall, and make sure to allow enough time for exhalation before the next cycle. A pressure gauge, if attached, can help guide inspiration time.

Complications

Complications reported with needle cricothyrotomy are similar to those associated with surgical cricothyrotomy: bleeding, misplacement of the catheter, subcutaneous emphysema, and pneumothorax.^{111,112} Complications more specific to needle cricothyrotomy include catheter kinking¹¹³ and perforation of the posterior aspect of the trachea.¹¹⁴

One would assume that a translaryngeally placed catheter would not afford any airway protection against aspiration because the diameter of the catheter is not nearly large enough to occlude the lumen of the trachea. A few studies, though, have shown a decreased rate of aspiration in dogs that were ventilated with PTLV versus control animals who were not ventilated, thus suggesting some airway protection with this mode of ventilation.^{115,116}

The potential complications more specific to PTLV than to ventilation through a tracheostomy tube stem from the idea that, especially in cases of complete upper airway obstruction, egress of inspired gas is limited through the relatively small translaryngeal catheter. It has been reported that PTLV inevitably causes retention of CO₂ in adults. This leads to poor ventilation despite adequate oxygenation. This assumption may be a remnant of earlier oxygenation techniques in which continuous low-flow "apneic oxygenation" was used without ventilation.⁹⁰ Many animal studies have shown that adequate ventilation, normal blood pH, and normal arterial CO₂ partial pressure can be maintained with PTLV for 30 or even 60 minutes.¹¹⁷⁻¹²² Factors that seem to improve ventilation are increased expiratory time¹²³ and a high-flow oxygen source.¹²⁴ Even with partial or nearly complete oropharyngeal obstruction, adequate ventilation has been achieved.^{125,126} Unfortunately, none of these studies looked at ventilation for extended periods. Barotrauma is a significant risk associated with PTLV and occurs when upper airway obstruction is preventing air from being exhaled. This causes an increase in lung volume and pressure and leads to lung injury.^{127,128} Lenfant and colleagues¹²⁸ found that, using a lower respiratory rate and the ENK oxygen flow modulator versus the Manujet (Mainline Medical, Inc.,

PERCUTANEOUS TRANSLARYNGEAL VENTILATION

1

Hyperextend the patient's neck if possible. Locate the cricothyroid membrane with your nondominant hand.

2

Attach a 14-gauge angiocatheter to a saline-filled syringe. Insert the needle through the skin, subcutaneous tissue, and membrane directed at a 30° to 45° angle caudally.

3

Aspirate the syringe as you advance the needle; air bubbles will be seen in the syringe when the trachea is entered.

4

Once the trachea is entered, advance the catheter over the needle until the hub is flush with the skin.

5

Remove the needle.

6

Attach the oxygen supply and begin to ventilate the patient.

Figure 6.16 Percutaneous translaryngeal ventilation.

Norcross, GA), decreases pulmonary pressure, which theoretically reduces the likelihood of barotrauma. The ENK oxygen flow modulator may also be superior to a three-way stopcock for similar reasons.¹³⁰ The Ventrain device (Armstrong Medical Ltd, Coleraine, Northern Ireland), which allows more rapid expiration, has also been shown to have improved minute ventilation, peak airway pressures, and decreased hemodynamic depression compared to previous methods when studied in animal models.^{131,132} Use of a bidirectional valve or an expiratory ventilation assistance ejector device has been shown to

improve ventilation dynamics and decrease the complications associated with PTLV in patients with complete upper airway obstruction^{133,134} (Box 6.4).

CONCLUSION

The majority of crash airway scenarios are controlled successfully with ET intubation. The development of airway aids such as the gum elastic bougie, laryngeal mask airway, and

BOX 6.4 Complications of Percutaneous Translaryngeal Jet Ventilation**COMPLICATIONS ASSOCIATED WITH NEEDLE PLACEMENT**

Pneumomediastinum
Hypercapnia, respiratory acidosis

fibroscopic laryngoscope has obviated the need to convert efforts to an invasive surgical technique. Situations arise when an airway cannot be secured with one of these aids or the patient cannot be ventilated via bag-mask-valve ventilation, and then a surgical approach is indicated.

Researchers have attempted to delineate which method of gaining emergency airway access is superior by comparing all techniques across the spectrum from traditional surgical cricothyrotomy to needle cricothyrotomy to commercially available kits such as the QuickTrach (Teleflex Medical, Morrisville, NC). Given the variety of equipment and techniques to choose from and the advantages and disadvantages reported about each throughout the literature, it would be difficult for an inexperienced physician to know which to choose in a critical situation. As most physicians do not perform this procedure during residency on a living patient, and only approximately 68%¹³⁵ do so on a recently deceased patient, familiarity with equipment is paramount. Aside from being familiar with the equipment available in the ED, research shows that physicians at all levels of training have increased success rates when they are exposed to simulated situations before an actual airway emergency.^{133,134,136}

Tracheostomy Care

John C. Greenwood and Michael E. Winters

INTRODUCTION

Placement of a tracheostomy tube is a common procedure in critically ill patients. Common indications for this procedure include upper airway obstruction, head or neck trauma, and prolonged respiratory failure.^{1,2} Approximately one fourth of patients in the intensive care unit (ICU) will require a tracheostomy tube for prolonged respiratory support or weaning from mechanical ventilation.³ Advances in health care allow many patients with tracheostomies to live at home or in other relatively low-technology environments such as rehabilitation facilities and nursing homes. Tracheostomy care is often provided by a variety of caregivers, including family members, home health care nurses, and patient care technicians.^{4,5}

Patients with tracheostomies are seen in emergency departments (EDs) for a variety of problems related to the tracheostomy.⁶ Many emergency clinicians will have minimal experience with such patients and it should be emphasized that complications or problems with tracheostomies often require specialty consultation in the ED to be fully evaluated or definitively remedied.

Common complaints include difficulty breathing as a result of tube obstruction, tube displacement, or equipment failure; poor oxygenation from infection or altered patient anatomy; and bleeding. In some cases, complications can be life threatening. Emergency physicians must be knowledgeable regarding the evaluation and management of patients with tracheostomies. This chapter reviews the relevant tracheal anatomy and essential tracheostomy equipment, discusses pertinent tracheostomy care, provides a systematic approach to the evaluation and management of selected complications, and identifies high-risk patient populations.

BACKGROUND

Most tracheostomies are performed electively. For elective tracheostomies, the surgical site is between the first and second or the second and third tracheal rings. With an open, or surgical, tracheostomy, the anterior aspect of the trachea is generally left sutured to the skin until the tract matures, approximately 4 to 5 days after the procedure. In recent years, percutaneous dilational tracheostomy has become the preferred technique for many ICU patients. It can be performed at the bedside and eliminates the risks associated with transporting critically ill patients to an operating room. Postoperative complications vary and depend on the timing and insertion technique (Box 7.1). Early postoperative complications tend to arise in the first few days to weeks. Sixteen to twenty percent of patients experience early complications, and 6% to 8% experience late complications.⁷ Although elective and emergency tracheostomies are generally performed with the same technique, the complica-

tion rate associated with emergency procedures may be higher than the rate for elective tracheostomies.⁸⁻¹⁰

TRACHEAL ANATOMY AND PHYSIOLOGY

The lower respiratory tract begins at the vocal cords. Inferior to the vocal cords lies the cricoid cartilage, which encases the 1.5- to 2-cm subglottic space. Inferior to the cricoid cartilage is the trachea (Fig. 7.1). The typical adult trachea is 10 to 12 cm in length. The anterior and lateral walls of the trachea are supported by 18 to 22 incomplete cartilaginous rings. A fibromuscular sheet lying anterior to the esophagus completes the posterior wall. The interior diameter of the adult trachea is 12 to 25 mm, and it is lined with mucosa covered by respiratory epithelium.⁸ Blood is supplied to the trachea by branches of the inferior thyroid, innominate (brachiocephalic), bronchial, and subclavian arteries. Critically, the innominate artery (IA) lies in close proximity to the tracheostomy stoma. From its origin at the aortic arch, the IA courses between the sternum and the anterior aspect of the trachea and veers right at the sternomanubrial joint. The location of the IA is important because erosion of the anterior tracheal wall can lead to life-threatening bleeding. The recurrent laryngeal nerve innervates the intrinsic laryngeal muscles and mucosa below the vocal cords. Efferent vagal fibers stimulate bronchoconstriction, mucosal secretions, and vasodilation. Efferent sympathetic fibers of the pulmonary plexus stimulate tracheal bronchodilation and vasoconstriction.

The upper airway, including the oropharynx and nasal passages, filters particulate matter, humidifies inspired air, and aids in the expectoration of secretions. These functions are reduced in patients with a tracheostomy.⁸ Placement of a tracheostomy bypasses humidification and results in the formation of thick, dry secretions.¹¹ In the absence of humidification, squamous metaplasia and chronic inflammatory changes develop in the trachea.¹² Bronchoconstriction resulting in reduced airflow can occur if the inspired air temperature is below room temperature. Normal mucociliary clearance is also impaired because of the increased viscosity of respiratory secretions, which underlies chronic illness and respiratory infections, particularly with *Mycoplasma* or viral pathogens.¹³

The tracheostomy procedure weakens the anterior tracheal wall and blunts the normal cough mechanism, an important component for clearance of secretions by the trachea.¹³ Normally, the epiglottis and vocal cords close to trap air in the lungs and raise intrathoracic pressure before a cough. Patients with a tracheostomy tube are generally unable to generate sufficient pressure to initiate a strong cough and facilitate airway clearance.¹⁴ In addition to an impaired cough mechanism, immune responses are often blunted in patients with tracheostomies as the result of underlying illnesses, chronic lung disease, chemotherapy, or acquired immunosuppression.

EVALUATION OF TRACHEOSTOMY PATIENTS

Every ED patient with a tracheostomy who has a respiratory complaint or a complaint related to the tracheostomy should be thoroughly evaluated. Begin the primary assessment with a review of the patient's vital signs and evaluation of the airway. Examine the tracheostomy and consider dislodgement, obstruction, and fracture of the tube. Next, assess the patient's

BOX 7.1 Complications of Tracheostomy**EARLY COMPLICATIONS (DAYS TO WEEKS)**

Hemorrhage—postoperative
 Tube dislodgement or obstruction
 Subcutaneous emphysema
 Soft tissue infection
 Pneumothorax, pneumomediastinum

LATE COMPLICATIONS (>3 WEEKS)

Tracheal stenosis or tracheal malacia (granulation tissue)
 Tube dislodgement or obstruction
 Equipment failure
 Tracheoinnominate artery fistula
 Tracheoesophageal fistula
 Infection—pneumonia, aspiration

Figure 7.2 Suggested equipment for tracheostomy care.

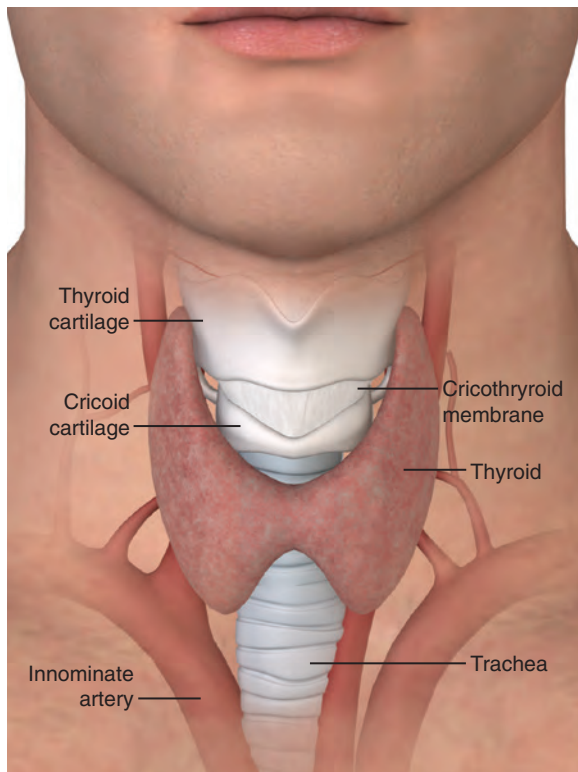

Figure 7.1 Normal tracheal anatomy.

respiratory status. If the patient is receiving mechanical ventilation on arrival and is in acute distress, remove the patient from the ventilator and replace it with manual ventilation with a bag-valve-mask device. Initiate continuous cardiac monitoring, pulse oximetry, and capnography, if available, in all tracheostomy patients in respiratory distress.

In the history of the present illness, include the indications for placement of a tracheostomy, the length of time from placement to arrival at the ED, and any previous complications. Discuss any planned or existing voice prosthesis, previous bleeding complications or strictures, and whether a permanent tracheostomy or decannulation of the tracheostomy is anticipated. Ask whether there have been any recent changes in

ventilator settings or tracheostomy care, including increased oxygen use, increased suctioning, equipment failure, or changes in equipment.

After the primary assessment and focused history, perform a thorough physical examination to differentiate between tracheostomy complications and other causes of the patient's respiratory complaint. The differential diagnosis may include pneumonia, exacerbation of chronic obstructive pulmonary disease, congestive heart failure, pulmonary embolism, pneumothorax, and acute coronary syndrome. During the secondary evaluation, evaluate the patient's stoma for signs of bleeding, infection, or skin breakdown. Make a note of the specific type and model of equipment used in the event that a replacement tube is needed.

GENERAL EQUIPMENT FOR TRACHEOSTOMY PATIENTS

Before performing any procedure on the tracheostomy tube, it is important that the emergency physician ensure that essential equipment is readily available at the patient's bedside. These items are shown in [Fig. 7.2](#). Adequate preparation is crucial in preventing a poor outcome should complications arise. Most of this equipment can be placed in a designated airway box that can easily be accessed within the room or ED.

ROUTINE TRACHEOSTOMY MAINTENANCE

Routine tracheostomy maintenance involves (1) regular cleaning of the tube, (2) frequent stomal care, and (3) periodic monitoring of cuff pressure. There are many different types of tracheostomy tubes, and the focus of this section is on the most common, those with a removable inner cannula ([Fig. 7.3A](#)). Regular cleaning of the tracheostomy tube and inner cannula can prevent the accumulation of dried secretions. Lack of cleaning and maintenance of the inner cannula is the primary cause of tube obstruction (see [Fig. 7.3B](#)). Under normal circumstances the inner cannula should be in place. It sits snugly within the tracheostomy tube and can easily be removed without disturbing the tube itself. The inner cannula should be cleaned daily.

Figure 7.3 Shiley tracheostomy tube. **A**, The obturator is placed inside the tube (while the inner cannula is removed) to facilitate insertion through the stoma. The inner cannula must be inserted into the tube to ventilate the patient. **B**, The inner cannula should always be in place and removed only for daily cleaning. An inner cannula clogged with mucus and debris, as seen in this figure, is the most common cause of respiratory distress in patients in the emergency department.

Soak it in a half-strength hydrogen peroxide solution for 10 to 15 minutes and remove encrustations with a soft-bristle tracheostomy brush.¹⁵ Clean dried debris and blood from the tracheostomy tube flanges as well. To prevent damage to the tracheal mucosa, rinse all airway equipment with sterile saline before reinsertion.¹⁶ Important stomal wound care includes changing contaminated tube ties, cleaning the tube flanges regularly, and using pre-cut tracheostomy gauze. Loose fibers from hand-cut gauze may induce inflammatory changes at the stomal site.¹⁴

The tracheostomy cuff provides a tight seal to allow positive pressure ventilation and prevent aspiration. Cuff pressure should ideally be maintained below 25 mm Hg.¹⁶ Overinflation is common and can cause disastrous injury to the tracheal wall and mucosa and lead to tracheomalacia, tracheal stenosis, or the development of a fistula between surrounding anatomic structures.¹⁷ It is a good practice to regularly check and document cuff pressure with a handheld pressure manometer to document inflation volumes. If an air leak occurs at the

Figure 7.4 Close-up of a Shiley tracheostomy tube. Note that only the *inner* cannula has a 15-mm adapter that will accept an Ambu bag or a ventilator; the *outer* cannula will not. The inner cannula **MUST** be in place to ventilate the patient.

maximum recommended cuff pressure, the tube may have become dislodged, which requires further evaluation.

It is essential that adequate air humidification be provided to patients with a tracheostomy. Inadequate humidification can result in obstruction of the tube from thick secretions, sputum retention, keratinization or ulceration of the tracheal mucosa, and impaired gas exchange as a result of lung atelectasis. Ambulatory patients and those who require low-flow oxygen can be fitted with a heat-moisture exchanger that attaches to the external opening of the tracheostomy tube. Patients receiving long-term ventilation or high-flow oxygen require regular saline nebulizer treatments delivered by an in-line humidification system.

VENTILATING TRACHEOSTOMY PATIENTS

To properly ventilate ED patients with a tracheostomy, it is important to determine the make, model, and type of tube (Fig. 7.4). For proper ventilation, a 15-mm tube/Ambu bag or ventilator tube adapter must be present, either on the tube itself or on the end of an inner cannula that has an inflatable cuff. The inner cannula adapter will accept an Ambu bag or ventilator tubing, and the cuff will allow positive pressure ventilation. If the patient requires manual or mechanical ventilation and the tracheostomy tube is not suitable for ventilatory support, immediately replace it with a 6-0 cuffed endotracheal (ET) tube for ventilation.

TRACHEAL SUCTIONING

Tracheal suctioning is required to remove secretions or aspirated material from the upper airway in patients whose cough is impaired or in whom an artificial airway is in place. Tracheal suctioning can be performed through an ET tube, a tracheostomy tube, a minitracheostomy placed in the cricothyroid membrane, or the nasopharynx. The indications, equipment, procedure, and complications are similar for each technique.

Indications

The primary indications for tracheal suctioning are to remove secretions, enhance oxygenation, or obtain samples of lower respiratory tract secretions for diagnostic tests. In the ED, tracheal suctioning should be performed to enhance oxygenation in any tracheostomy patient in respiratory distress. In addition, tracheal suctioning should be performed when the patient has coarse rales, rhonchi, or tubular breath sounds; acute or worsening dyspnea; or arterial oxygen desaturation. It is important to emphasize that tracheal suctioning should be performed only when it is clinically indicated; frequent, routine suctioning is not recommended.^{18,19}

There are no absolute contraindications to tracheal suctioning. Relative contraindications include severe bronchospasm, which may worsen with suctioning, and persistently elevated intracranial pressure (ICP), which is exacerbated by suctioning.²⁰ Bronchodilators, sedatives, and paralytics may alleviate these symptoms. Tracheal suctioning should be undertaken with caution in patients with cardiovascular instability because of an increased risk for associated dysrhythmias.²¹

Equipment

A suction catheter and vacuum system, open or closed, is required to perform tracheal suctioning (Fig. 7.5). It is recommended that the diameter of the suction catheter be no larger than half the inner diameter of the tracheostomy tube.^{22,23} The size of the suction catheter in French gauge (Fr) can be calculated as follows:

$$\text{Size (Fr)} = 2 \times (\text{Size of the tracheostomy tube} - 2)$$

For example, a 7-0 tracheostomy tube will require a 10-Fr suction catheter because $2 \times (7 - 2) = 10$ Fr. If the catheter is too small, it will not remove excess secretions adequately. If

the catheter is too large, it can obstruct airflow during insertion and cause alveolar collapse with resultant hypoxemia.

In adults, the suction catheter should be inserted only 10 to 15 cm, depending on the length of the tracheostomy tube. The goal of suctioning is to remove secretions only from the proximal airways. *Shallow suctioning* occurs when the catheter is placed just beyond the hub of the tracheostomy tube to remove proximal secretions. *Premeasured suctioning* occurs when a catheter is inserted such that the distal side ports are beyond the caudal end of the tracheostomy tube. *Deep suctioning* occurs when the suction catheter is advanced until resistance is met. It is used for clearing excess secretions in the lower airways.¹⁹ Deep suctioning has not been shown to be more beneficial than shallow suctioning and should not be performed routinely

Figure 7.5 Closed-system suction catheter.

Tracheostomy Suctioning

Indications

- Removal of excess secretions
- Worsening dyspnea
- Decreased oxygenation in the presence of rales, rhonchi, or tubular breath sounds
- Arterial oxygen desaturation
- Respiratory distress

Contraindications

- Absolute**
 - None
- Relative**
 - Severe bronchospasm
 - Persistently elevated intracranial pressure

Complications

- | | |
|---------------------------------|----------------------|
| Hypoxemia | Atelectasis |
| Increased intracranial pressure | Mucosal injury |
| Dysrhythmias | Bleeding |
| Patient agitation | Infection/tracheitis |

Equipment

Review Box 7.1 Tracheal suctioning: indications, contraindications, complications, and equipment.

because it might damage the mucosal epithelium and lead to an increase in granulation tissue.^{24,25}

A number of suction catheter tips have been designed to maximize removal of secretions without causing mucosal injury. Tips may have a single or multiple side ports proximal to the distal tip. Directional or Coude tip catheters are available for selective suctioning of the main stem bronchi.

A closed-system airway encases a suction catheter in a sterile sheath attached to ventilator tubing. This prevents the suction catheter from being contaminated by contact with the outside environment and allows tracheal suctioning to be performed without interrupting ventilatory support. The vacuum should be set to the lowest possible pressure to reduce atelectasis. Vacuum pressure should not exceed 80 mm Hg in infants or 150 mm Hg in adults.²²

Procedure and Technique

Before tracheal suctioning, continuous pulse oximetry, cardiac monitoring, and continuous capnography, if available, should be initiated (Fig. 7.6, step 1). Awake and alert patients should be sitting upright with their head in a neutral position. For mechanically ventilated patients, the head of the bed should

be elevated to 30 degrees to improve respiratory mechanics. Aseptic technique should be used throughout all suctioning procedures to prevent the introduction of bacteria. Backup airway equipment should be readily available (see Fig. 7.2). Preoxygenate the patient for at least 30 to 60 seconds. For mechanically ventilated patients, increase the fraction of inspired oxygen (FiO₂) to 100%. For nonventilated patients, provide 10 to 15 L of high-flow oxygen. Humidify the air before suctioning to reduce the viscosity of respiratory secretions. Routine instillation of normal saline has not been shown to provide regular clinical benefit and is no longer recommended.^{22,26}

Once the patient has been adequately preoxygenated, insert the suction catheter through the inner cannula in situ (see Fig. 7.6, step 2). If the carina is irritated during deep suctioning, a vigorous cough reflex will be activated. After reaching the desired depth, withdraw the suction catheter 1 to 2 cm and then apply suction while slowly removing the catheter (see Fig. 7.6, steps 3 and 4). Gently rotate the catheter as it is withdrawn to facilitate removal of secretions. The duration of suctioning should not exceed 10 to 15 seconds.²⁷

Monitor the patient throughout the procedure for signs of cardiac dysrhythmia, hypoxia, or a rise in end-tidal CO₂. Immediately stop suctioning if any of these signs develop (see

TRACHEAL SUCTIONING

Place the patient on a pulse oximeter, cardiac monitor, and continuous capnography (if available). Preoxygenate with 100% O₂.

Insert the suction catheter through the inner cannula in situ.

Advance the catheter to the desired depth.

Apply suction while slowly removing the catheter; gently rotate the catheter to facilitate removal of the secretions.

section on [Complications of Suctioning](#)). If marked respiratory distress is presumed to be secondary to significant tracheal obstruction, continue with expeditious suctioning to remove the obstruction (see section on [Obstruction and Complications from Tube Changes](#)).

Complications of Suctioning

Complications that occur during or after suctioning are relatively common and can result in significant morbidity. Most complications can be anticipated and simple maneuvers can reduce their incidence and severity.

Hypoxemia from suctioning may cause increased ICP, dysrhythmias, or even death. In neonates, hypoxia during suctioning may contribute to spontaneous intracerebral hemorrhage.²⁸ A number of factors contribute to suctioning-related hypoxia, including interruption of mechanical ventilation, aspiration of air from the respiratory tract, and suctioning-related atelectasis.²⁹ Use in-line suction catheters for ventilator-dependent patients to allow continuous oxygen delivery and positive pressure ventilation. Select the catheter size carefully to reduce the evacuation of airway gases during suctioning and help prevent atelectasis. Limit the duration of suctioning to 10 to 15 seconds and perform no more than three passes in succession. Measurement of arterial oxygen saturation may not be sufficient to assess hypoxia after suctioning. Oxygen consumption increases during suctioning despite insignificant changes in oxygen saturation. This increase in oxygen consumption is more prevalent in patients who possess a vigorous cough, are agitated, or resist suctioning.³⁰

Dysrhythmias associated with suctioning may be caused by hypoxia, increased myocardial oxygen consumption, vagal stimulation, hypoventilation, or catecholamine release. Vagal stimulation caused by suctioning can cause bradycardia and hypotension.³¹ Bradycardia in the setting of hypoxia potentiates ventricular dysrhythmias, including ventricular fibrillation. Nebulized or intravenous atropine is recommended for bradycardia and can be used as pretreatment in patients at risk for bradycardia, particularly infants. Digoxin enhances vagal activity and may potentiate the vagal stimulation of ET suctioning.³² Sympathetic stimulation may occur as a result of hypoxia, pain, or stress of the procedure. Pain medications, anxiolytics, and preparation of the patient for the procedure may blunt the sympathetic response. Suctioning should be stopped immediately if a dysrhythmia develops.

Increases in ICP during suctioning are well documented.^{33–35} ET suctioning can induce a strong cough reflex, which is thought to contribute to the increased ICP by raising intrathoracic pressure, reducing cerebral perfusion pressure, and increasing systemic blood pressure. In susceptible patients, increases in ICP can lead to devastating outcomes.^{28,34,36} If there is concern that increases in ICP could harm the patient, several preventive steps should be taken before initiating ET suctioning. The most important interventions are providing adequate sedation and maximizing oxygenation.²⁰ Hyperventilation before and between passes of the suction catheter can transiently lower ICP by reducing systemic CO₂.³⁴ One minute before suctioning, hyperventilate the patient by increasing the respiratory rate to approximately 30 breaths/min. If not heavily sedated, most patients will cough vigorously when suctioned. Lidocaine can be instilled into the trachea to blunt the cough reflex, thereby preventing an increase in ICP. To anesthetize the trachea locally, instill 1 to 1.5 mg/kg of 2% lidocaine into the tracheal tube.

After administering the medication, prepare the patient for suctioning by ensuring that sedation and oxygenation are adequate. After 10 minutes to allow the lidocaine to produce its local effect, begin tracheal suctioning. This method has been shown to prevent increases in ICP and changes in cerebral hemodynamics.³⁷

Atelectasis can occur when airway gases are suctioned too rapidly. To reduce this complication, choose a suction catheter that is less than half the inner diameter of the tracheostomy tube and minimize the duration and suction pressure. Atelectasis can be minimized by using a closed suction system and providing positive end-expiratory pressure after suctioning.³⁸ Hyperventilation should not be performed routinely to resolve suction-related atelectasis.²⁹

Mucosal injury is a common complication of tracheal suctioning. Invagination of the mucosa into the side ports of the catheter occurs during suctioning and causes the tracheal mucosa to become denuded, edematous, and predisposed to bleeding. Mucosal damage also interferes with mucociliary transport. Tracheitis can occur as a result of frequent or improperly performed suctioning.

Minitracheostomy Suctioning Procedure

The minitracheostomy (*minitrach*) was designed to improve tracheal hygiene in patients with intact cough reflexes, normal ventilatory function, and vocalization. The minitrach serves as a small port solely for suctioning secretions. Commonly, a 4-mm indwelling cuffless cannula is inserted through the cricothyroid membrane into the trachea. Patients who are suctioned through a minitrach are at lower risk for gagging and aspiration because they are able to maintain laryngeal and glottic function.³⁹ The minitrach device is seldom used in children because they have smaller airway diameters.

The technique used to suction through a minitrach is the same as that for tracheal suctioning. The smaller port size may require that smaller catheters be used. Most patients with minitrachs are decannulated before discharge from the ICU and are rarely seen in EDs.

CHANGING A TRACHEOSTOMY TUBE

Indications

Maturation of the tracheostomy tract is generally completed by postoperative day 7.⁴⁰ Most ED patients with a tracheostomy are seen after the stomal tract has matured, so routine changes of the tracheostomy tube can be done safely in the ED.⁴¹ Indications for exchange of the tracheostomy tube include cuff rupture or leak, leakage around the tube caused by tracheomalacia, other changes in tracheal anatomy, complete or partial tube occlusion, and conversion to an alternative tube style.⁴² There are no absolute contraindications to exchanging a tracheostomy tube in the ED as long as the stomal tract has matured. Before undertaking the exchange, consider whether further tissue trauma or hemorrhage might occur as a result of it⁴² or whether anatomic abnormalities could make the exchange difficult.

There is conflicting evidence on how frequently tracheostomy tubes should be changed.⁴³ Do not perform tube changes on a predetermined schedule, but rather as the patient's clinical condition dictates. There is some evidence that tubes left in

Changing a Tracheostomy Tube

Indications

- Complete or partial tube obstruction
- Mechanical failure
 - Peritubal leak
 - Cuff rupture
- Conversion to an alternative tube style (only with a mature stomal tract)

Contraindications

- Absolute:* None
- Relative:* Tracheostomy placement <7 days earlier

Complications

- Hemorrhage
- False passage
- Obstruction
- Prolonged procedure time
- Tract closure
- Hypoxia
- Subcutaneous emphysema
- Aspiration

Equipment

Review Box 7.2 Changing a tracheostomy tube: indications, contraindications, complications, and equipment.

TABLE 7.1 Common Tracheostomy Tube Sizes With Dimensions

Portex Cuffed D.I.C. Tracheostomy Tubes				Shiley Tracheostomy Tubes ^a			
TUBE SIZE (mm) AND COLOR CODE	INTERNAL DIAMETER (mm)	OUTER DIAMETER (mm)	LENGTH (mm)	TUBE SIZE (JACKSON)	INTERNAL DIAMETER (mm)	OUTER DIAMETER (mm)	LENGTH (mm)
6.0 (orange)	6.0	8.5	64.0	4	5.0	9.4	62
7.0 (green)	7.0	9.9	70.0	6	6.4	10.8	74
8.0 (white)	8.0	11.3	73.0	8	7.6	12.2	79
9.0 (blue)	9.0	12.6	79.0	10	8.9	13.8	79
10.0 (yellow)	10.0	14.0	79.0				

^aShiley also offers tracheostomy tubes with both distal and proximal (relative to the cuff) extended lengths for patients with large necks or other abnormal anatomy.

DIC, Disposable inner cannula.

place longer than 3 months are at higher risk for infection.⁴⁴ Most manufacturers recommend that tracheostomy tubes be changed approximately 30 days after placement.

Equipment

When changing a tracheostomy tube, familiarize yourself with the resources and equipment available in the ED. Keep the equipment readily available, if not at the patient’s bedside. The necessary equipment is depicted in Fig. 7.2.

Tracheostomy tubes may be made from metal or other synthetic material such as plastic. Plastic tubes are either polyvinyl chloride, which softens at body temperature, or silicon, which is naturally soft and unaffected by temperature. Metal

tubes are constructed of silver or stainless steel and lack both a cuff and a 15-mm connector for attachment to a ventilator or Ambu bag.

Sizing

To determine the appropriate size of tube, consider the internal diameter (ID), outside diameter (OD), length, and curvature of the tube. The Chevalier Jackson sizing system indicates the length and tapering of the OD. This sizing method applies to metal tubes and most Shiley dual-cannula tracheostomy tubes. Table 7.1 lists common tracheostomy tubes and their dimensions. For dual-cannula tracheostomy tubes, the inner cannula has a 15-mm connection for a ventilator. Note that tracheostomy

tubes with the same ID can have very different ODs and lengths. Consider the pretracheal distance before selecting a replacement tube of the appropriate size for obese patients (see section on [Special Populations](#)).

Single-cannula tracheostomy tubes are sized by the ID of the tube at its smallest dimension. The size of the tube is usually stamped on the flange. Before changing a tube, have the appropriate size of tube at the bedside along with tubes that are one or two sizes smaller. As a rule of thumb, most women can accommodate a tube with an OD of 10 mm, and most men can accommodate a tube with an OD of 11 mm.⁴⁵ [Table 7.1](#) lists the recommended sizes of tracheostomy tubes.

Components

Most tracheostomy tubes have three standard components: an outer cannula, an obturator, and an inner cannula (see [Fig. 7.3A](#)). The outer cannula is the permanent portion of the tracheostomy tube and should not be removed unless complications arise or a tube change is needed. Attached to the outer cannula is a flange on either side with eyelets used to tether the tube to the patient's neck. The obturator is a white rounded or cone-shaped object that is used to facilitate insertion of the tube. When inserted into the outer cannula, it extends several millimeters beyond the distal end of the tube.

Tracheostomy tubes can be cuffed or uncuffed. Cuffed tracheostomy tubes are used for patients on long-term mechanical ventilation and those at risk for aspiration. Cuffed tubes also prevent loss of volume during positive pressure ventilation while preventing air leaks across the vocal cords. Speech is not possible for patients with a cuffed tube. Most tubes have a high-volume, low-pressure cuff that reduces mucosal injury and the risk for tracheal erosion or stenosis.⁴⁶ Low-volume, low-pressure cuffs may be more effective in preventing aspiration.^{47,48} Inflate the tracheostomy cuff and deflate it by attaching a syringe to the Luer-Lok port at the proximal end of the pilot balloon and either injecting or removing approximately 10 mL of air. Determine cuff pressure by connecting the Luer-Lok port to a handheld manometer.

Uncuffed and metal tubes are used in patients with adequate ventilatory effort who are alert and at low risk for aspiration. Depending on the size of the tracheostomy tube and how much of the tracheal diameter is filled by the tube itself, the patient may be able to speak. Air must be able to bypass the tube and be transmitted across the vocal cords. Digital occlusion of the tracheostomy tube or the use of specialized speaking valves can occlude expired air from the tracheostomy and facilitate voice production. Fenestrated tubes also allow air to be transmitted across the vocal cords. The fenestrations are generally located at the superior, posterior arch of the tube but can also be found on the inner cannula in some models.

During weaning from tracheostomy, tracheal buttons can be used to maintain patency of the stoma in patients who do not require mechanical ventilation. They can be retained permanently if decannulation is not possible. Tracheal buttons have a hollow outer cannula and a solid inner cannula and extend from the outer skin into the tracheal lumen. Tracheal buttons can become displaced into the tracheal lumen if they are not tethered correctly and may become clogged with secretions.⁴⁹ They may also have a speaking valve, such as the Passy-Muir (Passy-Muir, Inc., Irvine, CA) or the Shiley Phonate (Mallinckrodt Medical, St. Louis, MO). These devices generally clip or twist onto the 15-mm coupling of the tracheostomy

tube or inner cannula. Remove the speaking valve before changing the tracheostomy tube.

Procedure

It is essential to ensure that all airway equipment is at the patient's bedside before performing the tube exchange. In addition to having airway equipment ready, place the patient on continuous pulse oximetry, cardiac monitoring, and capnography, if available, to confirm tube placement. Identify the tracheostomy tube model and determine its size. Have this size and two other tubes that are one or two sizes smaller in the event that tube replacement is difficult. Inspect all equipment for proper function, including the replacement tube cuff for leaks and the obturator for ease of insertion and removal ([Fig. 7.7, step 1](#)). Coat the replacement tracheostomy tube with a water-based lubricant (see [Fig. 7.7, step 2](#)).

Place the patient in a semirecumbent position with the neck slightly extended to ensure proper alignment of the external stoma and the tracheostomy tract. Do not flex the neck because this may misalign the tissues and make tube replacement more difficult. Remove the old tracheostomy dressing and clean the stomal site. If awake, preoxygenate the patient by placing a non-rebreather oxygen mask over the tracheostomy site for 3 minutes and then suction the oropharynx. If the patient is ventilator dependent, increase the FiO₂ to 100% for at least 1 minute before beginning the tube exchange to ensure adequate oxygenation. If needed, provide the patient with soft restraints or anxiolytic medication to improve compliance.

The tracheostomy tube can be changed by either of two methods. If the tracheostomy tract is well matured, the tube can be exchanged with an obturator. To remove the old tracheostomy tube, first deflate the cuff completely (if present) (see [Fig. 7.7, step 3](#)). Remove the existing tube with an "out-then-down" movement while the patient exhales (see [Fig. 7.7, step 4](#)). Next, with the obturator in place, insert the new tube into the stoma at a 90-degree angle to the cervical axis (see [Fig. 7.7, step 5](#)). If two experienced providers are available, one can be responsible for deflating the cuff and removing the old tube while the other inserts the new device.⁵⁰ Next, gently push the tube downward in a fluid, sweeping motion so the external flange is flush against the neck. If necessary, use a tracheal hook to hold the stoma open. Remove the solid obturator immediately, insert the hollow internal cannula, inflate the cuff, return the patient's head to the neutral position, and secure the external flange (see [Fig. 7.7, steps 6 to 8](#)).

The second technique involves exchanging the tube with a modified Seldinger technique using a red rubber catheter, nasogastric tube, gum elastic bougie, or fiberoptic nasopharyngeal scope ([Fig. 7.8](#)).^{45,51} This technique is preferable if the tracheostomy tract is not well defined or if there is concern that tube exchange could be difficult. Using a nasopharyngeal scope can also confirm placement by way of direct visualization. To exchange tubes with this method, first premeasure the distance needed to extend the guidewire device beyond the distal tip of the old tracheostomy tube. Advance the guide to the premeasured distance, deflate the cuff, and remove the tube as described previously. Next, without the obturator in place, advance the new device over the guide until it is seated securely in the trachea. Remove the guide and secure the new tube. Weinmann and Bander developed a modified Seldinger technique involving the use of an airway exchange catheter to allow jet or bag ventilation into the trachea during tube

CHANGING A TRACHEOSTOMY TUBE

1 Inspect the tube for proper function; check for a cuff leak.

2 Apply a water-based lubricant to the tube.

3 Deflate the cuff on the old tube completely.

4 Remove the old tube during exhalation.

5 Insert the new tube (with the obturator in place) into the stoma at a 90-degree angle; push the tube downward in a fluid, sweeping motion.

6 Remove the obturator, and insert the inner cannula.

7 Attach the ventilator to the tracheostomy tube.

8 Inflate the cuff.

Figure 7.7 Changing a tracheostomy tube. Maintain the neck in the same position (slightly extended) for removal and insertion so that the tract is not lost. If the tube is already out, and the specifics of the tract are unknown, extending the neck to align the stoma with the tissue tract is the first best position for tube replacement.

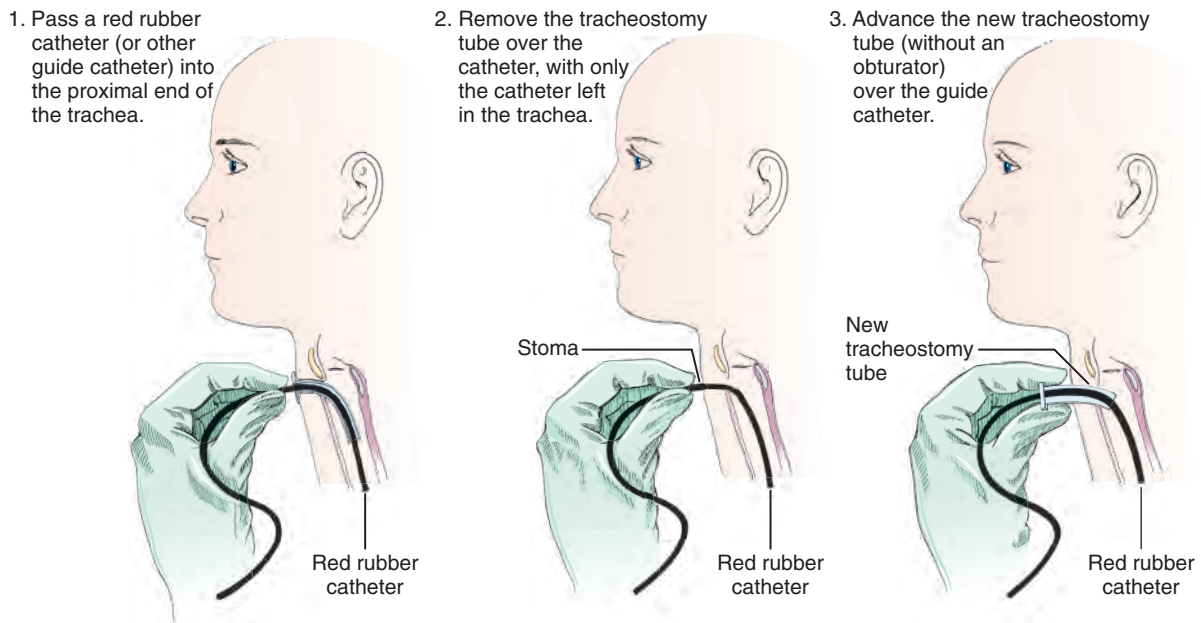

Figure 7.8 Changing a tracheostomy tube over a guide catheter.

exchange. This adjunct delivers intratracheal oxygen and is helpful if hypoxemia is likely to occur.⁴²

Confirm proper placement of the tube within the trachea with one of several possible techniques. Traditionally, the patient is ventilated and correct tube placement confirmed by observation of equal chest rise and auscultation of bilateral breath sounds. Although both signs are important to confirm correct placement, quantitative waveform capnography is now a class I American Heart Association recommendation for confirmation of ET intubation.⁵² It should be used for tracheostomy tube placement, if available. Multiple studies have shown quantitative capnography to be a highly sensitive tool for confirming correct placement of airway devices.^{53,54} Correct tube placement can also be confirmed by direct visualization of the tracheal rings with a fiberoptic scope.

COMPLICATIONS OF TRACHEOSTOMY

Complications related to tracheostomy placement are common and sometimes life-threatening. This section addresses the emergency development of late postoperative complications (occurring more than 3 weeks after the operation). Patients with immediate and early postoperative complications are usually still hospitalized and are less likely to be seen in the ED.⁵⁵ Late postoperative tracheostomy complications encountered in ED patients include obstruction, dislodgement, equipment failure, infection, anatomic disruption, and hemorrhage. Management of the patient varies depending on the type of complication that the patient is experiencing. Rapid recognition of the problem is paramount and can drastically affect the outcome.

Obstruction and Complications From Tube Changes

Obstruction of the tracheostomy tube is a common complication and can occur at the external opening of the tube, within the

inner cannula, or at the distal end of the outer cannula. In one review, 30% of ED visits for respiratory distress were due to an obstructed tube.⁴¹ Obstruction is caused most commonly by dried respiratory secretions and, less often, by blood, aspirated material, or granulation tissue. The obstructing object may act as a ball valve and allow air to enter but restricts expiration.⁸ Such obstruction is easily remedied in the ED by removing the inner cannula and then cleaning and replacing it.

Preparation

First, assess the patient's airway for patency and respiratory status. Place the patient on a cardiorespiratory monitor, a pulse oximeter, and continuous capnography. Gather appropriate airway equipment at the bedside. Be sure to have a large-bore suction catheter available in case the appropriate size of catheter is inadequate. Examine the tracheostomy tube to see whether the inner cannula is obstructed or any obvious external obstruction is present.

Interventions

Administer high-flow oxygen and encourage patients who can breathe spontaneously to cough. Manually remove any obstruction seen at the external tracheal tube opening. If there is no obvious external obstruction, remove the inner cannula and suction the secretions. Inspect the inner cannula and remove any obstructing objects. If the patient's tracheostomy does not have an inner cannula, suction the tracheostomy tube to remove obstructing plugs. Thick secretions can be loosened in a *critically ill* patient by instilling normal saline into the tracheostomy tube, but this is no longer recommended for routine suctioning.²⁶

If the obstruction persists, evaluate the distal tip of the tracheostomy tube. First, deflate the tracheostomy cuff and supply high-flow oxygen via face mask if the patient is breathing spontaneously or via a bag-valve-mask device if the patient is unable to breathe without assistance. *Note that if the tracheostomy cuff is inflated, you will not be able to provide oxygen or ventilatory support from above the tracheostomy tube.* If the patient is still in

respiratory distress despite these interventions, remove the outer tube and replace it. If these maneuvers are ineffective, consider more distal causes of airway obstruction, such as granulation tissue, a mass, or a clot. Be sure to have a surgical airway kit available at the patient's bedside.

Dislodgement

Displacement of the tracheal tube is a serious complication that can have a disastrous outcome if not recognized and corrected quickly. Patients at highest risk for poor outcomes from a dislodged tube are those who are obese, who have recently inserted or changed tubes, who have anatomic anomalies, and who are difficult to ventilate or were difficult to intubate in the past.^{56–58} Evidence of tube dislodgement is usually obvious. Signs and symptoms include hypoxemia, agitation, respiratory distress, altered mental status, subcutaneous emphysema, and high airway pressure. Dislodgement can occur during patient transfers, when traction is placed on the tube, or when the tube is manipulated for bag-valve-mask ventilation or ventilator tube connection. If a tracheostomy tube is too long, it can become dislodged inferiorly, which causes the tip to either abut the mucosal wall of the trachea, or obstruct it at the level of the carina.

It is important to know when and why the tracheostomy was placed because such information will influence evaluation and management of the patient.⁵⁹ If a tracheostomy tube becomes dislodged within the first 7 days after initial placement, the stoma can close rapidly and make reinsertion difficult. Blind, forceful attempts at reinsertion of the tracheostomy tube in the early postoperative period can result in the creation of a false passage and possible respiratory arrest. If accidental decannulation occurs before the tract has time to form, orotracheal intubation is the safest approach in the ED, unless the patient has had a laryngectomy (see section on [Special Populations](#)). Reinsertion of the tracheostomy tube is possible, but the patient will most likely require ET intubation to secure the airway.⁵⁹ Patients with abnormal neck anatomy or other causes of a “difficult airway” may not benefit from reinsertion in the ED. In these cases, the procedure may need to be performed in the operating room. Seek emergency surgical consultation for complicated cases.

Preparation

As for all patients with tracheostomy complications, begin with a quick primary assessment and place the patient on appropriate monitoring devices. Continuous waveform capnography can be invaluable in determining whether the tracheostomy tube is placed properly. Absence of a waveform or end-tidal CO₂ partial pressure less than 10 mm Hg is an indication that the airway device has become dislodged or was placed inappropriately.⁶⁰ It is essential to have advanced airway equipment at the bedside, including two replacement tracheostomy tubes (each with an inner cannula). A fiberoptic nasopharyngeal scope or bronchoscope, if available, can be helpful. Position the patient with the neck in extension to maximize alignment of the stoma and trachea. Neck flexion can cause downward displacement of the tube by as much as 3 to 4 cm.¹⁶

Interventions

First, determine that the tube flanges rest snugly at the skin. Lateral neck x-ray films may reveal that the opening of the

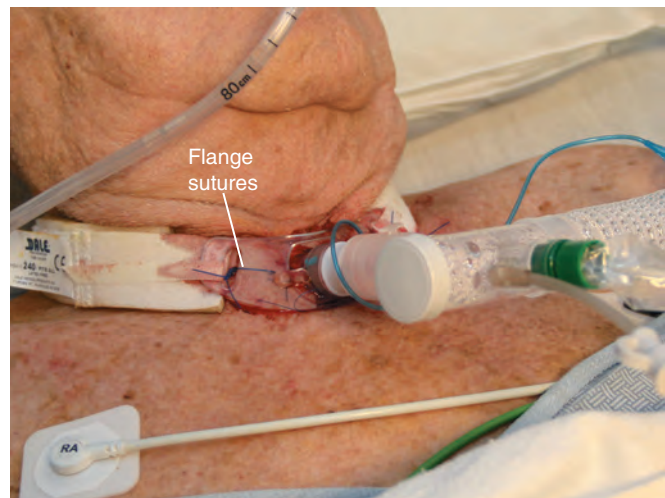

Figure 7.9 Newly inserted tracheostomy tube. Replacement under emergency conditions can be difficult, particularly if the event occurs soon after the tube is initially placed and before a tract has formed (usually approximately 5 days after the procedure). Blind forceful attempts at reinsertion in this circumstance can be associated with the creation of a false passage and respiratory arrest. Orotracheal intubation is another option for accidental decannulation occurring before tract formation. In patients with surgical tracheostomies, traction on stay sutures placed circumferentially around the tracheal rings (which are generally cut long and often taped to the anterior chest wall—not shown here) will facilitate reintubation.

tracheostomy tube is abutting the anterior tracheal wall or obstructing the tracheal lumen. If the tracheostomy tube appears to be minimally displaced, attempt to reposition the tube by gentle manipulation. If the tracheostomy tube is completely dislodged or no waveform is present on capnography, tube replacement should be attempted.

If the tracheostomy stoma was created less than 7 days earlier, be prepared to orally intubate the patient. First, cut any flange sutures and remove the tracheostomy tube ([Fig. 7.9](#)). Stay sutures may be placed to hold the stoma open and better visualize the tracheal opening. If the patient is stable, attempt to reinsert the tracheostomy tube with the assistance of a gum elastic bougie or fiberoptic scope.⁴⁵ If the patient is unstable with an obstructed tracheostomy tube, cut the flange sutures, remove the tube, and orally intubate the patient.

If the tracheostomy stoma was created 7 to 30 days earlier, remove the tube and any other cause of obstruction from the stoma. If the patient can ventilate independently, allow the patient to oxygenate and then reinsert the tube when ready. If the patient is unstable, occlude the stoma with moist gauze or other occlusive device and provide bag-valve-mask ventilation. Once the patient is stabilized, replace the tracheostomy tube. If a replacement tube is not available, check the outer diameter of the tracheostomy tube, and insert a cuffed ET tube of equal size (or at minimum, 6-0) as a substitute.

If the tracheostomy is more than 30 days old, the tube may not need to be replaced. If the patient is unstable, prepare as described for reinsertion or ET intubation. If the patient is stable and ventilating spontaneously without any signs of distress, contact the appropriate specialty care physician to discuss the need for emergency reinsertion.

Once the tube is reinserted, confirm correct placement with auscultation and waveform capnography. Tube position can also be confirmed by direct visualization with a fiberoptic scope.

False Passage

A false lumen can be created during replacement of a tracheal tube or during repositioning of a dislodged tube. Obese patients are at high risk for false passage because of their redundant neck tissue (see section on [Special Populations](#)). Subcutaneous air, crepitus, or distortion of anterior neck landmarks may indicate placement of the tracheostomy tube into a false passage. Absence of a waveform on capnography confirms misplacement of the tracheostomy tube. Abdominal distention after bag-valve-mask ventilation may indicate placement of the tracheal tube through a tracheoesophageal fistula (TEF). If a false passage is suspected, remove and replace the tracheostomy tube expeditiously.

Equipment Failure

Fracture

Tracheostomy tubes do not fracture frequently. When fractures do occur, they are most often located at the juncture of the flange and the tube connection.^{61,62} A fractured tube fragment may migrate inferiorly and obstruct the tracheal lumen. Patients may have acute respiratory complaints such as cough, dyspnea, choking, or wheezing. Prolonged retention of a foreign body can result in chronic respiratory symptoms such as wheezing, coughing, or recurrent bouts of pneumonia or bronchiectasis. To manage this problem, replace the tube if possible and consider bronchoscopy for retrieval of the tube fragment.⁶³

Tracheal Cuff Complications

Complications related to the tracheal tube cuff include perforation, which results in a poor seal and increased risk for aspiration; overinflation, which causes pressure on or impingement of the esophageal lumen; and distention of the cuff distal to the tracheal tube, which results in obstruction of the tracheal tube opening. Mucosal injury is less common since the use of low-pressure cuffs has become standard practice. Pain with ventilation or swallowing, inadequate oxygenation, or the presence of gastric secretions in the tracheostomy tube may indicate cuff problems. Verify inflation pressure with a manometer (target range, 18 to 25 mm Hg) and appropriate cuff position. Replacement of the tube is indicated if the symptoms persist.

Infection

Patients who require long-term tracheostomy and mechanical ventilation are at high risk for nosocomial pneumonia, ventilator-associated pneumonia (VAP), and tracheobronchitis. In general, the frequency of infection increases with the duration of mechanical ventilation, and the risk for infection is highest in the first week following intubation. Nonventilated tracheostomy patients are also at increased risk for pneumonia, tracheobronchitis, stomal infections, and other soft tissue infections.

Risk factors for systemic infection include impairment of host defenses and exposure to large numbers of bacteria that bypass the upper airway defense systems. In healthy patients, the upper respiratory tract is colonized by normal oropharyngeal flora. In tracheostomy patients, the normal flora can be replaced by virulent pathogens such as enteric gram-negative bacteria.⁶⁴ The organisms most commonly cultured from tracheostomy stomas and tubes are *Pseudomonas aeruginosa*, *Acinetobacter*, and

Staphylococcus aureus.⁶⁵ Colonization rates are high in these patients, even in the absence of systemic infection. The tracheostomy tube bypasses the natural protective barriers of the upper airway. Suctioning a colonized tracheostomy tube can introduce bacteria into the lower respiratory tract. Underlying medical conditions, prolonged hospitalization, impaired host defense mechanisms, and poor nutrition all increase susceptibility to infection.

Ventilator-associated tracheobronchitis (VAT) is the result of colonization of the upper airway and can eventually progress to VAP.⁶⁶ Patients with VAT have fever, production of purulent sputum, and positive respiratory cultures but no evidence of a new infiltrate on chest radiography.⁶⁶ VAT is frequently caused by multidrug-resistant organisms. When choosing antimicrobial therapy, consider recent hospitalizations, previous infections, recent antibiotic use, and the hospital's antibiogram.

Tracheostomy patients on long-term ventilation are also at risk for VAP. These patients are similar to those with VAT, except that they have an infiltrate on chest radiography. A common cause of VAP is aspiration. Patients become predisposed to aspiration if they have altered neurologic function, have an abnormal swallowing mechanism, or are mechanically ventilated and kept in the supine position for a prolonged time. Some degree of aspiration occurs in 33% to 61% of all patients with tracheostomies.^{67,68} To reduce the risk for aspiration, keep patients requiring mechanical ventilation in a semirecumbent position. It is generally recommended that 30 to 45 degrees is adequate to reduce the risk for VAP.⁶⁹⁻⁷¹

Stomal infections and cellulitis are also common.⁴¹ The bacteria cultured most frequently from patients with tracheostomy-related cellulitis are *S. aureus*, *Pseudomonas* species, and *Monilia*. Consider *Candida albicans* infection in patients previously treated with antibiotics and those who have an underlying immunocompromised state. Peristomal cellulitis can usually be treated with good wound care and oral antibiotics. The most dangerous complications from cellulitis are mediastinitis, mediastinal abscess, necrotizing fasciitis, and paratracheal abscess. Consider these complications in patients who have pain with breathing, pain with swallowing, or signs of systemic infection. Strongly consider a deep neck infection in diabetic patients.⁷² β -Hemolytic streptococci or coagulase-positive staphylococci are the cause in 90% of patients with craniocervical necrotizing fasciitis.⁷³ Sputum samples, obtained via tracheal suctioning, should be analyzed when infectious complications are suspected. Radiologic studies, namely, a chest radiograph, cervical computed tomography (CT), and chest CT, should be ordered as indicated.

Antimicrobial treatment in the ED should cover the most common organisms for the suspected site of tracheostomy-related infection. Broad-spectrum systemic antimicrobials, along with adjuvant aerosol therapy, should be given urgently to high-risk patients.⁷⁴ Depending on the patient's condition, surgical evaluation may be needed.⁴¹

Tracheal Stenosis and Tracheomalacia

Tracheal stenosis and tracheomalacia are late complications of a tracheostomy, often occurring weeks to months after decannulation. Its overall incidence is unknown, and clinically significant stenosis has been estimated to develop in 10% of all tracheostomy patients.⁷⁵ Tracheal stenosis occurs most often at the level of the stoma and can develop proximal (suprastomal) or distal to the stoma as a result of a poorly fitting tube or

Figure 7.10 A and B, Tracheomalacia. (From Patterson AG, Cooper JD, eds: *Pearson's thoracic and esophageal surgery*, Philadelphia, 2008, Elsevier.)

cuff. Pressure on the tracheal lumen from the tube or cuff can cause epithelial destruction, tracheitis, ulceration, persistent inflammation, and subsequent stenosis. Stenosis at the stoma can occur from rigid tube systems with excessive motion and pressure points.¹⁶ Symptoms become evident when the tracheal diameter is narrowed by 50% to 60%.⁷⁶ Stridor typically occurs when the tracheal lumen is narrower than 5 mm.¹⁶ Respiratory symptoms such as cough, retained secretions, and progressive dyspnea with exertion are indications of clinically significant stenosis.

Tracheomalacia is weakening of the tracheal cartilage from pressure necrosis and results in luminal widening. A loose tracheostomy tube with excessive mobility can cause air leaks or tracheal collapse (Fig. 7.10). Patients with significant tracheomalacia experience tracheal collapse on expiration. This can result in air trapping and retained respiratory secretions. Pediatric patients are less able to tolerate cartilaginous weakening and tracheomalacia.

Interventions

Relief of respiratory compromise is problematic because a high-grade stenosis may make ET intubation difficult or impossible. To treat a patient with respiratory distress secondary to tracheal stenosis, first attempt to improve ventilation by elevating the head of the bed and placing the patient on high-flow humidified oxygen. Nebulized bronchodilators, racemic epinephrine, and heliox may also be helpful. Keep a cricothyrotomy kit readily available in the event that ET intubation is impossible. Tracheal stenosis can be diagnosed definitively by laryngoscopy and flexible fiberoscopy.⁴¹ A CT scan of the patient's neck can be helpful in determining the level and grade of stenosis. Treatment of tracheal stenosis involves operative dilation or resection of granulomatous tissue in the operating room.

Tracheoesophageal Fistula

TEF is an uncommon, late complication of tracheostomy. It occurs in 1% of tracheostomy patients as a result of injury to the posterior tracheal wall.⁷⁷ Early TEF can occur if a puncture wound or small laceration is made in the anterior esophageal wall during placement of the tracheostomy. The most common

cause of a TEF is a poorly fitted tracheostomy tube or an overinflated cuff.⁷⁷ Injury to the esophageal mucosa from a nasogastric or orogastric tube can also cause a TEF.

Most patients with a TEF have increased secretions, recurrent pneumonia, or aspiration of gastric contents while receiving mechanical ventilation. The most frequent sign of a TEF is cough after swallowing. A persistent cuff leak or abdominal distention may also indicate a TEF. The clinician may be able to auscultate breath sounds over the lung fields and the epigastrium simultaneously, but this finding is unreliable. Bronchoscopy, barium esophagography, or mediastinal CT can aid in making the diagnosis.

Interventions

Once a TEF is diagnosed, the immediate goal should be to reduce the amount of tracheal and pulmonary soilage by inflating a cuff below the level of the fistula. If the current tracheostomy tube is not long enough to allow placement of a cuff distal to the TEF, exchange it with a longer tracheostomy tube or an ET tube. An orogastric or nasogastric tube can also be inserted to prevent gastric contents from further contaminating the respiratory tract. Early consultation with an otolaryngologist or thoracic surgeon is appropriate because the definitive treatment is surgical.⁷⁷ Antibiotics that target gram-negative, gram-positive, and anaerobic organisms should be initiated if there is a suspicion for pneumonia. TEF is not usually an immediately life-threatening complication, and tube exchange can be performed in conjunction with the surgical team.

Bleeding

Major Bleeding

Major bleeding is one of the most feared complications of tracheostomy. A history of bleeding or minor bleeding that has stopped spontaneously cannot automatically be attributed to minor irritation or skin erosion. It may not be possible to fully evaluate bleeding from a tracheostomy site in the ED without consultation or specialized equipment such as a fiberoptic endoscope. Sources of bleeding include the thyroid vessels, anterior jugular veins, brachiocephalic (innominate) artery, carotid artery, and aortic arch.^{78,79} Bleeding from esophageal or gastric sources may occur if a TEF is present

or if the patient has aspirated blood. Erosion of a major vessel from the cuff or tip of the tube is responsible for 10% of all tracheostomy hemorrhages and is a devastating complication. The IA is the vessel most commonly involved.⁸⁰

A tracheoinnominate artery fistula (TIF) is a late complication of tracheostomy that usually occurs within the first 4 weeks after insertion, but it can happen at any time.^{12,81} The mortality rate associated with a TIF approaches 100%.⁸² The anatomic proximity of the IA to the trachea places it at higher risk for fistulization if the anterior tracheal wall is injured. The vessel crosses from left to right as it moves superiorly and lies immediately anterior to the trachea at the level of the superior thoracic inlet. Risk factors for TIF include placement of the stoma below the third tracheal ring, caudal migration of the tracheal tube, and the presence of a cephalad-coursing IA.

A single episode of hemoptysis or tracheal bleeding may be the only warning sign of a TIF. Any amount of bleeding or hemoptysis exceeding 10 mL within 48 hours after placement of the tube should be considered a “sentinel bleed” and an indication that a fatal hemorrhage may be imminent. Some patients report only a new cough or retrosternal pain.⁸³ Presume that a history or evidence of 10 mL or more of blood is from an arterial source.

Preparation

When evaluating a patient with a suspected TIF, place advanced airway equipment at the bedside. Emergency surgical consultation is mandatory. Position the patient with the head of the bed elevated and the neck in slight extension. Secure adequate intravenous access, and prepare the patient to go to the operating room. In addition to the equipment noted in Fig. 7.2, have a scalpel with a No. 10 or 11 blade and a 50-mL syringe at the bedside.

Interventions

If the patient is stable, an attempt to visualize the bleeding site with direct visualization using a fiberoptic scope should be performed. Look for evidence of bleeding on the anterior tracheal wall at or below the sternal notch. If significant tracheal bleeding or a clot is present, first hyperinflate the tracheostomy tube cuff with the 50-mL syringe to compress the artery against the posterior sternal wall. Inflate the balloon slowly to prevent rupture of the cuff. Depending on the make and model of the tube, inflating the cuff with the entire 50 mL may not be possible. If a TIF has been caused by cuff erosion, this procedure should tamponade the bleeding. If the patient’s tracheostomy tube does not have a cuff, replace it with a cuffed ET or tracheostomy tube.

If cuff hyperinflation is unsuccessful, the TIF may be located at or beyond the distal tip of the tracheostomy tube. In this circumstance, the current tracheostomy tube must be removed and replaced with either an oral ET tube or an ET tube inserted through the stoma.

Position the cuff of the ET tube below the stoma at the level of the upper part of the sternum and hyperinflate it. If the patient continues to bleed despite this maneuver, apply digital pressure through the tracheal stoma to compress the anterior tracheal wall against the sternum. Digital pressure is considered the most reliable technique to stop hemorrhage and can provide control of bleeding during transport to the

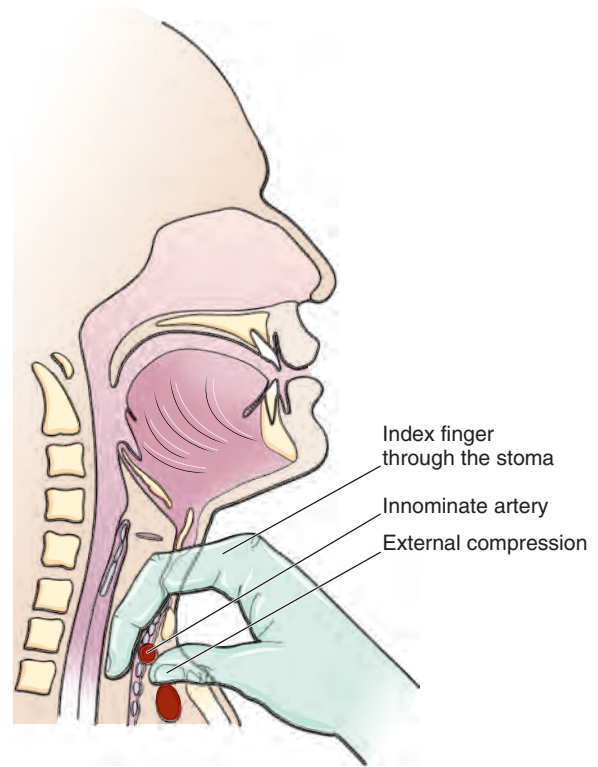

Figure 7.11 Technique to attempt to control innominate artery bleeding by digital compression. Any bleeding from a tracheostomy site can portend subsequent massive hemorrhage and should be carefully evaluated. Bleeding from erosion into the anteriorly positioned innominate artery is catastrophic.

operating room (Fig. 7.11).⁴¹ Extension of the stoma with a vertical incision to the jugular notch may be necessary if the provider cannot reach the TIF through the original stoma. The clinician should be careful not to damage surrounding vasculature when making the incision.

Minor Bleeding

All bleeding from a tracheostomy site must be evaluated for a potentially life-threatening event. Seemingly minor or self-limited bleeding may be a harbinger of subsequent severe hemorrhage. Sentinel hemorrhages frequently precede massive bleeding. Consider endoscopic examination for complete evaluation unless a superficial bleeding site is confirmed.

Minor bleeding is most likely the result of irritated granulation tissue and is usually confined to the skin surrounding the stoma. Bloody secretions from the tracheostomy tube may represent tracheitis, bleeding running down from the skin or thyroid, or superficial tracheal ulceration from tracheal suctioning or tracheal tube pressure.

Examine the stoma site and tube first in an attempt to locate the source and quantify the volume of blood loss. If the source of bleeding is within the stoma or from within the trachea, remove the tracheostomy tube if it was placed more than 7 days before the current event. Visualize the tracheal lumen, proximal end of the trachea, and inner stoma with a nasopharyngoscope or a small pediatric laryngoscope. It is important to differentiate superficial erosions from active bleeding. Do not attempt to remove clots in the trachea because this may increase the rate of hemorrhage. Consider obtaining a basic metabolic panel, complete blood count, and coagulation studies

to evaluate for other factors complicating bleeding, such as uremia, thrombocytopenia, or coagulopathy.

Preparation

Prepare patients with minor tracheostomy bleeding in the same way that you would those with major bleeding. Gather the appropriate airway equipment at the bedside. In addition to the standard equipment shown in Fig. 7.2, obtain the following:

- Sterile gauze
- Sterile saline for irrigation
- 22-gauge needle with syringe
- 1% lidocaine with 1:100,000 epinephrine
- Absorbable hemostat (e.g., Surgicel, Ethicon, Cincinnati, OH)
- Suture kit with suturing material
- Electrocauterization or chemical cauterization supplies, if available

Interventions

For external or stomal bleeding, begin with local irrigation to find the source of the bleeding. Most incisional or stomal bleeding can be stopped by applying direct pressure for 3 to 5 minutes. Application of absorbable hemostatic material may improve the outcome of direct pressure application. If an external bleeding site continues to ooze, consider adjunctive treatment. Options include injecting 0.5 to 1.0 mL of lidocaine with epinephrine near the source, placing a single suture for hemostasis, or using cauterization. Last, replace the tracheostomy tube. Following tube replacement, suction carefully to confirm resolution of the bleeding and to identify secondary sources of bleeding.

If stomal bleeding or intratracheal sites do not account for the bleeding, consider other causes. Placement of a nasogastric tube will help in the identification of gastrointestinal bleeding. Examine the nasopharynx and oropharynx for bleeding sources. If the patient has undergone radiation therapy, examine the area above the level of the tracheostomy stoma, where mucosal injury secondary to radiation damage may be the cause of blood in the tracheal secretions.

TRANSESOPHAGEAL PUNCTURE FOR VOICE RESTORATION

Transesophageal puncture (TEP) has become one of the most widely used and accepted techniques for voice rehabilitation. Developed in the 1980s, it can be performed as a primary or secondary procedure after laryngectomy or other pharyngeal surgeries. A puncture site is created through the anterior esophagus and posterior tracheal wall, where the TEP prosthesis is later inserted. The mucosa in segments of the pharyngeal esophagus vibrates in response to airflow, thereby creating speech.

Complications

Operative and immediate postoperative complications of TEP are infrequent.⁸⁴ Long-term complications include stomal stenosis, aspiration of the prosthesis, fistula leakage, TEP necrosis, and swallowing impairment. Reported infectious

complications associated with TEP include deep neck abscess, aspiration pneumonia, and cervical cellulitis.⁸⁵

The emergency care provider should be aware of the most common complications, few of which are life threatening. Accumulation of thick or inspissated secretions or food above the TEP can cause upper airway obstruction. Prosthesis dislodgement, occlusion, or erosion secondary to infection should be considered in all patients with acute changes in voice production or decreased ability to speak.⁸⁶ Esophageal edema causing dysphagia and loss of TEP speech has been reported and should be differentiated from other causes of esophageal obstruction.⁸⁶

When evaluating patients with a TEP, review the medical records, assess airway and esophageal patency, and determine whether the patient has experienced changes or difficulty in voice production. In stable patients, management of prosthesis complications should be referred to a specialist, most commonly an otolaryngologist.

TRANSTRACHEAL OXYGEN DELIVERY SYSTEMS

Low-flow oxygen is prescribed for patients who have adequate ventilatory function but chronic hypoxia. Many patients with chronic obstructive pulmonary disease, pulmonary fibrosis, sleep apnea, lung cancer, and α_1 -antitrypsin deficiency are candidates for outpatient use of supplemental oxygen.⁸⁷⁻⁸⁹ Traditionally, supplemental oxygen has been delivered by nasal cannula. Although nasal cannula oxygenation is easy to administer, it has several side effects, including drying of the nasal mucosa, epistaxis, ear discomfort, contact dermatitis from the oxygen tubing, and dry throat.^{87,89} Use of a nasal cannula is inefficient because it delivers oxygen only during inspiration and the oxygen must traverse the anatomic dead space of the nares and hypopharynx.

Transtracheal oxygen (TTO) delivery systems enhance the efficiency of oxygenation by administering oxygen directly to the lower respiratory tract. These systems reduce complications, improve patient comfort, and increase compliance.⁹⁰ Oxygen is delivered through all phases of the respiratory cycle and directly into the trachea, thereby bypassing dead spaces in the upper airway.⁸⁸ As a result, the required oxygen flow rate is commonly reduced by at least 50%.⁹⁰ Gas mixture in the distal end of the trachea is more effective in eliminating CO₂. Clinically, TTO systems usually reduce the patient's work of breathing and exertional dyspnea.⁸⁹ Physiologic benefits include reduced erythrocytosis, decreased pulmonary vascular resistance, improved cor pulmonale, improved arterial oxygen tension, and increased exercise capacity.⁹¹

TTO catheters are small tubes that deliver oxygen directly to the lumen of the trachea. The catheter is held in place by a subcutaneous tract, and is inserted into the lower part of the trachea. Low-flow oxygen (2 to 10 L/min) is supplied directly to the trachea by a narrow (7- to 11-Fr) catheter. Typically, an 11-cm catheter sits in the trachea with its tip 1 to 2 cm above the carina.⁸⁹ It can have a single or multiple distal ports for oxygen flow. The catheter is held in place by a thin band or necklace through two openings in the flange.

The surgical procedure is often done in an outpatient setting with the patient under local anesthesia. Initially, a small stent is placed percutaneously into the anterior aspect of the neck; it is then replaced with a TTO catheter in 1 to 2 weeks, after

the tract matures.⁸⁹ Dislodgement of the catheter during this time can result in closure of the tract within a matter of minutes. Once the tracheocutaneous fistula has epithelialized, the catheter may be inserted. Early catheter changes should be done in the clinician's office via a modified Seldinger technique if the integrity of the stoma is questionable. After the tract has fully matured, most patients can change their catheter at home.

Regular maintenance includes cleaning and changing the TTO catheter. One milliliter of sterile saline is instilled into the catheter, and a cleaning rod is inserted as far as possible. The cleaning rod is inserted and extracted three times to remove secretions and encrustations from the lumen of the catheter. Catheters are usually changed according to the manufacturer's recommendations, from twice daily to once every 2 weeks. The stoma should be cleaned twice each day and inspected thoroughly for signs of infection. All patients should be given supplemental oxygen by nasal cannula during catheter maintenance procedures. Adequate humidification, cleaning, and systemic hydration will help reduce the incidence of mucous blockage.

Early complications (developing within 3 weeks after the procedure) occur in approximately 30% of patients and include bleeding, infection, pneumothorax, costochondritis, and dislodgement (which can be caused by coughing).^{87,92} Pneumomediastinum and sudden death have been reported as possible, yet rare complications.⁹³ Late complications occur in approximately 40% of patients and include mucous plugging, bleeding, infection, and hemoptysis.⁹¹ A mucous ball is an accumulation of inspissated mucus that adheres to the outer surface of the TTO catheter tip. It can cause coughing, wheezing, and dyspnea. Life-threatening airway obstruction resulting from the formation of a large mucous ball has been reported.⁹⁴

Dyspnea or increased coughing may indicate that the TTO catheter is obstructed by a mucous ball, that the tube is kinked, or that the tip of the catheter is positioned cephalad to the stoma. Obstruction within the catheter tubing may cause a whistling sound from the oxygen tank humidifier. Always examine the patient for signs of subcutaneous air and catheter dislodgement.

If routine broad-spectrum antibiotics are used by the patient, *Candida* infections can develop at the stoma. Such infections are more common in patients receiving systemic antibiotics or long-term corticosteroids or those with diabetes. Tracheal chondritis may result from bacterial infection of the cartilage. Many patients with chondritis have a deep, indurated, nonfluctuant lump around the tract that may be tender to palpation. A 3-week course of an oral antibiotic that specifically covers *S. aureus* should be prescribed as treatment.

Interventions

If obstruction is suspected while the patient is in the ED, clean and replace the catheter. If the stoma tract has not healed or appears to be infected, change the catheter via a modified Seldinger technique. Use a water-soluble lubricant for the catheter change. If changing the catheter does not relieve the obstruction and the patient's airway is intact, encourage the patient to perform maneuvers that raise intrathoracic pressure to increase the force of the cough. Ask the patient to sit upright, hold a pillow to the abdomen, and cough forcefully after three deep inspirations. This maneuver may help mobilize secretions or small mucous plugs in the airway. Dyspnea and coughing should lessen with effective removal of the obstruction.

Manage minor bleeding at the catheter site with gauze packing or cauterization. If significant bleeding is identified or suspected, consult a specialist on an emergency basis and manage the airway definitively as clinically indicated (see the section on **Major Bleeding**). Manage skin and pulmonary infections with the techniques discussed for tracheostomy care.

Stents

Tracheal stenosis and tracheomalacia are known complications of artificial airways. Management options include surgery and placement of silicone stents in the trachea. Patients who have had their tracheostomy tubes successfully decannulated may need stents if symptomatic stenosis or tracheomalacia occurs. Indications for and complications of tracheal stents are beyond the scope of this chapter, but the clinician should be aware of the possibility that these indwelling devices may be present in patients who have undergone head and neck surgery or previous tracheostomies.^{57,95}

SPECIAL POPULATIONS

Obese Patients

The prevalence of obesity (body mass index [BMI] ≥ 30) and morbid obesity (BMI ≥ 40) has increased dramatically over the past few decades.^{96,97} Obesity increases the patient's risk for cardiovascular and metabolic comorbidity, and obese patients have a higher risk for ventilatory dysfunction secondary to altered respiratory mechanics.⁹⁸ Lung compliance, functional residual capacity, and expiratory reserve volume in an obese patient are reduced exponentially in relation to BMI.^{99,100} As weight increases, vital capacity and total lung capacity decrease.⁹⁹ Ultimately, obese patients have decreased pulmonary reserve, which can cause a rapid onset of hypoxia if they become critically ill.

Morbidly obese patients are particularly at risk for life-threatening complications related to tracheostomy.¹⁰¹ Tube obstruction and accidental dislodgement appear to be more common in obese patients. Dislodgement is specifically associated with increased rates of morbidity and mortality.⁵⁸ Delayed recognition of tube dislodgement because of abnormal neck anatomy accounts for nearly 30% of tracheostomy-related deaths in the obese population.^{58,101}

Preparation

For the management of an obese patient with a tracheostomy-related complaint, it is important to have all advanced airway equipment at the bedside (see Fig. 7.2). In addition to standard equipment, attempt to obtain an extra long or adjustable-flange tracheostomy tube to span the elongated pretracheal distance that is common in morbidly obese patients.¹⁰² In obese patients, standard tracheostomy tubes may be too short proximal to the cuff and have a higher risk for malposition.

In addition to standard monitoring, use continuous capnography, if available, to prevent delay in the recognition of tube dislodgement.⁵⁸ Physical signs, such as reduced breath sounds and subcutaneous air, may be more difficult to recognize in obese patients. Fiberoptic bronchoscopy may be needed to confirm correct tube placement. The patient should be positioned with the neck in slight extension, and the head of the bed should be elevated to approximately 30 degrees.

Interventions

Approach an obese patient with the same protocols outlined previously in this chapter for the applicable complication. If the tube is obstructed, deflation of the tracheostomy cuff may not be sufficient to allow adequate ventilation because external compression caused by abnormal neck anatomy may occur. If tube dislodgement is suspected, ET intubation may be preferred over blind reinsertion because of the increased risk for false passage.¹⁰¹ Tube placement can be confirmed with direct visualization via fiberoptic bronchoscopy.

Laryngectomy Patients

It is important to distinguish the patient with a routine tracheostomy from the patient with a laryngectomy as this could potentially limit the ability to provide ventilation by way of the upper airway. A patient who has undergone a total laryngectomy no longer has an upper airway that is in continuity with the lungs. A patient with a partial laryngectomy will have a contiguous upper and lower airway, and interventions by way of the upper airway may be limited.

The basic principles of emergency tracheostomy care still apply to the laryngectomy patient, and it is critical to recognize that a patient with a total laryngectomy cannot be resuscitated with traditional oxygenation and ventilation techniques, such as oropharyngeal bag-valve-mask ventilation and face mask oxygenation. Interventions should be made by way of the stoma rather than the upper airway. Partial laryngectomy patients should also be ventilated through their stoma, and their mouth and nose should be kept closed to avoid air escape.

Interventions

Should a patient with a laryngectomy need positive pressure ventilation, there are a few important steps to consider prior to inserting a cuffed tracheostomy or ET tube through the stoma. First, it is important to inspect the laryngectomy stoma for any mechanical obstruction. Suction the stoma to make sure it is clear of excessive secretions or mucous plugs. Stoma buttons should be removed, whereas tracheoesophageal speaking valves may be left in place as long as they are not displaced.

External ventilation with a pediatric face mask or laryngeal mask airway can be performed.¹⁰³ A standard cuffed-tracheostomy tube may be placed to facilitate mechanical ventilation. If inserting an ET tube, it is important that the provider avoid advancing it too far as this can lead to main stem bronchus intubation. The approximate distance between the skin of the stoma and carina is only approximately 6 cm.¹⁰⁴

Pediatrics

Most considerations for pediatric patients follow adult guidelines and are discussed in the appropriate sections of this chapter, but some specific considerations should be mentioned. The tracheostomy-related mortality rate in pediatric patients ranges from 0.5% to 6%.¹⁰⁵ The main causes of death are accidental dislodgement and obstruction of the tracheostomy tube.¹⁰⁶ Complication rates are highest in patients requiring tracheostomy for airway obstruction. In comparison, patients with central nervous system disorders, respiratory distress syndrome, and congenital heart disorders are less likely to experience complications.²⁴

Equipment

When replacing a tracheostomy tube in a child, always have at least two tracheostomy tubes available: the current size and a size smaller. Pediatric tubes generally have a much smaller diameter than adult tracheostomy tubes, and many of them do not have an inner cannula. Pediatric tracheostomy tubes rarely have inflatable cuffs, except for those used for certain special indications.¹⁰⁷ Suction catheters, a bag-valve-mask device, ET tubes, resuscitation medication, and equipment appropriate for the pediatric population should be available when treating pediatric tracheostomy patients. Continuous capnography may detect certain tracheostomy complications and is recommended.¹⁰⁸

Sizing

Pediatric tracheostomy tubes share most of the same components of the tubes used in adults. The ID of the tube is stamped on the outer cannula flange, and that information should guide the clinician's choice of replacement tubes. Recommended tube sizes according to age are listed in [Table 7.2](#). Age guidelines can be helpful, but they may not be reliable in pediatric patients because of complex medical problems. Premature infants may be small for their age and weight, thus making estimation of tube size even more difficult.

Like ET tubes, tracheostomy tubes are sized by the tube's ID. When the tracheostomy tube is seated correctly in a pediatric patient, it should extend at least 2 cm beyond the stoma and no closer than 1 to 2 cm above the carina. Its curvature should be such that when the tube is placed appropriately, the distal portion of the tube is concentric and collinear with the trachea. After replacing a tracheostomy tube, confirm its position by auscultating breath sounds, using capnography, and confirming the location of the distal tip with a chest radiograph.

Cuff

The general rule that cuffed ET tubes should not be used in patients younger than 6 years is under a great deal of debate and does not universally apply to tracheostomy patients. If a

TABLE 7.2 Tracheostomy Tube Sizes Based on Patient Age

AGE	SIZE	INNER DIAMETER (mm)	OUTER DIAMETER (mm)
Premature	00	3.1	4.5
Newborn–3 mo	0	3.4	5.0
3–10 mo	1	3.7	5.5
10–12 mo	2	4.1	6.0
13–24 mo	3	4.8	7.0
2–9 yr	4	5.0	8.5
10–11 yr	6	7.0	10
≥12 yr	8	8.5	12.0
	10	9.0	13.0

Adapted from Mullins JB, Templer JW, Kong J, et al: Airway resistance and work of breathing in tracheostomy tubes, *Laryngoscope* 103:1367, 1993.

patient requires high-pressure ventilation or only nocturnal ventilation or is at risk for aspiration, a cuffed tube may be appropriate. Cuffed tubes are also used in patients with a tracheal anomaly. Replacement of these tubes should ensure that the individual's anatomic and physiologic needs are met.

Cuff pressure recommendations for pediatric patients are less than 20 cm H₂O.¹⁰⁹ With few exceptions, low-pressure, high-volume cuffs should be used.²⁴

Humidifiers

Humidifiers for pediatric tracheostomy tubes attach to the external port. Some humidifiers have lithium-coated moisture exchangers. Systemic absorption of lithium is unlikely to cause clinical symptoms in adults but may be a consideration in children. Use humidifiers regularly to keep secretions loose and help prevent obstruction of the tube.

Suctioning

Suctioning recommendations in pediatric patients clearly support the use of a premeasured suction catheter to reduce the rate of mucosal irritation and to limit the development of granulation tissue. The premeasured technique uses an exact depth of insertion, which reduces epithelial damage if the catheter is inserted too deeply and inadequate suctioning if the catheter is not inserted deeply enough. Depth of insertion can be estimated by measuring a similar tube before inserting the suction catheter. In children with fenestrated tracheostomy tubes, suction catheters may accidentally go through the fenestrations and cause mucosal irritation. If this happens repeatedly, granulation tissue may develop at the site.²⁴

Complications

Pediatric tracheostomy complications are similar to those in the adult population. Their incidence is estimated to be between 5% and 49%.¹⁰⁵ Late complications most likely to be seen in the ED include obstruction, dislodgement, bleeding, pneumothorax, infection, pneumomediastinum, TEF, and TIF. Chronic respiratory complications include tracheomalacia, tracheal stenosis, vocal cord paralysis, and vocal cord fusion.

Granuloma formation is common in pediatric patients. It often occurs in the tracheal lumen either at the superior margin of the tracheostomy or at the level of the tip of the tube. The development of granulation tissue is the result of persistent mucosal irritation and inflammation. Any patient with a clinically

significant granuloma should be evaluated by a pediatric specialist for definitive care.

Pneumomediastinum and pneumothorax are generally thought to be early complications of tracheostomy, but they should always be considered in a pediatric tracheostomy patient. In children, the pleural apices rise higher than in adults and can even extend into the lower part of the neck. These complications can be caused by a dislodged tube positioned in a false passage or a malpositioned tube that causes an increase in intrathoracic pressure.¹⁰⁶

The most common bacterial species that colonize pediatric tracheostomies are *P. aeruginosa* and *S. aureus*. As in adults, colonization does not require treatment unless signs of acute infection are present.¹⁰⁶ Suprastomal collapse of the anterior tracheal wall is very common in pediatric patients and can cause air trapping. A tracheostomy tube that places excessive pressure on the tracheal rings will cause inflammation, chondritis, and weakening of the cartilaginous rings. Significant collapse can hamper subsequent decannulation success.

Management of major bleeding in pediatric patients follows the same recommendations given for adults. The smaller stoma size may prevent the application of digital pressure to the site of hemorrhage. If the clinician is unable to reach the source of the bleeding, expeditious ET intubation followed by cuff overinflation may temporize the bleeding until the patient can be taken to the operating room.

CONCLUSION

A tracheostomy emergency can be one of the most high-risk scenarios in the ED. The emergency physician must be well prepared for a variety of tracheostomy complications and should approach the patient in an organized, stepwise fashion so that interventions can be initiated in a timely fashion. Often specialty consultation in the ED is required to fully assess or treat complications. Tube dislodgement and obstruction are common and associated with an extremely high mortality rate, especially in obese patients. Always ensure correct tube position, have backup airway equipment readily available, and obtain surgical support early if the patient needs to go to the operating room.

Mechanical Ventilation

Jairo I. Santanilla

INTRODUCTION

Mechanical ventilation (MV) is an important tool for resuscitation of critically ill patients in the emergency department (ED). It is vital that ED practitioners have a thorough understanding of the basics of MV and to know when to apply these principles and how to support patients in respiratory or cardiac failure. Hospital overcrowding has led to a delay in transfer of mechanically ventilated patients out of the ED, and ventilator management often falls on the emergency medicine physician. In addition, during nights and weekends in some facilities, the ED physician may be called on to troubleshoot or stabilize mechanically ventilated patients in the intensive care unit (ICU). The traditional view of MV as a prescription that fits virtually all patients equally should be discarded as a gross misunderstanding of pulmonary pathophysiology. Increasing evidence has shown that the mechanism of lung ventilation by MV may be as deleterious as it is helpful.¹ Because patients remain in the ED while mechanically ventilated, ED clinicians should embrace the established paradigm of pulmonary-protective MV strategies as a cornerstone of care.

BASIC PHYSIOLOGY

Understanding basic pulmonary physiology is essential to understanding how to initiate MV. This ensures that the method of gas delivery meshes with the patient's underlying physiology to avoid ventilator-induced lung injury.

Minute Volume and Alveolar Ventilation

The volume of air that moves in and out of a patient's lungs per minute is termed *minute volume* (\dot{V}_E). \dot{V}_E is the product of tidal volume (VT) and respiratory frequency or rate (f):

$$\dot{V}_E = VT \times f$$

Normal \dot{V}_E is 7 to 10 L/min. VT can be further broken down into alveolar volume (VA) and dead space volume (VDS):

$$Vt = Va + Vds$$

In healthy young persons, the anatomic dead space is accounted for by the trachea and the larger airways and is approximately 2.2 mL/kg lean body weight. In disease states, in addition to the anatomic dead space, there is a variable amount of "pathologic" dead space, which corresponds to ventilated alveoli and respiratory bronchioles that are not adequately perfused. The sum of anatomic and pathologic dead space is often referred to as *physiologic dead space*.

Alveolar minute ventilation (\dot{V}_A) is the product of rate times VT minus dead space:

$$\dot{V}_A = (VT - VDS) \times f$$

\dot{V}_A and the rate of CO₂ production by the body determine the partial pressure of CO₂ in the alveoli (PACO₂), which is approximately equal to systemic arterial CO₂ tension.

Volume-Pressure Relationship

Volume and pressure are related for a given respiratory system. A given volume (V) will create a certain pressure (P) relative to the compliance (C) of the respiratory system. The respiratory system consists of the ventilator tubing, endotracheal (ET) tube, trachea, airways, lung parenchyma, chest wall, and diaphragm tension. For example, a 500-mL volume will create a certain pressure based on the compliance of the respiratory system. Increasing the volume will increase the pressure in the system. Decreasing the volume will result in lower pressure. Decreasing the compliance (i.e., making the system "stiffer") will increase the pressure in the system. Increasing the compliance will decrease the pressure in the system.

$$P = V/C$$

Conversely, this relationship also holds for volume. For example, a pressure of 20 cm H₂O will create a certain volume based on the compliance of the system. Increasing pressure will result in higher volume. Decreasing pressure will result in lower volume. Decreasing compliance will result in lower volume. Increasing compliance will result in higher volume.

$$V = P \times C$$

Airway Pressures

Plateau Pressure

Plateau pressure is measured at the end of inspiration with a short breath-hold (Fig. 8.1). At this point no airflow should be occurring. This is considered a static pressure. By understanding the aforementioned volume-pressure relationship, one can easily deduce how plateau pressure is inversely related to respiratory system compliance and directly related to volume. Anything that decreases compliance will increase plateau pressure. Increasing compliance will decrease plateau pressure. Decreasing volume will decrease plateau pressure (a major tenet in lung-protective ventilation).

Peak Airway Pressure

Peak airway pressure is derived during inspiration and thus incorporates airflow. Because there is air movement during this measurement, it is considered a dynamic pressure. It reflects the dynamic compliance of the entire respiratory system and incorporates static compliance and airflow. Peak airway pressure can never be lower than plateau pressure. In addition, because its main distinction is that it incorporates airflow, it is reflective of resistance to airflow. Anything that decreases compliance or increases resistance to airflow will increase peak airway pressure. Increasing compliance or decreasing resistance to airflow will decrease peak airway pressure.

A physiologically appropriate means of detecting and monitoring bronchospasm is the peak-plateau gradient. A normal gradient is less than 4 cm H₂O pressure, and elevated values indicate increased airway resistance. The efficacy of treatment with β_2 -agonists, steroids, intravenous magnesium, or diuresis may be assessed by monitoring the changes in this gradient (Fig. 8.2).

Figure 8.1 Schematic of a pressure-time curve showing an inspiratory breath-hold and subsequent plateau pressure (P_{plat}) measurement. P_{aw} , Airway pressure; $PEEP$, positive end-expiratory pressure.

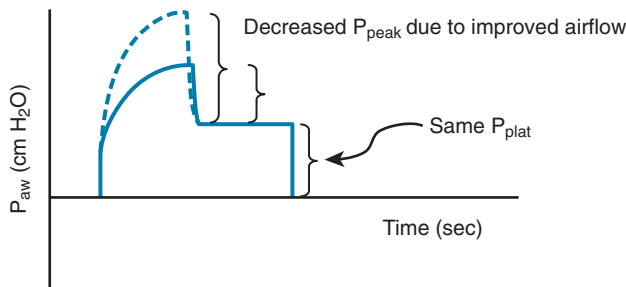

Figure 8.2 Schematic of two superimposed pressure-time curves showing an isolated decrease in peak inspiratory pressure (P_{peak}) with no change in plateau pressure (P_{plat}) as airflow resistance improves. P_{aw} , Airway pressure.

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) is the pressure in the airway at the end of exhalation. PEEP helps keep the large noncartilaginously supported airways and the smaller alveoli open to prevent collapse, atelectasis, and ensuing hypoxia. The ventilation required to compensate for this triad commonly worsens lung compliance and is associated with ventilator-induced lung injury. Progressive increases in PEEP result in elevations in both total lung pressure and total lung volume. For example, serial elevations in PEEP often result in increased plateau pressure and elevated functional residual capacity (FRC; i.e., lung volume).

Extrinsic PEEP

When discussing MV and PEEP, most often authors are referring to extrinsic PEEP ($PEEP_e$). This is also referred to as applied PEEP. It is the PEEP that is extrinsically applied by the ventilator. When PEEP is used without a subscript in this chapter, it refers to $PEEP_e$. The useful PEEP range is from 3 to 20 cm H₂O.² PEEP is used to increase FRC and move the zero pressure point of each alveolar unit more proximally in the airway and thereby prevents early alveolar collapse.³ By so doing, PEEP increases the available number of alveolar units that can participate in gas exchange. The primary effect of PEEP on gas exchange is improvement in oxygenation, not removal of CO₂. CO₂ clearance is rather efficient and will be well preserved, even in hypoxic situations. By opening one alveolar unit, the tendency of adjacent units is to open as well (i.e., alveolar codependency) (Fig. 8.3).⁴ Excessive PEEP will compromise hemodynamics. There are two primary questions to ask when using PEEP to augment

Figure 8.3 Alveolar interdependence. Note that alveoli are not round in shape; instead, they are polygons. Polygons have corners and may have two opposing surfaces that may adhere to one another via surface tension. Surfactant works to reduce this surface tension and allow alveoli to open with reduced shear stress at the junction of closed and open alveoli. Alveoli are connected via the pores of Kohn. These pores allow opening alveoli to pull a relatively closed alveolus open while equalizing pressure between adjacent alveoli. The central alveolus on the right is fairly closed in the upper part of the diagram, but it is pulled open by its neighbors as they expand and accept gas.

oxygenation: (1) What is the “optimal PEEP?” and (2) Is the current amount of PEEP compromising the patient’s hemodynamics?

PEEP is not without untoward side effects, and increased levels of PEEP can lead to lung injury and hemodynamic compromise.⁵ Increased intrathoracic pressure can result in cardiac compression and collapse, principally of the right atrium. It is imperative that the patient be adequately volume-resuscitated because preload depletion compounds this problem. Desired levels of PEEP simply may not be possible because of deleterious effects on cardiac output.

Optimal PEEP can be determined in several ways. One is to increase PEEP until there are no longer increases in partial pressure of oxygen (PO₂). However, this method may result in several untoward events. First, oxygen tension may increase steadily, but carbon dioxide pressure (PCO₂) may increase as a result of alveolar overdistention. With overdistention, alveolar pressure may exceed pulmonary arteriolar pressure and actually decrease pulmonary blood flow and clearance of CO₂. Second, alveolar overdistention may increase total intrathoracic pressure and result in diminished venous return and cardiac output. Third, decreased venous return may cause cerebral venous hypertension. The optimal PEEP for one organ system may be deleterious for another. For example, the optimal PEEP for ideal oxygenation may be the worst PEEP for cerebral venous drainage.

An alternative is to increase PEEP until a complication of PEEP occurs (e.g., elevation in PCO₂, hypotension) and then reduce PEEP if needed (inability to tolerate hypercapnia) or expand the patient’s intravascular volume to combat the decreased venous return.

Another excellent method of determining the optimal PEEP is guided by assessing changes in plateau pressure with changes

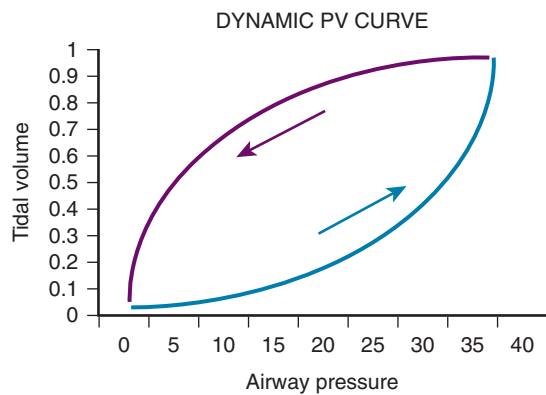

Figure 8.4 Dynamic pressure-volume (PV) loop. Note that as soon as pressure is delivered to the airway, there is an increase in measured tidal volume. The *lower arrow* denotes inspiration and the *upper arrow* indicates expiration. This indicates that the airways are open and do not need to be forced open by increasing the pressure in the airway. If this latter case were true, the PV loop would initially be flat along the x-axis.

Figure 8.5 Inadequate positive end-expiratory pressure (PEEP) and the pressure-volume loop. Compare this curve with that in Fig. 8.4. Note that the loop is initially flat (*lower segment*) along the x-axis. Once airway pressure is high enough to open the alveolar units, each increase in airway pressure is matched by a corresponding increase in tidal volume.

in PEEP. As PEEP is increased from a minimal level, the patient's peak airway pressure and plateau pressure will increase by the amount of PEEP_c. When the optimal PEEP for the lung units is achieved, plateau pressure will no longer increase. As the lung is optimally recruited, peak and plateau pressure may decrease because more volume of lung is available to receive a set VT. Once this level is exceeded, there will be further increases in plateau pressure beyond the incremental increase in PEEP as the units overdistend. Therefore the clinician must readily identify the plateau in this plateau pressure trend. The same relationship may be displayed graphically in the dynamic pressure-volume loop (Fig. 8.4). The lower limb of the loop represents the pressure required to open the alveolar units.^{6,7} In the absence of PEEP (or inadequate PEEP), this limb is prolonged and flattened and has an inflection point far to the right of the origin of the loop (Fig. 8.5). As PEEP is progressively increased, the inflection point travels to the left. When the optimal PEEP is achieved, there will be a rapid

Figure 8.6 Schematic of a flow-time curve showing potential air trapping. Note that full exhalation has not occurred before initiation of the next breath. This is seen by the fact that flow has not reached zero when the next breath is given. A square waveform is being used in this example. Continuation of this state can lead to intrinsic positive end-expiratory pressure.

upstroke of the loop because the vast majority of the functional lung units are already open and ready to be ventilated (see Fig. 8.4). This strategy is known as the *open lung model* of MV.⁶

Irrespective of what technique is used, it is currently widely agreed that plateau pressure should not exceed 30 cm H₂O. If respiratory system compliance is so low that plateau pressure exceeds 30 cm H₂O, either PEEP or VT has to be decreased. If this is not possible because of either recalcitrant hypoxia or acidosis, rescue therapies may need to be used (see the section on *Acute Lung Injury and Acute Respiratory Distress Syndrome*).

Intrinsic PEEP

Intrinsic PEEP (PEEP_i) is additional pressure that is generated within the airways from trapped gas that should have been exhaled but for various reasons (commonly obstruction to exhalation such as in chronic obstructive pulmonary disease [COPD]) was not. PEEP_i is also referred to as auto-PEEP, dynamic hyperinflation, and breath stacking. For the remainder of this chapter it will be referred to as PEEP_i.

PEEP_i can cause hemodynamic instability secondary to decreased venous return, just like high levels of PEEP.⁷ PEEP_i may be detected in two ways: (1) evaluation of the flow-time trace or (2) disconnection of the patient from the ventilator and listening for additional exhaled gas after an exhalation should have occurred.⁶ The flow-time trace will demonstrate that the exhalation is not yet completed before the next breath has been initiated (Fig. 8.6).⁸

INDICATIONS FOR MV

There are wide-ranging reasons for patients to require MV in the ED, and there are no absolute contraindications. Many time-honored indications for invasive ventilation are now identified as appropriate indications for noninvasive ventilation and are addressed later. Indications for MV range from loss of airway anatomy (edema, direct or indirect trauma, burns, infection), loss of protective airway mechanisms (intoxicants, brain injury, stroke), inability to ventilate, inability to oxygenate, or the expected clinical course. Indications for ET intubation may be separated into several categories—emergency, urgent, delayed, and elective—based on the urgency of establishing a definitive airway.

EQUIPMENT—STANDARD OPTIONS

Perhaps one of the most confusing aspects of MV is the plethora of terms and acronyms that are used. Understanding the basic terminology helps clarify this subject. The following discussion explores machine features and settings. Regardless of which ventilator is used, a limited number of standard features are common to each (Fig. 8.7).

Set Respiratory Rate

Most ventilators allow the clinician to set a respiratory rate. The respiratory rate and actual VT determine a patient's minute ventilation. Patients intubated for airway protection because of trauma or toxicosis often do well with a normal minute ventilation. Initially setting the respiratory rate at 10 to 14 breaths/min and VT at 7 to 8 mL/kg ideal body weight (IBW) is usually sufficient. Adjustments can be made based on arterial blood gas (ABG) analysis, end-tidal CO₂, or venous blood gas and pulse oximetry. Patients who are septic or have severe acidosis often require higher minute ventilation. Respiratory rates can be increased, as can VT, but volumes higher than 10 mL/kg IBW should not be used because of the risk of inducing ventilator-associated lung injury. In special scenarios such as acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), initial VT values should be lowered to 6 mL/kg IBW within 2 hours of intubation. Some of these specific scenarios are discussed later.

Figure 8.7 The Nellcor Puritan Bennett 840 Ventilator system (Mansfield, MA). Selected features common to all ventilators include the respiratory rate (A), FiO₂ (B), positive end-expiratory pressure (PEEP) (C), waveform (D), inspiratory-to-expiratory ratio (I/E) (E), and trigger (F).

Fraction of Inspired Oxygen

All ventilators can deliver an adjustable fraction of inspired oxygen (FiO₂). Recommendations are to set it initially at 1.0 because the act of transitioning from negative pressure ventilation (normal physiologic breathing) to positive pressure ventilation (PPV) may unpredictably alter ventilation-perfusion (\dot{V}/Q) matching. Although initially an FiO₂ of 100% is optimal, it is beneficial to quickly titrate FiO₂ down because of the theoretical risk for oxygen toxicity. Make adjustments based on ABG analysis or pulse oximetry, with a goal of keeping arterial PO₂ higher than 60 mm Hg or arterial oxygen saturation (SaO₂) at 88% to 92% to avoid potential oxygen toxicity (see Table 3.3 in Chapter 3). Such adjustments may best be accomplished in the ICU rather than the ED, after the entire clinical scenario can be analyzed and all interventions are appropriately adjusted. However, if there is a delay in transfer to the ICU, adjustments should be made in the ED.

PEEP

PEEP_e is typically set at 5 to 8 cm H₂O. Most patients should be started at a PEEP of 5 cm H₂O, which is considered a physiologic level. It is used to offset the gradual loss of FRC in supine, mechanically ventilated patients. PEEP can be increased by 2 cm H₂O every 10 to 15 minutes as needed or tolerated by patients who remain hypoxic. The initial goal is to reduce FiO₂ to nontoxic levels. This goal is coming under increasing scrutiny as new information challenges the time frame and concept of O₂-induced lung injury at FiO₂ levels greater than 0.6.⁹ Exercise care when using PEEP levels higher than 8 cm H₂O in the setting of elevated intracranial pressure (ICP),¹⁰ unilateral lung processes, hypotension, hypovolemia, or pulmonary embolism. High PEEP can potentially lead to hypotension as it increases intrathoracic pressure and decreases venous return and, subsequently, cardiac output.

Flow Rate

The flow rate is the speed, in liters per minute, that the ventilator is delivering gas. It is found in volume-targeted modes, but not pressure-targeted modes. The flow rate is typically set at 60 L/min, which means that a set VT will be delivered at that speed. Patients wanting higher flow rates will not receive them and may display air hunger. Increase flow rates to deliver the set volume faster and shorten the inspiratory time (thereby increasing the inspiratory-to-expiratory [I/E] time ratio).

Waveform

The waveform determines how the ventilator delivers the flow of gas. It is traditionally set to a “decelerating waveform” in an effort to optimize recruitment because of different time constants in the lung.

Decelerating (Ramp)

Once the maximal inspiratory flow is reached, the rate of gas delivery immediately begins to slow in a preprogrammed fashion. When compared with the square waveform, longer time is spent in inhalation to deliver the set VT or achieve the target pressure and allow improved oxygenation. This waveform also achieves lower peak airway pressure and higher mean airway pressure.

Square

Once the maximal inspiratory flow rate (IFR) is achieved, gas flow is constant until the set volume is delivered. When that point is reached, gas flow is terminated. This waveform is best for patients with asthma, COPD, and head injury because gas delivered with this waveform allows a longer expiratory time (T_e , thereby increasing the I/E time ratio) and lower mean airway pressure. The longer T_e is beneficial for patients with restrictive airway disease such as asthma or COPD. Spending a longer time in exhalation allows improved venous drainage from the brain and greater loss of trapped V_T . The drawback with this waveform is increased peak airway pressure, which often requires lower V_T . This can lead to inadequate alveolar recruitment in patients with ALI.

I/E Time Ratio

The ratio of inspiratory time (the time that it takes to take a breath) to expiratory time (the time that it takes to exhale a breath) is automatically reported in some modes, whereas in others it is dialed in.

The normal I/E ratio in a spontaneously breathing, non-intubated patient is 1:4.¹¹ Intubated patients commonly achieve I/E ratios of 1:2. Shorter ratios may lead to decreased exhalation by compromising T_e . In its extreme form, inverse ratio ventilation (IRV), the normal pattern of breathing is reversed. A longer time is spent in inhalation to allow more time for oxygenation and recruitment. The decrease in T_e can lead to air trapping, elevated mean airway pressure, and rising PCO_2 . These problems lead to hypercapnia, respiratory acidosis, and PEEP.¹² (Fig. 8.8).

Trigger

The trigger is the aspect that initiates a machine-generated breath. The trigger can be set to detect either a pressure or a flow gradient. It should be set so that the patient can trigger the ventilator without great effort.

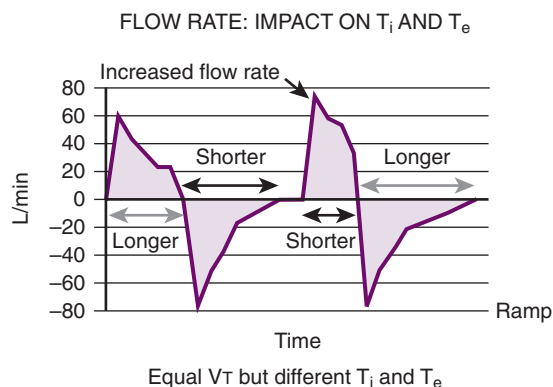

Figure 8.8 Effect of flow rate on inspiratory (T_i) and expiratory (T_e) time. Note that as the flow rate changes, there are corresponding alterations in the effective times for inspiration and exhalation. Deflections above the x-axis (time) indicate inspiration, and those below indicate exhalation. The tidal volume (V_T) delivered for each cycle is the same, but T_i and T_e are different.

Sensitivity

This refers to the sensitivity of the trigger. If the trigger is set too high (not sensitive enough), the work of breathing incurred by the patient can be substantial. Some providers have been known to set the sensitivity at a high level if the patient is markedly overbreathing the set rate. This is not recommended because it causes an undue increase in the work of breathing. Many ventilators are set to a pressure trigger with a sensitivity of 1 to 3 cm H_2O .¹³ If the sensitivity is set too low (too sensitive), the ventilator can “auto-trigger” (inappropriate initiation of machine-generated breaths) because of oscillating water in the ventilator tubing, hyperdynamic heartbeats, or patient movement.

MODES OF VENTILATION

Once some of the standard features are understood, the next step is determining the ventilator’s target. Most ventilators can be set to achieve spontaneous breathing, volume-targeted ventilation, pressure-targeted ventilation, or some combination. In volume-targeted ventilation, the ventilator is set to reach a determined volume regardless of the pressure required to do so. Pressure-targeted modes are set to reach a determined pressure regardless of the volume generated. Dual modes combine the benefits of both strategies (Fig. 8.9).

Spontaneous Breathing

Spontaneously breathing patients can be supported on the ventilator by pressure support ventilation (PSV). In this mode, the ventilator provides a supplemental inspiratory pressure to each of the patient-generated breaths. The clinician sets FI_{O_2} and PEEP. The patient dictates the respiratory rate and generates the desired flow rate. The applied pressure is turned off once the flow decreases to a predetermined percentage. V_T is dictated by the pressure support given, patient effort,

Initial Ventilator Settings for Standard Patient

VCV: AC, RR 10–14, V_T 7–8 mL/kg IBW, PEEP 5, FI_{O_2} 100%
Flow rate 60 L/min, Decelerating waveform

PCV: AC, RR 12–16, pressure high 20, PEEP 5, FI_{O_2} 100%

- Monitor size of V_T obtained with this pressure, adjust pressure to obtain a V_T around 7–8 mL/kg IBW

- SIMV can be picked for either VCV or PCV. If SIMV is picked, add PSV at a sufficient level to obtain an adequate V_T

- Adjust FI_{O_2} based on PO_x or PaO_2

- Adjust PEEP based on hypoxia

- Adjust minute ventilation based on blood pH (remember that on AC, decreasing the RR does not change minute ventilation in a patient breathing over the set rate)

Figure 8.9 Initial ventilator settings for standard patients. AC, Assist/control mode; FI_{O_2} , fraction of inspired oxygen; IBW, ideal body weight; PEEP, positive end-expiratory pressure; PCV, pressure-cycled ventilation; PSV, pressure support ventilation; RR, respiratory rate; SIMV, synchronized intermittent mandatory ventilation; VCV, volume-cycled ventilation; V_T , tidal volume.

and compliance of the respiratory system. There is no set respiratory rate, although most modern ventilators have a backup apnea rate.

Volume-Cycled Ventilation

Volume-cycled ventilation (VCV) may also be termed volume-limited, volume-control, volume-assist, or volume-targeted ventilation. Volume-targeted modes are the most commonly used and the most familiar mode of MV in adults. As its name implies, “volume”—in this case V_T —is the ventilator’s targeted parameter. With this target, the ventilator seeks to deliver a preset amount of gas. The ventilator will generate the necessary driving pressure to reach this “target.” In addition to V_T , the clinician sets the desired respiratory rate, F_{IO_2} , and PEEP. It should be noted that other important aspects of the mechanical ventilator can be controlled in this setting, such as waveform (decelerating or square), I:E ratio, flow rate, trigger, and sensitivity.

The time of gas flow is determined by the set volume, flow rate, and waveform of gas delivery. When the set volume is reached, gas flow is terminated and expiration passively begins. An advantage is that VCV delivers a reliable volume, but it does not take into account dynamic changes in lung compliance, which may alter the ability of the lung to accept delivered gas in gas-exchanging alveoli.

Pressure-Cycled Ventilation

Pressure-cycled ventilation (PCV) may also be termed pressure-limited, pressure-control, pressure-assist, or pressure-targeted ventilation. As its name implies, “pressure” is the ventilator’s targeted parameter. The ventilator will generate an inspiratory pressure that has been set by the clinician. With this target, the ventilator alters gas flow to achieve and maintain a preset airway pressure for the duration of a preset inspiratory time (T_i). Gas flow is terminated when the preset pressure is achieved. The volume delivered is determined by the compliance of the patient’s respiratory system, airway resistance, T_i , and the pressure target. In addition, the clinician sets the desired PEEP, respiratory rate, F_{IO_2} , T_i , I:E ratio, and trigger mode. Pressure is maintained with a variable or intermittent flow rate for the set T_i . In the setting of hypoxemia, T_i may be increased quite precisely to increase mean airway pressure and oxygenation. This strategy is much more difficult, if not impossible, to manipulate with VCV.

An advantage of PCV is that airway pressure is tightly managed to limit or eliminate alveolar overdistention and to reduce ventilator-induced lung injury.¹⁴ It should be noted that the clinician does not control waveform or peak inspiratory flow. Patients can generate their desired flow rate and thus reduce air hunger. Pressure-targeted modes, which are growing in popularity, might have better pressure distribution, improved dissemination of airway pressure, and greater distribution of ventilation.¹⁴

One problem with PCV is that the volume received by the patient is potentially variable. Any change in system compliance or resistance (or both) will affect the V_T generated. For example, if the patient bites on the ET tube or a mucous plug develops, the set pressure that was generating an adequate volume will no longer do so. In contrast, a sudden increase in system compliance might result in the generation of V_T that may be considerably larger than desired. Instead of the traditional

pressure alarm limits, one must adjust and be cognizant of V_T and minute ventilation alarm settings. Uncertainties such as these have led many clinicians to favor volume-targeted strategies or dual-controlled strategies in the acute care setting.

Modes of Ventilation Commonly Used in the ED

Assist/control (AC) and synchronized intermittent mandatory ventilation (SIMV) are the ventilation modes most commonly used in the ED. Both are acceptable, and no data have demonstrated a better outcome with either mode. Other modes are also acceptable based on clinician preference.

AC Ventilation

Here, ventilator-initiated breaths, known as *machine breaths* (i.e., control breaths), are provided at a preset rate. Every breath is fully supported by the ventilator, regardless of whether the breath is initiated by the patient or the ventilator. The clinician sets the base ventilation rate, but if the patient tries to breathe faster than the set rate, additional breaths can be initiated by the patient, known as *spontaneous breaths* (i.e., assist breaths). A potential downside is inappropriate hyperventilation.

AC modes may be either volume or pressure cycled. Both assist breaths and control breaths will reach the set target, be it a set volume (in a volume-targeted mode) or a set pressure (in a pressure-targeted mode). In VCV, the spontaneous breath receives the same V_T that is set for the machine breath. In PCV, the spontaneous breath receives the same *pressure* that is set for the machine breath. To be more specific, in the *volume-targeted mode*, the clinician sets V_T , as well as the IFR, flow waveform, sensitivity to the patient’s respiratory effort (i.e., trigger), and the basal ventilatory rate. In the *pressure-targeted mode*, the clinician determines the basal ventilatory rate and how sensitive the ventilator will be to the patient’s respiratory effort and also selects pressure levels and T_i . Hence, in this mode V_T is not set by the ventilator but is dependent on the compliance of the lung and chest wall and airway pressure. This helps avoid pressure-induced lung injury, but a specific V_T is not guaranteed.

For the patient to trigger the ventilator and initiate flow for a spontaneous breath, mean airway pressure must decrease by a preset amount below PEEP if set on a pressure trigger or flow to be generated if set on a flow trigger. The amount necessary to open the inflow valve is the sensitivity setting.

Caution should be exercised to *avoid auto-PEEP* (also known as breath stacking) when using volume-targeted AC modes. Because each mechanically delivered breath is given at full V_T , patients with a high actual respiratory rate on AC may not have sufficient time to completely exhale between breaths. This results in progressive air trapping, which leads to an increase in auto-PEEP ($PEEP_i$) (see Fig. 8.6). This is of clinical concern in patients with asthma, in whom auto-PEEP can significantly reduce cardiac output and even promote cardiovascular collapse.

SIMV

SIMV provides breaths at a preset rate (machine breath), similar to the AC mode. The patient can initiate an additional spontaneous breath between the mandated or preset number of ventilator-supported breaths. Such spontaneous breaths above the preset ventilatory rate are not supported by the ventilator,

and the patient receives only a spontaneous V_T that reflects the depth and time spent in the patient-controlled inspiration. For each of these nonmandatory (i.e., spontaneous) breaths, the patient has a high work of breathing. SIMV is typically partnered with PSV to aid in spontaneous breathing support and to overcome the intrinsic resistance associated with MV. This mode was initially recommended by those who thought that, as a patient's need for mechanical ventilatory support decreased, the set respiratory rate could be decreased and the patient "weaned" to PSV alone and ensuing extubation. Subsequent data have shown that this method of liberation actually increases the number of ventilator days.¹⁵ The synchronized version of intermittent MV allows the ventilator to attempt to coordinate spontaneous and machine breaths to prevent it from delivering a scheduled breath on top of a spontaneous breath or during exhalation after a spontaneous breath. This could lead to elevated mean airway pressure, alveolar overdistention, and biotrauma.¹⁶

Both volume-targeted ventilation and pressure-targeted ventilation modes can be set to either an AC or SIMV mode to achieve the desired minute ventilation. In a chemically paralyzed patient with no intrinsic respiratory drive, AC and SIMV look virtually identical. Both will reach their target (volume or pressure) at the set rate. If a patient triggers the ventilator at a rate greater than the set rate, these two strategies diverge. In AC, each breath above the set respiratory rate will result in a full mechanically supported breath to reach either the set volume or pressure target. In SIMV, the ventilator will give only the set number of breaths that the clinician has selected. Each additional breath will require the patient to generate a spontaneous V_T without mechanical assistance. This patient-generated breath must overcome any resistance caused by the artificial airway and ventilator circuitry. Pressure support should be added to SIMV for patient-generated breaths to reduce any increase in the work of breathing related to the resistance imposed by the ventilator circuit and ET tube.

Advanced Modes of MV

Dual-Control Modes

Advanced modes of MV use a closed-loop ventilator logic that combines the features of volume- and pressure-targeted ventilation (Box 8.1). These modes automatically alter control variables, either breath to breath or within a breath, to ensure a minimum V_T or minute ventilation.¹⁷ Detailed explanation of these modes is beyond the scope of this chapter. If these modes are encountered, one should discuss options with a respiratory therapist and critical care medicine specialist.

Other Modes

High-Frequency Ventilation

High-frequency ventilation (HFV) attempts to achieve adequate gas exchange by using asymmetric velocity profiles when combining very high respiratory rates with V_T levels that are smaller than the volume of anatomic dead space. It is used more commonly in neonates and infants with neonatal respiratory failure. There has been renewed interest in using HFV in adult patients with ALI or ARDS under the rationale that the small V_T may cause less ventilator-associated lung injury. More trials are necessary to determine whether HFV can improve mortality outcomes in these patients.¹⁸

BOX 8.1 Advanced Modes of Mechanical Ventilation

BREATH TO BREATH

- Pressure-regulated volume control (PRVC)
- Auto flow
- Volume control plus (VC+)
- Adaptive pressure ventilation (APV)
- Variable-pressure control (VPC)

WITHIN A BREATH

- Volume-assured pressure support ventilation (VAPSV)
- Pressure augmentation

OTHER

- High-frequency ventilation (HFV)
- Airway pressure release ventilation (APRV)
- Bilevel
- Proportional assist ventilation

Airway Pressure Release Ventilation and Bi-Level Ventilation

Both these modes are proprietary names yet function in essentially the same manner. The clinician sets a pressure high, a pressure low, and a time at each level (time high and time low). Although at first glance this appears to be similar to PCV, it differs markedly in that the majority of time is spent at pressure high with brief periods at pressure low. The patient typically spends 4 to 6 seconds in time high. Pressure high may be as high as 40 cm H_2O or greater. Ventilation occurs during the release from pressure high to pressure low. Time low is typically 0.2 to 0.8 second in restrictive lung disease and 0.8 to 1.5 seconds in obstructive lung disease. It is probably prudent to start at 0.8 and titrate to meet individual patient requirements. Time low is also referred to as the release phase.¹⁹ The long time that high-level pressure is maintained achieves oxygenation, and the short release period achieves clearance of CO_2 (Fig. 8.10). The long time at high-level pressure results in substantial recruitment of alveoli from markedly different regional time constants at rather low gas flow rates. The establishment of $PEEP_i$ by the short release time enhances oxygenation. CO_2 clearance is aided by recruitment of the patient's lung at close to total lung capacity. Elastic recoil creates large-volume gas flow during the release period.

In a paralyzed patient, airway pressure release ventilation and bilevel ventilation (APRV/Bi-Level) are identical to pressure-targeted IRV. For these reasons, some have described this mode as *inverse ratio ventilation*. A major difference between APRV/Bi-Level and IRV is that IRV typically requires chemical paralysis or heavy sedation. APRV/Bi-Level is a fundamentally different mode from cyclic ventilation. This mode allows the patient to spontaneously breathe during all phases of the cycle, thus making it relatively more comfortable and reducing the level of sedation or paralysis needed. This mode is enabled to succeed by having a floating valve that is responsive to the patient's needs, regardless of the location within the respiratory cycle. The patient is allowed to breathe in or out during the pressure high phase and during the release phase. Accordingly, the sequence is called a *phase cycle*. There is no set T_i or T_e .

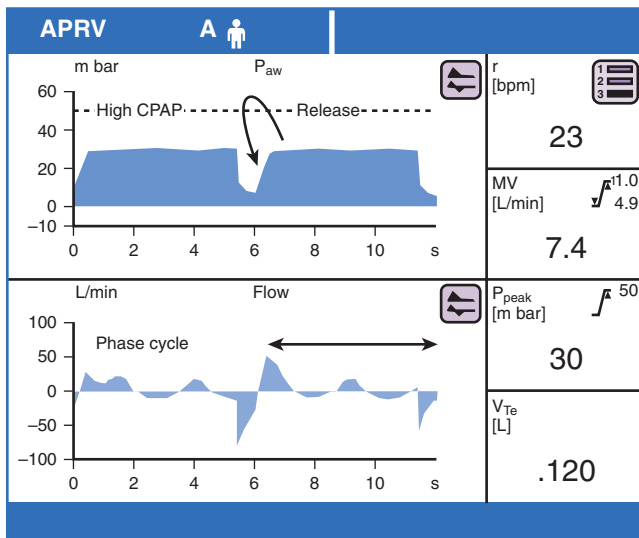

Figure 8.10 Airway pressure release ventilation (APRV)—airway pressure–time and flow–time traces. Note that peak airway pressure (P_{aw} high) is maintained for a long period. This phase establishes oxygenation (T_{high}). There is a short period of release when most CO_2 is cleared (T_{low}). The bottom trace indicates flow over time. The combined time for T_{high} and T_{low} is known as a *phase cycle*. Note that the number of phase cycles is not the respiratory rate because patients breathe within the entirety of T_{high} . As the release phase is initiated, the flow rate is identified as negative and is of a high rate (here, ≈ 7.5 L/min), consistent with significant alveolar recruitment. During the high continuous positive airway pressure (CPAP) phase, the patient is allowed to exhale (negative deflections on the flow–time trace). Thus, APRV is quite dissimilar from traditional cyclic ventilation. This unique mode is made possible by a floating valve system.

and no readily identifiable respiratory rate in the traditional sense. During the pressure high phase, patients may exhale 50 to 200 mL or more of gas as the lung volume becomes full of gas. This is not a full exhalation, and the release of excess gas should not be counted as a breath. APRV has been used successfully for neonatal, pediatric, and adult forms of respiratory failure. It is considered an alternative open–lung model approach to MV.¹⁹

Given the spontaneous nature of the mode, there should be virtually no need for continuous infusion of neuromuscular blocking drugs in patients placed on this mode of ventilation. This may result in a shorter length of ICU stay and a reduced incidence of prolonged neuromuscular blockade syndrome. The need for sedatives is reduced because patients are more comfortable on this spontaneous mode than on cyclic ventilation.²⁰ APRV/Bi-Level has gained popularity in patients with hypoxemic respiratory failure because it improves oxygenation by optimizing alveolar recruitment and V/Q matching.²¹

A common mistake with this mode is setting time low too long. This essentially mimics a pressure-targeted SIMV strategy. Transport of patients on APRV with pressure high greater than 20 cm H_2O should occur with the patient attached to the ventilator instead of being hand-ventilated.²² Hand ventilation is unable to match the manner of gas delivery and pressure dynamics that the patient requires. Attempts at hand ventilation, even with an appropriately set PEEP valve, are frequently complicated by unexpected hypoxemia and hemodynamic instability.

Figure 8.11 Continuous positive airway pressure (CPAP) mask (Vital Signs, Inc., Totowa, NJ). The device shown provides continuous positive airway pressure and is run simply by attaching the mask tubing to a wall oxygen source. The amount of CPAP delivered can be adjusted by changing the threshold resistor valve (*arrow*).

Noninvasive Positive Pressure Ventilation

Noninvasive ventilation is defined as the provision of ventilatory assistance without an invasive artificial airway. Noninvasive ventilators consist of both negative and positive pressure ventilators. Because negative pressure ventilation is so rarely used today, our discussion is limited to PPV.

Before the 1960s, the use of negative pressure ventilation in the form of a tank ventilator (the “iron lung”) was the most common form of MV outside the anesthesia suite. It was not until the 1952 polio epidemic in Copenhagen that anesthesiologist Bjorn Ibsen showed that he could improve the survival of patients with respiratory paralysis by using invasive PPV.

Nonetheless, negative pressure or “iron lungs” were the mainstay of ventilatory support for patients with chronic respiratory failure until as late as the mid-1980s. In the early 1980s, nasal continuous positive airway pressure (CPAP) was introduced to treat obstructive sleep apnea. These tightly fitting masks proved to be an effective means of assisting ventilation, and noninvasive positive pressure ventilation (NPPV) quickly displaced traditional negative pressure ventilation as the treatment of choice for chronic respiratory failure in patients with neuromuscular and chest wall deformities. Current NPPV devices are able to provide a set respiratory rate, set V_T , and set FIO_2 . The use of NPPV has also been integrated into the acute inpatient setting, where it is now used to treat acute respiratory failure.²³

Definitions

The current literature uses different definitions for NPPV. Although some authors use NPPV as an umbrella term that includes CPAP and bilevel positive airway pressure, more recently, authors have used the term NPPV as synonymous with bilevel and consider CPAP a separate entity. The terms NPPV and noninvasive intermittent positive-pressure ventilation (NIPPV) are often used interchangeably with bilevel.

As its name suggests, CPAP supplies continuous positive pressure via a tightly fitting face mask (Fig. 8.11). NPPV

Figure 8.12 Bilevel positive airway pressure (BiPAP) S/T noninvasive ventilation system (Philips Respironics, Inc, Andover, MA). Adjustable parameters include inspiratory positive airway pressure, expiratory positive airway pressure, and breaths per minute. Both BiPAP and continuous positive airway pressure are used to support ventilation in patients with decompensated congestive heart failure, chronic obstructive pulmonary disease, pneumonia, and asthma, but neither mode has a clear benefit over the other.

or bilevel provides an inspiratory positive airway pressure (IPAP) in addition to end-expiratory positive airway pressure (EPAP), and breaths are usually triggered by the patient (Fig. 8.12). On many such devices, backup rates may be set that deliver bilevel pressure, even if patients fail to initiate a breath.

Rationale for Using NPPV

The most important advantage of NPPV is avoiding the complications associated with invasive MV. It has been well documented that invasive MV increases the incidence of airway and lung injury and augments the risk for nosocomial pneumonia. NPPV avoids these complications by keeping the upper airway defense mechanisms intact and allows the patient to retain the ability to eat, clear secretions, and communicate normally when NPPV is used intermittently (NIPPV).²³ NPPV has the potential to reduce the mortality of a selected group of patients with acute respiratory failure and may shorten hospital stays, thereby reducing cost. Specific to the ED, appropriate initiation of NPPV may avoid unnecessary intubation of certain patients, hence avoiding ICU admission, reducing cost, decreasing complications, and improving mortality.

Pathophysiologic Effects of NPPV

CPAP increases alveolar recruitment and size, thereby enhancing the area available for gas exchange, and improves the V/Q relationship. The term CPAP is synonymous with PEEP_e and bilevel EPAP. It can also negate the effects of PEEP_i. In patients with dynamic hyperinflation (such as asthma or COPD), an escalating PEEP_i increases the magnitude of the drop in airway pressure that the patient must generate to trigger a breath. This causes increased work of breathing for the patient. Careful application of PEEP_e can reduce this gradient and decrease the patient's work of breathing. PPV also creates an increase in intrathoracic pressure. This causes preload to decrease as a result of diminished venous return and also decreases transmural pressure, which reduces afterload.²⁴

BOX 8.2 Indications for Initiating Noninvasive Positive Pressure Ventilation

- Exacerbation of chronic obstructive pulmonary disease
- Exacerbation of congestive heart failure and cardiogenic pulmonary edema
- Exacerbation of asthma
- Immunocompromised patients
- Hypoxemic respiratory failure
- Do-not-resuscitate/do-not-intubate advance directive

In NPPV, IPAP is similar to pressure support and, when combined with EPAP, further augments alveolar ventilation, thereby allowing some rest of the respiratory muscles during the inspiratory phase (Box 8.2).

Acute Exacerbation of COPD

Numerous studies have shown that NPPV can reduce the need for intubation, length of hospital stay, and in-hospital mortality in patients with acute exacerbations of COPD.^{25,26} NPPV should be initiated early and along with standard medical therapy. If it is started late, after the failure of medical treatment, the benefits conferred by NPPV (hospital mortality, length of ICU stay, number of days on the ventilator, overall complications) are eliminated.²⁷ Early implementation of NPPV in patients seen in the ED with an acute exacerbation of COPD and without contraindications should be considered the standard of care.

Acute Cardiogenic Pulmonary Edema

CPAP has been shown to produce a reduction in the rate of intubation and a trend toward decreasing mortality.²⁸ CPAP and NPPV both reduce the risk of intubation in the ED.²⁹ An early article described an increased rate of acute myocardial infarction in patients with acute cardiogenic pulmonary edema treated with NPPV,³⁰ but several subsequent trials have refuted this increased risk for myocardial infarction.

Hypoxemic Respiratory Failure

Although some of the literature suggests that NPPV may be beneficial in the setting of acute hypoxemic respiratory failure, doubt still exists. A large multicenter trial of NPPV in patients with acute hypoxemic respiratory failure that excludes patients with cardiogenic pulmonary edema and COPD may help clarify the use of NPPV in this setting.

NPPV has been used increasingly in the ICU for hypoxemic respiratory failure. It can be considered for patients who are hemodynamically stable with single-organ (i.e., pulmonary) failure, but extremely close monitoring is required.

Immunosuppressed Patients

When faced with a severely immunosuppressed patient with acute hypoxemic respiratory failure in the ED, early initiation of NPPV may be beneficial in avoiding the serious complications of ET intubation. NPPV can keep upper airway defenses intact and minimize the risk for ventilator-associated pneumonia, which is universally fatal in these patients.³¹ NPPV has been shown to be associated with a lower rate of ET intubation, shorter ICU stay, and lower ICU mortality. In-house mortality did not differ significantly.³²

“Do-Not-Intubate/Do-Not-Resuscitate” Patients

In do-not-intubate/do-not-resuscitate (DNI/DNR) patients willing to undergo NPPV, success would be measured by improved ventilation, oxygenation, and comfort. NPPV can provide support for the patient while the underlying cause of the respiratory failure is being treated. NPPV should be discontinued if it is not producing the desired response or if the patient is unable to tolerate this therapy. In these circumstances it should be a joint decision between the health care team, the patient, and the family to limit NPPV and transition toward comfort measures.

In patients who have chosen to forego any life-sustaining therapy and are receiving comfort care measures, NPPV might be used as a form of palliative care in an attempt to reduce the associated dyspnea. In this circumstance, the use of NPPV is considered successful if it alleviates the patient’s symptoms. If it causes any discomfort to the patient, it should be discontinued. This use of NPPV is controversial, and no studies have assessed the benefits of NPPV in these patients.³³ Another use of NPPV in patients who have chosen comfort care measures is a time-limited trial to achieve the goal of survival until the arrival of family and friends. In this situation, NPPV would be used to provide life support until friends and family can achieve closure.

Even if a patient with a known DNI advance directive arrives at the ED with acute respiratory failure of reversible etiology, it can be beneficial discussing the use of NPPV with the patient and family. In this situation, communication about the expectations and goals of care is of utmost importance.

Initiation of NPPV

There is no standard approach to the initiation of NPPV. Different methods have been used in clinical trials, yet these methods have never been compared. There are two main strategies: a high-low approach and a low-high approach (Fig. 8.13).

Emphasis should be placed on the importance of close follow-up of patients in whom NPPV is started in the ED. It

is important to serially assess patient response as soon as 30 minutes after the initiation of NPPV. Those who are persistently tachypneic and acidemic should be considered for intubation sooner rather than later. It is imperative to closely observe patients for deterioration. ABGs should be checked within 1 to 2 hours after initiation of NPPV to assess treatment success or failure. Patients who do not improve clinically should be considered for intubation.

Cautions With the Use of NPPV

Most studies involving NPPV have excluded patients who were hemodynamically unstable, had an altered level of consciousness, or were unable to protect their airway. This was based on the concern that a depressed sensorium would predispose the patient to aspiration. The International Consensus Conference in Intensive Care Medicine on Noninvasive Positive Pressure Ventilation in Acute Respiratory Failure held in April 2000 considered the presence of severe encephalopathy, as manifested by a Glasgow Coma Scale score lower than 10, to be a contraindication to NPPV.³⁴

Other accepted contraindications to NPPV are listed in Box 8.3.

Recently, studies have looked specifically at the use of NPPV in patients with hypercapnic coma secondary to acute respiratory failure. This was based on the observation that some DNI patients who declined intubation had successful outcomes with NPPV therapy despite their initial comatose state. Diaz and colleagues conducted an observational study and found that success rates were comparable between the comatose and noncomatose group.³⁵ Scala and coworkers performed two studies, both showing that NPPV could be used successfully in treating patients with exacerbations of COPD and hypercapnic encephalopathy. Their 2007 study showed that performance of NPPV by an experienced team led to similar short- and long-term survival, fewer nosocomial infections, and shorter durations of hospitalization than in patients who underwent MV.^{36,37} Of note, these studies were conducted in the ICU³⁵ or specialized respiratory care units³⁷ with a nursing ratio of at least 1:3. The patients were very closely monitored by staff while they received NPPV. This high nursing-to-patient ratio may not be feasible in a busy ED, however.

The other key point in these studies was the rapid improvement in neurologic status that occurred 1 to 2 hours after the initiation of NPPV. The importance of close monitoring of patients in whom NPPV is started is crucial in identifying those who will fail this therapy.

Properly fit face mask
Explain the procedure to the patient
Encourage the patient

Initial NPPV Settings
Low-High Approach:
IPAP 10, EPAP 5, FiO₂ 100%

High-Low Approach:
IPAP 20–25, EPAP 5, FiO₂ 100%

Start with an EPAP of 8 if morbid obesity or intrinsic PEEP

- Titrate IPAP up (low-high) or down (high-low) based on dyspnea, decreased respiratory rate, increased tidal volume, and patient-ventilator synchrony
- Increase PSV (IPAP-EPAP) if hypercapnic
- Titrate FiO₂ to keep PO_x at 86–92%
- Increase EPAP if hypoxic

BOX 8.3 Contraindications to Noninvasive Positive Pressure Ventilation

- Impending cardiovascular collapse or respiratory arrest
- Severe upper gastrointestinal bleeding
- Facial surgery, trauma, or deformity limiting placement of the mask
- Upper airway obstruction
- Inability to cooperate or protect the airway, altered mental status
- Inability to clear respiratory secretions
- High risk for aspiration

Figure 8.13 Initiation of noninvasive positive pressure ventilation (NPPV). EPAP, End-expiratory positive airway pressure; IPAP, inspiratory positive airway pressure; PEEP, positive end-expiratory pressure; PSV, pressure support ventilation.

High-Flow Nasal Cannula

The high-flow nasal cannula (HFNC) is a relatively new oxygen delivery system. A conventional nasal cannula uses a low-flow system and at higher flow (> 6 L/min) can cause nasal dryness, epistaxis, and patient discomfort. The HFNC system (Fig. 8.14) is a novel device that combines oxygen, pressurized air, and warm humidification to deliver tolerable flow of up to 40 L/min through a nasal cannula. FiO_2 and flow rates can be adjusted. With higher flow, less room-air entrainment occurs, and the higher flow rates match the dyspneic patient's increased minute ventilation.

Its use has been studied more extensively for neonatal respiratory care, where ongoing studies suggest that HFNC may be as effective as nasal CPAP in preterm neonates.³⁸ One study looked at the effect of HFNC on exercise performance in adults with COPD.³⁹ Currently, there are no published studies that have investigated the use of HFNC in patients with acute respiratory failure. Anecdotally, this system has been used with some success in adults in the ICU, with immunosuppressed patients being targeted in the hope of avoiding intubation. It seems to be better tolerated than NPPV, and at higher flow it is believed to provide a certain amount of continuous positive pressure. More studies will have to be performed before this technology becomes a mainstay of treatment in patients with acute respiratory failure.

Figure 8.14 High-flow nasal cannula system. *A*, High-flow flowmeter; *B*, oxygen blender; *C*, low-flow flowmeter; *D*, nasal cannula; *E*, low compliance, heated-wire circuit; *F*, high-flow humidifier; *G*, water reservoir; *H*, air/ O_2 supply. (From Yeow ME, Santanilla JI: Noninvasive positive pressure ventilation in the emergency department, *Emerg Med Clin North Am* 26:835–847, 2008.)

Conclusions

NPPV has been shown to work well in patients with reversible conditions and acts as a bridge while allowing medical therapy (e.g., bronchodilators, steroids, diuretics) to take effect, thereby potentially avoiding the need for ET intubation. Those with less reversible causes of their acute respiratory failure (ARDS, pneumonia) may be less likely to respond. With careful patient selection, NPPV can be safely initiated in the ED, give time for medical treatment to work, and potentially avoid ICU admission. Patients being considered for intubation should be evaluated for the potential use of NPPV.

Close monitoring and follow-up of patients placed on NPPV is crucial in determining whether the therapy has been successful or whether further intervention is needed. In EDs in which the staff has been adequately trained, selected patients, even those in a hypercapnic coma, can be considered for a short trial of NPPV. Extreme diligence in monitoring these patients must be used, and if improvement is not seen in 1 to 2 hours, intubation should not be delayed.

NEUROMUSCULAR BLOCKADE/PARALYZING AGENT FOR MECHANICALLY VENTILATED PATIENTS

The short-term administration of paralyzing agents, in addition to sedation and analgesia, for mechanically ventilated patients in the ED is appropriate to improve patient-ventilator synchrony, enhance gas exchange, diminish the risk for barotrauma, decrease muscle oxygen consumption, facilitate short procedures, and prevent movement in patients with elevated ICP. Importantly, neuromuscular blocking agents (NMBAs) have no sedative, amnestic, or analgesic properties, and all patients administered such an agent must receive concomitant sedation and analgesia.

The long-term use of chemical paralysis in the ICU has greatly diminished because of prolonged recovery secondary to drug and metabolite accumulation. Cases of prolonged paralysis, also known as critical illness myopathy, postparalysis syndrome, polyneuropathy of critical illness, and acute quadriplegic myopathy syndrome, lead to protracted ICU stays.⁴⁰ In the ICU, daily discontinuation of NMBAs for a few hours or avoiding their use entirely has been recommended to potentially decrease the incidence of these conditions. When clinically feasible, it is advisable to stop administration of the NMBA in the ED and reassess the need for continued paralysis.

A number of drugs are available, but the nondepolarizing agents vecuronium and pancuronium are the most commonly prescribed agents for short-term paralysis in the ED.⁴¹ Both are given by intermittent bolus administration as needed. Continuous infusion, though potentially useful, is rarely used or indicated in the ED. Nondepolarizing NMBAs can be reversed by neostigmine at a dose of 0.035 to 0.07 mg/kg.

Vecuronium has an intermediate duration of action with a half-life of 80 to 90 minutes, slightly longer in the elderly, but not affected by renal or hepatic failure. Minimal adverse cardiovascular side effects have been reported, and there is minimal risk for hypotension. Vecuronium has minimal adverse cardiovascular effects and is the drug of choice for patients with cardiovascular disease or hemodynamic instability. The dose for intermittent bolus administration is 0.1 mg/kg.

BOX 8.4 Common Sedatives and Analgesics Used With Mechanical Ventilation

SEDATIVES

Propofol, 5–80 $\mu\text{g}/\text{kg}$ per min
 Dexmedetomidine, 0.2–1.5 $\mu\text{g}/\text{kg}$ per hr
 Lorazepam, 1–5 mg IV prn; infusion at 0.5–7 mg/hr if multiple doses required
 Midazolam, 1–6 mg IV prn
 Haloperidol, 2–10 mg IV every 20–30 minutes until stable, then 25% of the loading dose q 6 hr prn
 Remifentanyl infusion: 0.025–0.2 $\mu\text{g}/\text{kg}$ per hr (no bolus used, provides both sedation and analgesia)

ANALGESICS

Fentanyl, 25–100 μg IV q 15–30 min prn
 Hydromorphone, 0.2–1 mg IV prn
 Morphine, 2–5 mg IV prn
 Fentanyl infusion: 50–200 $\mu\text{g}/\text{hr}$ if more than 2–3 boluses per hour of above agents are needed

q, Every; prn, as needed.

Pancuronium is long acting with a half-life of 100 to 130 minutes. Its duration of action is prolonged in patients with renal or hepatic failure. There is a moderate risk for adverse cardiovascular effects associated with pancuronium, such as tachycardia, hypertension, and increased cardiac output secondary to vagal blockade. The dose for intermittent bolus administration is 0.05 to 0.1 mg/kg.

SEDATION

See Box 8.4 for common sedatives and analgesics. It is recommended that only the minimal amount needed to achieve comfort be used. Sedation should be targeted to a specific sedation scale (such as the Richmond Agitation Sedation Scale). Agents with a quick offset are preferable to improve spontaneous awakening and for breathing trials once the patient is a candidate for extubation. Benzodiazepines should be avoided if possible. If paralyzing drugs are used for neuromuscular blockade, it is imperative to provide aggressive sedation because pain and anxiety in paralyzed patients cannot be evaluated. It is prudent to conclude that a paralyzed ventilated patient is awake and can hear and feel unless sedated.

SPECIFIC DISEASE PROCESSES

Asthma and COPD (Fig. 8.15)

As asthma and COPD treatment (β -agonists, steroids) take effect, peak pressure will begin to lower, the peak expiratory flow rate should increase, and the expiration flow time should shorten (Fig. 8.16). It is necessary to adequately sedate these patients because their hypercapnic state is a powerful stimulus to breathe rapidly. Opiates such as fentanyl and sedatives such as propofol and ketamine have gained increased roles in these patients. Occasionally, one will be required to chemically weaken

Peri-intubation

Monitor the rate of BVM ventilation
 Provide an IVF bolus
 Consider ketamine as an induction agent if available
 NaHCO_3 bolus if known to have a pH <7 before RSI

Initial Ventilator Settings

Volume targeted (VCV), AC, RR 8–10, V_T 6 mL/kg IBW, PEEP 5, FIO_2 100%
 Flow rate 80 L/min, square waveform

- These strategies may worsen hypercapnia (termed permissive hypercapnia) because of a decrease in minute ventilation and is tolerated if pH >7.15
- NaHCO_3 infusion or the administration of THAM (tris[hydroxymethyl] aminomethane) may be required to keep arterial pH above 7.15 to 7.20

After Intubation

Adequate sedation and analgesia. Consider the use of propofol, ketamine, or opiates
 Monitor flow-time curves and pressure-time curves
 Follow peak pressure and plateau pressure
 Consider chemical weakening as a last resort (goal TOF 2–4)
 Consider heliox if available

Figure 8.15 Initial ventilator settings for exacerbation of asthma. AC, Assist/control mode; BVM, bag-valve-mask ventilation; FIO_2 , fraction of inspired oxygen; IBW, ideal body weight; IVF, intravenous fluid; NaHCO_3 , sodium bicarbonate; PEEP, positive end-expiratory pressure; RR, respiratory rate; RSI, rapid sequence induction; THAM, tris(hydroxymethyl)aminomethane; TOF, train of four; VCV, volume-cycled ventilation; V_T , tidal volume.

Figure 8.16 Schematic of a flow-time curve showing improvement in an obstructive process. Note that the peak expiratory flow rate (PEFR) increases and the expiratory time (T_e) decreases with improvement and flow reaches zero before the next breath is given.

these patients with the use of paralytics to keep their respiratory rate and expiratory time controlled. This should be a final option and be done with the understanding that the side effects of steroids and paralytics can be quite devastating,^{42,43} but paralysis cannot be avoided in certain cases. In the ICU, paralysis is commonly titrated to an effect monitored by a peripheral nerve monitor applied over the ulnar or other peripheral nerve

distribution.⁴⁴ No blockade results in four twitches of the adductor pollicis muscle causing four supramaximal triggering stimuli; complete blockade yields no response. A common goal of blockade is to use enough of the agent to result in two twitches out of a “train of four.” A peripheral nerve monitor is not commonly used in the ED and is not a standard intervention during resuscitation and interim ED care.

Valuable information can be gained from flow-time curves and pressure-time curves. Improvement (see Fig. 8.16) or worsening of airway obstruction and air trapping (see Fig. 8.6) can often be evident in these curves before becoming clinically apparent. In ideal situations, PEEP_i can be measured with an end-expiratory hold. This measurement is often inconsistent and difficult to obtain. Some authors have recommended that PEEP_e be applied at 80% of the measured PEEP_i.⁴⁵ Because of the difficulty in accurately measuring PEEP_i and the potential hazard of adding too much PEEP_e,⁴⁶ others have suggested that it should be set at 50% of the measured PEEP_i. If PEEP_i becomes severe enough, it will begin to affect plateau pressure. Current recommendations for obstructive airway disease are to keep plateau pressure below 35 cm H₂O,^{47,48} but many clinicians follow the ALI/ARDS recommendations and maintain plateau pressure at less than 30 cm H₂O.

PEEP_e can be used to decrease some of the negative pressure that the patient has to generate to initiate a breath. For example, a patient with a PEEP_i of 10 cm H₂O and a set pressure trigger of -2 cm H₂O (and no applied PEEP) has to generate an alveolar pressure of 12 cm H₂O to produce a breath. Adding a PEEP_e of 5 cm H₂O means that the ventilator will trigger a breath when alveolar pressure is 3 cm H₂O. The patient has to generate a decrease of only 7 cm H₂O (instead of 12 cm H₂O), thereby reducing the inspiratory effort required.

Though seemingly counterintuitive, decreasing the respiratory rate and VT in a critically ill asthmatic may be beneficial and result in an acceptable elevation in PCO₂, termed permissive hypercapnia.⁴⁹ Hence, it may not be advisable to meet arbitrary PCO₂ levels in a ventilated asthmatic but rather concentrate on maintaining acceptable oxygenation (PO₂ > 60 mm Hg, SaO₂ of 88% to 92%) while minimizing PEEP_i and optimizing plateau pressure.

If cardiovascular collapse occurs in a ventilated asthmatic with either pulseless electrical activity or sudden hypotension, a first step in troubleshooting is to remove the patient from the ventilator. This is both a diagnostic and a therapeutic maneuver for air trapping. Some clinicians also advocate fluid loading and rapid and deep chest compressions while the patient is disconnected from the ventilator to expel the excess volumes of air trapped by prior aggressive ventilation (Fig. 8.17).⁵⁰ Tension pneumothorax must also be considered (see later).

ALI and ARDS

Initial ventilator settings for patients with ALI and ARDS can be found in Fig. 8.18.

Efforts should be made while patient is in the ED to decrease VT down to 6 mL/kg IBW, as recent data have shown settings made in the ED are continued in the ICU. Forty-one percent of patients never received recommended settings during hospitalization.⁵¹ Fuller and colleagues also showed lung protective ventilation was used only 47% of the time in patients with ARDS in the ED.⁵²

A common finding in lung-protective ventilation is the occurrence of patient-ventilator dyssynchrony. This is thought

Figure 8.17 The crashing asthmatic. Once a struggling asthmatic is intubated, the temptation is to rapidly hyperventilate with deep breaths, but this may cause cardiovascular collapse because of exacerbating previous auto-positive end-expiratory pressure (PEEP)/breath stacking. A hyperinflated asthmatic lung severely diminishes venous return, which leads to a marked decrease in cardiac output, even pulseless electrical activity. If a recently intubated asthmatic suffers these consequences, stop ventilating the patient entirely (arrow), compress the chest until no more air is exhaled, and then continue ventilating as per discussion in text. Acceptable permissive hypercapnia may ensue.

ALI/ARDS/Diffuse Lung Injury Initial Ventilator Settings

VCV, AC, RR 20, VT 8 mL/kg IBW, PEEP 8, FIO₂ 100%
Titrate FIO₂ and PEEP based on oxygenation (goal PaO₂ ≥60, PO_x 88–92%). An ARDSNet PEEP table is helpful
Titrate VT down to 6 mL/kg IBW over the first 2 hours (may need to increase RR if minute ventilation is not adequate to keep pH >7.2)

Monitor plateau pressures (keep below 30)
• If >30, incrementally lower VT to 4 mL/kg IBW

Monitor blood pH

- Permissive hypercapnia expected and tolerated at pH >7.2
- NaCO₃ infusion may be required to keep pH 7.15 to 7.20.
- Continuous renal replacement therapy may be required if patient is oliguric/anuric and markedly acidotic.

Insert a central venous catheter:

If not in shock, follow a fluid conservation strategy

Figure 8.18 Initial ventilator settings for acute lung injury (ALI), acute respiratory distress syndrome (ARDS), and diffuse lung injury. AC, Assist/control mode; FIO₂, fraction of inspired oxygen; IBW, ideal body weight; NaHCO₃, sodium bicarbonate; PEEP, positive end-expiratory pressure; THAM, tris(hydroxymethyl)aminomethane; RR, respiratory rate; VCV, volume-cycled ventilation; VT, tidal volume.

to be due to the patient wanting a higher flow rate than the ventilator is providing while on a volume-targeted strategy. This occasionally leads to double or triple cycling of the ventilator. It should be noted that in this situation the patient is actually receiving a higher VT and not benefiting from lung-protective ventilation. Sedation needs to be optimized, and at times different modes, such as pressure-targeted modes, may be attempted. Temporarily weakening the patient with paralytics may be considered.

There are several areas of uncertainty with MV in patients with ALI or ARDS. Patients with traumatic brain injury, intracranial hemorrhage, fulminant hepatic failure, and elevated ICP in whom ARDS develops must be managed carefully because lung-protective ventilation may induce hypercapnia. Acutely, this may lead to cerebral vasodilation and an increase in ICP. There is little evidence to support the recommendation for any particular rescue therapy in patients with severe refractory hypoxia, such as recruitment maneuvers, high-dose albuterol, IRV, HFV, prone ventilation, and extracorporeal membrane oxygenation. In dire circumstances, these modalities may be used on the basis of clinician preference and expertise and consultation with a critical care specialist.

COMPLICATIONS OF MV

Though necessary to sustain life, MV is associated with a number of pathophysiologic derangements that can lead to morbidity and mortality, including pulmonary barotrauma, ventilator-associated lung injury, hemodynamic compromise, PEEP, and elevated ICP.

Pneumothorax

Pneumothorax that is not associated with trauma in a mechanically ventilated patient typically stems from alveolar overdistention (continuous or episodic) and leads to alveolar rupture and escape of gas into the pleural space.⁵¹ In patients receiving PPV, it is wise to drain the pleural space to prevent a simple pneumothorax from progressing to tension pneumothorax with hemodynamic compromise. Loculated pneumothoraces may be successfully drained percutaneously under ultrasound (US) or computed tomography (CT) guidance. Successful drainage of air space disease leads to enhanced liberation from MV.⁵² Pneumothorax or tension pneumothorax may also result from aggressive bag-valve-mask ventilation. Patients with intrinsic lung disease such as COPD or asthma are more prone to the development of pneumothorax than the average patient is.⁵³

A simple pneumothorax can be drained by surgical tube thoracostomy with a small-bore tube (24 Fr), a commercially available pneumothorax kit (Arrow [Teleflex, Morrisville, NC]), or a pigtail catheter placed into the pleural space via the Seldinger technique (see Chapter 9). Each of these catheters should be placed into a chest drainage collection unit that incorporates a water seal chamber and variable suction control. Treat persistent air leaks initially with continuous suction (usually suction at 20 cm H₂O) to evacuate the pleural space and promote coaptation of the visceral and parietal pleurae. Reduce suction and place the chest tube on water seal only after resolution of any air leak. Remove the chest tube directly from the water seal if no pneumothorax is apparent on a chest film or after a test period of tube clamping and subsequent radiographic evaluation. The author favors a 4-hour period of clamping because recurrent pneumothorax is easier to treat by unclamping a tube than by placing a new one. Not all patients with a pneumothorax require invasive techniques to evacuate air from the pleural space. It is important to recognize that small pneumothoraces occurring in *spontaneously breathing patients* (i.e., negative pressure ventilation) may be reevaluated in 4 to 6 hours with a repeated chest radiograph and drained only if they are expanding. This option is *not* advised for patients who are on any form of PPV because a simple pneumothorax

can rapidly become a tension pneumothorax with subsequent hypotension and death. Tension pneumothoraces may be recognized by tachycardia, hypotension, elevated peak airway pressure (if mechanically ventilated, tachypnea if not), jugular venous distention, thoracic resonance by percussion *on* the affected side, diminished or absent breath sounds *on* the affected side, and tracheal deviation *away from* the affected side. Because not all signs or symptoms are present in all patients, treatment should be dictated by the patient's clinical condition.

Loculated pneumothoraces or fluid collections develop in certain patients. If the collections are either single or immediately adjacent to one another and readily identified, they may be drained under US guidance at the bedside.⁵⁴ Loculations are frequently in inaccessible areas or are difficult to image with US. CT scanning of the thorax can provide precise anatomic definition of the presence and number of loculated collections and be used as a guide for the interventional radiologist. Successful treatment involving CT-guided drainage of loculated pleural collections (air and fluid) to assist in weaning of patients from mechanical ventilator support has been reported.⁵²

Ventilator-Induced Lung Injury

There are several causes of ventilator-induced lung injury, including biotrauma, volutrauma, barotrauma, and atelectasis-related trauma. *Biotrauma* refers to the self-sustaining process of lung injury from MV that follows alveolar overdistention or rupture, alveolar hypoperfusion, and repetitive shear stress across alveolar walls. Originally, this problem was thought to be caused by too much pressure (barotrauma).⁵⁵ Current principles hold that elevated airway pressure is a straightforward reflection of excess volume delivered to a lung that cannot accept excess gas (i.e., in volutrauma, excess volume is delivered).⁵⁶ Lung injury is an inhomogeneous process with areas of normal lung immediately adjacent to diseased and injured segments.⁵⁷ The healthy and compliant segments with shorter regional time constants will readily accept gas, but their neighbors with reduced compliance and longer regional time constants will not. The end result is overdistention of the compliant segments, alveolar injury, liberation of inflammatory cytokines and chemokines, activation of endothelin and arachidonic acid pathways, and the expression of adhesion molecules along the vascular endothelium.⁵⁸ This leads to infiltration of inflammatory cells, release of destructive lysosomal enzymes, and induction of toxic oxygen metabolites. Avoiding this inflammatory cascade is an intelligent means of protecting a patient's lungs from volume-induced lung injury. Such a notion has given rise to lung-protective ventilator strategies based on low-V_T ventilation (6 mL/kg IBW) and low plateau pressure (< 30 cm H₂O).⁵⁹ Several studies have reported the development within hours of ventilator-induced lung injury in patients with normal lungs that were ventilated with larger V_T (12 mL/kg).^{60–64} Current recommendations are for all MV to be conducted with lower V_T than the once-standard 12 to 15 mL/kg. Patients with abnormal lungs (interstitial lung disease, lung resection, severe pneumonia, edema) or the presence of an ALI risk factor (sepsis, aspiration, transfusion) should be ventilated at a V_T of 6 mL/kg IBW. These patients may initially be markedly acidotic and may require starting V_T at 8 mL/kg IBW and titrating down to 6 mL/kg IBW within 2 hours. Those with normal lungs and no ALI risk factors should be started at a V_T of less than 10 mL/kg IBW.⁶⁴

Hemodynamic Compromise

In all circumstances, the volume of venous return exactly matches the volume of cardiac output. Any process that impedes venous return will decrease the available volume that establishes cardiac output. For patients receiving PPV, each gas delivery increases intrathoracic pressure, and exhalation decreases that pressure. Venous return principally occurs during exhalation. If the ventilator settings lead to increased intrathoracic pressure during exhalation, venous return will be reduced. Variables that can lead to this circumstance are increased PEEP, auto-PEEP, and IRV. Venous return not only depends on a relatively negative pressure within the thoracic cavity but also relies on a sufficient amount of time for flow into the thoracic vasculature and right side of the heart. Significantly high respiratory rates may compromise venous return. An additional untoward side effect of impaired venous return is cerebral venous hypertension from impeded venous drainage. Because of the absence of valves between the cerebral parenchyma and the right atrium, increased pressure on the right atrium reduces cerebral venous flow and may contribute to cerebral ischemia in patients with traumatic brain injury or stroke, especially in those with compromised systemic hemodynamics. These patients are prone to watershed infarction, and cerebral venous hypertension may increase this risk.

Intrinsic PEEP

Maneuvers directed at elimination of PEEP_i result in a decrease in inspiratory time and an increase in expiratory time. Decreasing the respiratory rate and VT and increasing the IFR effectively accomplish this goal. Frequently, this cannot be achieved without sedation and possibly requires the addition of pharmacologic paralysis.

Difficulty Triggering the Ventilator

To trigger a ventilator, a patient must cause either a drop in pressure or an increase in airflow at the proximal airway, depending on the type of settings used. The magnitude of change required to trigger the ventilator is adjusted by setting the sensitivity, usually in the range of -1 to -2 cm H₂O below the level of PEEP_e. Difficulty triggering the ventilator is often hard to detect. When it becomes obvious by physical examination that the patient is using the accessory muscles of respiration to trigger the ventilator, the problem may be severe. The condition can be detected earlier by inspecting the pressure-volume time curve on the ventilator display, if available. A large negative deflection at the beginning of inhalation suggests that ventilator sensitivity needs to be increased.

More commonly, high PEEP_i is the cause. The patient must first lower intrathoracic pressure enough to overcome PEEP_i before airway pressure can drop to the threshold sensitivity. The solution to this problem is to raise PEEP_e to a level half to three quarters of PEEP_i, which allows the patient to perform less work to trigger each inhalation. This process mandates frequent reassessment of PEEP_i and manipulation of the ventilator during this dynamic period.

Auto-Cycling

Auto-cycling refers to a phenomenon when the ventilator set in AC mode begins to rapidly trigger without the patient initiating respiration. The cause is usually vacillations in airway

pressure that the ventilator “interprets” as patient effort. Tremors, shivering, voluntary motion, convulsions, and oscillating water in the ventilator circuit are all potential causes. Auto-cycling should prompt immediate disconnection from the ventilator circuit and ventilation with a bag-valve device until the problem is resolved.

Rapid Breathing

When attempting to ventilate a patient with an obstructive process, the goal is to eliminate PEEP_i. Permissive hypercapnia is best achieved at low respiratory rates, but at the same time hypercapnia is a powerful stimulus to breathe. This can typically be quelled with a combination of sedation with high-dose opiates, ketamine, or propofol. Neuromuscular blockade should be considered a last resort undertaken only after careful consideration of the risk of prolonged paralysis and potential development of neuropathy in critical illness. If undertaken, the goal should be to weaken the patient sufficiently to inhibit dyssynchrony with the ventilator. Other common causes of rapid breathing include sepsis, pulmonary embolism, pregnancy, hepatic encephalopathy, intracranial hypertension, stroke or hemorrhage, and hypercapnia.

Outstripping the Ventilator and Double Cycling

Hypercapnia will develop in patients receiving low-VT ventilation for ARDS or for an obstructive process and generate an increased respiratory drive. Outstripping the ventilator refers to the patient's effort to draw a higher VT than set while in a volume-targeted mode. This can be detected by observing the exhaled VT or by finding a negative deflection at the end of inhalation on the pressure-volume time plot. Double cycling occurs when the patient desires a larger VT than is set and continues to inspire despite the delivery of a breath. The ventilator will then provide a second breath almost immediately after the first. This is especially problematic because the actual VT delivered is twice the set volume. As with controlling rapid breathing, the solution is sedation and analgesia, particularly with opiates. Switching to a pressure-targeted mode or increasing the set VT may alleviate this issue.

Straining Over the Ventilator

Straining over the ventilator indicates that the patient on a volume-targeted mode is attempting to inhale at a flow rate in excess of the set IFR. On the pressure-volume time plot, the rise in pressure during inhalation will be concave rather than convex. Potential solutions are to raise the IFR, switch to a pressure-targeted mode or PSV, or use sedation and analgesia.

Coughing

Coughing is a common problem that arises from increased secretions, airway foreign body (ET tube), or an underlying pulmonary disease process. Coughing can lead to auto-cycling, poor patient comfort, dislodgment of the ET tube, and rarely airway injury. Accurate placement of the ET tube above the carina should be confirmed. Suctioning and provision of warmed, humidified air are often helpful. If these simple measures fail to provide relief, aerosolized lidocaine or suppression with opiates may increase patient comfort.

Equipment Failure

Whenever a patient decompensates while undergoing MV, consideration should be given to equipment failure as the cause. Interruption of the oxygen supply, erroneous settings, disconnected ventilator circuitry, and obstructed tubes are all potential culprits. Immediate action should include disconnection from the ventilator and bag ventilation with 100% O₂. The mnemonic made popular by the American Heart Association Pediatric Advanced Life Support Course is useful for recalling the causes of unexpected decompensation: DOPE (*D*islodgment of the ET tube, *O*bstruction of the tube, *P*neumothorax, and *E*quipment failure). Confirmation of ET tube placement, suctioning via the ET catheter, auscultation, chest radiography, and equipment troubleshooting are necessary actions.

TROUBLESHOOTING

Critically ill patients are encountered in the ED every day. Some of them required intubation in the prehospital setting, whereas others are intubated on arrival or during ED evaluation. After their airway has been secured and their condition stabilized, patients may remain in the ED because of a lack of critical care beds. In some hospitals, a dedicated intensivist will take charge of these patients, but in others, this type of coverage may not be available. Acute complications or deterioration must be handled by the emergency physician.

This section provides a framework for managing crashing, mechanically ventilated patients. The information provided will assist the practitioner in determining whether the patient's condition is related to the underlying pathology that necessitated MV or whether it is being caused by MV itself.

Determine Hemodynamic Stability

The initial step in managing a crashing ventilated patient is to determine the patient's hemodynamic stability. A ventilated patient is, by definition, critically ill. The patient can fall anywhere on the spectrum from being ventilated for airway protection, with normal vital signs, blood pressure, and oxygen saturation, to being ventilated and in cardiac arrest. Determining where the patient is on this spectrum, including assessment for hypotension and hypoxia, will dictate how much time that the practitioner has to implement rescue strategies. In addition, it is important to anticipate the patient's clinical course. The approach to a patient who is intubated for hypoxia stemming from pneumonia and whose blood pressure and oxygenation gradually trend down over a period of hours or days is different from the approach to a patient who is declining over a span of minutes (Fig. 8.19).

As a general rule, the following evaluation should be performed on patients with new unexplained hypotension (systolic blood pressure [SBP] < 90 mm Hg), new unexplained hypoxia (SaO₂ < 90%), or a new marked change in vital signs (a drop in SBP by more than 20 mm Hg or a drop in SaO₂ by more than 10%) within an hour. Patients with *stable* SBP between 80 and 90 mm Hg and SaO₂ between 80% and 90% should be evaluated expeditiously in the hope of halting the decline. Those with SBP lower than 80 mm Hg or SaO₂ less than 80%, and those who continue to decline rapidly, should be evaluated quickly, with consideration given to entering the cardiac arrest/near arrest algorithm. These values are arbitrary

demarcation points and do not take precedent over bedside clinical judgment.

Cardiac Arrest and Near Arrest Patients

Time is of the essence in a patient with cardiac arrest or near arrest. Advanced cardiac life support should be implemented quickly, and there are some key points to remember in a ventilated patient in cardiac arrest or one who becomes acutely hemodynamically unstable. The ED practitioner should develop a stepwise approach in this situation. During each step, the practitioner should “look, listen, and feel” to run through the differential diagnosis.

During stabilization of these patients it is important to keep in mind the original pathology that necessitated intubation. Sudden decompensation in an asthmatic is a common example of physician intervention worsening the scenario unless the pathophysiology of the arrest is appreciated (see Fig. 8.17). A crashing ventilated patient may simply be worsening from the primary pathology. A multitrauma patient may have an intrathoracic or intraabdominal catastrophe, and a septic patient may be deteriorating clinically from lack of source control.

It is also important to determine and address special circumstances that the ventilator can precipitate, the most significant of which are tension pneumothorax and severe auto-PEEP. Tension pneumothorax can lead to marked hypotension as a result of decreased cardiac output and marked hypoxia from \dot{V}/\dot{Q} mismatch.⁶³ Auto-PEEP (also referred to as PEEP_i, breath stacking, or dynamic hyperinflation) is caused by trapped volume in the pulmonary system. If severe enough, it will eventually lead to increased intrathoracic pressure. This can cause hypotension and decreased cardiac output from decreased venous return and marked hypoxia from \dot{V}/\dot{Q} mismatch.⁶⁴

In critically ill ventilated patients with respiratory distress who are hemodynamically unstable, the following steps will assist the ED physician in determining the cause of the decompensation.

Step 1: Disconnect the Patient From the Ventilator

This is perhaps the easiest step to perform. It can be both diagnostic and therapeutic in a crashing ventilated patient. A quick rush of air or prolonged expiration of trapped air from the ET tube can be diagnostic of ventilator-induced auto-PEEP. A few seconds of observation can determine whether this entity is present. Return of hemodynamic stability implies that the maneuver was successful.

Patients undergoing cardiopulmonary resuscitation (CPR) should not be connected to a ventilator. The variations in intrathoracic pressure caused by CPR will trigger ventilator breaths at high rates if set on AC mode. Patients treated with inhaled nitric oxide (iNO) should not be removed from iNO abruptly, and effort should be made to quickly establish this supply through the bag-valve system. In addition, care should be taken when disconnecting patients who are on high PEEP, such as those with ARDS. When disconnecting the ventilator, it is important to address auto-PEEP because derecruitment can occur and hypoxia may be worsened. Once auto-PEEP has been ruled out, PEEP valves may be used to maintain PEEP levels and thus avoid derecruitment. PEEP valves may be problematic in a markedly hypotensive patient. They may increase intrathoracic pressure and decrease venous return.

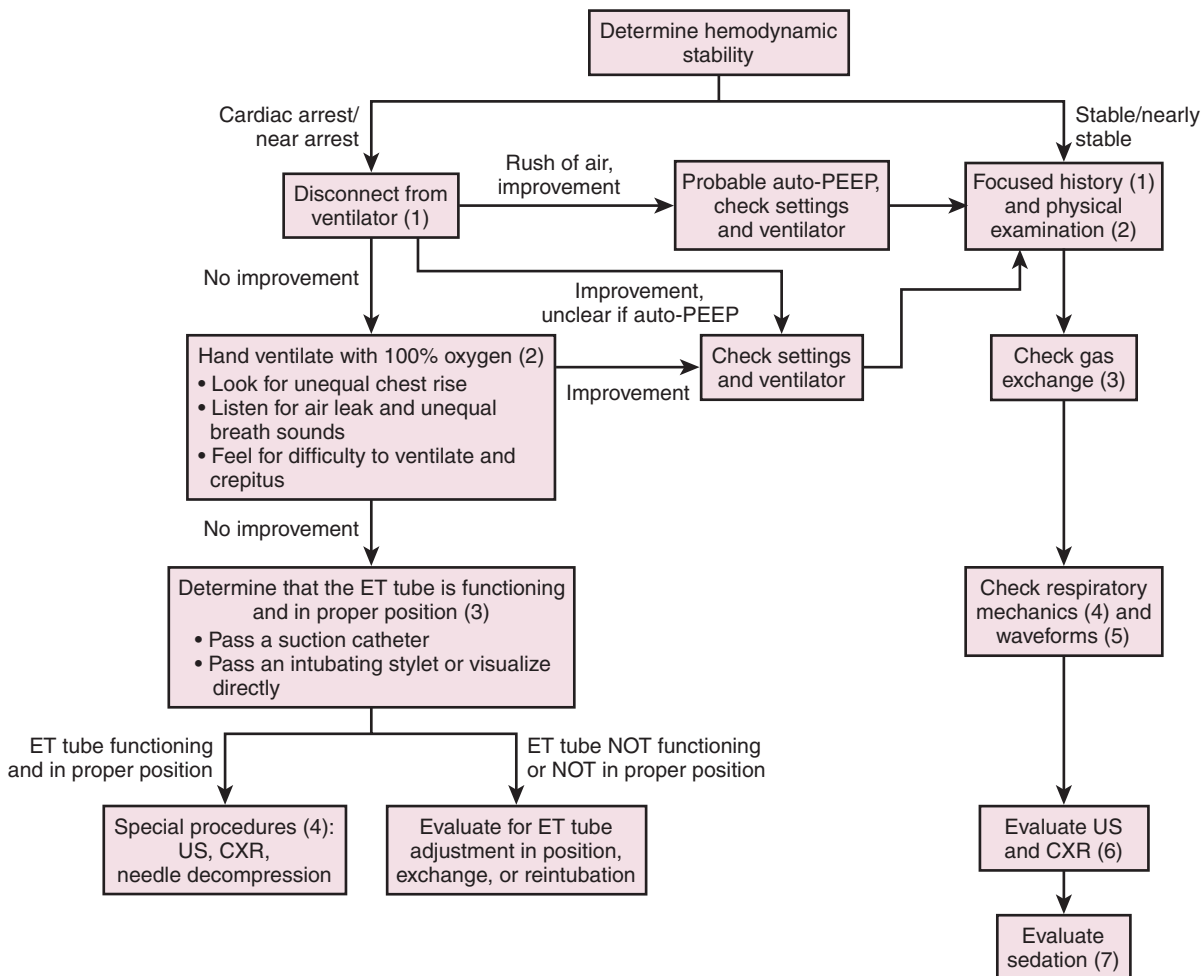

Figure 8.19 Troubleshooting algorithm for respiratory distress and hemodynamic instability in critically ill ventilated patients. *CXR*, Chest x-ray; *ET*, endotracheal; *PEEP*, positive end-expiratory pressure; *US*, ultrasound.

Step 2: Breathing—Hand-Ventilate With 100% Oxygen

Ensure that 100% oxygen is being delivered and limit the respiratory rate to 8 to 10 breaths/min. Particular attention should be paid to the delivery of hand ventilation. Inadvertent rates as high as 40 breaths/min are often used in codes.^{65,66} Excessive rates will increase intrathoracic pressure and lead to a decrease in venous return and cardiac output.⁶⁷ Look at both sides of the chest to determine whether there is equal chest rise. Unequal chest rise can signify main stem intubation, pneumothorax, or a mucous plug. Listen for air escaping from the mouth or nose (a sign of an air leak). Listen over the epigastric area and in both axillae. Decreased breath sounds may provide clues regarding main stem intubation, pneumothorax, or an atelectatic lung. Feel for subcutaneous crepitus (a sign of pneumothorax) and assess for difficulty in hand ventilating (a sign of low dynamic or static respiratory system compliance).

Step 3: Airway—Determine That the ET Tube Is Functioning and in the Proper Position

The ET tube functions by providing a conduit to the lower part of the trachea. The cuff creates a seal between it and the inner wall of the trachea. To determine whether the ET tube is functioning properly, pass the suction catheter and listen

for an air leak (Fig. 8.20). Easy passage of the suction catheter does not guarantee that the ET tube is in the trachea because the catheter may be passing down the esophagus. If it is difficult or not possible to pass the suction catheter, the ET tube is either dislodged or obstructed. Attempt to correct this by repositioning the head in the case of a twisted or bent ET tube or inserting a bite block if the patient is biting on the tube. Dislodged or obstructed ET tubes require reintubation. Patients with dislodged ET tubes should be treated as difficult intubations because unplanned extubations are notorious for causing trauma to the glottis and for leading to vocal cord edema.⁶⁸

In a cardiac arrest or near-arrest patient, the best choice for determining that the ET tube is in the proper position is direct visualization of the ET tube passing through the cords. This step is often omitted in a crashing ventilated patient because of the belief that the ET tube has not migrated. Unfortunately, unrecognized ET tube migration can occur during routine care of a critically ill patient. Patients are frequently moved in and out of emergency medical service vehicles, transferred to and from stretchers for imaging studies, and turned for procedures or bathing, all of which are capable of dislodging the tube. This visualization step can be performed while providing ventilation by hand.

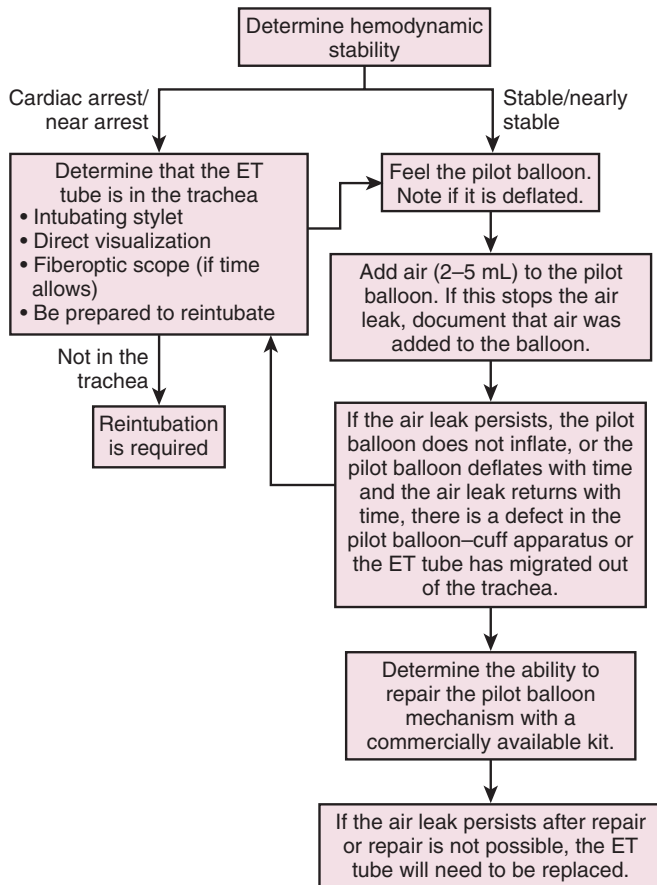

Figure 8.20 Troubleshooting an air leak. *ET*, Endotracheal.

Other simple techniques may be used to confirm that the ET tube is in the trachea. Direct visualization of the carina with a fiberoptic scope is an option, but this device is not typically readily available to the ED practitioner. Another quick and readily available technique is to pass an intubating stylet (gum elastic bougie or Eschmann introducer).⁶⁹ The stylet is passed gently through the ET tube. If resistance is met at 30 cm, the ET tube is most likely in the trachea. If the stylet passes beyond 35 cm without resistance, the ET tube is probably in the esophagus. If resistance is met too soon, the intubating stylet may be catching on the ET tube.

At least one of these techniques to determine proper positioning should be used early enough in the resuscitation to correct any airway issues. In addition, proper positioning should be confirmed before simply removing the ET tube and reintubation, particularly if the patient is deemed to have a difficult airway (unless it is glaringly evident that the patient is extubated).

Step 4: Special Procedures

If the patient is still in cardiac arrest or near arrest after being disconnected from the ventilator, ensuring proper placement of the ET tube, and hand-ventilating with 100% oxygen, a clinical decision will be required regarding needle decompression of the chest. If time permits, a focused history from the bedside nurse, respiratory therapist, or paramedic and a focused physical examination will indicate which side of the chest to decompress. In addition, depending on the urgency of the

Figure 8.21 Ultrasound image of a lung slide (“seashore sign”) in M-mode. This patient does not have a pneumothorax.

Figure 8.22 Ultrasound image of the “bar code” sign in M-mode, indicative of pneumothorax. See the [Ultrasound Box](#) in [Chapter 10](#) for additional details.

situation, bedside US and chest radiography may be used. Bedside US has been shown to exclude pneumothorax in the presence of “lung slide.” This is depicted in M-mode as the “seashore sign” (Fig. 8.21) and, in its absence, as the “stratosphere sign/bar code sign” (Fig. 8.22).^{70–72}

At times, the clinical situation does not allow imaging studies, and the focused history and physical examination may not be helpful. In these cases, needle decompression of both sides of the chest should be considered if other more likely causes of acute decompensation are not found. It is important to remember that chest tube placement is required in patients after needle decompression.^{73–75}

Stable and Nearly Stable Patients

If the patient is deemed stable or near stable or quickly regains stability after disconnection from the ventilator and ventilation by hand, the event should be approached in a systematic manner.

The patient should be placed on 100% oxygen during this evaluation.

Step 1: Obtain a Focused History

A focused history should be obtained from the practitioners most involved in the patient's care (bedside nurse, respiratory therapist, resident, paramedic). Valuable information includes the indication for intubation, difficulty of the intubation, depth of the ET tube, ventilator settings, and recent procedures or moves (central line insertion; chest tube placement; removal or transition to a water seal; thoracentesis; ET tube manipulation; transport off the stretcher; rotation for cleaning, a procedure, or chest radiography).

Step 2: Perform a Focused Physical Examination

Take a general survey of the patient. Observe for agitation, attempts to pull at the ET tube and lines, gasping for breath (the patient will have the mouth open and appear dyspneic), and tearing of the eyes.

Airway

Look at the ET tube and determine if it has migrated from its previous position. It is possible that the ET tube has migrated out of the trachea or into a main bronchus. Adjust if necessary. Listen for escaping air (an air leak) from the mouth or nose (see Fig. 8.20). This typically signifies that the tube has lost its seal with the trachea and occurs with extubation or cuff failure. Feel the pilot balloon. If it is deflated, the cuff is deflated. Add air to the pilot balloon. If this stops the air leak, make a note that air was added to the balloon. If the pilot balloon does not inflate or deflates with time, there is a defect in the pilot balloon-cuff apparatus, and the ET tube will probably need to be exchanged. Occasionally, it may be possible to repair the pilot balloon mechanism with commercially available kits. This is a good option in patients who are difficult to intubate.

Determine that the ET tube is functioning properly by passing the suction catheter. If it is difficult or not possible to pass the suction catheter, the ET tube is either dislodged or obstructed. Attempt to correct by repositioning the head in the case of a twisted or bent ET tube or inserting a bite block if the patient is biting on the tube. Dislodged or obstructed ET tubes require reintubation.

Determine that the ET tube is in proper position if at any point in the evaluation it is suspected that extubation has occurred. Any of the techniques discussed in the previous section may be used.

Breathing

Look at both sides of the chest to determine whether there is equal chest rise. Unequal chest rise can signify main stem intubation, pneumothorax, or a mucous plug. Look at the ventilator tubing and determine whether there is an oscillating water collection. Listen for air escaping from the mouth or nose (a sign of an air leak). Listen over the epigastric area and in both axillae. Decreased breath sounds may provide clues regarding main stem intubation, pneumothorax, or an atelectatic lung. Feel for subcutaneous crepitus (a sign of pneumothorax).

Circulation

Check for pulses and cycle the blood pressure cuff frequently. If the patient has an arterial line, make sure that the transducer is level. Determine the need for fluid bolus or vasopressors.

Step 3: Assess Gas Exchange

Hypoxia can be diagnosed with pulse oximetry if the waveform is reliable. The waveform should not be highly variable and the frequency of the waveform should match the heart rate on the cardiac monitor. In a few instances, such as carbon monoxide poisoning, pulse oximetry is not reliable.⁷⁶ In these cases or if the pulse oximeter is not picking it up, an ABG sample should be obtained. Patients with a partial pressure of O₂ (PaO₂)/FIO₂ ratio of less than 200 should be evaluated for ARDS. Those with a ratio between 200 and 300 should be evaluated for ALI.⁷⁷ A lung-protective strategy should be implemented in those determined to have ALI or ARDS (see Fig. 8.18).⁷⁸ Hypoventilation cannot be identified with pulse oximetry. ABG analysis is beneficial in this event.

Step 4: Check Respiratory Mechanics

Determine whether peak pressure and plateau pressure have changed from their previous values. These values should be obtained on volume-targeted modes. Airway pressure is a function of volume and respiratory system compliance. The respiratory system incorporates the ventilator circuit, ET tube, trachea, bronchi, pulmonary parenchyma, and chest wall. A set volume with a set system compliance results in a specific pressure. Peak pressure is a function of volume, resistance to airflow, and respiratory system compliance. Plateau pressure is obtained during an inspiratory pause, thus eliminating airflow, and therefore reflects only respiratory system compliance. An isolated increase in peak pressure is indicative of increased resistance to airflow. An isolated increase in plateau pressure is indicative of a decrease in respiratory system compliance. Note that plateau pressure can never be higher than peak pressure and that if plateau pressure rises, so will peak pressure. It is important to keep in mind the Δ relationship (peak pressure – plateau pressure). These measurements assume a comfortable patient, and peak pressure and plateau pressure values are not reliable in a “bucking” patient.^{79,80}

Step 5: Observe Ventilator Waveforms

The two most helpful ventilator waveforms are the flow-time curve and the pressure-time curve. The flow-time curve can be used to detect air trapping. The pressure-time curve can be used to determine plateau pressure with an inspiratory hold (see Fig. 8.1).

A notching in the pressure-time curve during inspiration can signify air hunger. In this situation, the patient desires a higher flow rate than the ventilator is delivering. It is commonly seen in volume-targeted modes. Increasing the flow rate will often alleviate this phenomenon. Another solution is to change to a pressure-targeted mode.

Double cycling can also be seen on ventilator waveforms. This occurs when the patient desires a higher V_T than the ventilator is set to deliver. The patient is still inspiring when the first breath has finished cycling and the ventilator immediately gives a second mechanical breath. This is frequently seen with low-V_T ventilation, which is used in patients with ARDS and status asthmaticus. It is important to recognize because the actual V_T being provided is essentially twice the set V_T. This has important ramifications for patients with ARDS and obstructive processes such as asthma and COPD, for whom the goal is lower V_T. Typically, improved sedation with emphasis on blunting the respiratory drive with opiates alleviates double cycling. Other adjustments that may prove helpful are increasing the flow rate, increasing V_T by 1 mL/

kg of predicted body weight up to 8 mL/kg, or changing from a volume-targeted mode to a pressure-targeted mode.

Step 6: Imaging Studies—Chest Radiograph and Bedside US

Evaluate the chest radiograph for ET tube position, main stem intubation, lung atelectasis, pneumothorax, and a worsening parenchymal process. Bedside US, if available, is typically quicker in evaluating for pneumothorax, but it will not provide information on the location of the ET tube, lung atelectasis, or parenchymal processes (see [Figs. 8.21](#) and [8.22](#)).

Step 7: Evaluate Sedation

Patients requiring MV often need sedation and analgesia to make the ET tube and ventilation tolerable. Some patients, such as those with drug overdoses or traumatic head injuries, may not require any sedation. Others may tolerate intubation quite well while almost fully awake. The majority of patients require some form of sedation or analgesia. Note that a plethora of non-MV-associated conditions, such as unrecognized bladder obstruction, alcohol or drug withdrawal, occult fractures, compartment syndrome, or bowel ischemia, can cause significant agitation that can mistakenly be attributed to the stress of intubation and ventilation.

Selection of agents should be based on the desired effect. If a patient appears agitated, sedative-hypnotics should be used. Such drugs include benzodiazepines, propofol, dexmedetomidine, and haloperidol. It is important to note that these agents do not provide an analgesic component. If a patient is being given adequate sedative doses and still appears agitated, consider pain as a cause. Typical opiates that can be used are fentanyl, hydromorphone, and morphine. A remifentanyl infusion is ultrashort acting and can provide both sedation and analgesia. Remifentanyl does not accumulate in patients with renal or hepatic insufficiency. Prompt reversal of analgesia and sedation are seen on discontinuation. Remifentanyl is an alternative to fentanyl for patients requiring frequent neurologic assessment or those with multiorgan failure.

The goal of sedation and anesthesia in ventilated patients who are not being evaluated for extubation is one in which the patient will arouse with gentle stimulation but will return to a sedated state when left alone. Patients who are being sedated and require deep stimulation to get a response are oversedated.

Patients who display air hunger and have a high respiratory rate can be given a trial of opiates to relieve their symptoms. Proper sedation and analgesia are paramount in patients being treated with a strategy that allows or permits hypercapnia, such as those with status asthmaticus, and in patients being treated with lung-protective strategies, such as those with ARDS. Hypercapnia is a powerful stimulus to the respiratory drive, and opiates are often required to control respiratory rates. Patients who tend to be difficult to control (besides those with status asthmaticus and ARDS) include patients with hepatic encephalopathy or intracranial processes such as a mass effect or hemorrhage. Chemical weakening with intermittently dosed paralytics may be required if patients have undergone a good trial of sedation, analgesia, and ventilator changes and are still markedly tachypneic. Careful consideration should be given before this step because prolonged paralysis has been implicated in critical illness polyneuropathy.^{81,82} In addition, expert consultation should be obtained before prolonged paralysis of a neurosurgical patient. The goal in chemical paralysis in these

patients is to weaken them enough to control their interaction with the ventilator. Usually, this does not require a full dose of the paralytic.

Hemodynamic instability in mechanically ventilated and sedated patients may be a result of medications because sedatives and analgesics can precipitate or worsen hypotension. As a general rule, continuous infusions should be withheld in these cases. Patients who are hypoxic and agitated but not hypotensive may benefit from improved sedation. It is possible that their pulmonary status is so tenuous that they are agitated from the hypoxia and their condition is worsened by the oxygen consumption caused by their agitation. Patients who are agitated and hypotensive may respond well to a low-dose benzodiazepine and opiate if the agitation is a precipitant of hypotension. In all these cases, it is imperative to determine whether sedation is a factor in the decompensation. Chemical paralysis should be reserved as a final option. It is important to remember that without continuous electroencephalographic recordings, seizure activity cannot be monitored if the patient is paralyzed.

SPECIAL SCENARIOS

Two special scenarios should be mentioned. One is a crashing intubated pediatric patient and the second is a patient with a tracheostomy. The approach described earlier can be used in pediatric patients, but there are a few caveats that may improve the approach. The first is to recognize that migration of the ET tube is common with small movements of the head and neck. A simple solution is to use a cervical collar for immobilization. Second, small ET tubes are often uncuffed and do not have a pilot balloon. Air leaks in this scenario should prompt the clinician to consider that the ET tube is either dislodged or too small. Finally, specialized equipment such as intubating stylets and fiberoptic scopes are typically not available in pediatric sizes.

Important questions that have ramifications in the care of a crashing ventilated patient with a tracheostomy are the following: (1) Does the patient have a laryngectomy? (2) Why does the patient have a tracheostomy? and (3) How old is the tracheostomy? These are important questions because patients with a laryngectomy cannot be intubated orally, patients with a tracheostomy secondary to anatomic considerations or difficult or failed airways may be difficult to intubate orally, and the tract in a patient with a recent tracheostomy (less than a week old) may not have matured enough to safely reintroduce a tracheostomy tube.

LIBERATION FROM THE VENTILATOR

Occasionally, patients can be considered for extubation while still in the ED. Before extubating a patient, several questions should be answered in the affirmative ([Fig. 8.23](#)). Common scenarios include resolution of exacerbations of COPD or asthma, exacerbation of congestive heart failure, and metabolism of intoxicants. Patients who were difficult intubations or required multiple attempts should have a planned extubation. It may be prudent to allow the edema from a traumatic intubation to subside.

Once these screening questions have been answered in the affirmative, one should perform an awakening trial followed

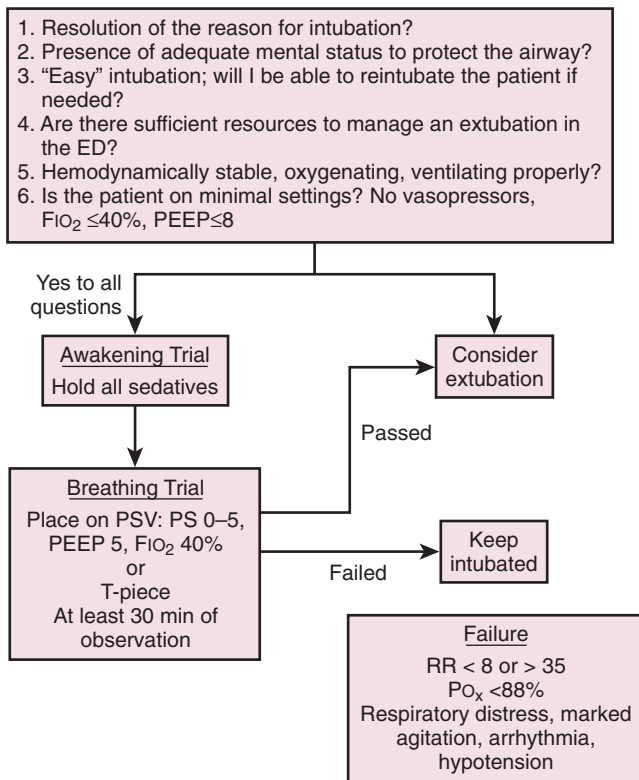

Figure 8.23 Liberation from ventilator. *ED*, Emergency department; FiO_2 , fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure; *PSV*, pressure support ventilation; *RR*, respiratory rate.

by a spontaneous breathing trial. Extubation should be considered if the patient does not fail the breathing trial.

For patients intubated for exacerbation of COPD, NPPV should be considered. For patients with COPD who failed a spontaneous breathing trial, extubating to NPPV decreases mortality, hospital length of stay, the incidence of ventilator-associated pneumonia, and the total duration of MV.⁸³

CONCLUSION

Mechanically ventilated patients are typically the most critically ill patients that the ED practitioner will manage. The underlying disease process that required intubation is typically life-threatening. When patients become unstable, the physician should take a stepwise approach toward determining whether the patient is deteriorating because of the underlying disease process or because of interaction with the ventilator. It is hoped that the approach presented here will assist practitioners with a framework to evaluate and stabilize crashing ventilated patients. For further information, Wood and Winters present an up-to-date review of the care of ventilated patients in the ED and evaluation of potential problems.⁸⁴

Thoracentesis

Barbara K. Blok

Thoracentesis is a percutaneous procedure during which a needle is inserted into the pleural space to remove fluid for diagnostic or therapeutic purposes. When performed using real-time ultrasound (US) guidance, thoracentesis has an extremely low rate of complications.

ANATOMY

The thoracic cavity is lined by thin serous membranes: the visceral pleura, which wraps around the lungs, and the parietal pleura, which lines the inner surface of the thoracic cavities and meets the visceral pleura at the root of the lungs in the mediastinum. The space between these two linings is called the *pleural space*. Each pleural membrane consists of a superficial mesothelial cell layer and an underlying connective tissue layer containing systemic capillary beds. These membranes are leaky, allowing for easy movement of both fluid and protein. In the healthy state, hydrostatic pressure of the systemic capillaries produces a small net movement of fluid across both pleurae into the low-pressure pleural space.¹ This fluid is removed primarily via lymphatic stomata found in the parietal pleura. Normally there is a small amount of fluid, estimated at 0.26 mL/kg of body mass, present in the pleural space.² An excess amount of fluid in the pleural space is termed *pleural effusion*.

Because the lymphatic system has the ability to remove 30 times more pleural fluid than its basal rate,³ it is believed that in most instances the development of a pleural effusion requires both an increase in fluid entry into the pleural space and a decrease in its removal.

ETIOLOGY OF PLEURAL EFFUSIONS

The most common causes of pleural effusion in adults are congestive heart failure (CHF), pneumonia, malignancy, pulmonary embolism (PE), and cirrhosis.^{1,4} The most common cause in children is pneumonia, followed by heart failure, and malignancy.^{5,6} Pleural effusions can be classified as either transudates or exudates. Distinguishing between transudates and exudates narrows the differential diagnosis and directs management and therapy. A comprehensive list of causes can be found in [Box 9.1](#). The most common are discussed in the following sections.

Transudates: Overwhelming the System

Transudates are caused by either an increase in intravascular hydrostatic pressure or a decrease in intravascular oncotic pressure. This generates an increased flow of fluid into the pleural space across noninjured capillary beds. These effusions

are typically straw colored and serous with very low cellular and protein content.

The most common cause of a transudate is CHF. The increased pulmonary capillary hydrostatic pressure in patients with CHF results in a net flow of fluid into the pulmonary interstitium. This fluid readily moves across the leaky visceral pleura into the pleural space. In addition, elevated systemic capillary pressures associated with CHF increase fluid flow across the pleural membranes into the pleural space and decrease lymphatic flow out of the thorax. Any process that causes compromised left ventricular outflow can result in a pleural effusion, including myocardial infarction, cardiomyopathy, and valvular disease. These effusions are typically small and bilateral with larger effusions on the right ([Fig. 9.1](#)).⁷ Highly asymmetric and large effusions should raise suspicion for another cause.

Patients with cirrhosis are frequently hypoalbuminemic, which leads to a chronic state of decreased plasma oncotic pressure. This imbalance between the hydrostatic and oncotic forces across the pleural membrane results in an effusion.⁸ In addition, experiments have shown that high volumes of ascites can stretch the diaphragm enough to allow fluid to pass through preexisting microdefects.

Similarly, in several other disease states such as the hypoalbuminemic state of patients with nephrotic syndrome, intraabdominal fluid associated with peritoneal dialysis, or retroperitoneal fluid with obstructive uropathy can cause transudative pleural effusions in patients with renal disease.

Exudates: Pathology of Tissues, Destroying the System

Exudates are caused by pleural inflammation, increased pleural membrane permeability, or lymphatic obstruction. More than 90% of exudative effusions are due to malignancy, pneumonia, PE, and gastrointestinal diseases (e.g., pancreatitis, esophageal perforation).¹ Tuberculosis (TB) should be added to this list in patients from high-TB prevalence regions.⁹

The primary mechanism of cancer-related pleural effusion is obstruction of pleural lymphatic outflow, either via damage to lymphatic stomata or more distal involvement of the mediastinal lymph nodes. Other mechanisms include metastases to the pleurae increasing capillary permeability and obstruction of the thoracic duct with consequent chylothorax.

A pleural effusion associated with pneumonia or a lung abscess is termed a parapneumonic effusion. In the first, or exudative, stage of parapneumonic effusion, an increase in pulmonary interstitial fluid leads to flow of sterile fluid and inflammatory cells across the visceral pleura into the pleural space. When the infection and resultant inflammation continue unchecked, there is increased capillary permeability with bacterial and additional inflammatory cell transfer to the pleural space, causing the parapneumonic effusion to become complicated. This worsening pleural space inflammation results in the deposition of fibrin on the pleural surfaces with formation of loculations, and finally, in a tough peel that encases the lung.

A pleural effusion develops in at least 20% of those with PE.^{10,11} Therefore when the cause of the effusion is unclear, PE should be strongly considered. The effusions associated with PE are often too small to require thoracentesis, but they have been shown to be uniformly exudative, probably resulting from ischemia- and infarction-induced increases in pulmonary capillary permeability.

BOX 9.1 Causes of Pleural Effusion**TRANSUDATES****Most Common**

- Congestive heart failure
- Cirrhosis

Less Common

- Nephrotic syndrome
- Peritoneal dialysis
- Pericardial disease
- Central venous occlusion
- Myxedema
- Acute atelectasis
- Bone marrow transplantation
- Urinothorax

EXUDATES**Most Common**

- Malignancy
- Pneumonia
- Pulmonary embolism
- Tuberculosis (high-prevalence region)

Less Common

- Post–myocardial infarction
- Post–coronary artery bypass graft
- Trauma
- Esophageal perforation
- Pancreatitis
- Intraabdominal abscess
- Abdominal surgery
- Collagen vascular disease
- Drug-induced
- Chylothorax
- Asbestosis
- Sarcoidosis
- Uremia
- Meigs syndrome
- Ovarian hyperstimulation syndrome
- Radiation therapy

Figure 9.1 Effusion from congestive heart failure. **A**, A frontal chest radiograph in a patient with pulmonary edema shows cardiomegaly, bilateral pleural effusions (*arrows*), and central interstitial thickening, including Kerley's A lines. Note that the right effusion is slightly larger than the left effusion. **B**, High-resolution computed tomography scan in a patient with pulmonary edema shows interstitial edema with bilateral, basilar, centrilobular ground-glass opacity nodules (*arrowheads*) and smooth interlobular septal thickening (*arrow*). Bilateral pleural effusions are also present. (Courtesy Michael B. Gotway, MD, Department of Radiology, University of California, San Francisco.)

Traumatic Effusions: Acute and Catastrophic Destruction of the System

Effusions can also result from significant injuries such as the following. Esophageal rupture can result from forceful vomiting, as in the case of Boerhaave's syndrome, or from instrumentation, as in the case of endoscopy, gastroesophageal balloon tamponade tube placement, or rigid nasogastric tube placement. Hemothorax can result from traumatic injuries, cannulation of the subclavian vein or artery, PE, or aortic aneurysm rupture. Chylothorax develops from acute disruption of the thoracic

duct, usually in the setting of trauma or malignancy. These effusions are usually large-volume collections that accumulate over an extremely short period and rapidly compromise both oxygenation and circulation.

CLINICAL PRESENTATION

Symptoms of small pleural effusions are usually representative of the underlying disease process and not the effusion itself. An effusion greater than 300 mL may cause symptoms on its

own, usually dyspnea, chest pain, or cough. The dyspnea from a larger pleural effusion is typically the result of impaired chest wall and diaphragm movement and not decreased oxygenation or lung function.¹² Chest pain may be dull and aching from the effusion itself or pleuritic from localized irritation of the parietal pleura, which has abundant nerve fibers. Cough is usually attributed to bronchial irritation from compression of the lung parenchyma. Patients occasionally present in extremis from a large pleural effusion that is compressing the heart and causing tamponade physiology with cardiovascular compromise.¹³

There are numerous described physical exam findings for pleural effusion, but these may be difficult to appreciate in the emergency department (ED) environment depending on the acuity of the patient and the ambient noise (Box 9.2). Dullness to percussion and decreased tactile fremitus over the effusion have been shown to be the most useful physical exam findings on systematic review.¹⁴ Percussion over the effusion produces a characteristic dull resonance, which shifts when the patient changes position if the fluid is free flowing. Placing the flat hand over the patient's back while the patient says the word "toy" or the phrase "blue moon" will demonstrate a reduced or absent fremitus because the fluid separates the lung from the thoracic wall and absorbs vibrations from the lung.

RADIOLOGIC DIAGNOSIS

Chest Radiograph

Because pleural fluid is denser than air-filled lung, a free-flowing effusion will first accumulate in the most dependent parts of the thoracic cavity: the subpulmonic space and the lateral costophrenic sulcus. Pleural effusions are usually visible on an upright chest radiograph if 200 to 250 mL of fluid is present. A lateral radiograph may reveal an effusion of 50 to 75 mL.

The earliest recognized sign of a pleural effusion on an upright chest radiograph is blunting of the lateral costophrenic angle, which may be seen on either the frontal or the lateral view (Fig. 9.2). With a larger free-flowing effusion, the pleural fluid appears as a meniscus that curves downward toward the mediastinum in the frontal view and appears "lowest" midway through the thoracic cavity on the lateral view (Fig. 9.3). The presence of air from pneumothorax or abscess may alter the appearance of the meniscus to more of a straight line (air-fluid level).

Occasionally, up to 1000 mL of fluid collects in the subpulmonic space and causes neither blunting of the costophrenic angle nor a meniscus appearance on the upright radiograph. This is called a *subpulmonic effusion* (Fig. 9.4). This should be

Figure 9.2 Posteroanterior upright chest radiograph indicating a pleural effusion with a bilateral meniscus at the costophrenic angles. The pleural effusion has a curvilinear upper margin concave to the lung and is higher laterally than medially.

Figure 9.3 Left-sided pleural effusion seen on **A**, posteroanterior and **B**, lateral radiographs. The meniscus can be visualized on both views (arrows).

BOX 9.2 Exam Findings in Pleural Effusion

- Decreased chest wall excursion
- Bulging intercostal spaces
- Egophony at superior border of effusion
- Diminished breath sounds
- Dullness to percussion
- Decreased tactile fremitus
- Pleural friction rub

Figure 9.4 Right-sided subpulmonic pleural effusion. On erect **A**, posteroanterior and **B**, lateral radiographs, the effusion simulates a high hemidiaphragm. It is also seen with **C**, ultrasound and **D**, computed tomography.

suspected if the hemidiaphragm is elevated and the hemidiaphragm dome peaks more laterally than expected on the upright frontal radiograph.

Pleural effusions are challenging to identify on chest radiograph in the supine patient, and even a significant amount of fluid may not be appreciated. If the effusion is large enough, a diffuse haziness may be appreciated (Fig. 9.5). Other findings include apical capping, obliteration of the hemidiaphragm, partial opacification of a hemithorax, and a widened minor fissure.

Obtaining bilateral decubitus radiographs when a pleural effusion is seen or suspected will confirm the presence of a free-flowing effusion and allow for visualization of loculations, contained abscesses, infiltrates, or masses. With the side of the effusion down, a simple pleural effusion will follow gravity and layer between the floating lung and the chest wall (Fig. 9.6). A lateral decubitus view on the opposite side draws the fluid toward the mediastinum and allows further visualization of the lung parenchyma.

With a diseased or scarred lung, tissue adhesions can trap pleural fluid within the parietal, visceral, or interlobar surfaces. Because these adhesions anchor the fluid, loculated effusions are often described as “D-shaped” (Fig. 9.7). Fluid loculated in the fissures assumes a lenticular shape.

In the case of a massive pleural effusion, the entire hemithorax is opacified (Fig. 9.8). On such films, identification of mediastinal shift is a key to identifying the underlying disease process. In the absence of a diseased lung or mediastinum, large fluid collections push the mediastinum contralaterally. When the mediastinum is shifted toward the effusion, the lungs and main stem bronchi are diseased, obstructed, or both. When the mediastinum is fixed midline, it is likely invaded by tumor.

Computed Tomography

Computed tomography (CT) is more sensitive than plain films in detecting very small effusions and can readily assess the

Figure 9.5 **A**, Supine radiograph of a patient with a large pleural effusion. Note the generalized homogeneous (“ground glass”) increase in radiopacity of the right side of this patient because of posterior layering of a pleural effusion. Also note the difference in the appearance of the pleural effusion when the patient is supine. As opposed to the upright radiograph (see Fig. 9.3), there is minimal blunting of the costophrenic angles and the vascular opacities are preserved in the overlying lung. **B**, A chest computed tomography (CT) scan of the same patient confirms the presence of a right-sided pleural effusion. Note the typical sickle-shaped appearance of the effusion on CT.

Figure 9.6 Left lateral decubitus chest radiograph demonstrating the presence of free pleural fluid. The amount of pleural fluid can be semiquantified by measuring the distance between the *two arrows*. Thoracentesis may be difficult to perform if the fluid distance is less than 1 cm on the lateral decubitus radiograph. This view may also differentiate simple effusions from loculated effusions.

extent, number, and location of loculated pleural effusions. In the distinct anatomic relationships shown on cross-sectional CT, free-flowing pleural fluid will form a sickle shape in the most dependent regions (see Fig. 9.5), whereas loculated fluid collections will remain lenticular and relatively fixed in space. CT can also be extremely useful in elucidating the underlying disease process.

Ultrasound

There are definite advantages to using US for assessment of pleural effusions as well. In particular, it is noninvasive and can be performed at the bedside. US is superior to chest radiographs in diagnosing effusion and can detect effusions as small as 5 mL. Although some details can be seen only with CT, US can identify fluid loculations, separate fluid from pleural thickening, and distinguish solid from fluid pleural lesions. US can also be used to identify both pulmonic and abdominal causes of pleural effusion (Fig. 9.9). Most importantly, US-guided thoracentesis is associated with a significantly lower rate of complications.¹⁵⁻¹⁷

INDICATIONS

Thoracentesis can be performed for either diagnostic or therapeutic purposes. With diagnostic thoracentesis, 50 mL of pleural fluid is obtained for laboratory studies to elucidate the cause of effusion. Most new effusions that measure greater than 1 mm on decubitus radiograph, CT, or US require diagnostic thoracentesis unless there is a clear clinical diagnosis (e.g., CHF) and no evidence for superimposed pleural space infection. Therapeutic thoracentesis is performed to relieve the dyspnea associated with a large pleural effusion and typically involves removal of 1.5 L of fluid.

CONTRAINDICATIONS

There are no absolute contraindications to thoracentesis. One relative contraindication is cutaneous infection or herpes zoster of the overlying chest wall. In this case an alternate patient position and site can typically be chosen. Preprocedure

Figure 9.7 Loculated pleural effusion. **A**, A posteroanterior radiograph demonstrates the D-shaped appearance of a right-sided loculated pleural effusion (*arrows*) in the midchest region. **B**, Occasionally, pleural effusions (*arrows*) may become loculated in the fissures.

Figure 9.8 Massive pleural effusion **A**, before and **B**, after thoracentesis. Notice the underlying mass that is seen following thoracentesis. A computed tomography scan would have prospectively confirmed this radiograph.

coagulation abnormality (international normalized ratio >1.6 , platelets <50 cells/ mm^3 , creatinine >6 mg/dL) is another relative contraindication, but this risk can be virtually eliminated with the use of US-guidance.¹⁸ US-guided needle placement should also be used for loculated effusions to mitigate the risk of pneumothorax and in patients who are undergoing mechanical ventilation because of a theoretical increased risk of tension pneumothorax.

TECHNIQUE

Thoracentesis is usually an elective procedure. Obtain and document informed consent, according to hospital policy, before starting the procedure. Follow sterile technique throughout the entire procedure to avoid introduction of infection.

Equipment

The specific device used for thoracentesis depends on type of procedure, hospital availability, and provider experience. For diagnostic purposes in which a small volume of fluid is being

withdrawn, a 2-inch 22-gauge needle (spinal needle for larger patients) can be used. For therapeutic procedures, using an over-the-needle thoracentesis catheter (e.g., 8-French catheter over an 18-gauge needle) avoids prolonged insertion of a needle in the pleural space while large volumes of fluid are being removed. Commercial thoracentesis catheters have built-in safety features which may include a blunt spring-loaded safety cannula that extends beyond the sharp needle tip once the pleural space is entered to protect the lung from puncture, a one-way valve that prevents air entry into the catheter during removal of the needle, and a built-in side port for drainage of fluid (Fig. 9.10). It is important to familiarize yourself with the features of the thoracentesis catheter available in your institution.

Gather all the necessary equipment before the procedure (see Review Box 9.1 for a list of recommended equipment). If the procedure is diagnostic, remember to draw and send peripheral blood to the laboratory for serum protein and lactate dehydrogenase (LDH) measurement. Keep atropine available at the bedside in case the patient has a vagal reaction during the procedure. Monitor oxygen saturation by pulse oximetry and administer supplemental oxygen as needed.

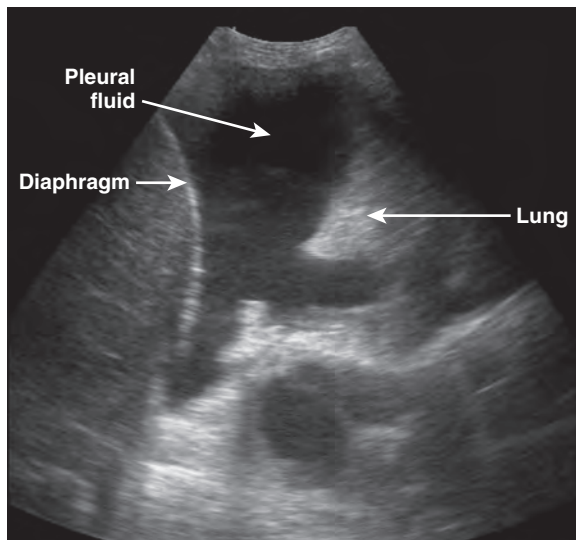

Figure 9.9 Ultrasound image of a patient with a large right-sided pleural effusion. Note the dark appearance of the pleural effusion with a free-floating lung. Ultrasound is also useful for identifying the diaphragm (right of the screen) and the top of the effusion (left of the screen). (From Thomsen T, Setnik G, editors: Procedures consult—emergency medicine module, 2008 Elsevier Inc. All rights reserved.)

Figure 9.10 The Safe-T-Centesis (Becton, Dickinson and Company, Franklin Lakes, NJ) needle, which is available in a prepackaged kit. Safety features of this device include a blunt-tipped obturator needle, a color-changing indicator, a pigtail catheter, and an attached three-way valve. The blunt-tipped obturator retracts with pressure, exposing the sharp needle tip. This causes the color in the device to change from white to red. Once the pleural space is entered and there is no longer pressure on the tip, the spring-loaded obturator covers the sharp needle tip, preventing damage to the lung. This will cause the color to revert back to white. Devices from other manufacturers have similar features.

Thoracentesis

Indications

- Suspected pleural space infection
- New effusion without a clear clinical diagnosis
- Relief of dyspnea associated with a large effusion

Contraindications

Absolute

None

Relative

- Severe clotting abnormality
- Infection or herpes zoster at selected site

Complications

- | | |
|--------------|----------------------------------------|
| Pneumothorax | Reexpansion pulmonary edema |
| Cough | Air embolism |
| Infection | Catheter fragment in the pleural space |
| Hemothorax | Intraabdominal hemorrhage |

Equipment

Review Box 9.1 Thoracentesis: indications, contraindications, complications, and equipment.

Patient Position and Site of Entry

Fig. 9.11 illustrates various patient positions for thoracentesis. Upright positioning is desired for draining most pleural effusions. For this position, have the patient sit upright on the edge of the bed with arms extended on a bedside table or

Mayo stand (Fig. 9.12). If the effusion is sufficiently large, allow the patient to lean forward slightly. Locate the height of the effusion and the level of the diaphragm using US (Fig. 9.13 and **Ultrasound Box 9.1**). The site of entry should be one to two intercostal spaces below the highest level of the effusion in the midscapular or posterior axillary line (Fig. 9.14). In all

A

B

C

Figure 9.11 A–C, Various patient positions for thoracentesis. Note the midscapular line when the patient is sitting upright. This anatomic line is important in that thoracentesis should not be performed medial to this marker because of the increased incidence of trauma to the neurovascular bundle.

cases, the entry level must be above the ninth rib as the risk for diaphragmatic or hepatic/splenic injury increases with entry below this level. Also avoid entry medial to the midscapular line, as the intercostal artery runs more centrally and tortuously when it first enters the intercostal space at the spine, increasing the risk for arterial injury and hemothorax.^{19–21} Greater than 10 mm of fluid thickness should be present on US at the selected site. Mark your entry site using a skin marker. If the patient is too ill to sit upright, perform the procedure with the patient in the lateral decubitus position, with the side of the effusion down and the back at the edge of the bed. Insert the needle at the posterior axillary line in this position. Alternatively,

Figure 9.12 Preferred positioning for thoracentesis by the posterior approach is with the patient sitting upright and leaning over an adjacent Mayo stand.

Figure 9.13 Ultrasound image of a right-sided pleural effusion. Ultrasound can be used during the procedure itself if a sterile probe cover is used. This enables the operator to view the tip of the needle entering the effusion and to thus avoid vital structures such as the lung or diaphragm. Note the superior, inferior, and medial landmarks that are used during the procedure itself.

position the patient supine with the head of bed elevated as much as possible. Use the midaxillary line as the point of needle insertion for this position. For both these alternate positions, determine the fluid level and thickness by bedside US, and make sure the selected site is above the ninth rib. Take a time-out immediately before the procedure to verify the correct patient, procedure, and site.

Anesthesia and Pleural Fluid Localization

Once the skin has been sterilized and draped, create a skin wheal at the upper edge of the rib just below the marked entry site using 1% or 2% lidocaine and a 25-gauge needle. Use the upper edge of the rib as the needle insertion site to minimize

ULTRASOUND BOX 9.1: Thoracentesis

by Christine Butts, MD

Ultrasound is an excellent tool for both identifying and directing the aspiration of pleural effusions. It can be used to both “mark the spot” for thoracentesis and directly guide the procedure.

Equipment

A 3.5- to 5-mHz transducer will reliably identify most pleural effusions. A higher-frequency transducer should be used when direct visualization of the procedure is desired.

Interpretation of Images

A normal lung is filled with air and will typically appear as a hazy gray area when viewed by ultrasound (Fig. 9.US1). Reverberation or comet tail artifacts may also be seen (Fig. 9.US2). When pleural fluid is present, it will typically be seen in the most dependent area of the thorax, typically in the recesses above the diaphragm. Pleural fluid will appear as anechoic (black) collections of varying size (Fig. 9.US3). Depending on the consistency of the fluid, it may appear

heterogeneous, with areas of lighter gray representing more solid components (such as clotted blood).

Procedure and Technique

Once a pleural effusion is known or suspected to be present, scan the area over the posterior aspect of the thorax with a low-frequency transducer (Fig. 9.US4). Identifying the abdominal organs (such as the kidney, liver, and spleen) and diaphragm first will often help orient the sonographer (Fig. 9.US5). Assess the recess superior to the diaphragm for the presence and size of the effusion. If the procedure is to be performed blindly (such as with a very large effusion), mark a location several rib spaces above the diaphragm to avoid any possible intraabdominal injury. The procedure can then proceed in the usual fashion. If the procedure is to be performed under direct ultrasound guidance (such as with smaller effusions), cover the high-frequency transducer with a sterile sheath. Once the field has been prepared, use the sterile transducer again to locate the fluid pocket. At this time,

Figure 9.US1 Ultrasound images of a normal lung. **A**, High-frequency image. In this view, the pleura can be seen as a brightly echogenic (*white*) horizontal line deep to the ribs and corresponding rib shadows (*arrow*). **B**, Low frequency. In this image, less of the pleura is visible. However, abnormalities such as effusions may be recognized more easily.

Figure 9.US2 This image demonstrates two key artifacts seen in a normal lung. As with the previous image, the pleura is recognized as a hyperechoic horizontal line deep to the ribs (at the *far right and left* of the image). A comet tail, or a small vertical line, can be seen extending deep to the pleura (*arrow*). This is a normal artifact created by the pleura. A-lines, or a series of horizontal lines extending deep to the pleura, can also be seen (*arrowhead*). These artifacts are created by reverberation and may be seen in a normal aerated lung.

Figure 9.US3 Large pleural effusion seen on ultrasound with a low-frequency transducer. In this longitudinal image, the thorax is seen on the left side of the image, and a large anechoic (*black*) fluid collection can also be seen (*arrow*). Within the thorax the lung can be seen as the hypoechoic (*dark gray*) mass on the left of the image.

ULTRASOUND BOX 9.1: Thoracentesis—cont'd

Figure 9.US4 Placement of the ultrasound transducer over the posterior of the thorax to identify a pleural effusion.

Figure 9.US5 Longitudinal image of the lower part of the thorax and upper part of the abdomen demonstrating a large pleural effusion. The *bright white* (hyperechoic) line arcing over the kidney (arrow) is the diaphragm, which is an important landmark in planning the location of aspiration.

introduce the needle alongside the transducer (see the basic ultrasound chapter for more on direct needle guidance).

Complications

Most complications occur when the sonographer incorrectly interprets the image or the anatomy. Special care should be taken during the initial evaluation to identify the diaphragm and to direct any attempts at aspiration superior to this point to avoid injury to the abdominal cavity. Effusions that are loculated may not be gravity dependent and may be found in varying areas of the thorax.

Do not insert the needle inferior to the ninth rib

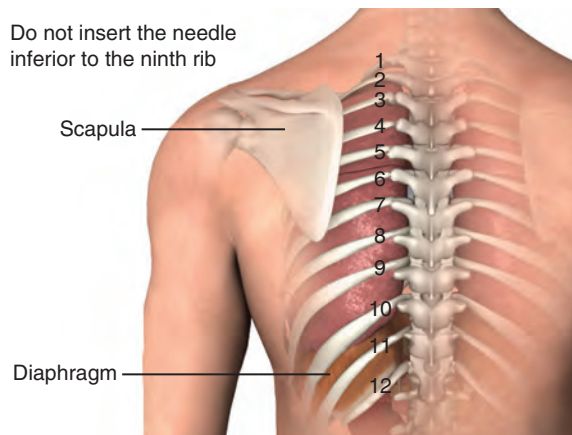

Figure 9.14 The inferior tip of the scapula is at the seventh rib. Do not insert the thoracentesis needle below the ninth rib. (From Thomsen T, Setnik G, editors: *Procedures consult—emergency medicine module*, 2008 Elsevier Inc. All rights reserved.)

accidental trauma to the intercostal artery located along the inferior margin of each rib. Next use a 22-gauge needle to anesthetize the deeper tissues. Hold the needle perpendicular to the chest wall to avoid inadvertent trauma to the intercostal artery. With each 1 to 2 mm of needle advancement, aspirate and then infiltrate the tissues with 1 to 2 mL of anesthetic. While the aspiration-infiltration process is continued, “walk”

the needle above the superior edge of the rib and advance it through the intercostal space until the pleural space is entered (Fig. 9.15). On entering the pleural space, a pop may be felt. Aspirate fluid to ensure that the pleural space has been reached. Once fluid is aspirated, withdraw the needle slightly and infiltrate a small amount of lidocaine to anesthetize the parietal pleura. Finally, grasp the needle just proximal to the skin with the thumb and index finger and withdraw it. This allows measurement of the proper depth of penetration needed during subsequent needle insertion. If no fluid is encountered (dry tap) in the setting of a free-flowing pleural effusion, the needle is too short or the site chosen is too high or too low. If air bubbles are encountered, the chosen sight is likely too high. For both of these scenarios, as long as the patient has no new symptoms to suggest pneumothorax or intraabdominal injury, reevaluate the fluid level using sterile US guidance and reattempt fluid localization.

Needle Aspiration Technique for Diagnostic Thoracentesis

Once you have completed anesthesia and pleural fluid localization, use a 22-gauge needle attached to a 60-mL syringe and the same technique to reenter the pleural space and aspirate 50 mL of fluid. Stabilize the needle at the skin with your thumb and index finger during fluid removal to prevent movement. Once aspiration is complete, instruct the patient to exhale fully, and then withdraw the needle.

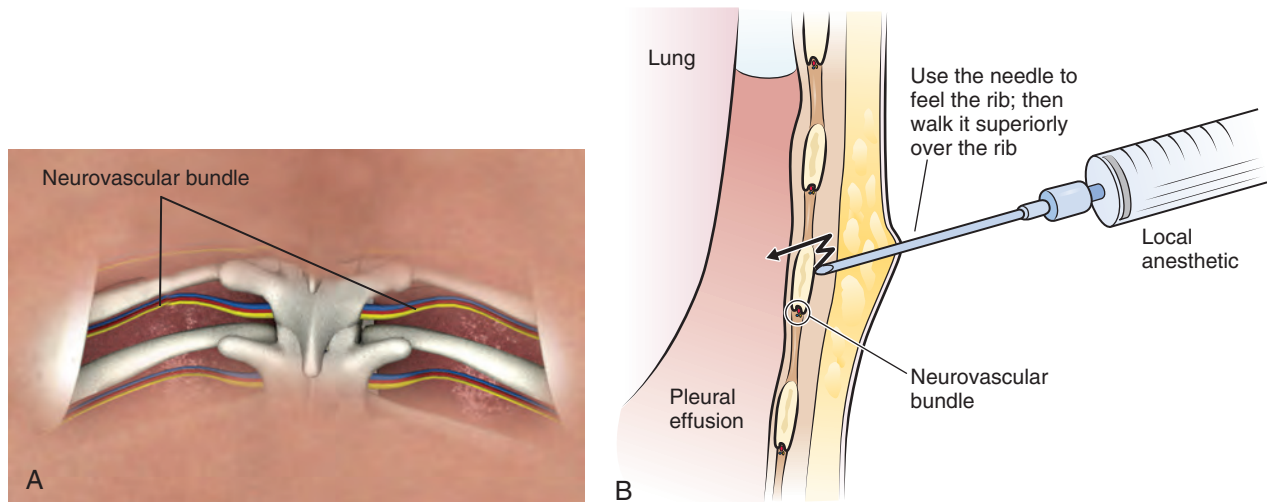

Figure 9.15 **A**, Anatomy of the neurovascular bundle. The intercostal nerve, artery, and vein typically run inferior to the rib. **B**, The proper approach mandates walking the needle up and over the rib to avoid these vital structures. (From Thomsen T, Setnik G, editors: *Procedures consult—emergency medicine module*, 2008 Elsevier Inc. All rights reserved.)

Over-the-Needle Catheter Insertion Technique for Therapeutic Thoracentesis

As mentioned previously, there are numerous over-the-needle catheters available, each with varying types and degrees of safety features. Here we will discuss performing the procedure with the most basic needle-catheter. Familiarize yourself with the features present on the device at your institution prior to initiating the procedure.

Once you have completed anesthesia and pleural fluid localization, use a scalpel to pierce the skin at the needle insertion site. This will ease entry of the catheter through the skin. Attach the thoracentesis catheter to a 10-mL syringe (Fig. 9.16). Mark the depth of the pleural space that was determined from the anesthetic needle by gently grasping the shaft of the needle-catheter unit with the index finger and thumb of the nondominant hand. This stabilizes the device and controls the advance. Walk the needle-catheter unit over the rib through the anesthetized area and into the pleural space while applying gentle negative pressure with the syringe. When fluid is encountered, angle the needle-catheter unit slightly caudally. While holding the needle steady, twist the catheter to break its seal and advance it into the pleural space. Withdraw the needle and immediately cover the exposed hub of the catheter with your finger to prevent entry of air into the pleural space. Next, attach a three-way stopcock with 60-mL syringe into the catheter hub. The lever should be closed to the unused stopcock port. Aspirate fluid with the syringe for diagnostic studies, then close the lever to the patient. Now connect the high-pressure collection tubing with attached vacuum bottle to the unused stopcock port. Turn the lever closed to the syringe and fluid should begin to drain into the vacuum bottle. The syringe can now be removed. If you do not have a vacuum collection system, you can alternate syringe aspiration with expelling fluid from the syringe, through the tubing, and into a sterile collection bag. Turn the stopcock lever off to the patient when changing collection devices. Stop the procedure when 1500 mL of fluid is removed. The recommended maximum of 1500 mL is to avoid significantly negative

pleural pressures, which has been associated with both symptomatic hypovolemia and the potentially fatal complication of reexpansion pulmonary edema.^{22,23} Larger volumes of fluid may be removed if pleural pressure is monitored, but this is not typically done in the ED setting. Once aspiration is complete, instruct the patient to exhale fully, and then withdraw the needle.

Commercial thoracentesis catheters with safety features can greatly simplify the procedure. Most have a self-sealing valve that obviates the need to cover the catheter hub with your finger as the needle is removed, and a built-in side port that allows fluid collection without a three-way stopcock (see Fig. 9.10).

PEDIATRIC PATIENTS

The indications for and contraindications to performing thoracentesis are much the same in children as in adults. Positioning is also similar but will probably require an assistant to help hold the patient and prevent movement. Sedation may be helpful when respiratory distress is minimal. Determine the effusion level by exam and bedside US. Make sure that the needle insertion site is not lower than the ninth rib. The smallest possible needle or needle-catheter device is recommended.

POSTPROCEDURE EVALUATION

Traditionally, postprocedure imaging, either x-ray or bedside US, is considered an important part of the process. Patients who are at risk for adhesions, have new symptoms after thoracentesis, require multiple needle passes, have lung disease, or are mechanically ventilated are at higher risk and should have either x-ray or bedside lung US performed after the procedure. Notably, the postprocedure radiograph rarely shows new findings that aid in identifying the cause of the effusion, such as an underlying mass or infiltrate (Fig. 9.17).

Thoracentesis

1 Position the patient, and then identify and mark the insertion site. The insertion site is best chosen after ultrasound evaluation.

2 Prepare the area with antiseptic and apply a sterile drape.

3 Anesthetize the skin and underlying tissues; "walk" the needle above the superior rib surface.

4 Pierce the skin with a scalpel or large-gauge needle.

5 Advance the catheter over the rib into the pleural space. Stabilize and control the shaft with the left hand during advancement.

6 Aspirate and stop advancing once pleural fluid is obtained.

7 Slide the catheter over the needle into the pleural space.

8 Collect diagnostic specimen with a 60-mL syringe.

9 Remove the pleural fluid with an evacuated container or a syringe and stopcock assembly.

10 Remove the catheter and apply an occlusive dressing.

Figure 9.16 Steps in the thoracentesis procedure. (From Thomsen T, Setnik G, editors: *Procedures consult—emergency medicine module*, 2008, Elsevier Inc. All rights reserved.)

Figure 9.17 Chest radiographs before and after thoracentesis. Postprocedure films are not always routine but should be performed if air was aspirated, the patient has postprocedure chest pain or dyspnea, multiple attempts were made, or the patient is on a ventilator.

PLEURAL FLUID ANALYSIS

Pleural fluid should be analyzed in an organized and thoughtful manner based on clinical suspicion for a disease process. The most cost-effective approach is to perform an initial evaluation to determine whether the fluid is transudative or exudative and obtain other tests only if the fluid is an exudate. Many laboratories are comfortable performing all required tests from the initial 60-mL syringe, so dividing the specimens into individual tubes at the bedside is often unnecessary. Analyze the fluid within 4 hours when possible, but results remain accurate for much longer if the sample is refrigerated at 4°C.²⁴ Exceptions include using an anticoagulant-containing tube (e.g., lavender top) for differential cell count to prevent clumping of cells, inoculating aerobic and anaerobic blood culture bottles in addition to standard fluid culture to increase the yield of identifiable organisms, and transferring samples for pleural fluid pH immediately to a blood gas syringe, placing it on ice, and analyzing it within 1 hour to prevent falsely high pH measurements.²⁵ Because of differences in laboratory preference, consult your individual laboratory for its policies on specimen collection and delivery.

Visual Inspection

Identifying a cause based on pleural fluid appearance alone is inaccurate, but certain findings are suggestive. The presence of blood suggests trauma, malignancy, pulmonary infarction, or pneumonia. White or milky fluid suggests the presence of lipids, whereas purulent, malodorous fluid indicates empyema. Pleural effusion containing food particles is highly suggestive of esophageal rupture.

Distinguishing Transudate From Exudate: Light's Criteria

The first step in evaluation of pleural fluid is categorization of the fluid as exudative or transudative. As discussed earlier, exudates are caused by pleural inflammation, increased pleural membrane permeability, or lymphatic obstruction and therefore

BOX 9.3 Transudate Versus Exudate: Light's Criteria

If at least one of the following three criteria is present, the fluid is virtually always an exudate; if none is present, the fluid is virtually always a transudate:

- Pleural fluid : serum protein ratio >0.5
- Pleural fluid lactate LDH level greater than two-thirds the upper limit of the serum reference range
- Pleural fluid : serum LDH ratio >0.6

contain high levels of LDH and protein. Light and coworkers published criteria for distinguishing transudates from exudates in 1972 based on measurements of serum and pleural fluid protein and LDH.²⁶ The value for LDH was subsequently changed to accommodate variations in assay conditions. These criteria have since become known as Light's criteria (Box 9.3). Because Light's criteria have very high sensitivity but lower specificity, it may misclassify up to 25% of transudates. An exception to using Light's criteria for differentiating transudates from exudates is in the setting of diuretic-treated CHF, as diuretic use has been shown to increase pleural fluid protein and LDH concentrations, thus making the transudative fluid appear exudative by Light's criteria. Other criteria for differentiating exudate from transudate should be used in this setting (Box 9.4).^{27,28}

Once the fluid is classified as transudative, it requires no further fluid analysis, and therapy is directed at the underlying cause of the effusion (e.g., CHF, cirrhosis, nephrotic syndrome).

In the presence of an undiagnosed exudative effusion, however, more extensive fluid evaluation is required.

Evaluation of Exudates

For all undiagnosed exudates, pleural fluid should be sent for differential cell count, glucose, Gram stain and culture, and cytologic examination at a minimum (Table 9.1). Add pleural

fluid hematocrit if the fluid appears bloody. Clinical suspicion for an underlying disease process should guide additional fluid assessment.

Differential Cell Count

Exudates typically have a pleural fluid white blood cell count greater than 1000 cells/mm³, and counts may reach levels higher

BOX 9.4 Separating Exudate From Transudate in the Diuretic-Treated CHF Patient

The effusion is likely a transudate if one of the following is present:

Serum protein minus pleural protein > 3.1 g/dL

Serum albumin minus pleural albumin > 1.2 g/dL

Pleural fluid N-terminal pro-brain natriuretic peptide > 1500 pg/mL

CHF, Congestive heart failure.

than 100,000 cells/mm³, most commonly with parapneumonic effusions. The differential cell count can be useful in identifying the cause of an exudative effusion. A predominance of neutrophils indicates an acute process, such as pneumonia or pulmonary infarction. A predominance of lymphocytes is consistent with a more chronic pleural process, such as malignancy or TB. Eosinophil counts greater than 10% often have no clear etiology but have traditionally been associated with blood or air in the pleural space.

Glucose

The concentration of glucose in exudates is extremely variable and, in general, does not correlate with any specific disease process. Routine measurement of pleural fluid glucose for exudative effusions is recommended because a low glucose concentration (< 60 mg/dL) narrows the differential diagnosis to complicated parapneumonic effusion, malignancy, TB, rheumatoid effusion, and the uncommonly seen paragonimiasis or Churg-Strauss syndrome.¹ Keep in mind, however, that these diagnoses are not excluded by a high or normal pleural fluid glucose.

TABLE 9.1 Exudates: Evaluation of an Undiagnosed Exudative Effusion

PLEURAL FLUID ASSAY	RESULT	PROBABLE DIAGNOSIS (DIFFERENTIAL DIAGNOSIS)
Standard Testing: Perform on All Exudative Effusions		
<i>Differential Cell Count</i>		
WBC count	> 10,000 cells/mm ³	Parapneumonic effusion (pancreatitis, PE, collagen vascular disease)
Neutrophils	> 50%	Acute pleural process: infection, pulmonary infarction
Lymphocytes	> 50%	Chronic pleural process: malignancy, chronic TB
Eosinophils	> 10%	Air or blood in the pleural space (numerous other causes)
Cytology	Abnormal cells	Malignancy
Glucose	< 60 mg/dL	Parapneumonic effusion, malignancy, TB, collagen vascular disease, esophageal rupture
Gram stain and Culture	Presence of organism	Pleural space infection
Pleural fluid hematocrit	> 50% of peripheral hematocrit	Hemothorax (trauma, malignancy, PE)
Selective Testing: Order if High Clinical Suspicion for Diagnosis		
Adenosine deaminase ^{34,35}	> 40 IU/L	TB (lymphoma, empyema)
Amylase	Pleural fluid amylase > serum amylase	Pancreatitis, esophageal rupture, malignancy
Cholesterol	> 45 mg/dL	Exudative effusions (inaccurate alone)
Creatinine (with serum measurement) ³⁶	Pleural fluid creatinine > serum creatinine	Urinothorax
N-terminal pro-brain natriuretic peptide ²⁸	≥ 1500 pg/mL	Congestive heart failure
pH	< 7.2	Complicated parapneumonic effusion (collagen vascular disease, esophageal rupture, malignancy, TB)
Triglycerides ³⁷	> 110 mg/dL (> 50 if fasting or malnourished)	Chylothorax (intrathoracic TPN infusion)

PE, Pulmonary embolism; TB, tuberculosis; TPN, total parenteral nutrition; WBC, white blood cell.

Culture

If bacterial infection is a consideration, culture the pleural fluid by both bedside inoculation of blood culture bottles and standard laboratory culture. The addition of blood culture bottles increases the overall yield of identifiable pathogens in parapneumonic effusions by 20%, from a baseline of 40% yield with standard laboratory culture alone.²⁹ As little as 2 mL of fluid can be used in each bottle without affecting the results.

Pleural Fluid Hematocrit

In general, the presence or absence of red blood cells is not useful in determining the cause of effusion because it takes only a small amount of blood to impart a blood-tinged appearance. A grossly bloody effusion is suggestive of trauma, malignancy, or pulmonary infarction. A pleural fluid hematocrit of greater than 50% of the peripheral hematocrit is indicative of hemothorax and often requires tube thoracostomy.

Cytology

Perform cytologic analysis on all undiagnosed effusions or when malignancy is suspected. The sensitivity for diagnosing pleural malignancy hovers at approximately 55%, regardless of whether small or large (> 50 mL) volumes are analyzed.³⁰

Parapneumonic Effusion

Patients with suspected parapneumonic effusions warrant rapid evaluation and outcome risk assessment based on pleural anatomy, pleural fluid bacteriology, and pleural fluid chemistry.³¹ All patients with parapneumonic effusions require at least diagnostic thoracentesis with the goal of identifying those with complicated parapneumonic effusions. Indications for tube thoracostomy or other surgical procedure include large or loculated effusions, pleural thickening on CT, aspiration of frank pus (empyema), pleural fluid pH lower than 7.20, pleural fluid glucose concentrations lower than 60 mg/dL, and positive Gram stain or culture (Box 9.5).

COMPLICATIONS

Pneumothorax

Pneumothorax is the most frequently reported complication of thoracentesis with an overall rate of approximately 6%.³² It can develop in even the most pristine and seemingly uncomplicated procedure and does not necessarily denote poor technique. Fortunately, thoracostomy tubes are required in only one third of cases. Procedure-related factors that appear

to contribute to pneumothorax include an inexperienced operator, larger needle size, multiple needle attempts, and large-volume fluid removal. A recent large observational study showed an increased risk of pneumothorax in patients who are underweight.¹⁵ The risk for iatrogenic pneumothorax is significantly lower in all patient groups when thoracentesis is performed using real-time US guidance.¹⁵⁻¹⁷

Pneumothorax Ex Vacuo

Pneumothorax ex vacuo is a form of pneumothorax that occurs when the lung is unable to reexpand during therapeutic thoracentesis due to the presence of an endobronchial lesion or other structural pathology.³³ Negative pleural pressures created in this scenario cause a transient passage of air from the lung to the pleural space. It is a likely explanation for pneumothorax occurring after a seemingly uncomplicated therapeutic thoracentesis.

Cough

Cough is typically considered a minor complication that results only in patient discomfort, though it can be a harbinger of a postprocedure pneumothorax. Terminate the procedure if persistent coughing occurs.

Uncommon Serious Complications

Less common, but serious complications include hemothorax, splenic rupture, abdominal hemorrhage, unilateral pulmonary edema, infection, air embolism, and fragmentation of the catheter in the pleural space.

Hemothorax is typically caused by intercostal artery laceration and should be suspected with rapid reaccumulation of pleural fluid or by a change in the patient's vital signs during or after the procedure. Other causes include laceration of the lung, diaphragmatic, or internal mammary vessels. Hemothorax requires immediate surgical consultation, thoracostomy tube placement, and close monitoring of hemodynamics with resuscitation as needed.

Puncture of the spleen or liver through the diaphragm may result in a localized organ hematoma or, more seriously, hemoperitoneum. Clinically, this is suspected when the needle pass does not yield fluid (dry tap) and is followed by the patient's complaint of abdominal pain. If this diagnosis is suspected, appropriate resuscitation is the initial treatment, followed by abdominal CT imaging with contrast, when possible. If the patient is hemodynamically unstable, obtain bedside FAST (focused assessment with sonography) US and immediate surgical consultation.

Reexpansion pulmonary edema is a complication associated with rapid reexpansion of the lung and negative pleural pressures during thoracentesis. Symptoms include dyspnea, tachypnea, tachycardia, cough, and frothy sputum. It is believed that this problem can be avoided by discontinuing the procedure when pleural pressure is greater than -20 mm Hg, which is unlikely to occur until after 1500 mL of fluid has been acutely removed.^{22,23} Because pleural pressure is rarely measured in the ED, 1500 mL of fluid is considered to be the maximum amount that can be safely withdrawn at one time.

BOX 9.5 Indications for Surgical Management of Parapneumonic Effusions

- Effusion > 50% of the hemithorax
- Loculated effusion
- Pleural thickening seen on a computed tomography scan
- Aspiration of frank pus (empyema)
- Pleural fluid pH < 7.2
- Pleural fluid glucose < 60 mg/dL
- Positive Gram stain or culture of pleural fluid

Tube Thoracostomy

Asa M. Margolis and Thomas D. Kirsch

Tube thoracostomy is a procedure used to evacuate an abnormal accumulation of fluid or air from the pleural space and can be performed on an elective, urgent, or emergent basis. Air or fluid can accumulate in the pleural space as a result of spontaneous or traumatic pneumothorax, pleural fluid accumulation of blood, malignancy, infection (empyema), or lymph (chylothorax). The first modern methods to evacuate the contents of the pleural space were developed in the 19th century, but these techniques did not become widespread until 1918, when they were used to treat postinfluenza empyema. Military experience demonstrated that thoracic drainage combined with antiseptics and antibiotics reduced mortality related to thoracic trauma from 62.5% during the Civil War, to 24.6% in World War I, and to 12% in World War II.¹

PATHOPHYSIOLOGY

The lung is surrounded by two layers, the parietal pleura, which lines the interior of the chest wall, and the visceral pleura, which covers the lungs. They are separated by a potential space that usually contains a thin layer of fluid that lubricates

the *pleural space*. A small negative pressure within the pleural space helps keep the lung inflated and the two layers closely apposed. With inspiration, chest expansion increases negative intrathoracic pressure and leads to inflation of the lung from an influx of air. If the pleural space is disrupted, air, blood, or other fluid can accumulate between the two layers of the pleura. The result is that the pressure gradient associated with normal respiration is compromised and can lead to “collapse” of the lung. As the amount of fluid or air increases, respiratory function worsens leading to symptoms of dyspnea, often with pleuritic chest pain and anxiety. The degree of respiratory compromise depends on the volume of fluid or air in the pleural space, the patient’s age, baseline pulmonary status, and the integrity of the chest wall. In severe cases, a one-way valve type of mechanism can occur within the respiratory apparatus, leading to tension pneumothorax physiology. The hallmark of tension pneumothorax is a progressive accumulation of air in the pleural space with each breath that will result in severe respiratory dysfunction, cardiovascular compromise, and ultimately obstructive shock if untreated.

Pneumothorax

A pneumothorax is caused by the presence of air in the pleural space and loss of the normal negative pressure (Fig. 10.1). Air can enter the pleural space from outside of the chest wall as a result of a penetrating injury. Air can also enter internally from a ruptured lung bleb or damaged trachea. Iatrogenic injuries can occur from needle procedures such as subclavian venous cannulation, transthoracic biopsy, thoracentesis, positive pressure ventilation (PPV), or cardiopulmonary resuscitation (Fig. 10.2).

Pneumothoraces are commonly divided into “open” and “closed.” An open pneumothorax indicates that the skin and

Tube Thoracostomy

Indications

Spontaneous and traumatic pneumothorax
Hemothorax
Empyema
Patients with penetrating chest trauma undergoing positive pressure ventilation or long-distance transport

Contraindications

Absolute

None

Relative

Presence of multiple pleural adhesions
Presence of emphysematous blebs
Coagulopathy

Complications

Infection
Laceration of an intercostal vessel
Pulmonary injury
Intraabdominal or solid organ tube placement
Failure of reexpansion of pneumothorax
Reexpansion pulmonary edema

Equipment

Review Box 10.1 Tube thoracostomy: indications, contraindications, complications, and equipment.

Figure 10.1 Pneumothorax. **A**, Anteroposterior chest radiograph of a right-sided, seemingly small, simple pneumothorax (PTX). Note the absence of peripheral lung markings on the right side and the distinct line indicating the edge of the collapsed lung (*arrow*). Although this appears to be a small PTX, it produced significant dyspnea in this patient with chronic obstructive pulmonary disease and therefore required a chest tube. **B**, Computed tomography scan showing the extent of the collapse. Adhesions kept part of the lung expanded.

Figure 10.2 **A**, After successful cardiopulmonary resuscitation and intubation, this patient began to deteriorate, with a precipitous drop in blood pressure and decreasing oxygen saturation. It was believed that the cause of the initial cardiac arrest was returning. Marked subcutaneous air was noted in the scrotum and abdominal wall, but little air was noted in the chest wall tissue. The subcutaneous air from a pneumothorax and positive pressure ventilations created by the resuscitation had curiously tracked via abdominal wall tissue planes, a distinctly unusual place for air to accumulate. Usually subcutaneous air is felt around the chest tube insertion site, neck, and chest wall. **B**, A chest tube (*arrow*) quickly reversed the decompensation from the pneumothorax. **C**, This patient suffered respiratory arrest from heroin injected into a neck vein (note the extensive scar). After bag-mask resuscitation the respiratory depression returned and the blood pressure dropped precipitously. He was unresponsive to naloxone and was very difficult to ventilate. He had a small pneumothorax from a nick in the lung from the neck injection. The positive pressure ventilations produced a tension pneumothorax.

Figure 10.3 Spontaneous pneumothorax. **A**, Spontaneous pneumothorax in a young male patient. There is nearly total collapse of the right lung, and lung markings are absent lateral to the visible pleural reflection (*arrow*). Note also the slight deviation of the mediastinum to the contralateral side. **B**, The patient was treated with a pigtail catheter inserted in the second intercostal space in the midclavicular line (*arrow*). Note that the lung has totally reexpanded and the mediastinum has shifted back to the midline.

underlying soft tissue sustained an injury that penetrated into the pleural space.

Spontaneous (Closed) Pneumothorax

Spontaneous pneumothorax is caused by the rupture of a subpleural lung bleb with little or no trauma and can be categorized as either primary or secondary based on the presence of underlying lung disease. *Primary spontaneous pneumothorax* occurs in a patient without overt lung disease. The typical patient with spontaneous pneumothorax is a tall, thin, 20- to 40-year-old male smoker (Fig. 10.3). *Secondary spontaneous pneumothoraces* occur in patients with underlying lung or pleural disease, including emphysema, chronic bronchitis, asthma, Marfan's syndrome, infection, and neoplasm. The morbidity, mortality, and long-term complications associated with pneumothorax increase in patients with underlying lung disease. Whereas a primary pneumothorax may be managed by selective observation or might simply be aspirated, a secondary pneumothorax often requires a more aggressive management approach.

The sudden onset of pleuritic chest pain and dyspnea with exertion or at rest is the most common finding. More subtle manifestations may also occur with little or no pain and only mild dyspnea on excursion that the patient may ignore for days. A person with a small spontaneous pneumothorax may never seek medical attention, and the process will resolve without treatment. The signs and symptoms do not always correlate well with the size or cause of the collapsed lung. Tube thoracostomy is the most common treatment, but new trials suggest that conservative management or aspiration of first-time primary pneumothoraces results in similar outcomes as traditional tube thoracostomy, though with fewer complications, shorter hospital stay, and lower cost. Depending on the size of the pneumothorax, conservative management and aspiration are both reasonable initial interventions in clinically stable patients. However, to date no high-quality clinical trials

have definitely demonstrated that aspiration is a superior treatment methodology.²⁻⁴ Rarely, spontaneous pneumothorax may be bilateral. In addition, in rare cases, a spontaneous pneumothorax may progress to tension pneumothorax as described previously, which can result in a potentially life-threatening condition.

Traumatic Closed Pneumothorax

Closed pneumothorax usually occurs from a rib fracture that penetrates the lung, but can also occur when an alveolus or bleb ruptures after blunt trauma. The air leak from a closed pneumothorax is generally self-limited but can, in rare cases, progress to a tension pneumothorax.

Traumatic Open Pneumothorax

An open pneumothorax occurs when the chest wall is penetrated and the negative intrapleural pressure is lost. Each breath can increase intrapleural pressure, especially if the diameter of the chest wound is greater than the diameter of the trachea. With each respiratory attempt, air moves preferentially through the chest wall opening rather than down the trachea and thus prevents meaningful ventilation of the involved lung.

Tension Pneumothorax

An open pneumothorax can occasionally manifest as a tension pneumothorax, which is a life-threatening condition that requires immediate intervention. A tension pneumothorax occurs when an injury creates a one-way "flap valve" mechanism that allows air into the pleural space with inspiration but then closes with expiration and traps the air (Fig. 10.4). The progressive accumulation of air in the pleural space leads to ipsilateral complete lung collapse and then impingement on the mediastinum with a shift of the heart toward the uninvolved side. This restricts ventricular filling and subsequently decreases cardiac output. This severe disruption in both respiratory and cardiac function can lead to hypotension and reduced ventilation

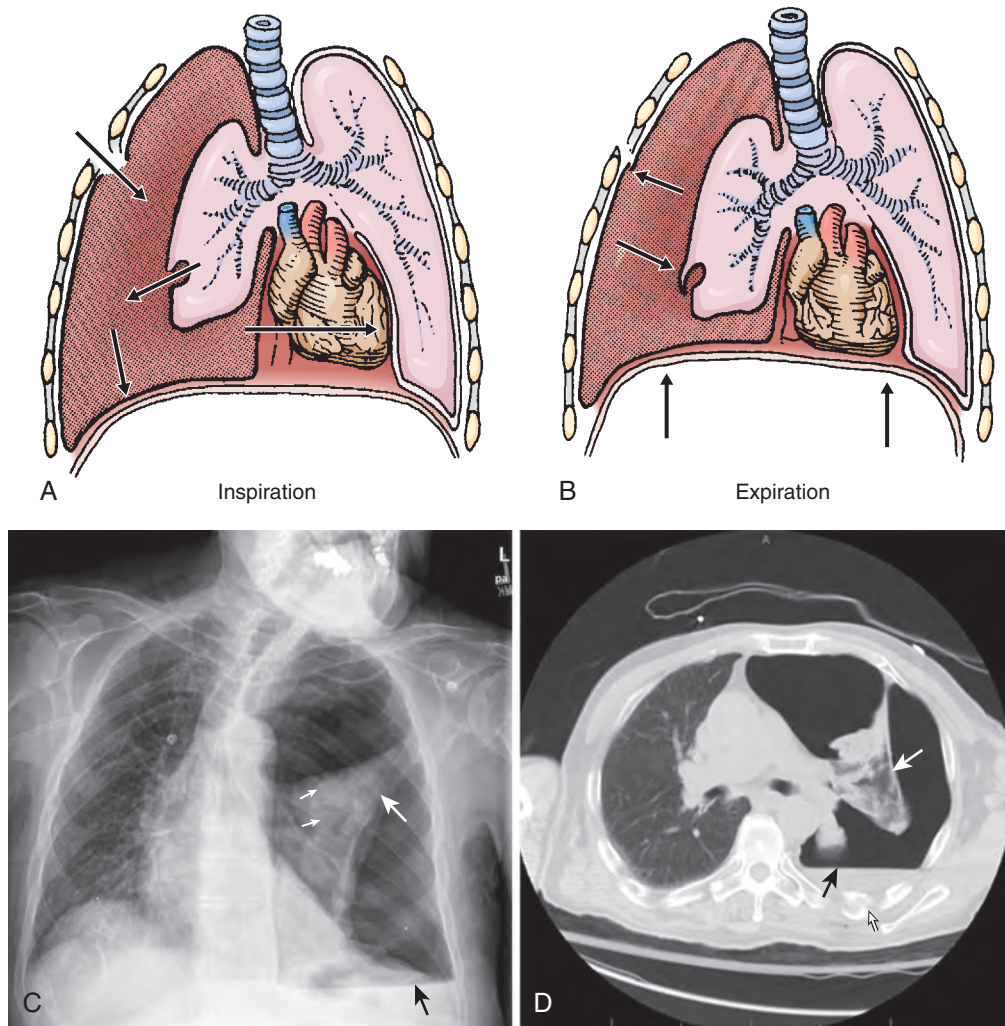

Figure 10.4 Traumatic tension pneumothorax. **A and B**, Pathophysiology of a tension pneumothorax. During inspiration, air enters the pleural space through a one-way valve either from the outside or from the lung itself. On expiration, the injury/valve closes and traps increasing amounts of air in the pleural space. Eventually, the mediastinum shifts and cardiac filling and ultimately cardiac output are compromised. **C**, This elderly patient sustained a tension hemopneumothorax after slipping and falling on ice. The left hemithorax is very dark (radiolucent) because of total collapse of the left lung (*large white arrow*). Note the dramatic shift of the mediastinum to the right, indicative of tension. Multiple posterior rib fractures are present but are difficult to appreciate on this film (*small white arrows*). The air-fluid level (*black arrow*) indicates the presence of air in the pleural cavity in addition to fluid (blood). **D**, A computed tomography scan of the same patient again demonstrates the findings seen on the conventional radiograph.

(both hypoxia and CO₂ retention) and eventually to cardiopulmonary collapse.

A tension pneumothorax is usually caused by penetrating chest injuries but can also result from fracture of the trachea or bronchi, a ruptured esophagus, the presence of an occlusive dressing over an open pneumothorax, and PPV. Patients with chest or lung injuries who are treated with PPV are at much greater risk for the development of a tension pneumothorax. Consequently, any patient with a penetrating thoracic injury (even without immediate evidence of a hemothorax or pneumothorax) should be considered for a “prophylactic” chest tube before mechanical ventilation. A pneumothorax may also develop in patients with asthma or emphysema from the high pressure required for ventilation, which can also lead to a tension pneumothorax.

Hemothorax

Hemothorax is an accumulation of blood in the pleural space as a result of injury to the heart, great vessels, or vessels of the lungs, mediastinum, or chest wall. Bleeding from the lung parenchyma is usually low pressure, self-limited, and ceases when a chest tube is inserted. However bleeding from an intercostal artery, a pulmonary artery, or the internal mammary artery can be profuse and often requires surgical intervention.

Empyemas and Effusions

An empyema is an accumulation of pus in the pleural space, usually from a parapneumonic infectious effusion (**Fig. 10.5**). An empyema can also be caused by violation of the thoracic

Figure 10.5 Empyema. This 34-year-old patient with a history of alcoholism had fever, cough, pleuritic chest pain, and hypoxia. **A**, Posteroanterior chest radiograph demonstrating nearly total opacification of the right hemithorax. The presence of a meniscus (*large arrow*) suggests a pleural effusion. However, small lucent areas (*small arrows*) can be seen throughout the opacity, which may represent air bronchograms in consolidated lung parenchyma. Thus, a computed tomography (CT) scan was performed. **B**, CT revealed nearly total collapse of the right lung with only a small portion of the apex remaining inflated (*white arrow*). A massive pleural collection was found with gas bubbles throughout (*black arrows*), suggestive of pyogenic empyema. Tube thoracostomy was performed and more than 1700 mL of purulent fluid was drained. Fluid cultures grew *Streptococcus anginosus*.

space during surgical procedures (e.g., tube thoracostomy), trauma, and esophageal perforation. Pleural infection rates have increased 3% per year in the United States in the last 2 decades. The bacteriology of pleural infections is commonly classified as either community or hospital acquired. Nearly 60% of cases of community-acquired empyema are caused by *Streptococcus pneumoniae* species, whereas *Staphylococcus* species account for nearly 45% of hospital-acquired infections.⁵

Chylothorax

Chylothorax results from injury to the thoracic duct during placement of a central line, operative injury, or chest trauma. Primary thoracic duct injury is usually asymptomatic because the chyle initially collects extrapleurally and may not begin to fill the pleural cavity for 2 to 10 days. As the fluid accumulates, respiratory symptoms slowly develop. The chest radiograph demonstrates a pleural effusion, and the diagnosis is made when thoracentesis reveals a milky fluid with a high fat and lymphocyte content and 4 to 5 g/dL of protein. Definitive treatment is either repeated thoracentesis or tube thoracostomy combined with parenteral alimentation until the volume of chyle decreases.

DIAGNOSIS

Symptoms

The symptoms of patients with abnormal collections in the pleural space range widely depending on the size of the pneumothorax, the rapidity of accumulation, the age of the patient, and the presence of comorbidities, especially underlying lung disease. Specific symptoms range from mild dyspnea with exertion and pleuritic chest pain with small disruptions

to hypotension or severe dyspnea, especially in those patients with tension pneumothorax. With a spontaneous pneumothorax, 95% of patients complain of the sudden onset of sharp, pleuritic chest pain, shoulder pain, or both. Sixty percent of patients experience dyspnea, and 12% have a mild cough. Dyspnea and anxiety are more common in older patients.

Tension pneumothorax (TP) must be considered in any patient with sudden or severe respiratory or cardiac deterioration and in intubated patients who become difficult to ventilate. Signs of TP include increased airway pressure, hypotension, or elevated central venous and pulmonary artery pressure. Severe dyspnea, restlessness, agitation, and a feeling of impending doom can develop rapidly in conscious patients with tension pneumothorax. Initially these patients may be tachycardic and tachypneic but can quickly become hypotensive.

The symptoms of hemothorax can be similar to those of pneumothorax but may be accompanied by hypotension as blood accumulates in the pleural space. The onset of symptoms with effusions is usually much more gradual, with increasing shortness of breath and dyspnea on exertion occurring over a period of days to weeks.

Physical Examination

Unstable Patients

During the initial phase of resuscitation (airway, breathing, circulation, disability), consider the diagnosis of pneumothorax in patients who are tachycardic, hypotensive, and dyspneic. These symptoms are not specific as similar ones do occur with pulmonary embolism, pericardial tamponade, large pleural effusion, and severe, multilobar pneumonia. Serial examination is critical as the diagnosis of tension pneumothorax by physical examination can be very subtle. Use the phrase “look, listen, and feel” as your guideline. Observe the chest wall, which may reveal asymmetric chest expansion, and the neck and forehead

veins, which may be distended, even if the patient is hypotensive. The trachea may be deviated away from the side of the pneumothorax. When percussing the chest wall, hyperresonance on the affected side and subcutaneous emphysema may be present. Auscultation may demonstrate diminished breath sounds on the injured side. In one prospective study, the sensitivity, specificity, and diagnostic accuracy of auscultation for hemothorax and pneumothorax were 84%, 97%, and 89%, respectively.⁶ A false-negative auscultation is more likely than a false-positive one.⁶ Pulsus paradoxus may be evident. For intubated patients, an early sign of tension pneumothorax is difficulty ventilating because of increased airway pressure. Additionally, poor compliance may be noted when providing respiratory support by bagging.

In injured patients with apnea, hypotension, or cardiopulmonary arrest, diagnose and treat a tension pneumothorax by immediate needle or catheter decompression thoracostomy. In patients who may have TP, do not take the time to obtain and review a radiograph because delay can lead to increased morbidity and mortality in patients with this emergency condition. X-rays cause a delay in therapeutic intervention. Confirm the diagnosis of tension pneumothorax after needle decompression by rapid improvement in vital signs and a rush of air through the needle.

Stable Patients

In more stable patients (and those with smaller accumulations) the findings on physical examination are less sensitive, and a chest radiograph, ultrasound, or even a computed tomography (CT) scan is usually necessary to make a definitive diagnosis. Physical findings may include unilaterally decreased breath sounds, tachypnea, tachycardia, decreased tactile fremitus, increased resonance with percussion, or subcutaneous emphysema. Alternatively, the examination may reveal little to no abnormalities with a small pneumothorax. Patients with a pneumothorax involving less than 20% of the hemithorax will often have completely normal findings on chest examination, including equal breath sounds (Fig. 10.6). Pleural fluid collections are difficult to detect by physical examination, particularly with less than 500 mL of fluid in the pleural space. Breath sounds may be decreased and percussion of the bases may be dull.

Parapneumonic empyemas are often accompanied by fever, cough, chest pain, dyspnea, and purulent sputum (see Fig. 10.5). Physical examination may reveal diminished breath sounds, dullness on percussion, egophony, and diminished tactile fremitus on the involved side. Fever will often develop in patients with an indwelling chest tube and empyema. The pleural fluid drainage may be copious and purulent, and respiratory symptoms may worsen.

Radiography

Plain Radiographs

In stable patients, a chest radiograph is an essential tool for diagnosing a pneumothorax. In unstable patients with a potential tension pneumothorax, the diagnosis should be made clinically, but in rare cases a portable radiograph may be obtained in the resuscitation room if the patient is being carefully monitored by a clinician. As will be discussed later in this chapter, bedside ultrasound may prove advantageous as a diagnostic modality in these peri-stable patients. The best plain radiographs for detecting hemothorax or pneumothorax are traditional upright inspiratory posteroanterior and lateral chest radiographs.

Figure 10.6 Smaller pneumothoraces such as this (note the faintly visible pleural reflection [arrow], absence of lung markings at the left apex, and relative crowding of vessels at the left hilum) can be difficult to see on radiographs and even harder—if not impossible—to appreciate on physical examination. Patients with a pneumothorax of less than 20% will often have completely normal findings on chest examination, including equal breath sounds.

Figure 10.7 Hydropneumothorax. This radiograph is an excellent example of a hydropneumothorax. When accumulated fluid in the chest cavity is seen as a straight line on a radiograph (an air-fluid level [black arrow]) with no meniscus up the side, air must be present in the pleural space. In this patient the pneumothorax is readily visualized, with no lung markings seen laterally or superior to the pleural reflection (white arrows).

Diagnostic sensitivity is not increased with an expiratory upright chest radiograph. Upright is preferable to a supine chest radiograph, particularly for a hemothorax, because even with large amounts of blood there may only be slight differences in the density of the lung fields as the blood may layer out evenly. With an upright chest radiograph, 300 to 500 mL of fluid is needed to cause blunting of the costophrenic angle (Fig. 10.7).⁷ When CT is not available, other useful views

Figure 10.8 Pneumothorax and bullous emphysema. This patient had a history of severe chronic obstructive pulmonary disease and arrived at the emergency department in respiratory distress. **A**, On the chest radiograph, both apices are relatively radiolucent and faint lines that are not clearly blebs or pleural reflections (*arrows*) can be seen coursing through. **B**, A computed tomography scan was obtained and defined the pathology in detail. In the right apex, there is no pneumothorax, but rather large blebs are present (*small white arrows*). On the left a pleural reflection is clearly visible (*large white arrow*), indicative of pneumothorax. Subcutaneous air is also noted in the thoracic soft tissues (*black arrows*), thus further supporting the diagnosis of pneumothorax. (This finding is also evident on the chest radiography but was overlooked on the initial interpretation.)

include a bilateral decubitus chest radiograph, with the pneumothorax expected to be seen on the side away from the table (upward) as gravity pulls the affected lung down. A pleural effusion or hemothorax, however, may be better seen on the side toward the table (downward).

On a chest radiograph, the partially collapsed lung of a pneumothorax appears as a visceral pleural line with no pulmonary markings beyond it (see [Figs. 10.1, 10.3, 10.6, and 10.7](#)). It is easy to initially mistake large blebs for a pneumothorax or to identify the scapular border, skin folds, or indwelling lines as a pneumothorax, but a CT scan quickly resolves the issue ([Fig. 10.8](#)). Other radiographic findings include hyperlucency of the affected hemithorax, a double diaphragm contour, increased visibility of the inferior cardiac border, better visualization of pericardial fat at the cardiac apex, and possibly a depressed diaphragm. If subcutaneous air is noted on the chest radiograph of a patient with blunt chest trauma, assume that the air came from an injured lung and that a pneumothorax exists until proven otherwise.

It is difficult to accurately predict the size of a pneumothorax on plain radiographs. Greater accuracy in predicting size can best be accomplished with a CT scan. With a tension pneumothorax, the chest radiograph reveals lung collapse, a depressed hemidiaphragm on the affected side, and a shift of the mediastinum and trachea to the opposite side (see [Fig. 10.4](#)). Keep in mind, with a bilateral pneumothorax, a mediastinal shift may not be seen.

Thoracic CT

The gold standard for diagnosis is a thoracic CT scan, which can even detect a pneumothorax that is not easily visible on a plain radiograph. CT scans of the chest are much more sensitive than plain radiographs in detecting hemothorax and pneumothorax. They are also more accurate for estimating the size and other characteristics of a pneumothorax (see [Figs. 10.1, 10.4, and 10.8](#)). CT scans are not routine for the diagnosis of

a pneumothorax, but are more useful for hemothoraces and other fluid collections. They also offer invaluable information on the cause of such abnormalities. A CT scan may be useful when the diagnosis is unclear or when looking for small amounts of pleural fluid. CT scans are particularly helpful in determining whether an empyema is loculated or draining successfully. Approximately 10% of trauma patients with normal findings on a chest radiograph will demonstrate a small hemothorax or pneumothorax.⁷⁻⁹ The clinical significance of a small, previously undetected occult injury is probably not great, and it has been suggested that a small pneumothorax seen only on CT may be left untreated and simply observed in otherwise stable patients. Some patients with a pneumothorax seen only on CT may also safely undergo PPV without placement of a chest tube.⁹

Ultrasound

Ultrasound is useful in diagnosing both hemothoraces and pneumothoraces, and its use is reviewed in the [Ultrasound Box](#).^{10,11}

Thoracic ultrasound is a useful tool at the bedside to rapidly assess the lung fields. This includes the ability to assess the pleural space, diagnose pleural and lung parenchymal abnormalities and guide pleural-based procedures, including thoracentesis with or without catheter placement, and evaluation of placement for tube thoracostomy. Thoracic ultrasound has several advantages over standard chest radiographic imaging, including absence of radiation, portability, real-time imaging, and the ability to perform dynamic imaging. Sensitivity of lung ultrasound in the detection of pneumothorax is higher than conventional chest radiography. Thoracic ultrasound is considered superior in the detection and characterization of pleural effusion, and provides an advantage for the guidance of bedside pleural interventions.¹² Additionally, bedside thoracic ultrasound is helpful in differentiating between consolidation, atelectasis, and effusion, all of which can appear as an opacity

ULTRASOUND BOX 10.1: Recognizing Pneumothorax

by Christine Butts, MD

To evaluate for pneumothorax, a high-frequency transducer should be used to ensure a high degree of resolution. In a supine patient the transducer should be placed on the anterior chest wall in the midclavicular line at approximately the second to third intercostal space (Fig. 10.US1). The depth of the image should be adjusted until the ribs are seen as brightly echogenic (white) arcs with acoustic shadows behind them. The pleural line can be found just deep to the ribs and is represented as a horizontal, echogenic line (Fig. 10.US2). In a normal lung, the visceral and parietal pleural layers are directly opposed to one another (save for a thin layer of pleural fluid). When the patient breathes in and out, the layers “slide” past each other to allow the lungs to expand. When this is viewed with ultrasound, the pleural line can be seen to slide back and forth with patient respiration. This is referred to as the “slide sign.” In cases in which this interface is disrupted (such as by a pneumothorax), the sliding is lost. When these patients are evaluated with ultrasound, the pleural line will be seen as a static echogenic line that does not change with respiration. Although the slide sign carries significant sensitivity for

ruling out a pneumothorax, other secondary confirmatory findings should be sought as well.¹

Comet-tail artifacts may be seen in a normal lung. These are hyperechoic vertical lines that extend deep to the pleural interface (Fig. 10.US3). Typically, they will be seen in small numbers in a normal lung. Patients in whom a pneumothorax is present are noted to lack comet tails because this artifact arises from the normal pleural interface, which is disrupted. The presence of comet tails may be used by the sonographer to further rule out a pneumothorax.^{2,3}

Motion mode (M-mode) may also be used to further evaluate for the presence of a pneumothorax. M-mode is used to evaluate objects in motion and plots a linear representation of motion on screen. Objects that move toward the surface (or toward the transducer) are

Figure 10.US1 Proper positioning of the probe for evaluation of pneumothorax.

Figure 10.US2 Ultrasound image of the pleura as seen with a high-frequency transducer. The pleura can be recognized as a hyperechoic (white) line (arrow) that normally moves back and forth with respiration. Identifying the rib, along with its accompanying shadow (arrowhead), often aids in identifying the pleura because it will lie immediately deep to the rib.

Figure 10.US3 This image demonstrates two key artifacts seen in a normal lung. As with the previous image, the pleura is recognized as a hyperechoic horizontal line deep to the ribs (at the far right and left of the image). A comet tail, a small vertical line, can be seen extending deep to the pleura (arrow). This is a normal artifact created by the pleura, and its presence aids in ruling out a pneumothorax. A-lines, or a series of horizontal lines extending deep to the pleura, can also be seen (arrowhead). These artifacts may be seen both in normal lungs and in the presence of pneumothorax.

Figure 10.US4 Seashore sign seen in a normal lung. This M-mode image shows movement of the pleura. The solid lines at the top of the image represent the immobile skin, soft tissue, and muscle. The hazy lines at the bottom of the image represent the back-and-forth movement of the normal pleura.

Continued

ULTRASOUND BOX 10.1: Recognizing Pneumothorax—cont'd

Figure 10.US5 Bar code sign consistent with a pneumothorax. This M-mode image shows lack of movement of the pleura. Unlike the previous image, the solid lines can be seen to continue past the point of the pleural line. Because the presence of the pneumothorax causes the pleura to appear stationary, no movement is seen in this image.

represented by an upward deflection. Objects that move away from the transducer are represented by a downward deflection. Objects that are not in motion are represented by a solid line.

In a normal patient, the pleura will slide back and forth as the patient breathes. Because this motion is neither toward nor away from the transducer but instead is parallel, the motion will be seen as a series of hazy lines deep to the pleura. The overlying soft tissue is not in motion and will be seen as a series of clear, flat lines. This typical appearance is described as the *seashore* sign (Fig. 10.US4).

In patients in whom a pneumothorax is present, no motion is detected by ultrasound. Therefore the M-mode tracing will show clear, flat lines throughout the frame. This is referred to as the *stratosphere* or *bar code* sign (Fig. 10.US5).

or “white out” on chest radiograph.¹³ Ultrasound can also be used to evaluate chest wall pathology.

Lower-frequency probes with smaller footprints, such as the phased-array probe, should be used for the evaluation of pulmonary and pleural pathology as the probe can allow for scanning between rib interspaces. For chest wall structures, changing from the 3.5 to 5 MHz phased-array probe to the linear probe with a frequency of 7.5 to 10 MHz will provide better visualization.¹⁴ Additionally, the linear high-frequency probe is better suited for evaluation of the pleural line, which is discussed later.

The normal pleura appears as an echogenic line between the chest wall and the air-filled lung. Lung sliding, which represents the visceral pleura moving against the parietal pleura, is a key finding in a lung without a pneumothorax. When air separates the two pleural layers, as in a pneumothorax, the movement disappears.

There are two main types of lung artifacts caused by air-tissue interfaces that are commonly observed, A-lines and B-lines.¹⁵ Horizontal artifact, or A-lines, are echogenic lines between rib shadows that are observed in normal lungs. B-lines arise at the border between aerated and compressed lungs. They are often described as comet-tail and are characteristic in that they spread to the edge of the screen without fading, move synchronously with the lung during respiration, and tend to erase A-lines. Multiple B-lines are often termed *lung rockets* and are pathologic.¹⁵

Thoracic ultrasound can be an integral part in the evaluation of pneumothorax in a variety of situations. Examples include patients with chest trauma, evaluation for postprocedural iatrogenic pneumothorax, patients presenting with undifferentiated shortness of breath, hypoxia or chest pain, and following chest tube placement to assess resolution of pneumothorax. When evaluating for pneumothorax the patient should ideally

be in the supine position for visualization of the lung apices. The probe indicator should be pointed cephalad at approximately the third-to-fourth intercostal space between the parasternal and midclavicular line. The probe is moved progressively toward the lateral chest, checking for lung sliding at different locations.¹⁷ Air will first move to the most superior part of the hemithorax, which in the supine patient, corresponds to the lung apices. The evaluation of pneumothorax should focus on observing for the presence of four sonographic artifact signs: lung sliding, including by M-mode sonography, B-lines, the lung pulse, and the lung point sign. The lung point sign is the most specific sonographic sign for pneumothorax and occurs when the lung intermittently comes into contact with the chest wall during inspiration. This represents the edge of the pneumothorax. The presence of a lung point is 100% specific for ruling in pneumothorax.¹⁸ Lung pulse describes the vertical movement of the pleural line synchronous to the cardiac rhythm and is caused by transmission of heartbeats through the lung.¹⁹

Furthermore, thoracic ultrasound can be advantageous when evaluating the need for a pleural procedure and during the performance of this procedure. Blind insertion of a chest tube can result in significant complications in a patient with pleural adhesions from prior infections, pleurodesis, or pulmonary surgery. Guidance by ultrasound can help mitigate the risk of complications.

Ultrasound-guided thoracentesis, with or without subsequent placement of the drainage catheter, can be performed either by static or dynamic technique. Placement of tube thoracostomy is typically performed by static technique (or simply by landmark) after the diagnosis has been made and evaluation of the previously mentioned potential complications completed. Static ultrasound guidance identifies the intercostal spaces, pleura, and effusion, as well as the best angle of approach.

The skin is then marked on the patient, the probe is removed, and the procedure carried out the same way as during landmark thoracentesis or tube thoracostomy. The examiner may also choose to observe diaphragmatic excursion through several cycles to avoid selecting a location where the instrumentation occurs too close to the diaphragm, potentially resulting in laceration.

Thoracic ultrasound is considered superior to chest CT in visualizing stranding and septations in complex pleural effusions. The ability to detect such findings may prove useful as they can predict difficulty with tube drainage.²⁰ Additionally, distinguishing large bullae from a pneumothorax can be very challenging, as plain radiograph of the chest may be inadequate to make the diagnosis. Making the correct diagnosis is critical as the management approach for these two entities varies significantly. Whereas CT of the chest remains the diagnostic modality of choice for characterization of large bullae, there are case reports in the literature where thoracic ultrasound was used to correctly differentiate bullae from pneumothorax. Specifically, the comet-tailing phenomenon of the movement of the lung tissue against the pleura during respiration was noted to be present in bullous disease but absent in pneumothorax.²¹

INDICATIONS FOR TUBE THORACOSTOMY

Pneumothorax

Tube thoracostomy is by far the most common treatment for all types of pneumothoraces, but controversy exists over the treatment of small traumatic and spontaneous primary pneumothoraces. Treatment should address several basic issues: (1) removal of air, (2) preventing further air accumulation, (3) healing the injury that caused the initial accumulation, (4) promoting lung reexpansion, and (5) preventing or limiting reoccurrences.²² The American College of Chest Physicians has developed useful guidelines for the management of primary and secondary spontaneous pneumothoraces (Box 10.1).²³

Chest tube placement is probably not necessary in healthy patients with small primary spontaneous or isolated small traumatic pneumothoraces in the absence of respiratory compromise or concomitant injuries, or when PPV will not be required. With no intervention, a small pneumothorax will resolve over a period of days to weeks. Supplemental oxygen will speed the process of lung reexpansion by increasing the rate of pleural air absorption. No controlled studies have been conducted to compare the various interventions for primary spontaneous pneumothorax, and there is wide variation in treatment approaches. In particular, no significant difference has been found between simple aspiration and tube drainage with regard to the immediate success rate, early failure rate, duration of hospitalization, and 1-year success and pleurodesis.²⁴ Needle aspiration is associated with reduced analgesia requirements, lower pain scores, and a lower percentage of patients being hospitalized. Studies have shown excellent short- and long-term outcomes after video-assisted thoracoscopic treatment (VATS) of primary and secondary spontaneous pneumothorax, and rates of recurrence are lower than after other treatment modalities. However, VATS continues to have a higher complication rate than simple tube thoracostomy, with 4.6% of patients with spontaneous pneumothorax experiencing serious side effects as a result of the procedure.^{25,26}

In patients with a simple pneumothorax, prolonged suction is rarely required, and the tube can simply be attached to a Heimlich valve or underwater seal.²⁷⁻²⁹

Treatment is different for patients with a secondary spontaneous pneumothorax because the presence of underlying disease leads to more serious compromise and more frequent complications. In patients with chronic obstructive pulmonary disease, malignancy, cystic fibrosis, pneumonia, and tuberculosis, a chest tube usually cannot be avoided.

The underlying lung pathology of a patient with a spontaneous pneumothorax is best initially evaluated with CT. Frequently, this is followed by diagnostic or therapeutic visual inspection of the lung and pleural space by fiberoptic thoracoscopy. Extensive evaluation is not, however, usually recommended for the first episode of a small primary pneumothorax. When patients have recurrent spontaneous pneumothoraces, further evaluation (CT, thoracoscopy) and evaluation for surgical treatment are indicated. Patients who have had one spontaneous pneumothorax have a 30% to 50% chance of recurrence within 2 years, and after the second pneumothorax there is a 50% to 80% chance of developing a third. Surgery may be recommended for a first pneumothorax in the following situations: life-threatening tension pneumothorax, massive air leaks with incomplete reexpansion, an air leak persisting 4 days after a second tube has been placed, associated hemothorax with complications, identifiable bullous disease, or failure of easy reexpansion in patients with cystic fibrosis.

In patients with traumatic causes, the urgency and type of treatment depend primarily on the stability of the patient; a hypotensive patient with a tension pneumothorax requires immediate decompression with a chest tube or needle thoracostomy, whereas a patient with normal vital signs and a small pneumothorax may be observed initially. Emergency needle thoracostomy is only a temporary solution for a compromised patient with a tension pneumothorax. Once done, needle thoracostomy necessitates an ipsilateral tube thoracostomy. Other factors that modify treatment include the patient's age, the size of the pneumothorax, whether bilateral pneumothoraces are present, and whether the current episode represents a recurrence. A chest tube is usually indicated for a pneumothorax created by needle decompression.

Because of the risk for tension pneumothorax, a chest tube should be considered in all patients with a penetrating chest injury if PPV will be used or if they will be transported a long distance for definitive care. However, CT scans of trauma victims have demonstrated that many patients with small pneumothoraces that would have escaped detection with standard radiographs have safely undergone PPV without clinically evident pneumothorax developing. Close observation for signs of tension pneumothorax is necessary for patients in whom a chest tube is not placed and PPV is used.

Hemothorax

Tube thoracostomy is the treatment for hemothorax, but it is also used to monitor the amount and rapidity of blood output, which determines the need for additional interventions, including video-assisted thoracoscopy or open thoracotomy. Approximately three fourths of patients with a traumatic hemothorax can be managed by tube thoracostomy and volume replacement alone. The remaining patients will require immediate or delayed elective thoracotomy. The indications for surgery after an acute hemothorax vary somewhat between authors but are summarized

BOX 10.1 Guidelines of the American College of Chest Physicians for the Management of Primary and Secondary Spontaneous Pneumothoraces

PRIMARY SPONTANEOUS PNEUMOTHORAX (NO UNDERLYING LUNG DISEASE)

A clinically stable patient must have all of the following present: respiratory rate lower than 24 breaths/min, heart rate higher than 60 beats/min or less than 120 beats/min, normal blood pressure, room-air O₂ saturation higher than 90%, and the ability to speak in whole sentences between breaths.

CLINICALLY STABLE PATIENTS WITH SMALL PNEUMOTHORACES (<3-CM APEX-TO-CUPOLA DISTANCE)

Clinically stable patients with small pneumothoraces (PTXs) should be observed in the emergency department (ED) for 3 to 6 hours and be discharged home if a repeated chest radiograph excludes progression of the PTX (good consensus). Patients should be provided with careful instructions for follow-up within 12 hours to 2 days, depending on the circumstances. A chest radiograph should be obtained at the follow-up appointment to document resolution of the PTX. Patients may be admitted for observation if they live distant from emergency services or follow-up care is considered unreliable (good consensus). Simple aspiration of the PTX or insertion of a chest tube is not appropriate for most patients (good consensus) unless the PTX enlarges. The presence of symptoms for longer than 24 hours does not alter the treatment recommendations.

CLINICALLY STABLE PATIENTS WITH LARGE PNEUMOTHORACES (≥ 3-CM APEX-TO-CUPOLA DISTANCE)

Clinically stable patients with large PTXs should undergo a procedure to reexpand the lung and should be hospitalized in most instances (very good consensus). The lung should be reexpanded by using a small-bore catheter (≤14 Fr) or placement of a 16- to 22-Fr chest tube (good consensus). Catheters or tubes may be attached either to a Heimlich valve (good consensus) or to a water seal device (good consensus) and may be left in place until the lung expands against the chest wall and the air leaks have resolved. If the lung fails to reexpand quickly, suction should be applied to a water seal device. Alternatively, suction may be

applied immediately after placement of a chest tube in all patients managed with a water seal system (some consensus).

Reliable patients who are unwilling to undergo hospitalization may be discharged home from the ED with a small-bore catheter attached to a Heimlich valve if the lung reexpanded after the removal of pleural air (good consensus). Follow-up should be arranged within 2 days. The presence of symptoms for longer than 24 hours does not alter management recommendations.

SECONDARY SPONTANEOUS PNEUMOTHORAX

Clinically Stable Patients With Small Pneumothoraces

Clinically stable patients with small PTXs should be hospitalized (good consensus). Patients should not be managed in the ED with observation or simple aspiration without hospitalization (very good consensus). Hospitalized patients may be observed (good consensus) or treated with a chest tube (some consensus), depending on the extent of their symptoms and the course of their PTX. Some of the panel members argued against observation alone because of a report of deaths with this approach. Patients should not be referred for thoracoscopy without prior stabilization (very good consensus). The presence of symptoms for longer than 24 hours did not alter the panel members' recommendations.

Clinically Stable Patients With Large Pneumothoraces

Clinically stable patients with large PTXs should undergo placement of a chest tube to reexpand the lung and should be hospitalized (very good consensus). Patients should not be referred for thoracoscopy without prior stabilization with a chest tube (very good consensus). The presence of symptoms for longer than 24 hours did not alter the panel members' recommendations.

This is meant to be a guide, and clinical judgment should always be used.

From Baumann MH, Strange C, Heffner JE, et al: Management of spontaneous pneumothorax: an American College of Chest Physicians Delphi consensus statement, Chest 119:590-602, 2001.

in Box 10.2. Early institution of blood replacement is recommended for patients with massive hemothoraces (>2000 mL) because they are often associated with continuing hemorrhage. Autotransfusion of the shed blood is desirable whenever possible. For patients with active blood loss but stable hemodynamics, VATS can be used to locate and stop the bleeding, evacuate blood clots, and break down adhesions.

Empyema

Treatment of empyema depends on the severity of the infection and the patient's underlying condition. Some patients with empyema can be treated with serial thoracenteses, but most will require continuous drainage with a chest tube (see Fig. 10.5). Thoroscopic decortication represents definitive therapy for severe cases. Usually, diagnostic thoracentesis is performed first to assess the fluid for signs of infection. Thick pus on thoracentesis, positive Gram stain, fluid glucose level lower

BOX 10.2 Indications for Surgery After Tube Thoracostomy Based on Results of the Thoracostomy

- Massive hemothorax, >1000-mL to 1500-mL initial drainage
- Continued bleeding
 - >300 to 500 mL in the first hour
 - >200 mL/hr for the first 3 or more hours
- Increasing size of the hemothorax on a chest film
- Persistent hemothorax after two functioning tubes are placed
- Clotted hemothorax
- Large air leak preventing effective ventilation
- Persistent air leak after placement of a second tube or inability to fully expand the lung

This is meant to be a guide and clinical judgment should always be used.

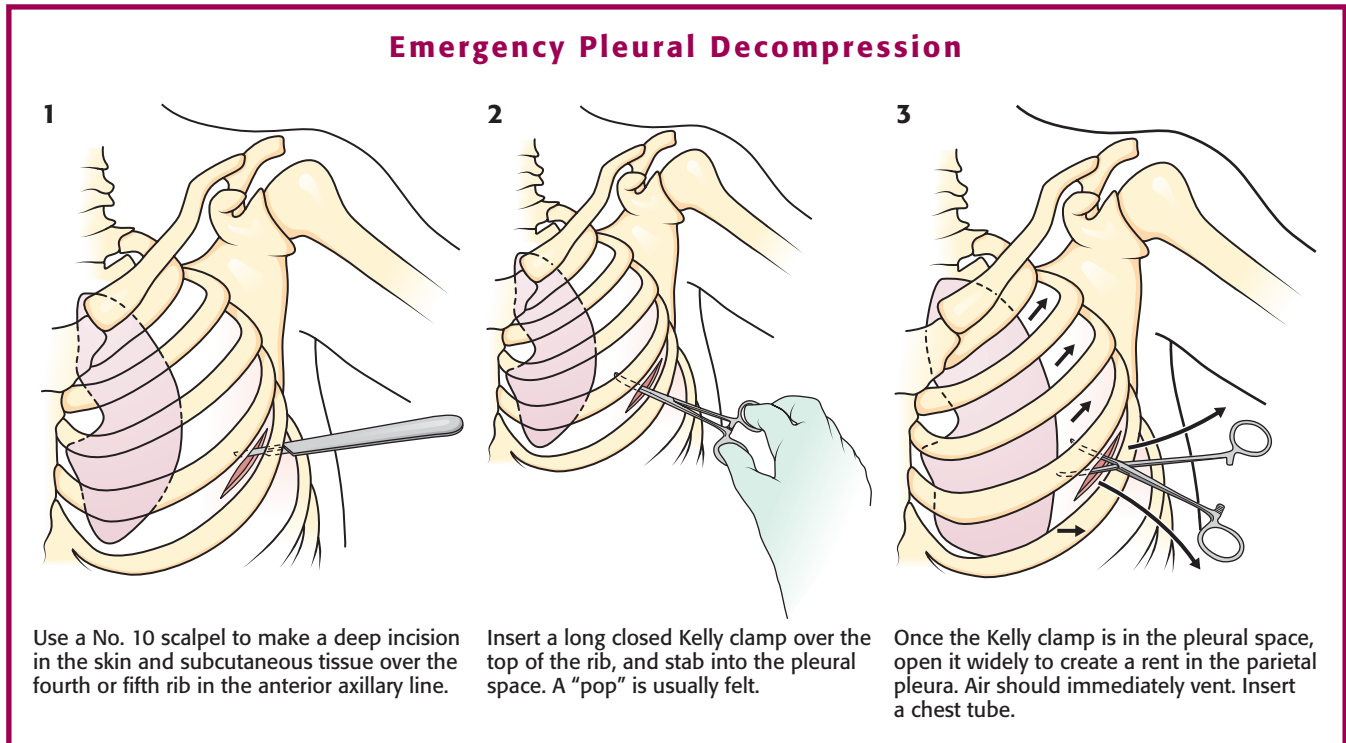

Figure 10.9 Emergency pleural decompression. During resuscitation of a patient with a tension pneumothorax there may be no time for a chest tube and needle decompression may not be rapid enough to be effective. Under these circumstances, the pleural cavity can be vented in seconds. This assumes that the patient is intubated.

than 60 mg/dL, pH less than 7.20, or elevated lactate dehydrogenase are all associated with infection and an effusion that requires chest tube drainage. Once an empyema is detected, therapy should not be delayed because the fluid can quickly become loculated. Generally, the tube is left in place until the pleural drainage fluid becomes clear yellow and accumulates less than 150 mL in 24 hours. An empyema that fails to resolve on chest radiography within 48 hours requires chest CT and a careful review of antibiotic choice. Multiloculated effusions are best managed by thoracoscopic decortication.

CONTRAINDICATIONS

For unstable trauma patients with a pneumothorax or hemothorax, there are no absolute contraindications to tube thoracostomy. In critical patients, placement of a chest tube is often performed empirically. In stable patients, relative contraindications include anatomic problems such as the presence of multiple pleural adhesions, emphysematous blebs, or scarring. Coagulopathic patients should be evaluated for replacement of clotting factors before any invasive procedure.

TREATMENT

Treatment of a Possible Tension Pneumothorax in an Unstable Patient

Immediate decompression of the chest must be considered in all injured patients with unexplained hypotension or tachypnea,

particularly those with penetrating chest injuries. The goal is to open the pleural space quickly to allow any accumulated air to escape and decompress the chest cavity. This can be accomplished with a scalpel and forceps, as is done at the beginning stages of a thoracostomy (Fig. 10.9), or more commonly, decompression can be achieved with a large-bore needle/angiocatheter combination (minimum of 16 gauge) (Fig. 10.10). Place the catheter in the second intercostal space at the midclavicular line on the side with diminished breath sounds or on both sides if the diagnosis is unclear. If unable to obtain access to this landmark, or if unsuccessful in penetrating into the pleural space, an alternative site in the fourth or fifth intercostal space at the midaxillary line can be used. Remove the needle, but leave the angiocatheter in place to create a simple pneumothorax. Regardless of whether needle decompression is successful in improving the patient's vital signs, a standard tube thoracostomy should be immediately performed following the decompression. If the needle decompression is not effective an open thoracostomy can be started, even without the immediate availability of a chest tube, to help create an exit for the air so that the patient's respiratory and cardiovascular functions can normalize. Needle decompression causes an open pneumothorax and in most cases needs to be converted to an open thoracostomy.

Prehospital Treatment

Emergency needle decompression thoracostomy may be used in the prehospital setting when a patient who is suspected of having a pneumothorax rapidly deteriorates or is initially seen *in extremis*. In such cases, attach the needle (or catheter) to a

Figure 10.10 Needle decompression. A large-bore needle/catheter combination is used to puncture the parietal pleura and establish the presence of fluid or air in the pleural space. The needle can be placed anywhere in the pleural space, but traditionally at the same sites used for tube thoracostomy: the anterior second intercostal space in the midclavicular line or the anterior axillary line in the fourth or fifth interspace. The needle is placed so that it enters over the rib to avoid neurovascular injury. The needle is then withdrawn while leaving the catheter behind to create a simple open pneumothorax. The procedure can be done either with or without the syringe attached to the catheter. This is only a temporary therapeutic maneuver for a tension pneumothorax, and a chest tube must also be inserted.

one-way (Heimlich) valve, underwater seal, or even a flutter valve (fashioned from the fingers of a surgical glove) so that the air can continue to escape during expiration but cannot enter during inspiration.

When a patient has an open chest wound in the prehospital setting, a three-sided occlusive dressing to cover the wound can create an appropriate one-way valve while providing wound protection. Similar to other one-way valve mechanisms, this dressing allows air to escape during expiration, but prevents air from entering the chest cavity during inspiration. Use a sterile dressing, such as petrolatum-impregnated gauze, that extends 6 to 8 cm beyond the wound in all directions. Tape down only three sides of the dressing. Additionally, there are multiple commercially available vented and nonvented chest seals that can be applied over the wound. In the case of the nonvented chest seal, the provider may need to release or “burp” the chest seal if the patient begins to demonstrate signs and/or symptoms again consistent with tension physiology after they were successfully needle decompressed. Instruct the patient to deeply inhale, perform a Valsalva maneuver, or cough while you place the dressing.

Emergency Department Treatment

Equipment

The standard instruments for a tube thoracostomy tray are listed in [Box 10.3](#) and depicted in [Review Box 10.1](#). The most basic needs are a scalpel, a large (Kelly) clamp, and the thoracostomy (chest) tube.

Thoracostomy tubes are clear plastic tubes of various diameters that are open at both ends ([Fig. 10.11](#)). There is a

BOX 10.3 Recommended Equipment for Tube Thoracostomy

PROCEDURE

- Sterile drapes
- 10- to 20-mL syringe and assorted needles (for local anesthesia)
- Local anesthetic (1% to 2% lidocaine)
- Antiseptic solution
- Scalpel with a No. 10 blade
- Large clamps (Kelly)
- Needle holder
- Chest tubes (size appropriate)
- No. 0 or 1-0 silk or similar suture
- Forceps
- Straight (suture) scissors
- Large, curved (Mayo) scissors
- Soft arm restraints

DRAINAGE SYSTEM AND TUBING

- Drainage apparatus with sterile water for the water seal
- Hard plastic serrated connectors
- Sterile tubing

DRESSING

- Petrolatum gauze or similar occlusive dressing
- Gauze or similar pads
- Adhesive tape—cloth backed
- Tincture of benzoin

Figure 10.11 Thoracostomy tube. Chest tubes are manufactured so that the radiopaque lines are interrupted at the level of the most proximal drainage hole. The gap in the line must be within the pleural cavity on the radiograph to ensure that the tube has been placed deep enough.

radiopaque strip along the length of the tube that is interrupted by a series of holes along the distal length of the tube. The strip allows visualization of the tube’s location on the post-procedure radiograph and ensures that the side ports are within the pleural cavity. Tube sizes vary from 12 to 42 Fr, with smaller tubes used for smaller pneumothoraces and larger (a minimum of 36 Fr) tubes for hemothorax and empyema. For pediatric patients, 14-, 16-, 20-, and 24-Fr tubes are adequate.

PROCEDURE

Conduct the procedure (Videos 10.1-10.8) as sterilely as possible and wear a gown, glove, mask, and goggles. When possible, obtain consent. ▶

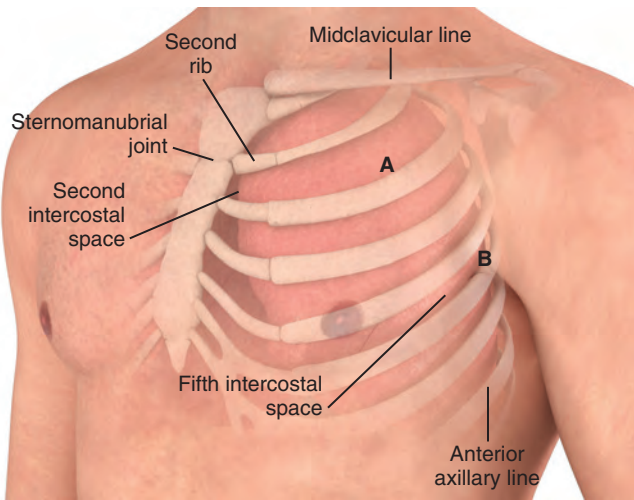

Figure 10.12 Entry sites for tube thoracostomy. The second intercostal space, midclavicular line, is the preferred site for needle aspiration or catheter insertion (*A*). To find the second intercostal space, first palpate the sternomanubrial joint. The second rib articulates with this structure. The second intercostal space is found below the second rib. The fourth or fifth intercostal space, midaxillary to anterior axillary line (lateral to the pectoralis muscle and breast tissue), is preferred for a chest tube (*B*). The fifth intercostal space is usually at the level of the nipple. In an obese woman an assistant has to retract the breast upward to identify landmarks and avoid low placement.

Tube Insertion Site

Insert the tube over the top of the rib rather than near the bottom to avoid the neurovascular structures located on the inferior aspect of the ribs. The most common location for a chest tube is the midaxillary to anterior axillary line, usually in the fourth or fifth intercostal space (Fig. 10.12). This approach is cosmetically preferable and better tolerated than the anterior chest wall approach in the second intercostal space of the midclavicular line. The fifth intercostal space is approximately at the level of the nipple or the inferior scapular border in most patients, although the position of the female breast mass leads to variance. To avoid penetrating the abdominal cavity, choose a more superior insertion site because the external landmarks can be misleading. An important point to consider is that the diaphragm of a supine patient who is not taking a deep breath is much higher than expected.

Hold the tube next to the chest wall with the tip of the tube at the level of the clavicle to estimate the distance that the tube needs to be advanced from the incision site to the apex of the lung. Place a clamp on the tube to mark the maximum length that the tube should be inserted to prevent the tube from advancing too far. Confirm that the last drainage hole is within the pleural space at the level of the insertion site to ensure that the tube has been advanced sufficiently far. In markedly obese patients, it is common to fail to advance the tube far enough, with the last hole being left in fatty tissue rather than in the pleural space.

Patient Preparation

If indicated clinically, start oxygenating and monitoring the patient continuously with cardiac and pulse oximetry. When

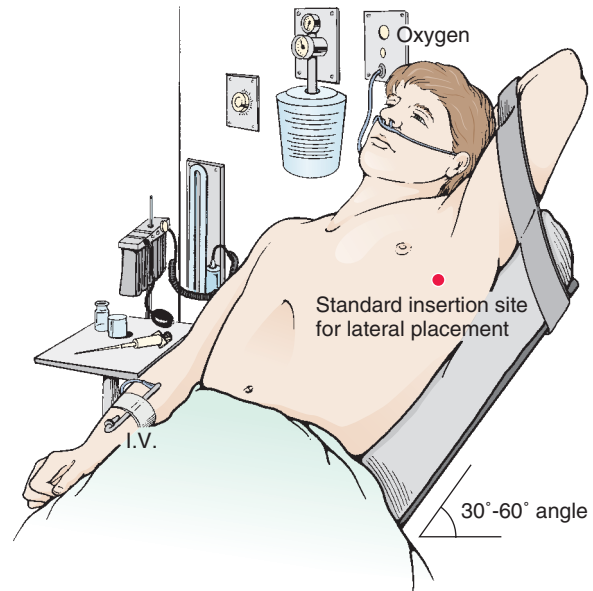

Figure 10.13 To insert a chest tube, position the patient semi-erect with the ipsilateral arm abducted as far as possible and preferably restrained. Supplemental oxygen and monitoring are recommended.

possible, elevate the head of the bed 30 to 60 degrees (Fig. 10.13) to lower the diaphragm and decrease the risk for injury to the diaphragm, spleen, and liver. Abduct the arm on the affected side, place it over the patient's head, and restrain it in that position. To facilitate, explain the process to the patient in detail if conditions are appropriate and use an assistant to help hold the patient and offer comforting support. Clean the skin with a standard surgical scrub and drape the field with sterile towels.

Anesthesia

Preprocedure

Tube thoracostomy can be extremely painful, so consider giving parenteral analgesics or procedural sedation to stable patients before starting the procedure. A common problem is inadequate systemic analgesia and local anesthesia. Use generous local anesthesia, such as up to 4 mg/kg of locally injected 1% lidocaine with or without epinephrine. Slowly inject local anesthetic over the superior aspect of the rib, through the muscle, periosteum, and parietal pleura and along the entire anticipated tract of passage of the tube (Fig. 10.14). Intermittently aspirate for air or fluid with the needle to find the pleural cavity. If air or fluid is not found, change the insertion site.

Procedure

During the procedure, an additional injection of local anesthetic (1% lidocaine) can be administered just prior to bluntly penetrating through the tough parietal pleura with the large Kelly clamp, as this is often the most painful part of the procedure.

Postprocedure

Once the tube is in place, administer local anesthetic through the chest tube into the pleural space to reduce pain caused by the tube rubbing against the pleura. In a stable patient, add

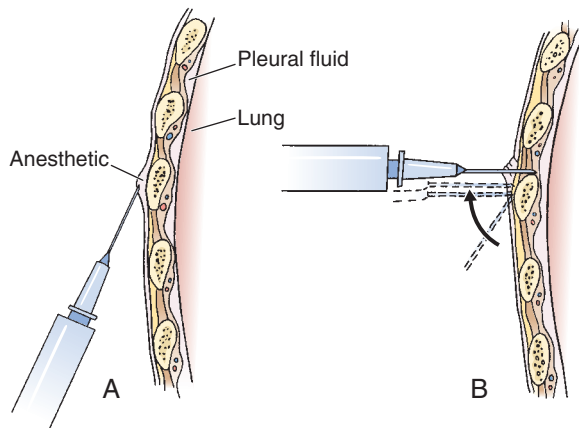

Figure 10.14 Local anesthesia is essential to reduce the pain from insertion of a chest tube. Both the skin and pleura should be infiltrated with a generous amount of local anesthetic. **A**, The anesthetic is first infiltrated over the rib at the site of the incision. **B**, The needle is then advanced slowly over the top of the rib while intermittently infiltrating and aspirating until the pleura is breached and air is withdrawn. Anesthetic is then injected liberally (maximum of 5 mg/kg of lidocaine) to cover the pleural lining. (Based on Hughes WT, Buescher ES: *Pediatric procedures*, ed 2, Philadelphia, 1980, Saunders p 234.)

10 mL of 0.5% bupivacaine through the chest tube while the patient is lying on the contralateral side.³⁰ After 5 minutes without drainage of the thorax, reinstate standard gravity or vacuum drainage. Use parenteral analgesic agents as needed to control pain.

Insertion

Choose an incision site lateral to the edge of the pectoralis major and breast tissue and not through these structures. A common problem is that the skin incision is too short to create and maintain an adequate tract to insert the thoracostomy tube. Make sure that the incision is no less than 3 to 5 cm long (Fig. 10.15, step 1). Make a transverse incision through the skin and subcutaneous tissue with a No. 10 blade over the rib. Some authors advocate making the initial skin incision at a location one rib lower than the intended intercostal space through which the tube will enter, followed by “tunneling” the tube under the skin and up over the next rib. This is theoretically done to prevent air leaks, but there is no good evidence to support this practice. It is more common to simply make the incision at the intended location so that there is a straight path to the pleural cavity over the appropriate rib. This avoids the problem of losing the entrance point or increasing damage to the soft tissues, both issues that are particularly problematic in obese patients. After the incision is made, insert a large Kelly clamp to push and spread the deeper tissues. Bluntly dissect a tract over the rib while avoiding the intercostal vessels and nerve on the inferior margin of each rib (Fig. 10.16; see also Fig. 10.15, step 2). Firm resistance will usually be felt when the tough parietal pleura is met. Close the clamp and push it forward with firm pressure to penetrate the pleura and enter the cavity. Considerable force may be needed. To prevent the clamp from penetrating too deeply, hold it at the midshaft a few centimeters distal to the incision and rest the tip against the pleura before pushing through (Fig. 10.17). As stated

previously, penetrating the pleura is usually the most painful portion of the procedure, so consider injecting extra anesthetic or analgesic at this point. On entering the pleural cavity, a palpable pop may be felt and a rush of air or fluid may occur. With only the tips of the clamp in the pleural cavity, spread the clamp to make an adequate hole in the pleura and then withdraw it (see Fig. 10.15, step 3). Make the opening in the parietal pleura wide enough to comfortably insert both a finger and the tube, but avoid a larger pleural opening to reduce the risk of an air leak (Fig. 10.18).

Another common problem occurs at this point, particularly in obese patients: the dissected tract and pleural opening can be lost when the clamp is withdrawn. To prevent this problem, slide a sterile gloved finger over the clamp and into the pleura before withdrawing the clamp (Fig. 10.19). This is done to further define the tract, to verify that the pleura has been entered, and to be sure that no solid organs have been penetrated. Whenever possible, leave the finger in the pleural space, make a 360-degree sweep to verify the correct space, to feel for adhesions, and to ensure that the hole is not lost (see Fig. 10.15, step 4). Pass the tube over, under, or beside the finger into the pleural space, with the fingertip being used to guide the course of the tube (Fig. 10.20). This step allows the clinician to feel the tube passing into the pleural cavity, avoids subcutaneous dissection by the tube, and enhances proper direction of the tube. Pass the tube alone or hold on to a large curved clamp with the tip of the tube protruding beyond the tip of the clamp (Fig. 10.21; see also Fig. 10.15, step 5). Normally, the tube should pass with little resistance. If resistance is met, the tube may not be in the pleural cavity and instead is passing subcutaneously, is in a fissure, or is abutting against the mediastinum (Fig. 10.22). Still using the finger that remains in the pleural space, direct the tube posteriorly, medially, and superiorly until the last hole of the tube is clearly in the thorax, the marker clamp that was previously attached touches the chest wall, or resistance is felt (see Fig. 10.15, step 6). Ensure that all the holes in the tube are within the pleural space. Rotate the tube 360 degrees to reduce the likelihood of kinking.

Attach the tube to the previously assembled water seal or suction before releasing the clamp. Ask the patient to cough and look for bubbles in the water seal chamber to check for patency of the system.

In cases in which there may be broken ribs or significant resistance, some authors recommend the use of a bougie to ensure that the tract (that was formed by the Kelly clamp and the inserted finger) is not lost. After confirmation of the correct space by finger sweep, insert the bougie while the finger is in the pleural space and direct it posteriorly, medially, and superiorly. Measuring the bougie in advance of the procedure and marking the bougie with an appropriate marking pin can help the operator identify the correct distance for advancement. Once the operator is satisfied that the bougie is in the correct place, the chest tube can then be inserted over it. As with most modified Seldinger techniques, the bougie must be secured by one hand at all times, and the tube must be advanced to its correct depth over the bougie, while the bougie remains stationary.

Confirmation of Tube Placement

There are many ways to confirm the location of the tube. Slide a finger along the tube to verify that it has entered the pleural cavity. Look for condensation on the inside of the tube and

Tube Thoracostomy

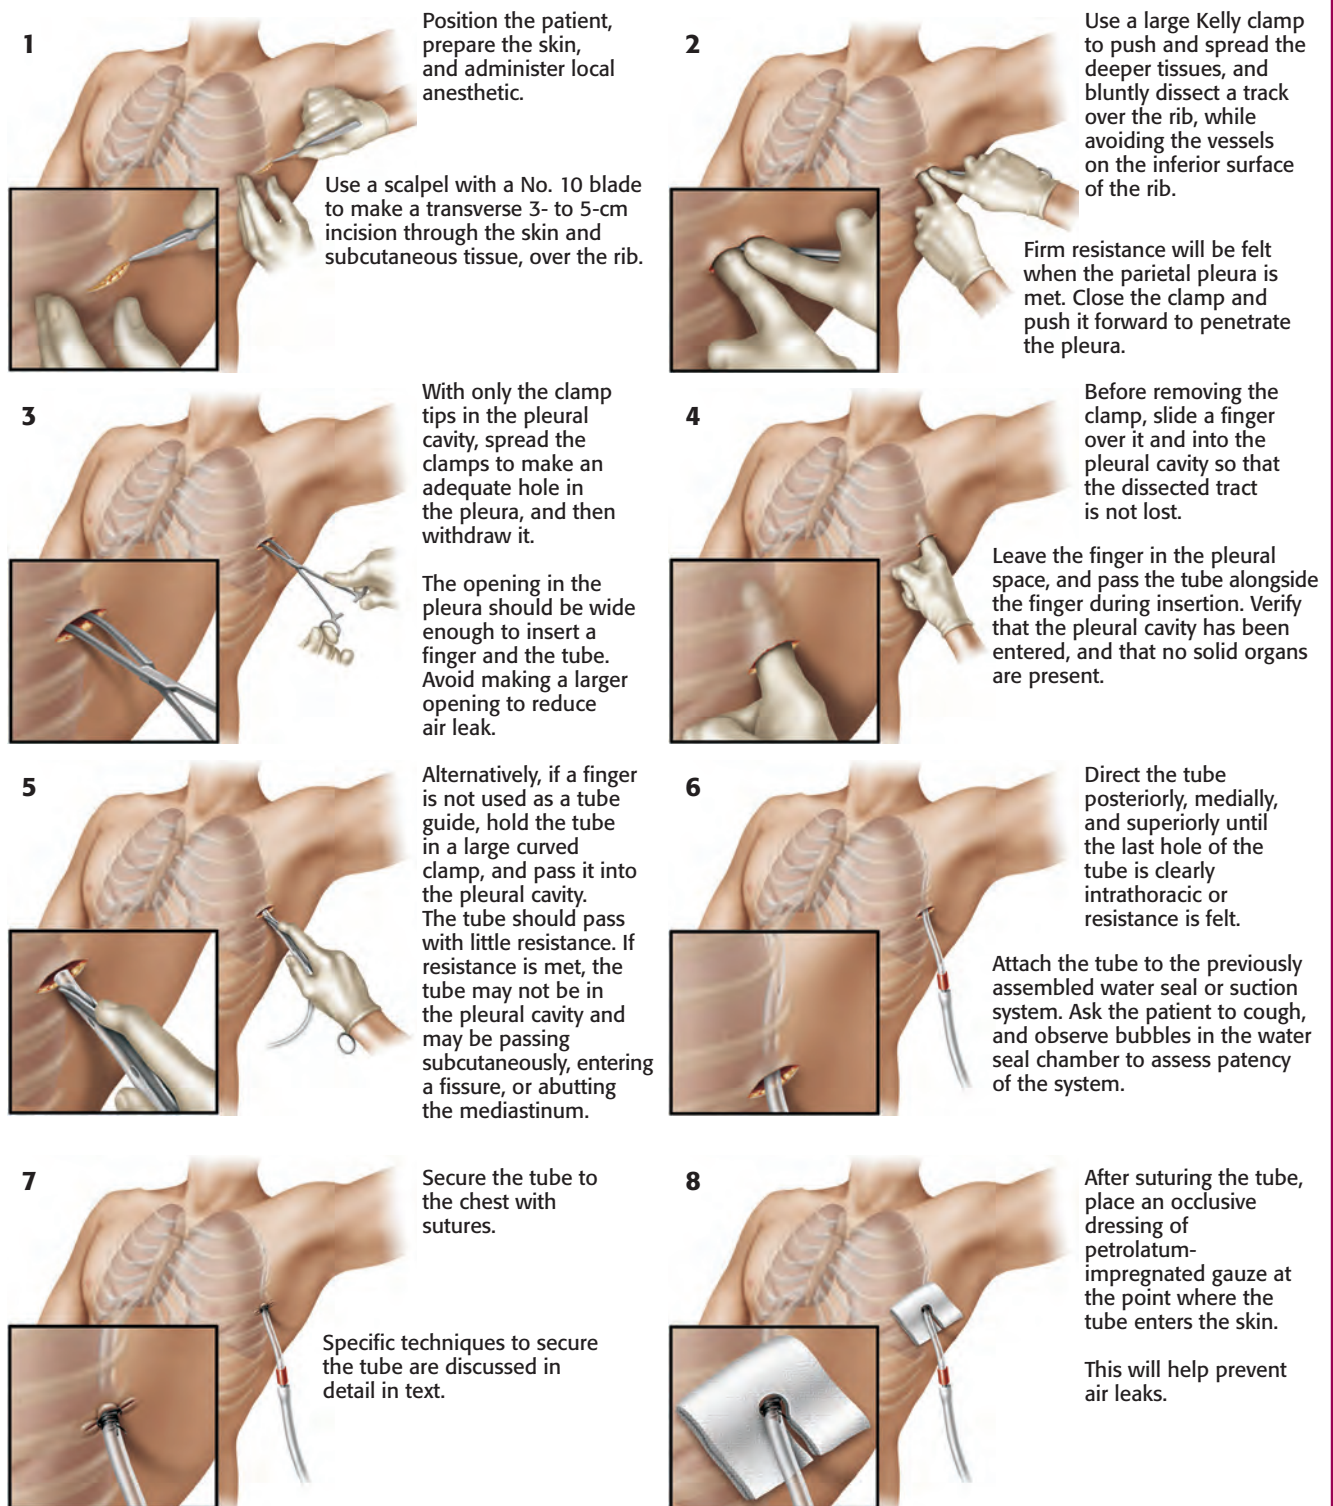

Figure 10.15 Tube thoracostomy. (From Custalow CB: *Color atlas of emergency department procedures*, Philadelphia, 2005, Saunders.)

listen for air movement, which is audible during respirations. Observe free flow of blood or fluid. Check to be sure that the tube rotates freely after insertion. A chest radiograph is used for definitive assessment of tube placement (Fig. 10.23). If the tube and the most proximal hole are not completely within the pleural space, and if the field has remained sterile, advance the tube. If the tube is kinked or dysfunctional or the sterile field has been lost and advancement is required, place a new tube in sterile fashion through the same tract. If the tube has been advanced too far, simply withdraw it to the correct depth.

Securing the Tube

Once the position of the tube has been verified with a radiograph, secure it. There are numerous methods to secure a

tube. The usual one is to sew the tube to the skin with large 0 or 1-0 silk or nylon sutures. Nylon sutures are acceptable but must be tied tightly or they will slip on the surface of the tube. One common method is to use a “stay” suture, in which the same suture that closes the skin incision is used to hold the tube (Fig. 10.24, *plate 1*). After this suture is used to close the skin incision at the site of insertion of the tube, wrap the ends tightly and repeatedly around the chest tube and tie it securely. Tie the sutures tightly enough to indent the chest tube slightly and avoid slippage. If the skin incision is especially long, use additional simple sutures to close it completely.

Another optional suture technique can both help close the skin around the tube and completely close the incision once the chest tube is removed. To do this, place a *horizontal mattress suture* approximately 1 cm across the incision on either side

Figure 10.16 Direct the Kelly clamp over the top of the rib to avoid the intercostal neurovascular bundle that courses along the inferior portion of the rib. Do not use excessive tunneling. (From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma, *Am J Surg* 140:739, 1980.)

Figure 10.18 Right-sided subcutaneous emphysema after chest tube placement secondary to making too large a hole in the pleura with a subsequent air leak (*arrows*). It is usually benign and self-limited, but with positive pressure ventilation it can be problematic. Because there is no way to close the pleura, making just the right-sized hole initially is the key to avoiding this complication.

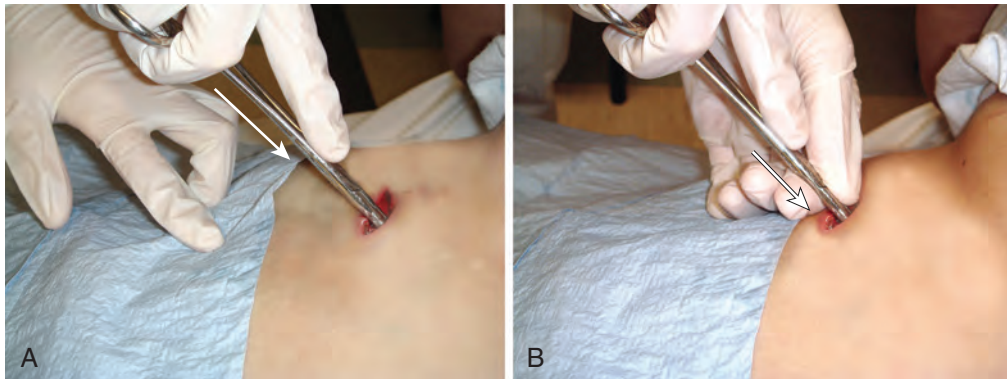

Figure 10.17 A and B, Use the right hand to push the clamp through the pleura (*white arrows*). Firmly encircle the midportion of the clamp with the fingers of the left hand to serve as a safety stop measure to avoid penetrating too deeply.

Figure 10.19 After puncturing the pleural lining and spreading with the clamp, slide a gloved finger over the clamp to ensure that the pleural space has been reached (*white arrow*) and that no solid underlying masses are present. Then withdraw the clamp but keep the finger inside the tract. Use the finger as a guide for the chest tube to ensure entry into the pleural cavity.

Figure 10.20 Leave your finger in the pleural space and use it to guide the course of the tube (*arrow*).

of the tube, essentially encircling it (see [Fig. 10.24, plate 2](#)). Secure it with a simple knot that can easily be untied so that it can be opened and retied to close the incision after the tube has been removed.

After suturing the tube in place, apply an occlusive dressing of petrolatum-impregnated gauze at the point where the tube enters the skin to help reduce air leaks. Cover the skin with two or more gauze pads with a Y-shaped cut from the middle of one side to the center (see [Fig. 10.24, plate 3](#)). Secure this dressing with wide (8 cm to 9 cm) cloth or elastic adhesive tape, with or without benzoin.

Use approximately 10 to 12 cm of tape split into three pieces and extending halfway along its length. Place the two outside pieces on the skin on either side of the tube site, and

Figure 10.21 Hold the tube with the tip of the tube protruding beyond the tip of the clamp to reduce the risk for pulmonary injury.

Figure 10.22 Subcutaneous placement of a chest tube (*arrows*) can occur because the tube can dissect through tissue planes with relative ease. If this tube had been directed posteriorly, the radiograph would erroneously “confirm” intrapleural placement despite the tube being subcutaneous throughout its entire course. There would be no air fogging the tube with respirations but a computed tomography scan would settle the issue of a misplaced tube.

wrap the center section tightly around the tube (see [Fig. 10.24, plate 4](#)). Repeat this with a second piece of tape placed at a 180-degree angle to the first. In addition, securely tape the tube connections. To further secure the tube, use tape to create a loop or stalk by wrapping it around the tube. Then press the tape together for 1 to 2 cm before applying the tape to the chest wall (see [Fig. 10.24, plate 5](#)).

Drainage and Suction Systems

A basic understanding of chest tube drainage systems is necessary to prevent life-threatening complications associated with their use. All drainage systems have two essential components: a one-way valve to allow air or fluid to drain out of the pleural

Figure 10.23 Definitive assessment of chest tube placement is with a chest radiograph. This patient has two chest tubes in place, and the radiopaque marking white lines on the tubes (*large arrows*) are readily visible. Chest tubes are manufactured so that these radiopaque lines are interrupted at the level of the most proximal drainage hole (*small arrows*). The gap in the line must be within the pleural cavity on the radiograph to ensure that the tube has been placed deep enough.

space without allowing air back into the pleural space, and a suction mechanism to increase the rate of drainage. The simplest drainage device is just a one-way valve without suction. This can be accomplished with either an underwater seal or a flutter (Heimlich) valve attached to the end of the chest tube (Fig. 10.25). Normal respiration and coughing are often sufficient to create the pressure necessary to remove excess air from the pleural space and allow the lung to expand. The Heimlich valve does not require suction and can be used for outpatient therapy.

With a one-bottle underwater seal system, the intrapleural fluid or air exits under a small amount of water. It collects in the single reservoir and mixes with the water (Fig. 10.26A). The water above the tube acts as a seal because it is too heavy to be drawn back into the chest. For drainage to occur, intrathoracic pressure must be greater than the water pressure at the distal end of the immersed tube. This pressure is determined by the height of the water above the exit port of the tubing. When the height is too great (the tube is too deep in the water), even coughing may not raise intrapleural pressure sufficiently to drain the chest. Place the collecting bottle below the patient, usually on the floor, to prevent inspiration from generating enough negative pressure to pull the contents of the collection bottle into the chest cavity.

Use suction initially to treat patients with pneumothorax or hemothorax, but replace it with a water seal once drainage and expansion are satisfactory and no persistent air leaks are present. The suction device should have high suction flow (≥ 20 L/min) and be able to keep the suction constant. Wall suction of -80 mm Hg is normally used, but the amount of suction in the chest tube depends on the depth of water in the water seal reservoir, not on the suction from the wall valve. When negative pressure from the suction source exceeds the depth of the water in the chamber, air enters from the top of the third tube and causes continuous bubbling (see Fig. 10.26B). This prevents a further increase in pressure in the chest tube. The wall suction dial can be turned down until only occasional

bubbling can be detected. Vigorous bubbling does not equate with more suction.

The bottle combinations example is provided to illustrate the principles but is rarely used now. Many types of commercial, enclosed systems are available that essentially combine a two-bottle method that can be connected to suction, but with the addition of an “air leak chamber” (see Fig. 10.26C). Bubbling in this chamber indicates the presence of an air leak, usually from the drainage system itself as a result of a loose tube connection. If bubbling is present, first check the drainage system, tube, and connectors for any problems or loose connections. If the leak continues, check whether all the holes of the chest tube are within the thorax. If the bubbling continues after these steps, a continued air leak may be due to a large hole in the lung parenchyma, which is usually seen only with expiration or with coughing. A continuous air leak or a leak during inspiration indicates a larger and possibly more significant lung injury.³¹ Surgical intervention is indicated if an air leak persists for longer than 72 hours or if the lung is not completely reexpanded.

The drainage reservoir must remain below the level of the chest to prevent the fluid in the collection system from reentering the chest. Place the reservoir on the floor or hang it from the edge of the bed. Simple respirations do not generate enough negative intrathoracic pressure to pull the water in the reservoir up to the height of the chest if the reservoir is kept on the floor and the patient is either sitting or lying at standard chair or bed height. The length of the tubing should be long enough so that the reservoir can be kept below the level of the patient, but not long enough to cause it to form dependent loops of fluid or kinks. Dependent loops collect fluid and create an additional water seal that, if large enough, can require greater intrapleural pressure to drain. If these pressures become high enough (15 to 25 cm H₂O), a tension pneumothorax may result.

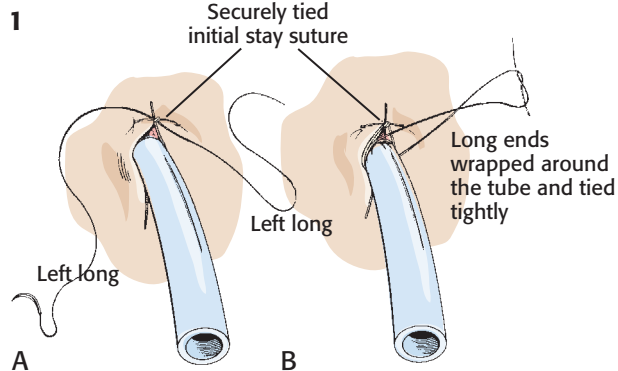

When the drainage system is functioning properly, the height of the fluid level in the drainage tube fluctuates with inspiration and expiration. Absence of respiratory fluctuation or a decrease in drainage may indicate that the system is blocked or that the lung is fully expanded. If the tube is blocked, the chest tube, collecting tubing, or both, can be changed or *stripped* to dislodge clots. Replacing the tube is a complicated process associated with risks, but the stripping procedure is controversial because of concern that the potentially high negative pressure from the procedure could damage lung tissue.³² For stripping, clamp the tube proximally and progressively compress it distally and then release it to allow the tube to spring open. The sudden increase in negative pressure may extract clots and fluid from a more proximal location. If the blockage is within the thorax, the tube can be cleared by forcing air or fluid back into the chest. The tube must be clamped distally and then compressed and stripped to force the contents proximally.

Perform occlusive clamping of a chest tube only with close monitoring because a tension pneumothorax can result in rare cases. Patients with chest tubes in place are best transported with a Heimlich valve or water seal only, not with the tube clamped. Avoid clamping the chest tube as a trial maneuver before removing it.

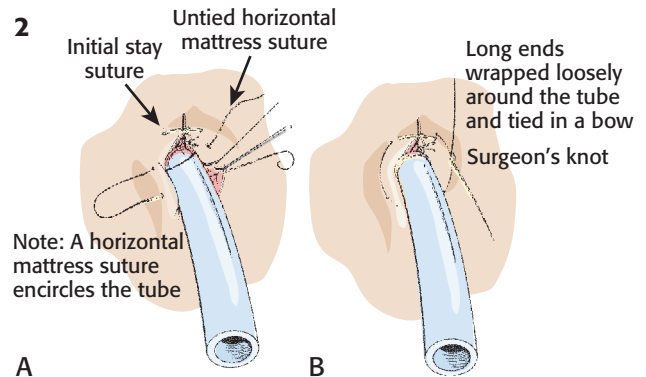

Prophylactic Antibiotics

The use of prophylactic antibiotics after placement of a chest tube in the emergency department (ED) is common, but no

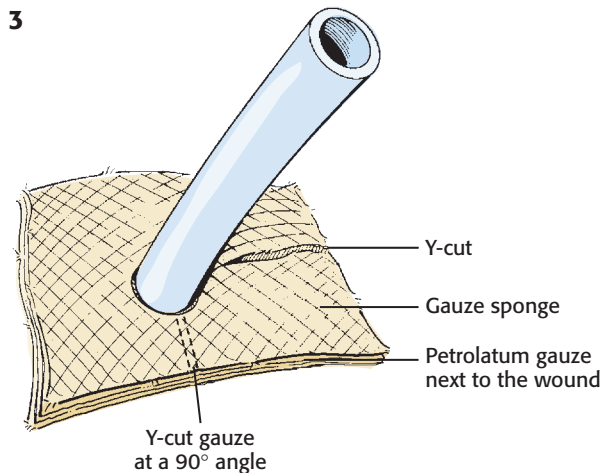

Securing a Thoracostomy Tube

A, To secure the tube, first close the skin incision with a “stay” suture near the tube. **B**, Tie the knot securely and leave the suture ends long for wrapping around and tying the tube. Wrap the suture tightly at least twice around the tube, enough to indent the tube slightly, and tie securely.

Another method to close the wound and secure the tube is with a horizontal mattress suture combined with a stay suture. **A**, A horizontal mattress suture is placed on either side (above and below) of the tube and held only with a surgeon’s knot. **B**, The loose ends are also wrapped around the tube and tied loosely in a bow to identify the suture. This suture will be untied and used to close the skin incision after removal of the tube.

To dress the wound and reduce the risk for air leaks, an occlusive dressing should be applied. First wrap the base of the tube at the skin incision with a petroleum-impregnated dressing. A two-layer dressing of gauze sponges with a Y-shaped cut centered at the tube is shown. Place the second layer at a 90° angle to the first.

One method to further secure the tube is to use wide, split cloth tape. **A**, The distal half of a 15- to 20-cm-long, wide piece of tape is longitudinally split into three pieces. The two outside pieces are placed on the skin on either side of the tube, and the center strip is wrapped around the chest tube itself. **B**, This process may be repeated with a similar piece of tape placed at a 90° angle. The tape is securely anchored to the skin (benzoin is optional, but the skin must be clean and dry), and the torn tape is wrapped around the tube. Each anchoring piece is covered by another piece of tape.

The tube can be further secured with an additional anchor system farther down on the tube. Wrap a 20- to 25-cm piece of tape or elastic, adhesive dressing around the tube and seal at least 3 cm of the tape together on the side of the tube nearest the chest wall. Spread the remaining tape against the dry skin of the chest wall and secure with additional tape.

Figure 10.24 Methods of securing a thoracostomy tube.

Figure 10.25 Pleural drainage devices. **A**, A one-way Heimlich valve alone is often sufficient to treat a pneumothorax, but it cannot be used to treat a hemothorax. **B**, Disposable water seal chest drain set.

specific standards exist. It appears reasonable to provide short-term antibiotic prophylaxis because analyses of many studies have shown that antibiotics reduce the incidence of chest tube-associated empyema or pneumonia.³³ Guidelines from the Eastern Association of Surgeons of Trauma recommend the use of first-generation cephalosporins during the first 24 hours for patients undergoing chest tube drainage for hemothorax.³⁴

Tube Removal

Chest tubes are rarely removed by emergency clinicians. The usual indication for removal of a chest tube is after a chest radiograph demonstrates complete resolution of the pneumothorax and there is no evidence of an ongoing air leak. Before removal, discontinue suction and establish a water seal. The literature is not clear about the use of a chest radiograph after suction is discontinued and after pulling the tube. Textbooks continue to recommend such practice, but studies have shown that it is not necessary for postoperative patients.^{35,36}

To remove the chest tube, ask the patient to sit upright at approximately a 45-degree angle. Use sterile technique, clean the skin, and drape the insertion site. Suturing equipment is needed to close the wound after the tube is removed, except when a purse-string suture was placed at the time of insertion,

Figure 10.26 **A**, A single-bottle (water seal) collection device. **B**, A two-bottle system. The trap reservoir proximal to the water seal keeps the accumulating drainage from affecting the water seal pressure. **C**, This has now been replaced by a disposable system that mimics the two-bottle system. (Courtesy Thora Klex System, Davol, Inc., Warwick, RI.)

in which case only sterile scissors are needed to cut the suture. Keep additional equipment available to reinsert a chest tube if the lung collapses. Prepare a petrolatum- or antibiotic-impregnated gauze dressing to cover the wound.

If a purse-string suture was placed previously, loosen it and prepare it for closing the wound. Cut the skin loop of the suture holding the tube to the skin and remove it from the skin. With the tube clamped, it has traditionally been advised to ask the patient to inhale fully and perform a mild Valsalva maneuver. Although this is theoretically beneficial in minimizing residual air following tube removal, it is of no proven value and many clinicians use no special protocols for removal of

the tube. Pull the tube out in one swift motion. Quickly tie the purse-string suture or suture the wound closed, and then cover it with an occlusive dressing. If no purse-string suture is present, once the tube is removed, suture the skin as quickly as is prudent for the physician. Observe the patient for 2 to 6 hours and obtain a chest radiograph before discharge. Any increase in symptoms requires prompt reevaluation. After 48 hours the patient may remove the dressing. Remove the sutures in 7 to 10 days.

OTHER TECHNIQUES

Small-Bore Tube Thoracostomy

Since the advent of common pleural drainage techniques in the early 20th century, physicians have preferred large-bore pleural drainage catheters (PDCs) inserted via blunt dissection for thoracic drainage and decompression. This preference for tubes greater than 16 Fr in diameter was born largely of concern for fibrin blockage, inadequate drainage capability, and the perception of frequent dislodgement of small-bore PDCs. To date, no quality randomized clinical trials have compared the use of large- versus small-bore PDCs, mainly because of the difficulty of conducting comparative studies in critically ill patients.

Despite these impediments, studies have hinted at the adequacy of small-bore PDCs for the treatment of many conditions. Review of the data available suggests that the rate of blockage and dislodgement is similar with large- and small-bore PDCs and that drainage capability is comparable in all but the most extreme circumstances.³⁷⁻⁴⁰ Another study has shown that large-bore PDC placement is associated with significantly more pain and slightly increased rates of empyema.⁴¹

Review of the pulmonology and critical care literature reveals no consensus on the appropriate use of small-bore PDCs; however, review articles have attempted to establish rough guidelines for their use. The literature suggests that patients with malignant effusion, simple pneumothorax without penetrating injury, or a suspected air leak, as well as those with simple or complex parapneumonic effusions, are good candidates for small-bore PDCs. Patients with empyema, penetrating injury, traumatic hemothorax or complex pneumothorax, and those on mechanical ventilation require large-bore PDCs because of the potential for large-volume air leaks in such patients and the need for rapid evacuation of the pleural space.^{42,43}

Many protocols are available for use of catheter aspiration as the first step in treating simple pneumothoraces. In general, patients with successful aspiration are observed in the ED for 4 to 6 hours after catheter insertion, and if a repeated radiograph shows no reaccumulation of air, the catheter is removed. After 2 more hours another chest radiograph is obtained, and the patient is released if there is no recurrent pneumothorax. Patients with continued residual pneumothorax often receive a conventional chest tube.

Guidewire Technique for Catheter Aspiration

Catheters designed specifically for aspirating a pneumothorax are made of flexible, thrombosis-resistant radiopaque material with multiple distal side ports to reduce the risk of occlusion. Commercially available small-bore catheter systems are ideal for this procedure.

The catheters are placed via a standard “over-the-wire” (Seldinger) technique. The most common insertion site is the second intercostal space in the midclavicular line, but either of the standard locations (the midaxillary to anterior axillary line, usually in the fourth or fifth intercostal space, or the midclavicular line, second intercostal space) can be used. Place the patient in a semi-upright position. Clean the skin with an antiseptic solution and drape the area. Infiltrate locally with lidocaine for anesthesia. Advance the guide needle in a straight line at a 60-degree angle cephalad over the top of the rib (Figs. 10.27 and 10.28). Unless a straight tract is created, it will be difficult to advance the floppy catheter, so a tunneling approach cannot be used. When the pleural space is identified by intermittent aspiration, halt advancement of the needle. Stabilize the needle and feed a guidewire through the needle and into the pleural space. Remove the needle while stabilizing the guidewire to keep it in the pleural space. Make a small incision in the skin with a No. 11 blade at the base of the wire to allow passage of the catheter through the skin. Some systems use a dilator over the wire to open the path through the soft tissue. Thread the mini-catheter over the guidewire and into the pleural space. Remove the wire and dilator while leaving the catheter in the pleural space. Advance the catheter through the subcutaneous tissue with a twisting motion. Secure the catheter to the skin with a suture and dress the incision site. The catheter may be removed after a period of observation, or suction may be maintained for a few days. If the catheter becomes clogged with mucus or blood, inject sterile saline through the device to clear it.

To aspirate the pneumothorax, attach a three-way stopcock to the catheter and slowly aspirate air with a 60-mL syringe until resistance is felt. Gentle wall suction can also be used because a number of aspirations may be required until all the air exits. Take a chest radiograph to determine whether the lung is fully expanded. If a residual pneumothorax is present, attempt further aspirations. If the residual pneumothorax persists and air cannot be aspirated, the catheter may be kinked or blocked with soft tissue. To relieve the blockage, place the patient in the full upright position and have the patient cough or take a deep breath. Alternatively, the catheter can be twisted or rotated gently.

TUBE THORACOSTOMY IN PEDIATRIC PATIENTS

Pneumothoraces can occur in the neonatal population. They are often associated with resuscitative measures (such as mechanical ventilation) for meconium aspiration or prematurity. For the rest of the pediatric population, trauma is the most common cause. A pneumothorax will develop in approximately one third of children with thoracic trauma. As in adults, physical examination of newborns and infants with pneumothorax can be highly variable, thus necessitating the use of a chest radiograph for diagnosis. Ideally, both anteroposterior and cross-table lateral x-ray projections are used because small pneumothoraces may be seen only on the lateral view. A chest CT is more sensitive and specific.

In general, tube thoracostomy is the treatment of choice once a symptomatic pneumothorax is detected in infants. When signs of tension pneumothorax are present, immediately aspirate with a plastic catheter-over-the-needle device. Small pneumothoraces (<20% of the hemithorax) in relatively asymptomatic

Catheter Aspiration of Pneumothorax: Seldinger Technique

The Seldinger-type catheter kit contains a pigtail catheter and all necessary equipment, including local anesthesia, introducing needle and syringe, scalpel, guidewire, and dilator.

After generous local anesthesia, advance the introducing syringe in a straight line over the top of the fifth rib until air is aspirated. Unless a straight tract is created, it will be difficult to advance the floppy catheter, and a tunneling approach cannot be used.

Advance the guidewire through the introducing needle into the pleural space, and then remove the needle. The procedural steps are analogous to initiating a central venous catheter via the Seldinger technique.

Puncture the skin at the site of wire insertion with a scalpel. Make the incision large enough to accept the dilator and pigtail catheter.

Advance the dilator over the wire to create a tract for the catheter. Remove the dilator while leaving the wire in place. Again, this is analogous to establishing a central venous line.

Advance the pigtail catheter over the wire through the dilated tract. It will assume its pigtail configuration when it is in the pleural space. A twisting motion may be needed to advance the catheter through subcutaneous tissue. Advance the catheter to the hilt and secure to suction. This catheter may be removed after a period of observation, or the suction may be maintained for a few days.

Figure 10.27 Aspiration of a pneumothorax with an Arrow 14-French Percutaneous Cavity Drainage Catheterization Kit (Teleflex, Morrisville, NC). This 23-cm pigtail multihole catheter is ideal for such purposes. Air can be aspirated from the catheter with a syringe, or the catheter can be attached to suction or a Heimlich valve. This catheter is not used for patients on a ventilator, those with continuing air leaks, or those with a hemothorax. It is ideal for stable patients who have a primary pneumothorax or a collapse that can be expected to be stable if the lung is reexpanded (such as induced by intravenous drug use, minor blunt trauma, or insertion of a central venous catheter). If used for a few days, the catheter will become clogged with mucus or blood, which may be cleared by injecting sterile saline through the device.

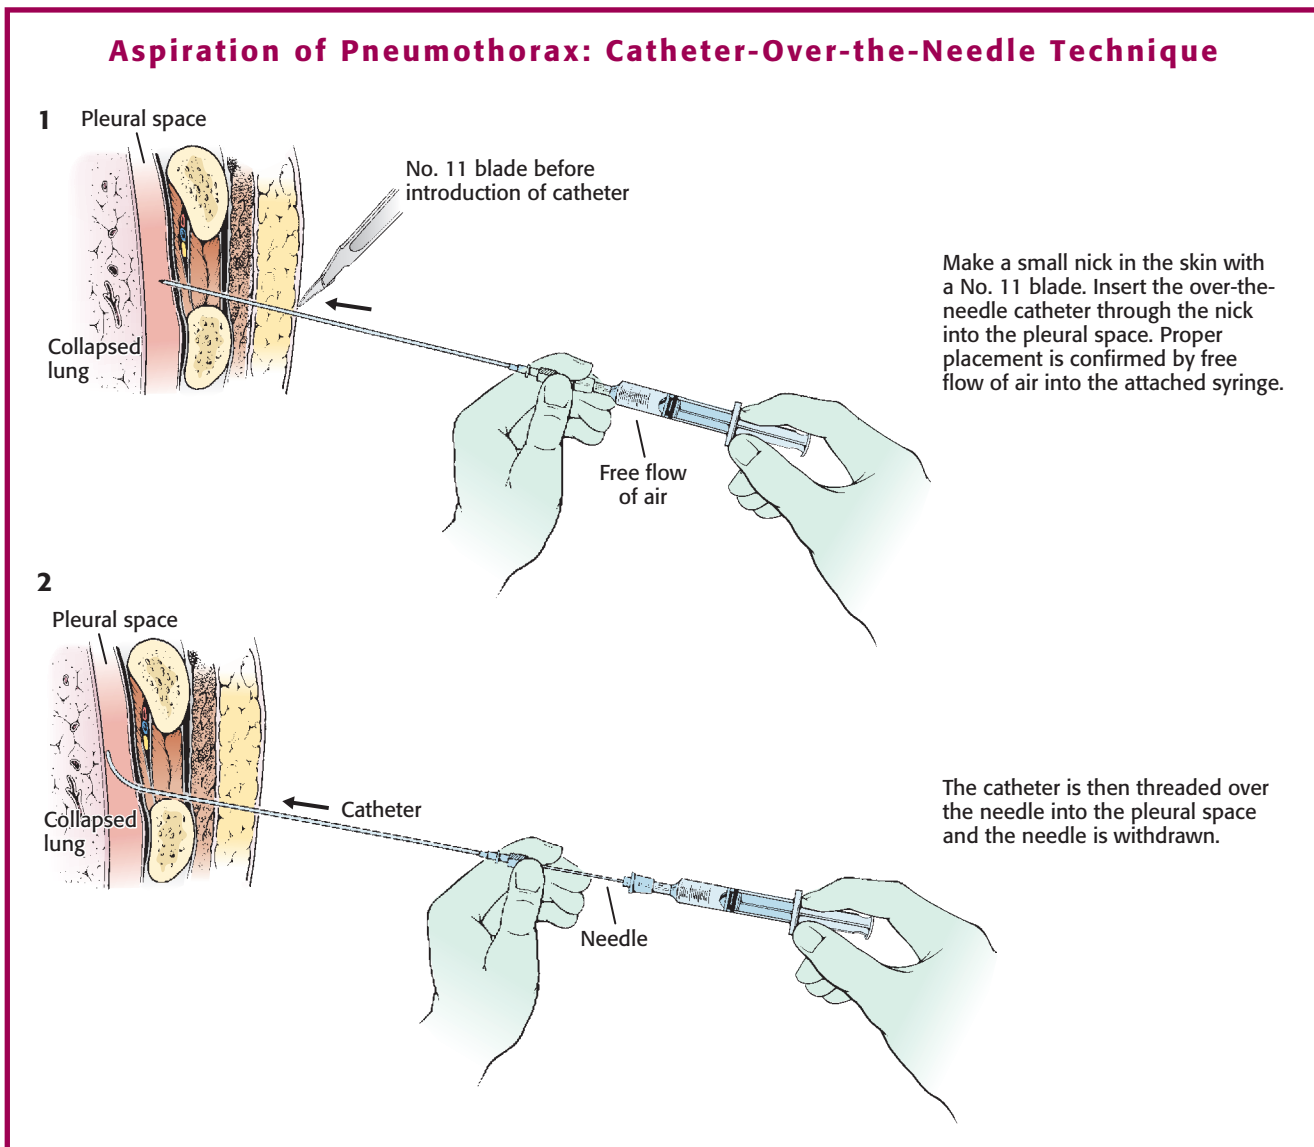

Figure 10.28 Catheter-over-the-needle technique for aspiration of a pneumothorax.

infants (e.g., those without other problems who do not require positive airway pressure) can be observed.

The technique of tube thoracostomy in pediatric patients is essentially the same as that in adults, but the body size and small spaces between the ribs make the procedure more difficult. The size of the tube increases with the patient's weight, starting with 8-Fr to 10-Fr catheters for premature infants (Table 10.1). Because of the risk for future breast deformities, avoid the midclavicular approach. Instead, use the anterior axillary line through the fifth intercostal space for newborns and infants.⁴⁴

COMPLICATIONS

The most common complications include infection, laceration of an intercostal vessel, laceration of the lung, and intraabdominal or solid organ placement of the chest tube (Boxes 10.4 and 10.5). Local infection at the insertion site is common and often related to the emergency nature of the procedure. Subcutaneous

TABLE 10.1 Approximate Pediatric Chest Tube Size by Weight

BOX 10.4 Physical Complications of Tube Thoracostomy

INFECTION

Pneumonia
Empyema
Local infection of the incision
Osteomyelitis
Necrotizing fasciitis

PHYSIOLOGIC

Allergic reactions to the surgical preparation or anesthesia
Pulmonary atelectasis
Reexpansion pulmonary edema
Reexpansion hypotension

INJURIES—BLEEDING

Local incision hematoma
Intercostal artery or vein laceration
Internal mammary artery laceration (with midclavicular line placement)
Pulmonary vein or artery injury
Great-vessel injury

INJURIES TO SOLID ORGANS OR NERVES

Lung, liver, spleen, diaphragm, stomach, colon; long thoracic nerve, intercostal nerve

MISCELLANEOUS

Subcutaneous or mediastinal emphysema
Persistent pneumothorax
Retained hemothorax
Recurrence of pneumothorax after removal of the chest tube

emphysema is a frequent, usually benign complication that is self-limited and generally caused by an excessively large opening in the pleura. Subcutaneous air may be a result of the incident that caused the pneumothorax in the first place. The development of palpable subcutaneous air is another complication of chest tube placement. It is usually limited to the insertion site but can become massive with PPV in a patient with continued air leak or an occluded tube.

Intercostal arteries or veins may be lacerated, but this can be minimized by using blunt dissection and carefully directing the tube just above the rib. The tube may adequately tamponade such bleeding. If the bleeding persists, extend the incision to ligate the bleeding vessel. If the bleeding continues, consult a thoracic surgeon.

BOX 10.5 Mechanical Complications of Tube Thoracostomy

MECHANICAL PROBLEMS

Dislodgement of the chest tube from the chest wall
Incorrect tube position
Subcutaneous placement
Intraabdominal placement

AIR LEAKS

Leaks within the drainage system (tubing or drainage device)
Last tube port not within the pleural space
Leaks from a skin site

BLOCKED DRAINAGE

Flow of drainage contents into the chest from elevation of the drainage bottles
Kinked chest tube or drainage tubes
Occlusion of the tube by clots

Failure of a pneumothorax to reexpand may be due to a mechanical air leak, but it may also indicate a bronchopleural fistula, a continued parenchymal lung leak, or a bronchial injury. Tension pneumothorax can occur if a blockage in the drainage system at any point is associated with a continued air leak from the lung. Reinsertion or placement of a second tube may be indicated if the first tube is not functioning properly. In general, if a chest tube is not functioning properly and the patient is deteriorating, remove the tube and insert another one. Manipulating the tube by pushing it deeper into the chest cavity can lead to an increased risk for infection.

A rare complication of tube thoracostomy is unilateral reexpansion pulmonary edema. The pulmonary edema ranges from mild to severe, but fatalities have been reported.⁴⁵ The condition may occur shortly after reexpansion or may be delayed a number of hours. A common factor in these cases seems to be a prolonged period between the development of a pneumothorax and the onset of treatment, but the exact time frame is quite variable. Usually, the pneumothorax has been present for at least 3 to 4 days. Proposed mechanisms include anoxic damage to the alveolar-capillary basement membrane from prolonged pulmonary collapse, loss of surfactant, or rapid fluid shifts. Treatment is supportive, with ventilatory support occasionally required. Reintroduction of air back into the pleural space and temporary occlusion of the ipsilateral pulmonary artery are other suggested, but unproved interventions.

Techniques for Supraventricular Tachycardias

Bohdan M. Minczak and Glenn W. Laub

INTRODUCTION

Patients in the emergency department frequently complain of palpitations, heart fluttering, or a rapid heartbeat, which is often coupled with weakness, chest pain, or dizziness. The physician must determine the exact rate, rhythm, origin, and cause of the tachycardia and then gain control of the heart rate (HR) by slowing or normalizing it, or by treating the underlying cause. Determining the cause, origin, and rhythm of the tachycardia is often complicated by the fact that the underlying rate may be very fast (in excess of 150 to 300 beats/min), which makes interpretation of the electrocardiogram (ECG) more difficult. Furthermore, the sources or pacemakers producing or facilitating the tachyarrhythmia may be from one or multiple locations: in the sinoatrial (SA) node, in one or more ectopic atrial foci, in the atrioventricular (AV) node, or in the ventricular free walls or septum. There may also be an abnormal conduction pathway between the atria and the ventricles. In some conditions, one or more pacemakers can be discharging simultaneously. To facilitate the diagnostic process, discrimination between atrial and ventricular electromechanical activity must be attempted. This chapter provides a framework to facilitate the decision-making process with a focus on emergency interventions for various tachydysrhythmias.

Techniques for unmasking, identifying, and treating the various forms of tachyarrhythmias are presented in [Box 11.1](#). This chapter addresses the utility of the vagal reflex in treating and managing various pathophysiologic conditions and the use of medications and cardioversion as they apply to the treatment of various supraventricular tachycardias (SVTs). The major focus is on the evaluation and treatment of SVTs.

A more comprehensive discussion regarding the treatment of ventricular tachycardia (VT) is provided in [Chapter 12](#).

OVERVIEW/SIGNIFICANCE: ANATOMY AND PHYSIOLOGY OF SUPRAVENTRICULAR TACHYCARDIA

Normally, the human heart beats at approximately 80 beats/min (± 20 beats/min). If the HR exceeds 100 beats/min, it is called tachycardia. If it drops below 60 beats/min, it is called bradycardia. The heart's ability to increase the rate of a normal sinus rhythm is primarily related to age: the maximum HR possible with a sinus tachycardia is approximately 220 beats/min minus age, with normal variations as high as 10 to 20 beats/min. As an example, a 60-year-old man cannot usually mount a sinus tachycardia higher than 160 beats/min in response to sepsis, exercise, fever, anxiety, or adrenergic stimulation. Faster rates would indicate a pathologic cardiac rhythm, not a physiologic response.

There are two general categories or types of tachycardias: SVT and VT. SVT describes a rapid HR that has its electrochemical origin either in the atria or in the upper portions of the AV node. VTs originate in the ventricular free walls or interventricular septum (or both). VTs can quickly become unstable and require special consideration ([Fig. 11.1F](#)).

SVTs can be further classified as narrow-complex (QRS duration < 0.12 second; or three small boxes on the ECG) and wide-complex tachycardias (QRS duration > 0.12 second). The rhythms of these dysrhythmias can be regular or irregular. Examples of narrow-complex SVTs are sinus tachycardia (see [Fig. 11.1A](#)); atrial fibrillation (AF) (see [Fig. 11.1C](#)); atrial flutter (see [Fig. 11.1D](#)); AV nodal reentry; atrial tachycardia (see [Fig. 11.1B](#)), both ectopic and reentrant; multifocal atrial tachycardia (MAT); junctional tachycardia; and accessory pathway-mediated tachycardia. The term wide-complex tachycardia describes rhythms such as VT (see [Fig. 11.1F](#)), SVT with aberrancy (see [Fig. 11.1E](#)), or a preexcitation tachycardia facilitated by an accessory pathway between the atria and ventricles.

Tachycardias can be benign or can have significant physical effects on the patient. When the HR is 60 beats/min, approximately one cardiac cycle of contraction (systole) and relaxation (diastole) occurs per second. The excitation for cardiac contraction typically originates in the SA node, the intrinsic pacemaker of the heart. The pacemaker impulse traverses across and depolarizes the atria, which causes atrial contraction or systole. Subsequently, the depolarization reaches the AV node. On initiating depolarization of the AV node, the conduction velocity of this depolarizing impulse transiently decreases (i.e., undergoes "decremental conduction") so that the ventricles can fill with blood from the antecedent atrial contraction. (Remember: the duration of diastole must be roughly twice the duration of systole to allow adequate ventricular filling.) The AV node also serves as a gate or selective block to prevent an excessive

BOX 11.1 Diagnostic and Therapeutic Approaches to Supraventricular Tachycardias

VAGAL MANEUVERS

1. Carotid sinus massage
2. Pressure on the carotid sinus
 - Valsalva technique
- Forced expiration of air against a closed glottis
 - Apneic facial exposure to cold water (“cold water diving reflex”)
- Immersion of the face into cold water
 - Oculocardiac reflex
- The trigeminovagal reflex initiated by pressure on the eyeball

PHARMACOLOGIC AGENTS

1. Adenosine
2. Calcium channel blockers (verapamil, diltiazem)
3. β -Blockers, including esmolol
4. Digoxin
5. Amiodarone
6. Procainamide

CARDIOVERSION

Administration of a synchronized shock

number of depolarizing impulses from reaching the ventricles when the atrial rate is accelerated.

Immediately thereafter, this depolarizing wave accelerates as it travels down the bundle of His to the Purkinje fibers and causes ventricular depolarization and contraction systole. Subsequently, the ventricles begin to relax (i.e., enter diastole and begin to fill with blood before the next depolarization). This describes the events of one cardiac cycle or heartbeat. The changes in electrochemical voltage during these events are depicted on the ECG in the usual sequential PQRST (the P wave indicates SA nodal depolarization, the PR interval denotes atrial depolarization followed by activation of the AV node, and the QRS complex summarizes electrical activity during ventricular depolarization) (Fig. 11.2).

The discharge rate of the SA node is usually modulated by a balance of input from the sympathetic and parasympathetic nerves (i.e., the autonomic nervous system). Sympathetic input to the heart is provided by the adrenergic nerves, which innervate the atria and ventricles, and by circulating hormones such as epinephrine and norepinephrine, which are released from the adrenal gland and cause the HR to increase. Parasympathetic input to the heart is provided by the vagus nerve (cranial nerve X) fibers. These nerve fibers innervate the SA and AV nodes. Vagal output to the SA node causes slowing of the HR by decreasing the depolarization rate of the “intrinsic pacemaker,” whereas vagal output to the AV node enhances nodal blockade of atrial depolarization impulses to the ventricles. Hence, vagal stimulation results in slowing of electrical activity, examples being termination of an SVT, slowing of the ventricular rate of AF (via the AV node), or simply producing a sinus bradycardia (via the SA node). Under normal physiologic circumstances, the HR is modulated to meet the metabolic needs of the body’s peripheral circulation. Changes in AV electrochemical events (i.e., rates and rhythms) are manifested as changes in the electrocardiographic intervals and waveforms.

As noted earlier, SVT rhythms can be either sinus (i.e., originating in the SA node: sinus tachycardia) or ectopic (i.e., originating in atrial myocytes above the ventricles). The rate of discharge of the SA node often varies as a result of various physiologic and pharmacologic stimuli, including fever, hypovolemia, shock, anemia, hypoxia, anxiety, pain, cocaine, and amphetamines. These conditions often require or precipitate increased blood flow and hence cardiac output (CO) to peripheral tissues. This increase in peripheral blood flow or CO is accomplished by an increase in HR ($CO = HR \times SV$ [stroke volume]). These are usually normal, benign physiologic responses to various stimuli or triggers. Direct treatment of these rhythms is not generally necessary; however, determining and treating the cause of the sinus tachycardia usually eliminates the fast HR. Nonetheless, when single or multiple ectopic, spontaneously discharging foci develop in the atria or upper portions of the AV node, they can begin to “take over” or “override” the normal pacemaker activity in the heart (i.e., the SA node) and produce a rapid HR exceeding 100 beats/min. These foci may develop as a result of increased irritability or automaticity of atrial myocytes secondary to electrolyte abnormalities, hypoxia, pharmacologic agents, or atrial stretch caused by volumetric overload. If these foci are not treated or suppressed and the atrial depolarization rate proceeds to accelerate to rates greater than 150 beats/min (i.e., the heart is beating in excess of 2 beats/sec) and the impulses get through the AV node to the ventricles, the time for diastolic filling of the ventricles will be compromised and result in a precipitous drop in SV. This will ultimately cause a drop in CO regardless of the increase in HR. Furthermore, as CO begins to drop, mean arterial blood pressure (MAP) will decrease and cause hypoperfusion of the brain and other peripheral tissue (MAP is the product of CO times total peripheral resistance [TPR]: $MAP = CO \times TPR$). Treatment of this tachycardia can be achieved pharmacologically by suppressing the automaticity of myocytes with medications (e.g., calcium channel blockers or β -blockers) and subsequently treating the underlying cause or causes, such as hypoxia, electrolytes, and the like. Decreasing the hemodynamic consequences of this arrhythmia requires increasing the “blocking” of these impulses from reaching the ventricles via the AV node. This can be done by enhancing vagal input to the AV node or by pharmacologic enhancement of AV blockade. Multiple rapid depolarizations of the atria, which are conducted to the ventricles, can ultimately have a bimodal type of response: a modest increase in HR will cause an increase in CO, whereas a massive increase in the atrial rate with a concomitant increase in the ventricular rate will cause a drop in CO. This can lead to an unstable patient with signs and symptoms such as confusion, altered mental status, or persistent chest pain. When the patient becomes unstable, immediate treatment is indicated.

In addition to areas of increased automaticity that can precipitate SVTs, *reentry* can also cause SVTs. Reentry describes a condition whereby a depolarization impulse is being propagated down a pathway in which some of the myocytes are still in the effective refractory period and a unidirectional block is present and preventing the impulse from traveling normally down this pathway.

However, as the impulse travels around the area of the unidirectional block, the tissue allows the depolarization front to travel in the opposite (antidromic) direction, back to the initial point of entry into this pathway. This allows the depolarization wave front to restimulate the myocytes and

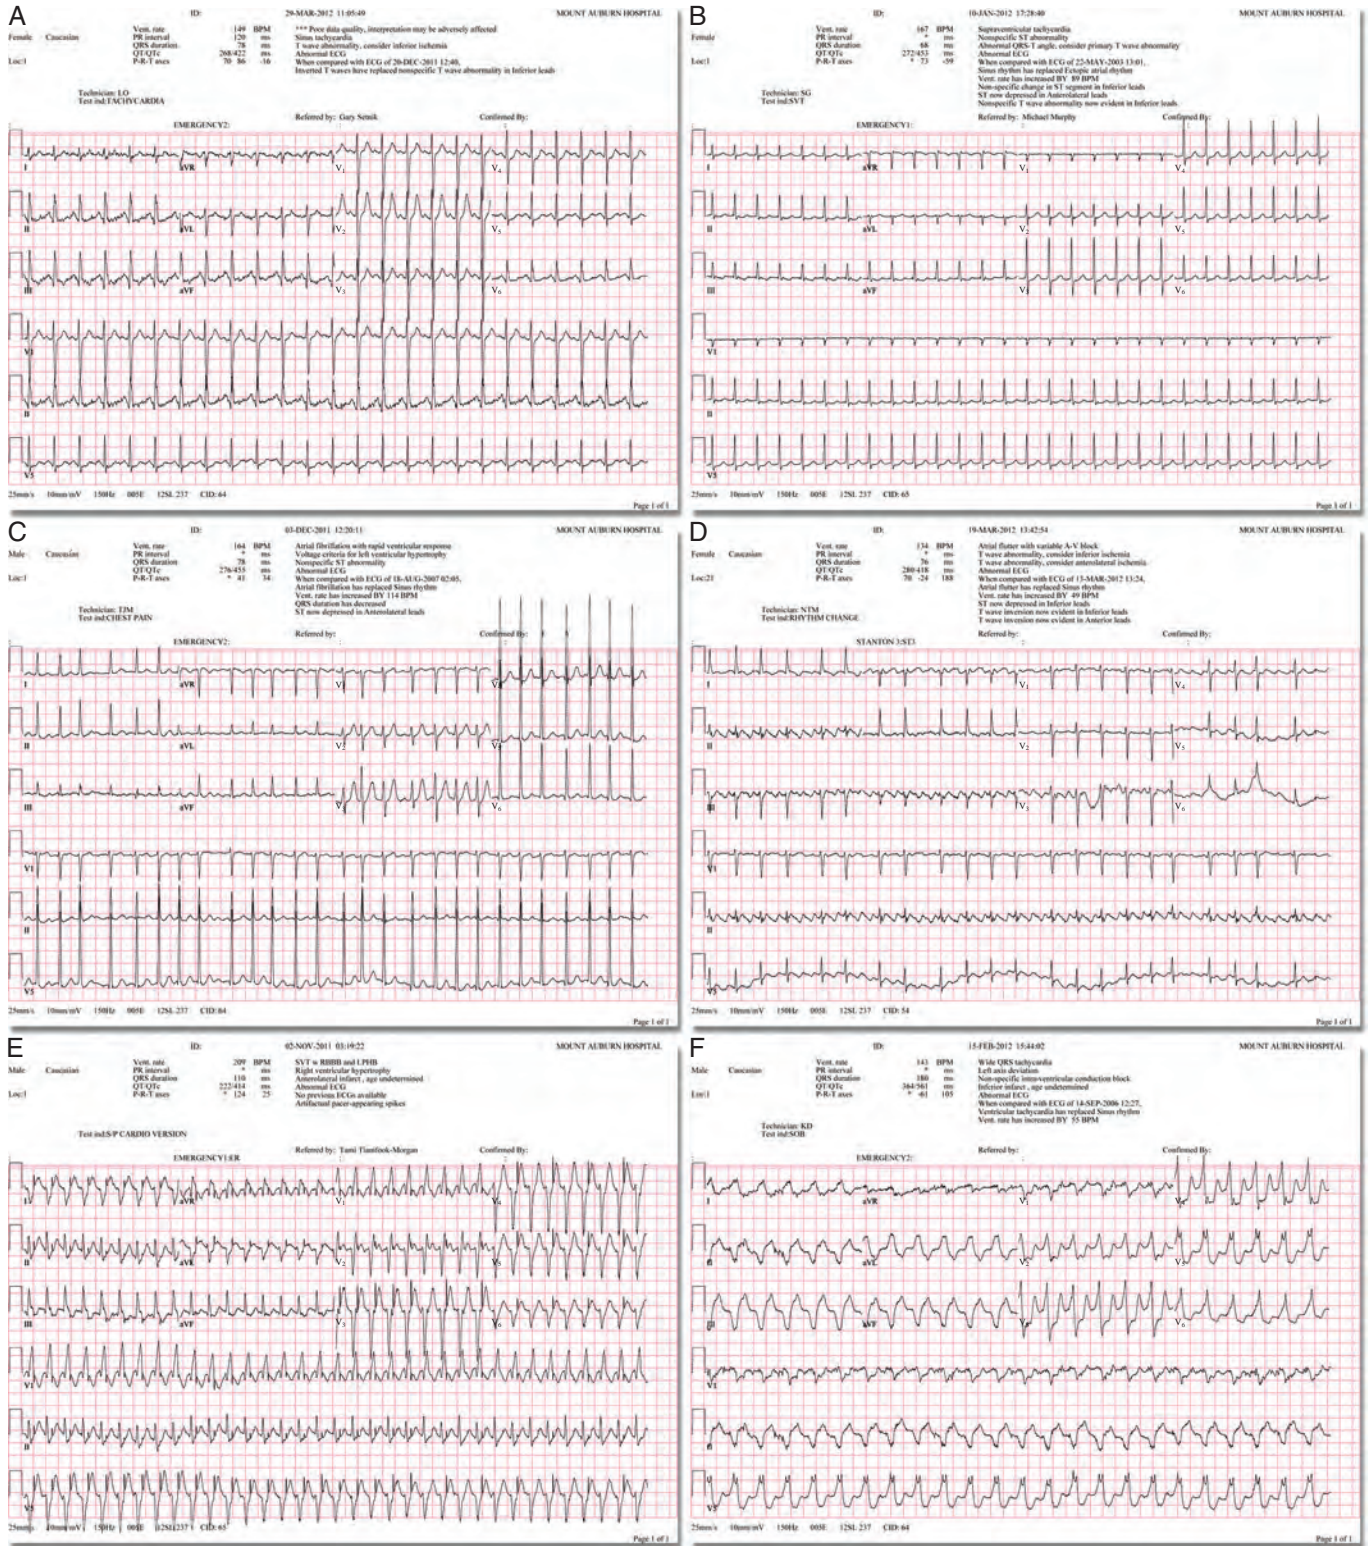

Figure 11.1 Tachydysrhythmias. **A**, Sinus tachycardia. **B**, Supraventricular tachycardia (SVT). **C**, Atrial fibrillation. **D**, Atrial flutter. **E**, SVT with aberrancy. **F**, Ventricular tachycardia.

initiate another propagated depolarization through the same tract (Fig. 11.3). If this condition persists and these impulses stimulate the atria effectively and traverse the AV node, an SVT may develop as a result of reentry. Suppression of this dysrhythmia can be achieved by terminating the conditions

favoring reentry, and the hemodynamic consequences may be attenuated by enhancing AV nodal blockade of the ventricles (e.g., through vagal stimulation, medication), thus slowing the ventricular response to this condition. Termination of reentry can be accomplished by either pharmacologic modification

ECG AND MEMBRANE POTENTIAL OF VENTRICULAR CELLS

Figure 11.2 Electrocardiographic and Membrane Potential of Ventricular Cells.

Figure 11.3 Cardiac Conduction in Supraventricular Tachycardia. A, Normal depolarization down path 1 and 2 that will “extinguish” or “cancel out” at point 3. Normal depolarization/repolarization and conductance. B, Reentrant pathway. 1: Normal conduction; 2: delayed/slowed conduction with unidirectional block; 3: normal conduction pathway.

of the myocytes to render them refractory to depolarization impulses for a longer period in a stable patient or by synchronized cardioversion to uniformly depolarize the myocytes and terminate the conditions favoring the SVT in an unstable patient.

Another situation to consider in the development and propagation of SVTs is the presence of preexcitation or an accessory pathway between the atria and the ventricles. Arrhythmias secondary to these causes can be managed with the use of appropriate pharmacologic agents to either suppress conduction through the accessory pathway or block AV nodal transmission without enhancing conduction through the accessory pathway.

To complete this discussion, we must also consider that there may be the possibility of an interventricular conduction delay (“aberrant conduction”) being present before the development of an SVT. If this is the case, the SVT may appear as a wide-complex tachycardia and can be confused with other dysrhythmias. However, an even more dangerous situation can occur if a wide-complex tachycardia of ventricular origin (VT) is present and is misdiagnosed as an SVT with aberrancy. As a result, the patient could be treated inappropriately with calcium channel blockers or β -blockers, resulting in vasodilation, loss of inotropy, and ultimately cardiac arrest. The safest course of action is to always assume that a regular wide-complex tachycardia is VT and treat with ventricular antiarrhythmia medications or electrical cardioversion. These therapies will generally result in successful cardioversion of the rhythm, regardless of whether the rhythm is actually VT or SVT with aberrancy.

The clinician must have a means of slowing down and sorting out these physiologic events so that appropriate diagnosis and treatment or intervention decisions can be made. With the application of vagal maneuvers, in some cases the activity of the atria and ventricles may be isolated enough to facilitate a correct diagnosis. An understanding of the underlying pathophysiology will guide appropriate treatment.

Indications for Vagal Maneuvers

Vagal maneuvers are potentially useful in attempting to slow down or break an SVT. They are also indicated in settings in which slowing conduction in the SA or AV node could provide useful information (Box 11.2 and Figs. 11.4A–E and 11.5A–D). Such settings include patients with wide-complex tachycardia, in whom carotid sinus massage (CSM) aids in the distinction between SVT and VT. CSM can elucidate narrow-complex tachycardia in which the P waves are not visible, or aid in detection of suspected rate-related bundle branch block or pacemaker malfunction. After CSM, a wide-complex SVT may be converted to normal sinus rhythm, P waves may be revealed after increased AV node inhibition, or ventricular complexes may narrow as the ventricular rate slows. Because CSM slows atrial and not ventricular activity, AV dissociation may be seen more easily and is indicative of VT (see Fig. 11.4). In rapid AF or atrial flutter with a 2:1 block, either P waves or irregular ventricular activity with absent P waves may be revealed (see Figs. 11.5A and B). Sinus tachycardia may also be more apparent once P waves are unmasked by slowing the SA node (see Figs. 11.4C and D). Adenosine may be used for the same diagnostic purpose in these situations as well.¹ In order of decreasing frequency, the electrocardiographic changes seen with CSM and vagal maneuvers are presented in Box 11.3.

BOX 11.2 Potential Observations With Vagal Maneuvers in the Management of Tachydysrhythmias

1. Vagal maneuvers may slow the atrial rate in VT or complete heart block and may therefore demonstrate previously hidden P waves or obvious (AV) dissociation.
2. Abrupt changes in the heart rate without conversion are a result of increasing AV block.
3. Gradual slowing of the ventricular rate suggests the presence of sinus rhythm. Only rarely do vagal maneuvers decrease AV conduction in the presence of a sinus mechanism.
4. The dysrhythmias most likely to convert to sinus rhythm are PAT and paroxysmal nodal tachycardia.
5. Dysrhythmias that are associated with AV conduction defects (PAT with block, atrial flutter, and atrial fibrillation) infrequently convert to a sinus rhythm, but the ventricular rate slows. Rarely, atrial slowing will be sufficient to allow 1:1 AV conduction, which may actually increase the ventricular rate (see Fig. 11.6).

AV, Atrioventricular; PAT, paroxysmal atrial tachycardia; VT, ventricular tachycardia.

BOX 11.3 Order of Decreasing Frequency of Electrocardiogram Changes With Vagal Maneuvers

1. Sinoatrial slowing, which occurs in approximately 75% of cases and leads to sinus arrest approximately 3% of the time.
2. Atrial conduction defects, as manifested by an increase in width of the P wave on the electrocardiogram.
3. Prolongation of the PR interval and higher degrees of atrioventricular block, which are seen in approximately 10% of cases.
4. Nodal escape rhythms.
5. Complete asystole, defined as sinus arrest without ventricular escape lasting longer than 3 seconds, which occurs in 4% of cases.
6. Premature ventricular contractions.

Vagal maneuvers, CSM in particular, may also be a useful aid in the diagnosis of syncope in the elderly. Some 14% to 45% of elderly patients referred for syncope are thought to have carotid sinus syndrome (CSS).^{2–4} CSS is defined as an asystolic pause longer than 3 seconds or a reduction in systolic blood pressure greater than 50 mm Hg in response to CSM (Fig. 11.6). Because it shares many characteristics with sick sinus syndrome, it has been suggested that both are manifestations of the same disease. CSS causes cerebral hypoperfusion, which can lead to dizziness and syncope. Analysis of patients with CSS indicates that it results from baroreflex-mediated bradycardia in 29%, hypotension in 37%, or both in 34%.^{5,6} Therefore syncope, chronic near-syncope, or a fall of unclear etiology in the elderly is an important indication for diagnostic CSM.^{7,8} Although the use of digoxin has been overshadowed by the use of other potentially less toxic agents such as calcium

Effects of Carotid Sinus Massage on Various Arrhythmias

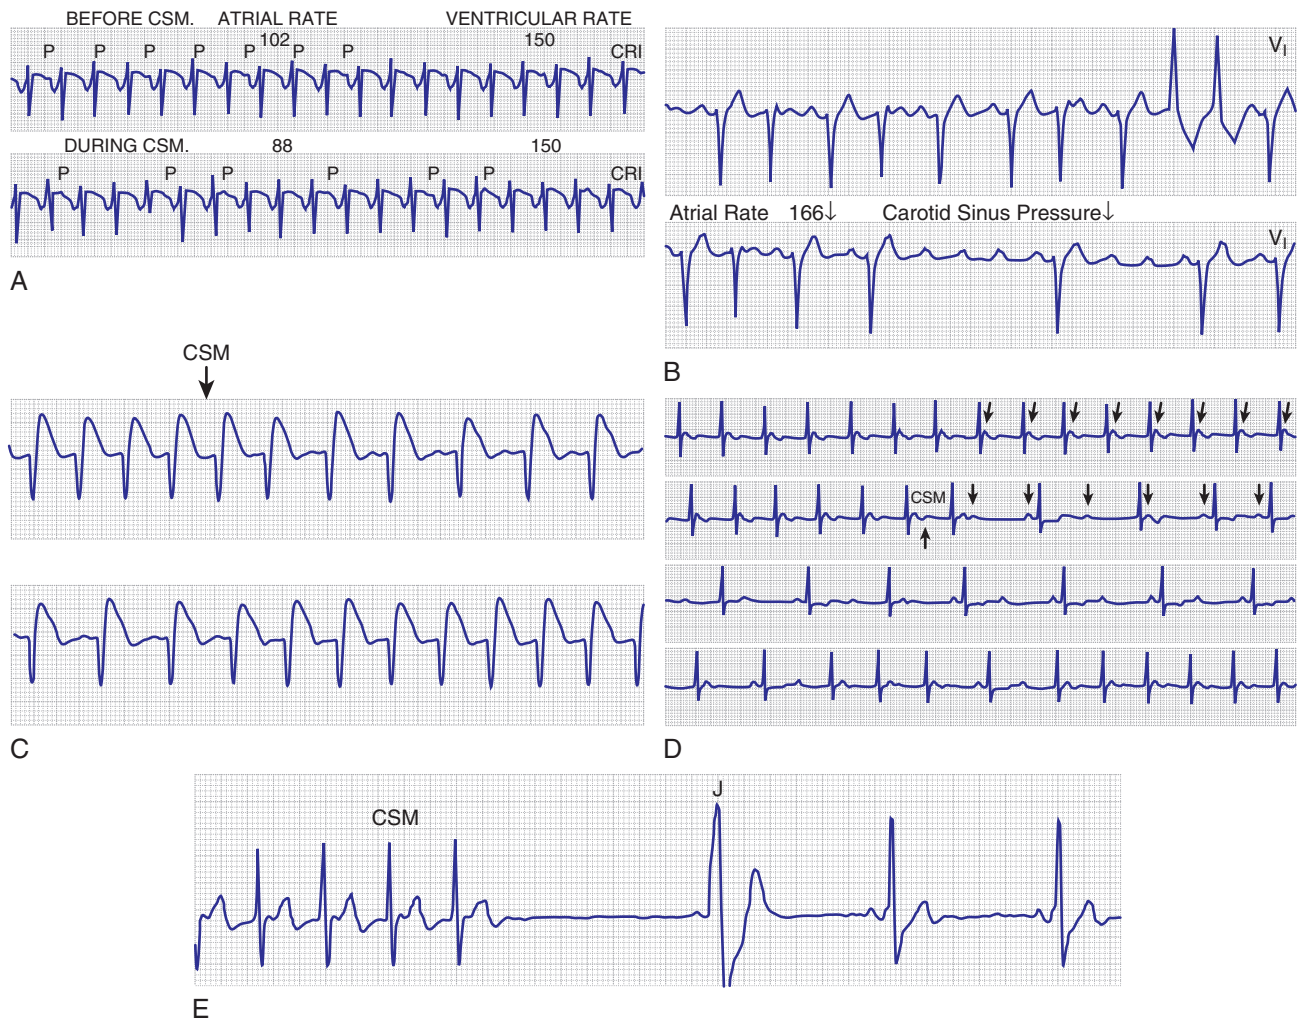

Figure 11.4 **A**, Ventricular tachycardia. Carotid sinus massage (CSM) slows the atria but not the ventricles, thus establishing the presence of atrioventricular (AV) dissociation and supporting the diagnosis of ventricular tachycardia. The QRS interval measures 0.16 sec. Note the atrial rate slowing from 102 to 88 beats/min whereas the ventricular rate is unaffected. **B**, Paroxysmal atrial tachycardia with variable block. CSM uncovers P waves hidden in the ventricular complex. The upper strip resembles atrial flutter or atrial fibrillation with ventricular ectopic beats. The lower strip shows paroxysmal atrial tachycardia with variable block at an atrial rate of 166 beats/min. **C**, Sinus tachycardia. The sinus P wave is obscured within the descending limb of the T wave. Carotid sinus massage (CSM) transiently slows the sinus rate and exposes the P wave. The rate then increases. The strips are continuous. **D**, Sinus tachycardia with a high-level block. Arrows indicate sinus P waves. Strips are continuous. The basic rhythm is sinus, but a marked first-degree AV block is present. A high-degree (advanced) AV block associated with transient slowing of the sinus rate is produced by CSM. **E**, Paroxysmal atrial tachycardia. CSM abolishes the dysrhythmia and results in a period of sinus suppression with a junctional (J) escape beat. Prolonged periods of asystole may produce anxiety in physicians waiting for the resumption of a sinus pacemaker.

channel blockers and β -blockers, the clinician can still prospectively simulate the cardioinhibitory effects of digoxin on a patient by performing vagal maneuvers. This can guide use and dosage of the medication before initiating treatment with digoxin. Significant slowing or block with CSM suggests a similar sensitivity to digoxin, and a smaller loading dose should be considered (Table 11.1).

Equipment and Setup

Before the initiation of any clinical intervention such as vagal maneuvers, administration of medication, or cardioversion for SVT, place the patient on a cardiac monitor, establish intravenous (IV) access, and infuse a slow, keep-vein-open (KVO; 60 mL/hr saline IV) solution through the IV line. Monitor the patient with a pulse oximeter and blood pressure monitor.

Effects of Carotid Sinus Massage on Various Arrhythmias

Figure 11.5 **A**, Atrial flutter. Carotid sinus massage (CSM) (*downward arrow*) produces marked slowing of the ventricular rate in atrial flutter. Note the obvious flutter waves with an atrial rate of 300 and a long period of ventricular standstill. The strips are continuous. **B**, Atrial fibrillation. CSM slows the ventricular response transiently, and thus the fibrillating baseline is revealed. The ventricular rate subsequently accelerates. **C**, Occult premature ventricular contractions. CSM reveals ventricular extrasystoles, thereby explaining the cause of palpitations in this case. **D**, A run of ventricular tachycardia is seen immediately after a supraventricular dysrhythmia is terminated by CSM. The patient remained asymptomatic, and a normal sinus rhythm was established spontaneously within a few seconds. If asystole is prolonged, ask the patient to cough vigorously (cough-induced cardiopulmonary resuscitation) or apply a precordial thump.

Figure 11.6 Hyperreactive Carotid Sinus Reflex. Gentle pressure was applied to the carotid sinus for 3 seconds, which resulted in a pause of approximately 7 seconds in sinus rhythm. This syndrome may be the cause of syncope. (From Bigger JT Jr: Mechanisms and diagnosis of arrhythmias. In Braunwald E, editor: *Heart disease*, Vol 1, Philadelphia, 1980, Saunders. Reproduced by permission.)

Keep antiarrhythmic medications readily available at the bedside. Keep a defibrillator/pacemaker at the bedside in anticipation of a worsening dysrhythmia. Administer oxygen for the procedure, especially if conscious sedation is anticipated. Place the patient in the Trendelenburg position if tolerated. Merely placing the patient in this position may terminate the SVT as a result of increased pressure on the carotids and maximum carotid bulb stimulation. This position may also prevent syncope if there is a significant decrease in blood pressure or HR.

CSM

CSM is a bedside vagal maneuver involving digital pressure on the richly innervated carotid sinus (Fig. 11.7). The procedure is likely underused by clinicians but should be routinely considered as an initial intervention. It takes advantage of the accessible position of this baroreceptor for diagnostic and therapeutic purposes. Its main therapeutic application is for termination of SVTs caused by sudden paroxysmal atrial tachycardia. It also has diagnostic utility in the assessment of

TABLE 11.1 Ventricular Response to Carotid Sinus Massage and Other Vagal Maneuvers

TYPE OF ARRHYTHMIA	ATRIAL RATE (beats/min)	RESPONSE TO CAROTID SINUS MASSAGE AND RELEASE
Normal sinus rhythm	60–100	Slowing with return to the former rate on release
Normal sinus bradycardia	< 60	Slowing with return to the former rate on release
Normal sinus tachycardia	> 100–180	Slowing with return to the former rate on release; appearance of diagnostic P waves
AV nodal reentry	150–250	Termination or no effect
Atrial flutter	250–350	Slowing with return to the former rate on release; increasing AV block; flutter persists
Atrial fibrillation	400–600	Slowing with persistence of a gross irregular rate on release; increasing AV block
Atrial tachycardia with block	150–250	Abrupt slowing with return to a normal sinus rhythm on release; tachycardia often persists
AV junctional rhythm	40–100	None; ± slowing
Reciprocal tachycardia using accessory (WPW) pathways	150–250	Abrupt slowing; termination or no effect; may unmask WPW
Nonparoxysmal AV junctional tachycardia	60–100	None; ± slowing
Ventricular tachycardia	60–100	None; may unmask AV dissociation
Atrial idioventricular rhythm	60–100	None
Ventricular flutter	60–100	None
Ventricular fibrillation	60–100	None
First-degree AV block	60–100	Gradual slowing caused by sinus slowing; return to the former rate on release
Second-degree AV block (I)	60–100	Sinus slows with an increase in block; return to the former rate on release
Second-degree AV block (II)	60–100	Slowing
Third-degree AV block	60–100	None
Right bundle branch block	60–100	Slowing with return to the former rate on release
Left bundle branch block	60–100	Slowing with return to the former rate on release
Digitalis toxicity–induced arrhythmias	Variable	Do not attempt CSM

AV, Atrioventricular; CSM, carotid sinus massage; WPW, Wolff-Parkinson-White (syndrome).

Adapted from Braunwald E, editor: *Heart disease: a textbook of cardiovascular medicine*, ed 6, Philadelphia, 2001, Saunders, p 642.

tachydysrhythmias and rate-related bundle branch blocks. In addition, it can provide clues to latent digoxin toxicity, as described previously, by potentiating manifestations of the toxicity. It can also be used to sort out the differential diagnosis of syncope.

Returning to the use of CSM as a diagnostic technique for assessing digoxin toxicity, the adverse effects and toxicity from digoxin depend more on the response of the host than on the actual digoxin level. In cases of suspected digoxin toxicity, before the digoxin level is available or when it is in the normal range, CSM may be a useful diagnostic adjunct. Significant inhibition of AV node conduction associated with ventricular ectopy, especially ventricular bigeminy, should lead to suspicion of digoxin toxicity.⁹

Contraindications

CSM is likely underused by clinicians but is contraindicated in the very rare patient likely to suffer neurologic or cardiovascular complications from the procedure. Patients with a carotid bruit should not undergo CSM because of the theoretical risk for carotid embolization or occlusion. A recent cerebral infarction is another contraindication because even a marginal reduction in cerebral blood flow may produce further infarction. Age, by itself, is not a contraindication to CSM. However, the elderly are more likely to have carotid artery disease and may experience transient and, very rarely, permanent neurologic or visual symptoms after CSM. Complications are thought to be due to transient cerebral ischemia or embolization of plaque, similar to a transient ischemic attack.

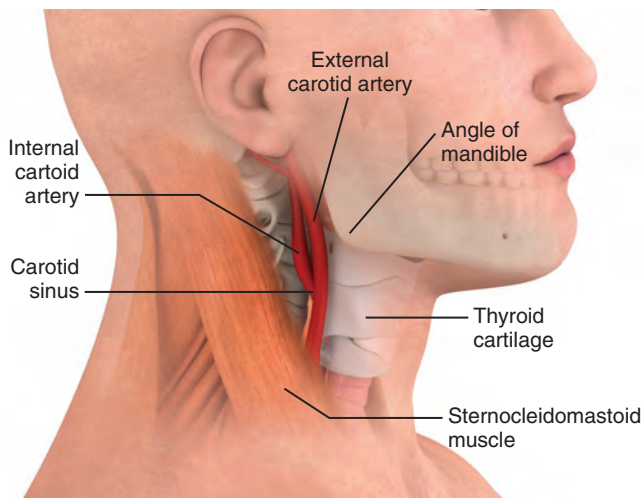

Figure 11.7 The Carotid Sinus. This baroreceptor is found just below the angle of the mandible at the upper level of the thyroid cartilage, anterior to the sternocleidomastoid muscle.

The presence of diffuse, advanced coronary atherosclerosis is associated with increased sensitivity of the carotid sinus reflex. This hypersensitivity is further augmented during an anginal attack or acute myocardial infarction. Brown and coworkers¹⁰ found that the degree of carotid sinus hypersensitivity was directly proportional to the severity of coronary artery disease as documented by cardiac catheterization. Patients with acute myocardial ischemia or with recent myocardial infarction are already at higher risk for VT or ventricular fibrillation (VF). A CSM-induced prolonged asystole may further predispose them to these dysrhythmias. Therefore CSM should be avoided in these patients.

Both digoxin and CSM act through a vagal mechanism to inhibit the AV node. Patients taking digoxin may experience greater inhibition of the AV node with a longer AV block as a result. Patients with apparent manifestations of digoxin toxicity or known digoxin toxicity should not undergo CSM because the AV inhibition may be profound.¹¹

Technique

This technique can be performed with or without a concomitant Valsalva maneuver. Alternatively, pressure can be applied to the abdomen by an assistant. Some clinicians prefer to place the patient supine or with the head of the bed tilted downward. Passively raising the supine patient's legs is an additional maneuver to be used with the Valsalva maneuver (Fig. 11.8). The use of both a Valsalva maneuver and supine position/leg raise are suggested as routine techniques. Begin CSM on the patient's right carotid bulb because some investigators have found a greater cardioinhibitory effect on this side.^{7,12,13} However, scientific agreement on this issue is not unanimous. Simultaneous bilateral CSM is absolutely contraindicated because the cerebral circulation may be severely compromised. Before attempting CSM, first auscultate for carotid bruits on both sides of the neck (Fig. 11.9, step 2). The presence of a bruit is a contraindication to massage.

Keep the patient relaxed for two reasons. A tense platysma muscle makes palpation of the carotid sinus difficult, and an anxious patient will be less sensitive to CSM as a result of heightened sympathetic tone.

Figure 11.8 Passively raising the patient's legs during Valsalva or carotid sinus massage is recommended, and may increase the probability of successful conversion.

Tilt the supine patient's head backward and slightly to the opposite side. Passively raise the legs. Palpate the carotid artery just below the angle of the mandible at the upper level of the thyroid cartilage and anterior to the sternocleidomastoid muscle (see Figs. 11.7 and 11.9, step 3). Once the pulsation is identified, use the tips of the index and middle fingers to administer CSM for 5 seconds in a posteromedial direction, aiming toward the vertebral column. Although earlier practitioners used a longer duration of massage, a shorter period minimizes the risk for complications and is adequate for diagnostic purposes in the majority of patients.¹⁴ Pressure on the carotid sinus may be steady or undulating in intensity; the force, however, must not occlude the carotid artery. The temporal artery may be simultaneously palpated to ensure that the carotid remains patent throughout the procedure.

If unsuccessful, repeat CSM after 1 minute. If the procedure is still unsuccessful, massage the opposite carotid sinus in a similar fashion. If not already performed, use simultaneous Valsalva maneuvers with the patient in the head-down position/leg raise to enhance carotid sinus sensitivity before the technique is abandoned (see Fig. 11.9, step 4). CSM may be repeated once antiarrhythmic medications (e.g., calcium channel blockers and β -blockers) have been given, and often the combination is more effective. However, repetition of CSM after the administration of adenosine is not thought to have any utility.

Complications

Neurologic complications of CSM are rare and usually transient. In a review of neurologic complications in elderly patients undergoing the procedure, Munro and associates¹⁵ found seven complications in a total of 5000 massage episodes, an incidence of 0.14%. Reported deficits included weakness in five cases and visual field loss in two others. In one case the visual field loss was permanent. Patients in this study were excluded from CSM if they had a carotid bruit, recent cerebral infarction, recent myocardial infarction, or a history of VT or VF. The duration of massage was 5 seconds. Lown and Levine⁹ described one patient with brief facial weakness during several thousand tests. Carotid emboli and hypotension have both been implicated as possible causes of the neurologic deficits. Unintentional

Carotid Sinus Massage

1 Prior to carotid sinus massage, place the patient on a cardiac monitor, initiate an IV line, and have antiarrhythmic medications and a defibrillator ready.

2 Auscultate for carotid bruits on both sides of the neck. The presence of a bruit is a contraindication to massage.

3 With the patient's head tilted backward and slightly to the opposite side, palpate the carotid pulse just below the angle of the mandible at the upper level of the thyroid cartilage and anterior to the sternocleidomastoid muscle. Once the pulsation is identified, use the fingertips to administer CSM for 5 seconds in a posteromedial direction, aiming toward the vertebral column.

4 If the initial massage is unsuccessful, repeat after 1 minute. The opposite side may be massaged in similar fashion.

Simultaneous vagal maneuvers may also be beneficial, such as the Valsalva maneuver depicted here, as might repeated massage after the administration of calcium channel or β -blockers.

Figure 11.9 Carotid Sinus Massage. CSM, Carotid sinus massage; IV, intravenous.

occlusion of the carotid artery may also be responsible for some neurologic complications.

Cardiac complications include asystole, VT, or VF. A normal pause of less than 3 seconds is part of the physiologic response to CSM; a longer pause may be diagnostic of CSS (see Fig. 11.6). In a review of reported cases of ventricular tachydysrhythmia, five cases were described.¹⁶ All five patients were receiving digoxin, and in several cases VT or VF followed AV block. Digoxin is associated with more prolonged AV block from CSM, which perhaps leaves these patients more vulnerable.

Valsalva Maneuver

In general, mean changes in bradycardia are greatest with the Valsalva maneuver and the diving response.^{17–19} During the Valsalva maneuver (i.e., exhaling against a closed glottis or bearing down as though to defecate), intrathoracic pressure increases and leads to increased arterial pressure as a result of increased afterload. It is easily done by having the patient take a deep breath, put their thumb in their mouth with closed lips, and attempt to exhale without expelling any air. This increased pressure is transferred to the peripheral vascular system. Venous

return to the heart is decreased, which results in a decrease in the SVT. This is followed by increased venous pressure. All these changes in pressure lead to an initial increase in HR and carotid sinus pressure. As the maneuver is sustained, vagal tone is increased, thereby leading to a compensatory decrease in SA and AV conduction. This is the expected or desired diagnostic or therapeutic response. There is no reason not to routinely perform a Valsalva maneuver/leg raise with CSM.

Contraindications

Patients must be able to cooperate with the clinician's commands. Dyspneic or tachypneic patients may not be able to hold their breath for the period needed to complete the maneuver.

Technique

The patient should be supine, with a cardiac monitor in place, IV access secured, antiarrhythmics available, and defibrillation available. Ask the patient to take a deep breath and hold it, or attempt to blow it out against their thumb in their mouth

encircled by closed lips. Instruct the patient to bear down and try to exhale without allowing air to leave the lungs. Passively raise the patient's legs (see Fig. 11.8). Ask the patient to try and hold this position for 10 to 20 seconds.^{20,21} An adjunctive method is to have the patient take and hold a deep breath and try to push against the clinician's hand with the abdomen while the clinician gently pushes on the anterior wall of the abdomen. Then perform CSM, first on the right side for 5 seconds. Perform CSM on the left side if this is not successful.

Apneic Facial Exposure to Cold (Diving Reflex, or Diving Bradycardia)

Technique

This technique can be viewed as a variation on the simple Valsalva maneuver. It has been found to be useful in children who may be unable to cooperate or may be incapable of performing a Valsalva maneuver. Classically, the technique consists of covering the face with a bag of crushed ice and cold water (0°C to 15°C) for 15 to 30 seconds and then observing the ECG for a break in the tachycardia. Another variation of this technique is to drip ice water into the nostril of a small child. The procedure is based on the classic diving reflex of bradycardia. Slowing the SVT to unmask the hidden, underlying

rhythm is similar to the effects of CSM. Conversion of sudden atrial tachycardia to sinus rhythm should be observed in 15 to 35 seconds. The procedure is convenient and noninvasive and can be self-administered.^{22–27}

Berk and colleagues¹² demonstrated in healthy volunteers that immersion of the face in cold water and the Valsalva maneuver can produce a greater vagal response than CSM. Lim and associates in 1998²⁸ and Mehta and coworkers in 1988¹³ also found that the Valsalva maneuver was more effective than CSM for conversion of induced SVT.

Another technique that was used, but has fallen out of favor, is direct ocular pressure. There are many contraindications to this technique, such as retinal or lens surgery, glaucoma, thrombotic-related eye conditions, and penetrating or recent blunt trauma to the eye. This procedure is no longer recommended.

Selected Pharmacologic Agents (Fig. 11.10 and Box 11.4)

After unsuccessful CSM, a pharmacologic approach to SVT is preferred in stable patients. In the presence of severe hypotension, chest pain, or other evidence of extremis, cardioversion

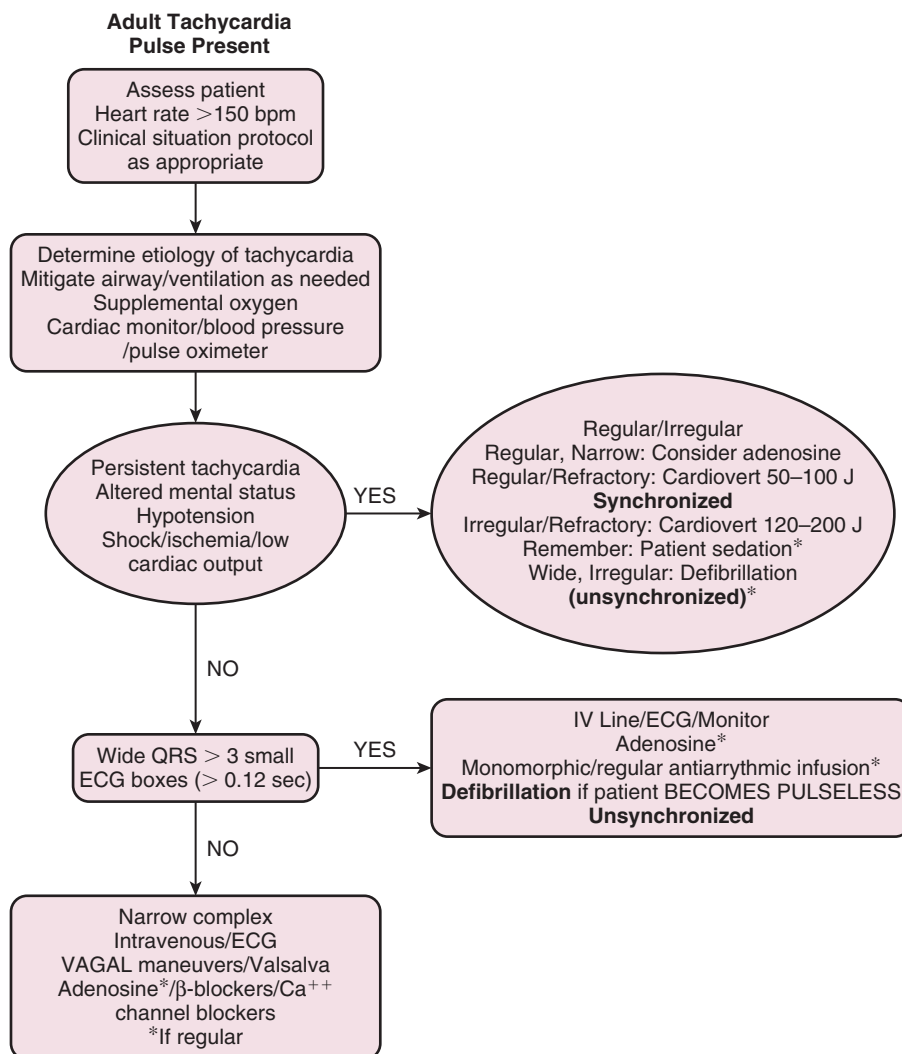

Figure 11.10 Approach to Patients in Supraventricular Tachycardia After Unsuccessful Carotid Sinus Massage. ECG, Electrocardiogram; IV, intravenous.

BOX 11.4 Electric and Chemical Cardioversion**ENERGY SETTINGS FOR CARADIOVERSION (SYNCHRONIZED)****Narrow Complex (< 0.12 sec)**

Regular rhythm: 50–100 Joules (biphasic).

Irregular rhythm: 120–200 Joules (biphasic).

Wide Complex (> 0.12 sec)

Regular rhythm: 100 Joules (biphasic).

Irregular rhythm: 120–200 Joules (biphasic). If patient is pulseless with wide irregular rhythm defibrillate unsynchronized at 200 Joules.

ANTIARRHYTHMIC MEDICATIONS**Adenosine**

Initial dose: 6 mg rapid IV push (flush with saline).

Repeat dose: 12 mg rapid IV push (flush with saline).

Procainamide (contraindicated in CHF or prolonged QT)

Initial dose: 20–50 mg/min IV infusion. (Endpoints for administration: termination of arrhythmia, hypotension, QT prolongation by 50%, or maximum dose of 17 mg/kg administered.)

Maintenance dose: 1–4 mg/min.

Amiodarone

Initial dose: 150 mg IV over 10 minutes.

Repeat dose: 150 mg IV over 10 minutes.

Maintenance dose: 1 mg/min for 6 hours.

Sotalol (contraindicated in prolonged QT)

Initial dose: 1.5 mg/kg over 5 minutes.

CHF, Congestive heart failure.

is the preferred intervention. In unusual circumstances, such as rapid AF in patients with known Wolf-Parkinson-White (WPW) syndrome, certain medications should be used with caution, and cardioversion may be considered the first-line intervention.

Adenosine

The use of vagal maneuvers has been eclipsed in recent years by the use of adenosine, an endogenous, ultrashort-acting, vagal-stimulating purine nucleoside that is ubiquitous in body cells. Its action is to slow conduction time through the AV node and depress the AV node. If vagal maneuvers have been attempted and failed to produce the desired response, use of adenosine is an appropriate subsequent intervention.

Extracellular adenosine is cleared rapidly from the circulation by the erythrocyte and vascular endothelium system that transports adenosine intracellularly. Here, rapid metabolism via a phosphorylation or deamination cycle produces inosine or adenosine monophosphate. Adenosine produces a short-lived pharmaceutical response because it is metabolized rapidly by the described enzymatic degradation. The half-life of adenosine is less than 10 seconds, with the metabolites becoming incorporated into the high-energy phosphate pool.^{29–32}

Indications and Contraindications

Most forms of paroxysmal supraventricular tachycardia (PSVT) affect a reentry pathway involving the AV node, and adenosine

Figure 11.11 Treatment of Supraventricular Tachycardia (SVT) With Adenosine. **A**, Because of its ultrashort half-life (< 10 seconds), adenosine must be given rapidly, followed by a 20-mL saline flush. **B**, Adenosine slows conduction through the atrioventricular node, thereby effectively converting SVT (left side of the screen) to sinus rhythm (right side of the screen).

depresses the AV node and sinus node activity. Adenosine is indicated for the conversion of PSVT associated with or without accessory tract bypass conduction (WPW, Lown-Ganong-Levine [LGL]). The other use of adenosine is for diagnostic slowing of SVT to unmask AF, atrial flutter, or VT. The diagnostic and therapeutic effects of adenosine on tachyarrhythmias are similar to those elicited by vagal maneuvers. Adenosine's safety is derived from its short duration of action, usually approximately 10 to 12 seconds.

Adenosine should not be used in patients with a known history of second- or third-degree AV block or sick sinus syndrome unless there is a functioning internal pacer. Additionally, if the patient has a known hypersensitivity to adenosine or a history of severe reactive airway disease or active wheezing, the drug should not be used. In addition, adenosine should not be used in patients with an underlying accessory pathway (WPW, LGL) in the setting of AF. In this circumstance, the HR may increase because the enhanced AV node blockade permits conduction through the bypass tract.

Dosage

The initial dose recommended is a 6-mg rapid bolus administered over a period of 1 to 3 seconds. The dose should be immediately followed by a 20-mL saline flush (Fig. 11.11). If no response occurs within 1 to 2 minutes, a 12-mg dose should be administered in the same manner as the initial dose. This second dose should also be followed by a 20-mL saline bolus.

Side effects of adenosine are common and transient. Many patients experience a rather unsettling feeling, and this should

be explained to the patient before administering the drug. Common sensations include flushing, dyspnea, and chest pain. Important drug interactions include theophylline or related methylxanthines (caffeine and theobromine), which can block adenosine receptor sites. If these medications are being taken by the patient, administer a larger dose of adenosine. If the patient is taking dipyridamole or carbamazepine, these drugs may block uptake of adenosine and potentiate its effects, so contemplate administering a smaller IV dose of adenosine (e.g., 3 mg).³³ Adenosine is safe and effective in pregnancy.³⁴ Also, if the patient has a central line or a transplanted heart, try an initial 3-mg dose.

Procainamide

A time-honored antiarrhythmic, procainamide slows conduction and decreases the automaticity and excitability of atrial, ventricular, and Purkinje tissue. It also increases refractoriness in atrial and ventricular tissue. Procainamide prolongs the QT interval without having much effect on Purkinje fibers or ventricular tissue.³³

Indications and Contraindications

A long-established clinical application is for management of the rate of SVT, SVT with aberrant conduction (wide-complex SVT), AF or atrial flutter associated with WPW conduction, and VT. The advantage of using procainamide is the ability to convert to the oral form when rate control is achieved. The dose of procainamide recommended by advanced cardiac life support is usually 20 mg/min, although in urgent situations up to 50 mg/min can be used. Procainamide is generally used in clinical situations in which time is not a factor in patient care. Long-term management in the emergency department necessitates monitoring of the plasma concentrations of procainamide and its N-acetylprocainamide metabolite. Hypotension and conduction disturbances (torsades de pointes, heart block, and sinus node dysfunction) are often signs of high plasma levels. Use caution in patients with a history of hypokalemia, long QT intervals, and torsades de pointes. Hematologic and rheumatologic disturbances are factors in long-term use. The endpoint of administration of the drug is when the arrhythmia is suppressed, hypotension occurs, the QT duration increases by 50% over baseline, or a maximum of 17 mg/kg of the drug has been administered (1.2 g in a 70-kg adult).²⁹

Amiodarone

Amiodarone has become one of the workhorses for treatment of dysrhythmias in the emergency department. It is often considered a Vaughan-Williams class III drug because it is a potassium channel blocker. However, this medication also blocks sodium and calcium channels and α - and β -adrenergic receptors. As a result of its potassium-blocking properties, amiodarone prolongs the action potential duration and increases refractoriness of the atrial and ventricular tissue, the sinus and AV nodal tissue, and Purkinje fibers. Amiodarone also blocks sodium channels in depolarized tissue. It slows depolarization in the SA node and slows conduction through the AV node. Its calcium antagonist effect is minimal.^{11,30,31,35}

Indications and Contraindications

Amiodarone is used for the control of narrow-complex supraventricular and ventricular dysrhythmias. It is useful in the management of narrow-complex tachycardias that originate from a reentry rhythm (SVT). It is effective in the conversion

of stable wide-complex tachycardias and is useful in managing polymorphic VT with a normal QT interval. Amiodarone can be used for wide-complex tachycardias of undetermined origin. This drug can also be used for the management of AF and atrial flutter with aberrancy, SVT with accessory pathway conduction, and the rare adult junctional tachycardia. Another use for this medication is control of the rapid ventricular rate as a result of accessory pathway conduction in preexcited atrial arrhythmias. It is a strong second-line choice with procainamide for hemodynamically stable VT.

Its use can precipitate heart failure, hypotension, and severe bradycardia. When used with β -blockers and calcium channel blockers, amiodarone can have the added risk of hypotension and bradycardia. Torsades de pointes has been reported after the use of amiodarone in conjunction with drugs that have increased the QT interval. In addition, amiodarone should not be used in the presence of AF with accessory pathways; there are multiple case reports of patients decompensating after receiving IV amiodarone when it was used for rapid AF plus WPW syndrome.³⁶⁻⁴¹ In the setting of possible AF with an accessory pathway, procainamide is safer. Finally, note that amiodarone will also prolong the QT interval, so it is best to avoid this drug in patients with a preexistent long QT interval, just like procainamide.

Dosage

The IV dosage is 150 mg administered over a 10-minute period. Follow this with a 1-mg/min infusion for 6 hours and then a 0.5-mg/min maintenance infusion over an 18-hour period. If a dysrhythmia is refractory or resistant, 150 mg can be repeated every 10 minutes to a maximum of 2.2 g/24 hr.³⁶⁻⁴¹ The major adverse effects of amiodarone are bradycardia and hypotension.

β -Adrenergic Blockade

β -Blockers are very useful agents for control of the ventricular response in patients with PSVT, AF or atrial flutter, and atrial tachycardia. No β -blocker offers a distinctive advantage over another because when used clinically, they can all be titrated to a desired effect on dysrhythmias and hypertension. Examples of β -blockers are atenolol, metoprolol, propranolol, and esmolol. Recently sotalol IV has been added to the *AHA 2015 Adult Tachycardia with a pulse algorithm* (more information later). Separating the different drugs and their use is the various pharmacologic characteristics that control adverse reactions, speed of onset, dosage regimens, contraindications, and drug interactions.

The electrophysiologic effect of β -blockers results from inhibition of binding of catecholamine at β -receptor sites. These medications reduce the effects of circulating catecholamines and this is manifested as a decrease in HR, blood pressure, and myocardial contractility. The PR interval may be prolonged, but the QRS and QT intervals are not affected. Their actions are most noted on cells that are most stimulated by adrenergic actions. Typically, these sites are the sinus node, the Purkinje fibers, and ventricular tissue when it is stimulated by catecholamines.^{17,30,31,42} These medications also have various cardioprotective effects in patients suffering from acute coronary syndromes. They exert their cardioprotective effects by decreasing myocardial workload, and hence they decrease myocardial oxygen consumption and demand.¹⁷ β -Blockers are useful in the treatment of narrow-complex tachycardias that originate secondary to a reentry phenomenon or an automatic focus (MAT, an ectopic pacemaker, or a junctional rhythm). These drugs can also be used to control rates in patients suffering from

AF or atrial flutter, as long as ventricular function is nominal. Some representative doses of these β -blockers are: (1) atenolol (β_1), 5 mg IV slowly over a period of 5 minutes; if no effect, repeat in 10 minutes; (2) metoprolol (β_1), 5 mg IV slowly, may repeat up to 15 mg total; and (3) propranolol, 0.1 mg/kg IV by slow push and divided into three equal doses at 2- to 3-minute intervals; the total dose may be repeated in 2 minutes. The administration rate of the drug should not exceed 1 mg/min.

In general, β -blockers should not be used in patients with diabetes, lung disease, bradycardia, or heart block; in conjunction with a calcium channel blocker; in patients with hypotension; or in the presence of a vasospastic condition. β -Blockers should also not be used in patients with AF in the presence of bypass tracts, as is true for the calcium channel blockers, adenosine and amiodarone.

Propranolol

Propranolol is the representative drug of the β -adrenergic blockade agents. It is nonselective and has β_1 and β_2 effects on the heart, which allows it to be used to control rapid ventricular rates. Rate slowing is caused by: (1) slowing of impulse formation in the SA node, and (2) depression of myocardial contractility. The usual effects on the ECG are rate reduction and prolongation of the PR interval. The QRS and QT intervals are not affected. Because it is relatively nonselective (it has effects on both β_1 and β_2 receptors), its contraindications are extensive.^{30,42,43}

Sotalol

Sotalol is a nonselective competitive β -adrenergic receptor blocker which manifests class III antiarrhythmic activity. This drug is now used to mitigate life-threatening VT and VF.

Its utility is providing the clinician with the ability to control symptomatic AF or atrial flutter. Use of the drug can be considered if the Valsalva maneuver does not resolve the AF or atrial flutter.

This medication should NOT be used in patients with significant bradycardia (HR < 50 beats/min), sick sinus syndrome, prolonged QT syndrome, cardiogenic shock, uncontrolled congestive heart failure, or those with respiratory issues such as bronchospasm or asthma. Also avoid its use in higher level blocks such as a second- or third-degree heart block. It can be used cautiously if the patient has a pacemaker.

Sotalol is excreted via the kidneys, therefore the clinician needs to be aware of the patient's creatinine clearance (> 40 mL/min) if this medication is to be considered.

Use caution when using this medication with a breastfeeding female as sotalol passes into the breast milk.

If possible, avoid using this drug in combination with calcium channel blockers, catecholamine-depleting medications, medications used to treat diabetes, β_2 -adrenergic agonists, and clonidine.

Some side effects of this medication are light-headedness, weakness, headache, fatigue, dizziness, and dyspnea. In addition, this drug can precipitate significant bradycardia. Due to the QT prolongation this drug produces, there is a potential proclivity for the development of torsades de pointes.

This medication blocks the β receptors, and prevents activation of the G-protein complex. This leads to a dearth in the production of cyclic adenosine monophosphate. As a result, normal calcium metabolism is derailed in the myocytes, causing a slowing of the HR and a decrease in the inotropic state of the heart, thus decreasing force of contraction and

potentially SV. In addition, this medication blocks potassium channels in the myocardium and prolongs the refractoriness of the heart to another excitatory impulse, potentially quelling the tachycardia.

Dosage. The dosing of sotalol is quite simple. The American Heart Association (AHA) recommends that 100 mg IV (1.5 mg/kg) be administered over 5 minutes.

The following drugs and medications are available and can be used at the discretion of the physician, depending on the clinical scenario and expert consultation. These medications are available and still in use by many clinicians.

The aforementioned medications are 2015 AHA recommendations.

Esmolol

Esmolol is a rapid-, short-acting, β_1 -selective (cardioselective) β -blocker. At therapeutic doses, it inhibits β_1 receptors in cardiac muscle. At higher doses, its selectivity is lost and it affects β_2 receptors in the lung and vascular system. Esmolol is rapidly metabolized in erythrocytes and has a half-life of approximately 2 to 9 minutes. Its elimination half-life is approximately 9 minutes.^{31,35}

The complicated dosing regimen of esmolol makes it more difficult to use.

Indications and Contraindications. Esmolol is indicated for the rapid conversion of SVT and rapid control of the ventricular rate in patients with non-preexcited AF or atrial flutter. In addition, it can be used to control the rate of noncompensated sinus tachycardia when the clinician believes that the tachycardia requires slowing. It has also proved beneficial as adjunctive therapy for the VT of torsades de pointes.^{31,33,35,42} Esmolol should not be used in patients with second- or third-degree heart block or in frank heart failure. Like all β -blockers, exercise care when using this drug in patients with bronchospastic disease and diabetes.

Dosage. Esmolol has a complicated dose regimen. First, give a loading dose of 0.5 mg/kg over the first 1 minute. Follow this with a maintenance infusion of 50 μ g/kg per minute over a 4-minute period. If this is not successful, administer a second bolus dose of 0.5 mg/kg followed by a maintenance infusion of 100 μ g/kg over a 4-minute period. The bolus/maintenance dosing can be repeated up to a maximum infusion rate of 300 μ g/kg per minute for 4 minutes.^{31,35,42} Similar dosing has been recommended for children: a 100- to 200- μ g/kg maintenance rate between 100- μ g/kg increases in bolus doses.³¹

Calcium Channel Blockers

Diltiazem

Diltiazem is a nondihydropyridine calcium channel blocker. It controls the rate of influx of calcium into myocytes during depolarization. This calcium channel blocker slows conduction of impulses through the AV node and prolongs the refractory period of the AV node. As a result, this drug is capable of terminating reentry-based tachycardias that have not converted with the use of adenosine or vagal maneuvers, and it can be used to control the ventricular response rate in a variety of SVTs (AF, atrial flutter). In addition, diltiazem can be used for the treatment of stable, narrow-complex tachycardias that are driven by automaticity (e.g., ectopic, multifocal, or junctional tachycardias). Its effects on AV nodal tissue are selective in

that it reduces AV conduction in tissue responsible for the tachydyrhythmia but spares normal conduction tissue.^{31,35,42,44}

Indications and Contraindications. The beneficial effects of diltiazem are: (1) ventricular slowing of rapid AF or atrial flutter without accessory bypass conduction, and (2) rapid conversion of narrow-complex PSVT to sinus rhythm.^{30,33,35,44,45}

Diltiazem is contraindicated in the following settings: (1) sick sinus syndrome, second-degree block, and third-degree block, except in the presence of an internal pacer; (2) severe hypotension or cardiogenic shock; (3) hypersensitivity to diltiazem; (4) use of IV β -blockade within a few hours of needing to use diltiazem; (5) AF or atrial flutter with coexisting accessory bypass tract conduction (WPW, LGL); and (6) VT.

Dosage. Give an initial dose of 0.25 mg/kg followed by a repeated dose of 0.35 mg/kg. Start a maintenance infusion of 5 to 15 mg/hr.^{11,33,35,44} Consider pretreating with IV calcium if the patient is hypotensive (see later).

Verapamil

Verapamil is also a calcium channel blocker. This medication blocks the slow channel for entry of calcium into myocytes. Verapamil blocks not only the calcium channels in the specialized conduction tissue of the myocardium but also the contracting cells of the heart. As a result, verapamil prolongs the effective refractory period within the AV node and slows conduction.^{17,42} It also has a modest effect on myocardial contractility.¹⁷

Indications and Contraindications. Verapamil is effective in: (1) converting narrow-complex PSVT to normal sinus rhythm, and (2) controlling the ventricular response in AF or atrial flutter if the AF or atrial flutter is not complicated by the presence of an accessory bypass tract (WPW, LGL). With specific regard to WPW syndrome and rapid AF, caution is advised with the use of verapamil. However, verapamil has been reported to be safe in those with overt or concealed accessory conduction pathways.⁴⁶

Verapamil should not be used or be used with caution in the following settings: (1) PSVT with accessory bypass tract conduction, (2) AF or atrial flutter with accessory bypass tract conduction (WPW syndrome), (3) coexistence of sick sinus syndrome or second- or third-degree AV block unless an internal pacer is present, (4) severe left ventricular dysfunction (systolic blood pressure < 90 mm Hg) or cardiogenic shock, and (5) patients with known verapamil hypersensitivity.^{1,30,31,35,42,44} Because of its prolonged activity, verapamil should be used with caution in patients with congestive heart failure.

In the presence of SVT, hypotension may be caused by the negative inotropic and vasodilating effects of verapamil. Administration of calcium before IV verapamil results in a decreased incidence of hypotension without compromising the effectiveness of channel blockers. The most common adverse effect of IV calcium is flushing. Use of digoxin does not contraindicate calcium pretreatment. A pre-verapamil dose of calcium gluconate, 1 g (ionized calcium, 90 mg) administered over a period of 3 minutes, is recommended for preventing or lessening the hypotensive effect of verapamil without affecting its antiarrhythmic effects.⁴⁷

Dosage. Administer 2.5 to 5 mg IV over a 1- to 2-minute period. It may be repeated every 10 minutes to a maximum of 15 to 20 mg total. Pretreatment with calcium (calcium

gluconate, 1 g IV over a period of 2 to 3 minutes) is suggested in hypotensive patients.

Digoxin

Digoxin was a time-honored drug used for the treatment of AF and atrial flutter. It is the only antidysrhythmic with inotropic characteristics. Digoxin is less useful for the emergency clinician because of its long delay of onset.

Digoxin is a cardiac glycoside found in a number of plants. It is extracted from the leaves of *Digitalis lanata*. Digoxin increases intracellular Na^+ and K^+ by inhibiting sodium-potassium adenosine triphosphatase, the enzyme that regulates the quantity of Na^+ and K^+ inside the cell. An intracellular increase in Na^+ stimulates Na^+ - Ca^+ exchange, which leads to increased intracellular Ca^+ . Digoxin acts both directly on cardiac muscle and indirectly on the cardiovascular system. The indirect effects are mediated by the autonomic nervous system. The results of these actions are vagomimetic effects on the SA node and the AV node.

The consequences of these actions are: (1) increased force and velocity of myocardial contraction (positive inotropic effect), (2) slowing of HR and AV nodal conduction (vagomimetic effect), and (3) a decrease in symptomatic nervous system effects (neurohormonal-deactivating effect).^{29,30,48-51}

Indications and Contraindications

Although its use in controlling the ventricular response rate in chronic AF is well established, digoxin is no longer the mainstay of therapy for narrow-complex tachycardias, as it has been replaced by newer agents. Its inotropic character is still widely used in the setting of heart failure.

Use of digoxin should be avoided in the clinical settings of sinus node disease and AV blockade. It may cause complete heart block or severe sinus bradycardia. Do not use digoxin in patients with accessory bypass tract rhythms (WPW or LGL). It may cause a rapid ventricular response or VF. Patients with idiopathic hypertrophic subaortic stenosis, restrictive cardiomyopathy, constrictive pericarditis, or amyloid heart disease are particularly susceptible to digoxin toxicity.⁵²

Dosage

Give an IV loading dose of 10 $\mu\text{g}/\text{kg}$ to 15 $\mu\text{g}/\text{kg}$, followed by individual parenteral dosing until the desired rate is achieved.^{29-31,33,42,53-56}

Electrical Cardioversion

Because it is more complicated, electrical cardioversion is usually considered after failure of medications, but it is successful in the majority of SVTs. In life-threatening or unstable situations, patients in AF are to be immediately cardioverted because the risk for continued AF outweighs the risk for thromboembolism.^{35,57-65} Cardioversion is specifically indicated when the patient is unstable; that is, a change in mental status occurs, the patient becomes hypotensive, ischemic chest pain develops, heart failure develops, or the ventricular rate exceeds 140 to 150 beats/min.⁴² Urgent restoration of normal rhythm in patients with symptomatic new-onset AF is best achieved by direct cardioversion with either a monophasic or a biphasic defibrillator. Success rates with biphasic defibrillators are reported to be approximately 94% to 95%.⁶⁶⁻⁶⁸ The cardioversion procedure is discussed in greater detail in Chapter 12. A brief synopsis, algorithm, and flow chart is included (see Fig. 12.18) to facilitate cardioversion.

Current guidelines for the treatment of symptomatic new-onset AF focus on the length of time that the patient has been in AF or atrial flutter. This is the determining factor for the initiation of anticoagulation when confronted by the need for cardioversion to sinus rhythm. Accordingly, onset within 48 hours or less has been determined to be the time limit that a patient with new-onset AF can undergo cardioversion without the need for anticoagulation. Studies have shown that staying under the 48-hour limit allows cardioversion to occur with the lowest risk for thromboembolism.^{35,58,63,72} Patients who have been in AF for longer than 48 hours and are not in need of urgent care need to undergo anticoagulation to an international normalized ratio (INR) of 2.0 to 3.0 for a 3-week duration before cardioversion.⁴³ If this approach is not clinically acceptable, transesophageal echocardiography (TEE) should be performed in addition to heparinization.

If no clot in the left atrial appendage is visualized on TEE, the heparinized patient should immediately undergo cardioversion and take anticoagulants for the next 4 weeks. If a clot is visualized in the left atrial appendage, the patient should first

be anticoagulated to an INR of 2.0 to 3.0 for 3 weeks before cardioversion^{73–77} (Boxes 11.5 and 11.6).

An alternative treatment strategy with a reported success rate of 50% to 70% is ibutilide in a bolus IV infusion. Be cautious when using ibutilide in patients with prolonged QT

BOX 11.5 Recommendations for Pharmacologic and Electrical Cardioversion of Atrial Fibrillation

1. Immediate electrical cardioversion is advised in patients with paroxysmal AF and a rapid ventricular response who have ECG evidence of acute MI or symptomatic hypotension, angina, or heart failure that does not respond promptly to pharmacologic measures.
2. Cardioversion is suggested in patients without hemodynamic instability when the symptoms of AF are unacceptable.

AF, Atrial fibrillation; ECG, electrocardiogram; MI, myocardial infarction.

BOX 11.6 Recommendations for Antithrombotic Therapy to Prevent Ischemic Stroke and Systemic Embolism in Patients With Atrial Fibrillation Undergoing Cardioversion

1. For patients with AF lasting 48 hours or longer or of unknown duration for whom pharmacologic or electrical cardioversion is planned, we recommend anticoagulation with an oral vitamin K antagonist (VKA), such as warfarin, to a target INR of 2.5 (range, 2.0 to 3.0) for 3 weeks before elective cardioversion and for at least 4 weeks after sinus rhythm has been maintained.
 - *Remark:* This recommendation applies to all patients with AF, including those whose risk factor status would otherwise indicate a low risk for stroke. Patients with risk factors for thromboembolism should continue anticoagulation beyond 4 weeks unless there is convincing evidence that sinus rhythm is maintained.
2. For patients with AF lasting 48 hours or longer or of unknown duration who are undergoing pharmacologic or electrical cardioversion, we recommend either immediate anticoagulation with IV unfractionated heparin (target PTT, 60 seconds; range, 50 to 70 seconds) or LMWH (at full DVT treatment doses) or at least 5 days of warfarin (target INR, 2.5; range, 2.0 to 3.0) at the time of cardioversion and performance of screening multiplane TEE. If no thrombus is seen, cardioversion is successful, and sinus rhythm is maintained, we recommend anticoagulation (target INR, 2.5; range, 2.0 to 3.0) for at least 4 weeks. If a thrombus is seen on TEE, cardioversion should be postponed and anticoagulation should be continued indefinitely. We recommend performing TEE again before attempting later cardioversion (all grade 1B addressing the equivalence of TEE-guided versus non-TEE-guided cardioversion).
 - *Remark:* The utility of the conventional and TEE-guided approaches is probably comparable. This recommendation applies to all patients with AF, including those whose risk factor status would otherwise indicate a low risk for stroke. Patients with risk factors for thromboembolism should continue anticoagulation beyond 4 weeks unless there is convincing evidence that sinus rhythm is maintained.
3. For patients with AF of known duration and shorter than 48 hours, we suggest that cardioversion be performed without

prolonged anticoagulation. However, in patients without contraindications to anticoagulation, we suggest beginning IV heparin (target PTT, 60 seconds; range, 50 to 70 seconds) or LMWH (at full DVT treatment doses) at initial encounter.

- *Remark:* In patients with risk factors for stroke, it is particularly important to be confident that the duration of AF is less than 48 hours. In such patients with risk factors, a TEE-guided approach is a reasonable alternative strategy. Postcardioversion anticoagulation is based on whether the patient has experienced more than one episode of AF and on the patient's risk factor status.
4. For emergency cardioversion in a hemodynamically unstable patient, we suggest that IV unfractionated heparin (target PTT, 60 seconds; range, 50 to 70 seconds) or LMWH (at full DVT treatment doses) be started as soon as possible, followed by at least 4 weeks of anticoagulation with an oral VKA, such as warfarin (target INR, 2.5; range, 2.0 to 3.0), if cardioversion is successful and sinus rhythm is maintained.
 - *Remark:* Long-term continuation of anticoagulation is based on whether the patient has experienced more than one episode of AF and on the patient's risk factor status.
 5. For cardioversion of patients with atrial flutter, we suggest the use of anticoagulants in the same way as for cardioversion of patients with AF (grade 2C).

ADDITIONAL GUIDELINES^c

1. Strict heart rate control in patients with AF is not more beneficial than lenient control.
2. The antiplatelet drug clopidogrel, plus aspirin, might be considered to reduce the risk for major vascular events, including stroke in patients who are poor candidates for the anticoagulant drug warfarin.
3. Catheter ablation is useful to maintain normal sinus rhythm in patients with AF.

AF, Atrial fibrillation; DVT, deep venous thrombosis; INR, international normalized ratio; IV, intravenous; LMWH, low-molecular-weight heparin; MI, myocardial infarction; PTT, partial thromboplastin time; TEE, transesophageal echocardiography.

intervals or severe left ventricular dysfunction. Ibutilide has a 4% risk for ventricular arrhythmia. Pretreatment with ibutilide before electrical cardioversion can increase the chance for successful conversion to nearly 100%.^{29,30,42,78–81}

CONCLUSION

The advent of β -blockers, calcium channel blockers, adenosine, amiodarone, and other effective medications to treat tachydysrhythmias, particularly SVT, has diminished the therapeutic use of vagal maneuvers. However, the vagal maneuvers still

remain an important diagnostic tool and are routinely used prior to medications. Vagal maneuvers are especially important in unmasking the underlying rhythms of narrow-complex tachydysrhythmias and in determining the presence of CSS in patients with syncope.

The advent and availability of medications that quickly and safely control the rate of tachydysrhythmias has given the emergency clinician a more varied and powerful armamentarium to be used in cardioverting these life-threatening dysrhythmias to normal sinus rhythm.

Defibrillation and Cardioversion

Bohdan M. Minczak and Glenn W. Laub

INTRODUCTION

Defibrillation is an emergency procedure performed to terminate ventricular fibrillation (VF) (Fig. 12.1A). VF is a potentially lethal, but survivable, rhythm commonly found in victims of sudden cardiac arrest (SCA).^{1,2} VF can be caused by myocardial infarction, myocardial ischemia, undiagnosed coronary artery disease, and electrical injuries. Medications such as tricyclic antidepressants, digitalis, quinidine, and other proarrhythmics can cause QT-segment prolongation and changes in the refractory period of the cardiac cycle that are capable of precipitating VF. Furthermore, chest trauma, hypothermia, cardiomyopathy, electrolyte disturbances, and various toxidromes can induce conditions favoring the development of VF. Hypoxia is another culprit that frequently precipitates VF in adults and the pediatric population. Congenital malformations of the heart and great vessels have also been associated with an increased incidence of VF in young children. The most effective treatment of VF in its early phase is defibrillation.³ It can also be used to terminate pulseless ventricular

tachycardia (VT) (see Fig. 12.1B). Patients with VF or pulseless VT are unresponsive, pulseless, and apneic. These patients sometimes require appropriate integration of cardiopulmonary resuscitation (CPR) with defibrillation to establish the return of spontaneous circulation (ROSC). Other dysrhythmias may also be encountered in patients with SCA, such as pulseless electrical activity (PEA) and even asystole; however, in this chapter the discussion is limited to the treatment of VF and pulseless VT.

Defibrillation entails passing a therapeutic burst of electrical current across the chest wall through the myocardium for the purpose of terminating the chaotic electromechanical activity that is impeding the ventricles from ejecting blood into the circulation (Fig. 12.2). Failure to recognize and terminate VF promptly makes suppression of VF via defibrillation more difficult.⁴ For every minute that the heart is in VF without treatment, the potential for the initial defibrillation to be successful and for the victim of SCA to survive decreases by 7% to 10%.⁵ However, the integration of CPR with defibrillation, when appropriate, increases the chance for successful defibrillation and survival from SCA.⁶

Cardioversion is performed to suppress dysrhythmias that produce a rapid pulse and cause the patient to become unstable; such dysrhythmias include supraventricular tachycardia (SVT), atrial fibrillation (AF), atrial flutter, and unstable monomorphic VT (Fig. 12.3). These patients do have a pulse, albeit weak, but can rapidly decompensate, become hypotensive, experience chest pain, or have a change in mental status that will require rapid intervention (i.e., cardioversion). CPR is obviously not indicated because these patients have a pulse and their peripheral tissues are being perfused. Cardioversion is very similar to defibrillation; however, the shock is administered during the

Defibrillation and Cardioversion

Indications

Defibrillation

- Ventricular fibrillation
- Pulseless ventricular tachycardia

Cardioversion (usually reserved for unstable rhythms)

- Ventricular tachycardia with a pulse
- Supraventricular tachycardia
- Atrial fibrillation
- Atrial flutter

Contraindications

Defibrillation

- Presence of a pulse
- Asystole or pulseless electrical activity
- Obvious signs of death
- Valid do-not-resuscitate order

Cardioversion

- Arrhythmias due to digitalis toxicity
- Sinus tachycardia

Complications

- Chest wall burns
- Shock of a health care worker
- Myocardial tissue injury

Equipment

Cardiac monitor/defibrillator
(other supportive equipment not shown)

Review Box 12.1 Defibrillation and cardioversion: indications, contraindications, and equipment.

Figure 12.2 During ventricular fibrillation, chaotic electromechanical activity prevents the ventricle from ejecting blood into the circulation. Defibrillation passes a therapeutic burst of current through the myocardium and terminates this activity.

refractory period of the cardiac cycle. This is accomplished by setting the defibrillator to the synchronized mode (Videos 12.1, 12.2, and 12.3).

The shock is delivered in similar fashion; however, the defibrillator discharges at a particular point in the cardiac cycle. Failure to set the synchronized defibrillator controls properly can result in the conversion of a perfusing rhythm to a non-perfusing rhythm, thereby leaving the patient pulseless.

PRINCIPLES OF RESUSCITATION

The clinical approach to cardiac resuscitation is an evolving and dynamic endeavor, and guidelines frequently change or

A

B

C

Figure 12.3 Atrial dysrhythmias. A, Supraventricular tachycardia. B, Atrial fibrillation. C, Atrial flutter.

are altered. Recommendations from the American Heart Association (AHA) are considered the most reasonable guidelines for the clinician, but many of the principles and caveats are based on minimal data, can be contradictory, and are subject to change; more importantly, any guideline is best applied by considering a specific clinical scenario. Most recently, cardiac resuscitation has been reviewed and new AHA guidelines were released in 2010.⁷⁻¹⁰ On the basis of the strength of the evidence available, the AHA developed recommendations to support the interventions that showed the most promise. The new algorithms reflect alterations in the sequence of actions to be performed and stress high-quality CPR with compressions of adequate rate and depth that allow complete chest recoil after compressions, minimize interruptions in chest compressions, and avoid excessive overventilation. These modifications stress the interposition of effective CPR (Fig. 12.4) with defibrillation and have been organized in such a way that the time until the first shock is minimized and time to initiation of effective chest compressions is not unnecessarily delayed.

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY

The normal human heart rate (HR) is approximately 80 (± 20) beats/min. With each beat the heart ejects a stroke volume (SV) of approximately 70 to 80 mL of blood from each ventricle. Multiplying HR by SV produces a value termed cardiac output (CO) (i.e., $HR \times SV = CO$). The product of CO times total peripheral resistance (TPR) produces the value for mean arterial blood pressure (MABP) (i.e., $CO \times TPR = MABP$). When the HR falls to zero or the heart fails to eject an SV (as in VF), MABP drops precipitously. Subsequently, vital organ perfusion is compromised. Hence, blood flow to the brain, the heart, the lungs, and other peripheral organs ceases. Failure to promptly restore blood flow will lead to significant mortality,

morbidity, and SCA. Therefore any interruption in cardiac contraction must be recognized quickly and corrected promptly. Cardiac contraction occurs as a result of a sequence of electromechanical events occurring in myocytes. The human heart has several unique characteristics that enable it to perform its

physiologic role. These myocardial characteristics are automaticity, conductivity, excitability, and contractility. Individual cells have a “variable blend” of these characteristics. Some characteristics are more prominent than others, depending on the anatomic location of the cells in the heart. For example, the pacemaker cells have more automaticity, the conduction system has increased conductivity, and ventricular free-wall myocytes have more contractility. The electrical properties of these cells can be assessed by performing regional recordings of the changes in voltage in the tissue with respect to time (i.e., action potentials) (Fig. 12.5). The electrical impulse for myocardial contraction originates spontaneously in the sinoatrial (SA) node and spreads through the atria, which causes it to contract. As the impulse arrives at the atrioventricular (AV) node, it undergoes decremental conduction in which the electrical impulse is slowed down as the atria contract and “preload” the ventricles. Subsequently, the impulse activates the bundle of His and Purkinje fibers, which then cause ventricular contraction via excitation-contraction coupling. The electrical events precede the mechanical events. These events are graphically represented in Fig. 12.6, which depicts the change in membrane voltage with respect to time as a result of temporal changes in ion permeability across the myocyte membranes. These sequential changes in ion permeability occur as the membrane potential varies, thereby producing the characteristic cardiac action potential.

As the original impulse from the SA node travels through the atria and into the ventricles, various action potentials are generated regionally. The summation of all these action

Figure 12.4 High-quality cardiopulmonary resuscitation is essential in the resuscitation of victims of sudden cardiac arrest. Push hard to a depth of 2+ inches and +fast at a rate of 100 compressions per minute. Minimize interruptions and avoid overventilating the patient. Allow full recoil of the chest between compressions.

Relation of Action Potential from the Various Cardiac Regions to the Body Surface ECG

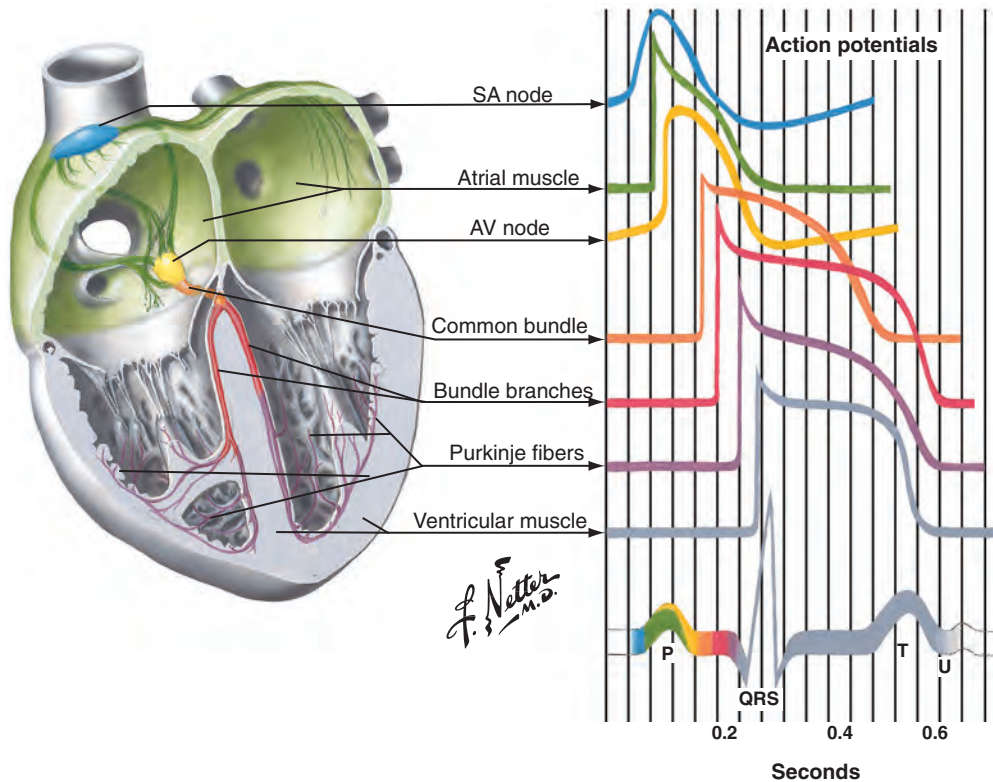

Figure 12.5 Regional action potentials and electrocardiographic correlation. AV, Atrioventricular; SA, sinoatrial. (Netter illustration from <https://www.netterimages.com>. © Elsevier Inc. All rights reserved.)

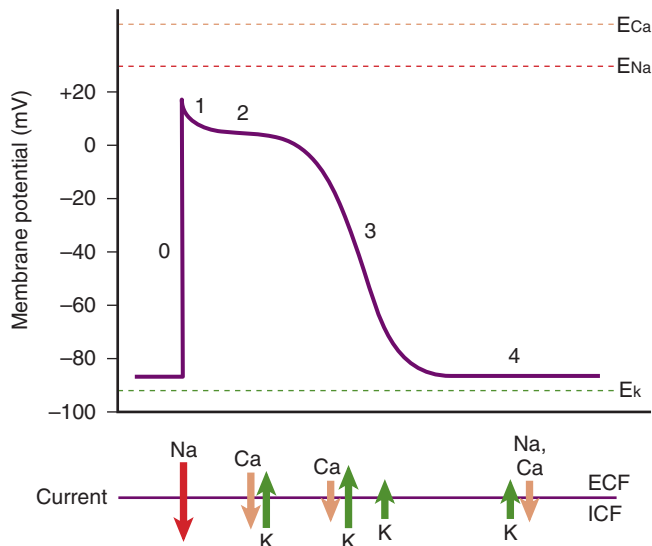

Figure 12.6 The cardiac action potential is a result of ion flux across the cell membrane. *ECF*, Extracellular fluid; *ICF*, intracellular fluid. (Adapted from Costanzo LS: *Physiology*, ed 4, Philadelphia, 2009, Saunders, Fig. 4.13.)

potentials produces the characteristic electrocardiographic (ECG) tracing PQRST (see Figs. 12.5 and 12.6). The ECG tracing is a graphic representation of the electrical activity that induces the mechanical activity of systole. Systole occurs as a result of excitation-contraction coupling. Calcium ion levels in the cytoplasm increase and trigger the contractile proteins to interact. As the ion channels reset, the myocytes return to the resting membrane potential (intracellular calcium is resequestered), and diastole occurs. The membrane pumps restore the ion concentrations to normal. This cycle keeps occurring approximately 80 times per minute. Each “cardiac cycle” lasts approximately 300 msec. During each cardiac cycle, there are two periods that need to be addressed: the absolute and relative refractory periods (Fig. 12.7). During the absolute refractory period, the myocytes do not respond to excitatory stimuli because the channels are in full operation. During the relative refractory period, the myocytes can be stimulated with a stimulus that is proportionately larger than usual as more and more ion channels reset. These facts have relevance with regard to cardioversion and will be discussed further later in the chapter.

Mechanisms of Cardiac Dysrhythmias

As is evident from the preceding discussion, normal cardiac activity is a compendium of complex, sequential electrochemical, physiologic, and mechanical events. It includes three mechanisms: enhanced automaticity, triggered activity, and reentry. If alterations in the action potential phases or a modification of the refractory periods occurs and another impulse stimulates the myocyte at a time that it is out of synch with the normal depolarization-repolarization process, the coordinated normal excitation-contraction coupling becomes asynchronous. If conditions favor the development of ectopic foci, individual loci in the ventricular free walls and septum become “pacemakers” and the myocardium begins to contract uncontrollably (see Fig. 12.2) and produce an irregular ECG tracing (see Fig. 12.1A). CO falls to zero, and SCA ensues. Another proposed

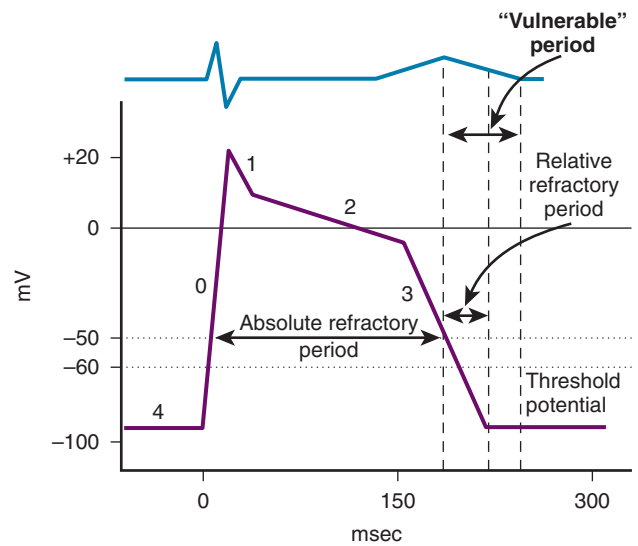

Figure 12.7 Absolute and relative refractory periods.

mechanism that can precipitate the development of a dysrhythmia is a malfunction in propagation secondary to errors in conductivity and excitability and reentry of already propagated impulses (Fig. 12.8).

Defibrillation and Sudden Cardiac Arrest

When the heart is in VF or pulseless VT, applying a sufficient “burst” of therapeutic current across the myocardium will cause all the membrane channels that are involved in excitation-contraction coupling to be activated and mobilized into the absolute refractory period. As the myocardium enters the relative refractory period and returns to the resting state, the SA node will resume the role of pacemaker of the heart and normal AV contraction will resume. HR will increase, the ventricles will resume ejection of a normal SV, and CO will be adjusted to meet tissue needs. Subsequently, ROSC should ensue.

Cardiopulmonary Resuscitation: Ventricular Fibrillation and Pulseless Ventricular Tachycardia

When SCA occurs and the heart is in VF or pulseless VT, ventricular contraction is absent and circulation of blood comes to a standstill. To initiate CPR, mechanically compress the heart between the sternum and vertebral column. This causes pulsatile ejection of blood into the circulation, including the coronary circulation. For these compressions to be effective, perform them quickly and with sufficient displacement of the sternum (i.e., at least 2 inches) to produce adequate flow. Furthermore, keep interruptions in CPR to a minimum so that adequate perfusion pressure is maintained in the vasculature. Although the flow is not at physiologic levels, enough circulation occurs in the tissues, especially the myocardium, that the by-products of VF are “washed out” and the myocardium becomes less refractory to defibrillation.¹¹ During VF, the myocytes are actually consuming oxygen and adenosine triphosphate at a rate believed to be the same or higher than during normal contraction.^{12,13} Several other concerns must be reinforced. During chest compressions, make sure that the chest recoils completely to the resting state so that blood can

Figure 12.8 Reentry as a mechanism of cardiac dysrhythmia. **A**, Two pathways are available for conduction of the cardiac impulse. **B**, One pathway has a unidirectional block to excitation (i.e., it can conduct only “backward”), and the other pathway has slowed conduction. **C**, As the impulse travels down the antegrade pathway (*left* in the schematic), it loops around and excites the other limb in a retrograde fashion. **D**, A reentrant circuit has been created, with the original limb now being excited by the impulse propagating up from the other side.

enter from the vena cava and pass into the right atrium. The rate of compressions should exceed 100 compressions/min so that adequate forward flow of blood is produced. Remember that $HR \times SV = CO$.

INDICATIONS FOR AND CONTRAINDICATIONS TO DEFIBRILLATION

Prompt electrical defibrillation is the most effective treatment of acute SCA and VF.^{3,4} Prompt initiation of CPR in patients with SCA or VF is also critical for successful resuscitation and ROSC. Starting with the onset of collapse, the survival rate for patients with SCA or VF drops 7% to 10% for every minute of downtime without defibrillation.⁵ If CPR is initiated, the survival rate declines less rapidly (i.e., 3% to 4% per minute of downtime).⁴ If an SCA is witnessed and immediate CPR is provided, coupled with immediate defibrillation, survival from such events has been reported to increase up to fourfold.⁴⁻⁶ Therefore immediate defibrillation is indicated as soon as VF or pulseless VT is diagnosed. Few absolute specific contraindications to early defibrillation exist other than the presence of a pulse, absence of SCA, medical futility for the procedure, or a valid do-not-resuscitate order.

If a patient is found unresponsive, pulseless, and apneic and the downtime is unknown, immediately perform good-quality, effective CPR while preparing for defibrillation. Previous recommendations called for immediate defibrillation in lieu of a short period of CPR. The newest development in the 2010 AHA guidelines for CPR is also a change in the basic life support sequence of steps from the “ABCs” (airway, breathing, chest compressions) to “CAB” (chest compressions, airway,

breathing) for adults and pediatric patients (children and infants, excluding newborns). As CPR is performed, prepare for rhythm analysis and initiate defibrillation if indicated. After performing CPR for 2 minutes (5 cycles at a rate of 30 compressions to 2 ventilations), perform rhythm analysis. If VF or pulseless VT is diagnosed, promptly perform defibrillation. When the time until the first shock is delayed during prehospital resuscitation (because of prolonged response times), data have demonstrated that the rate of successful defibrillation increases if patients receive bystander CPR before defibrillation.²⁻⁶ A scientific evaluation of this information proposed that CPR enhances the defibrillation threshold by restoring substrates to myocytes for the facilitation or resumption of normal excitation-contraction coupling. Furthermore, CPR may wash out myocardial depressants that have built up during prolonged VF. Therefore administration of CPR before defibrillation in patients with suspected, prolonged VF is recommended in the prehospital setting. Data to substantiate this sequence for in-hospital resuscitation have not been presented. Thus, the issue of unknown downtime, though not a definitive contraindication to immediate defibrillation, may be a factor in the clinician’s decision-making process regarding the resuscitation sequence.

Victims of SCA as a result of traumatic injuries do not usually survive.¹³ The heart, aorta, and pulmonary arteries may have sustained injury that will prevent resumption of normal cardiovascular function. There is a high probability that the underlying hypovolemia and organ damage may preclude successful resuscitation. However, the cause of the trauma may have been SCA with subsequent loss of consciousness. In such cases, if SCA or VF is present in a trauma patient, attempt treatment with CPR and defibrillation; if unsuccessful, search

for and treat the underlying cause of the trauma and pursue the SCA. Therefore trauma is not a contraindication to defibrillation, although the resuscitative effort may be futile.

If the victim of VF or pulseless VT is a pregnant female, treatment of the mother is critical. Therefore prompt defibrillation is indicated for the same guidelines and sequencing as for nonpregnant patients.¹⁴ No harm to the fetus has been reported as a result of defibrillation, and thus pregnancy is not a contraindication to defibrillation.

Previous recommendations suggested delivering a “stacked” sequence of up to three shocks without interposed chest compressions if the first shock was unsuccessful in terminating VF. This was done to decrease transthoracic impedance with the monophasic damped sinusoidal (MDS) defibrillators in use and to deliver more current to the myocardium. However, this recommendation has been rescinded because of lack of supporting evidence. Now, with the higher first-shock efficacy (90%) in successfully terminating VF (termination of VF for 5 seconds) through the use of biphasic defibrillators,⁸ the recommendation to repeat a shock if the first treatment was unsuccessful is harder to justify. Hence, the AHA now recommends a one-shock protocol for VF. Evidence has accumulated that even short interruptions in CPR are harmful. Thus, rescuers should minimize the interval between stopping compressions and delivering shocks and should resume CPR immediately after delivery of a shock.

Defibrillation is also an effective treatment modality for terminating pulseless VT. If the patient has a pulse, is stable, and has a perfusing rhythm while in VT, defibrillation is contraindicated. However, if the patient in VT becomes unstable and shows signs of poor perfusion, has a change in mental status or if persistent chest pain with pulmonary edema, hypotension, and subsequent shock develop, *synchronized cardioversion* is recommended. This procedure is addressed later. If the patient becomes unstable as a result of polymorphic VT or becomes pulseless during the episode of VT, an unsynchronized shock (i.e., defibrillation) is indicated.

Patients “found down” or who have just become unresponsive can have other “rhythms present” besides VF or pulseless VT (e.g., PEA or asystole). Defibrillation is contraindicated in individuals with PEA. True asystole is not a shockable rhythm, and current evidence suggests that defibrillating patients with “occult” or false asystole is not beneficial and may actually be harmful. Therefore defibrillation is contraindicated in patients in asystole as long as fine VF has been ruled out (see discussion later).

Some patients who succumb to SCA may have various medication-releasing patches (e.g., nitroglycerin, contraceptive hormones, antihypertensive agents, smoking cessation adjuncts) present on their chest. Their presence is not a contraindication to defibrillation. However, modify the placement of the electrodes or paddles used for defibrillation to avoid contact with these patches. If necessary, remove these items before defibrillation to avoid diversion of current from the myocardium, current arcing, sparks, and other problems.

Developments in defibrillation and computer electronics have led to the availability and use of implantable defibrillators (automatic implantable cardiac defibrillators [AICDs], pacemakers) in the chest of patients who have known coronary artery disease. These patients are prone to dysrhythmias and may have episodes of VT and VF that are automatically detected and defibrillated or cardioverted. However, these devices can malfunction, so if these patients have SCA or

VF, perform defibrillation as indicated. The presence of an AICD or pacemaker is not a contraindication to defibrillation. The only caveat is to avoid placement of the defibrillation paddles over the AICD or pacemaker because the current for defibrillation may be redirected away from the fibrillating myocardium and compromise termination of VF. In addition, because current from the defibrillation could enter the AICD or pacemaker, the device could be prone to future malfunction. These devices should be reevaluated after the patient has been defibrillated.

Current trends in fashion sometimes include piercing of the body in various locations. In addition, certain items of clothing and jewelry may require modification of electrode or paddle placement. The presence of metal in locations proximal to the heart or in locations on the chest should be avoided to minimize the potential for diverting the defibrillating current from the myocardium. In addition, if the metal object provides a potential short circuit from the patient or leads to “ground,” this object should be removed, if feasible, to avoid diversion of current from the myocardium or arcing and burns across the chest. However, the presence of these materials, such as jewelry or body piercings, is not a contraindication to defibrillation.

In this part of the chapter on defibrillation the recommendations are intended for application to an adult patient (defined as older than 8 years or weighing more than 25 kg [55 lb]) with SCA or VF. If the patient is a child (e.g., 1 to 8 years of age or weighing less than 25 kg [55 lb]), modifications in the sequence, defibrillation energy, energy attenuation equipment, and size of the defibrillation paddles are necessary. Pediatric defibrillation details are discussed later in this chapter. If a defibrillator or automated external defibrillator (AED) and equipment suitable for use in children are not available, the health care provider can resort to using a standard AED or defibrillator. Use of AEDs or defibrillators in infants younger than 1 year has not been studied.

Defibrillation can be an ignition source for explosion if arcing occurs or if there are any stray or aberrant electrical discharges that occur as a result of paddle or electrode discharge. Therefore in an environment in which volatile explosive material is present, such as the operating room or other areas of critical care, be careful during defibrillation to avoid electrical arcing and to ensure that electrical conductivity through the patient’s chest is optimal. Avoid using anesthetic agents and oxygen. A potentially explosive environment is a relative contraindication to defibrillation.¹⁵

When performing defibrillation, take care to avoid excessive moisture on the chest or around the patient. Although it is unlikely that there will be any significant or dangerous current leaks from the patient onto a wet floor, take care to avoid creating an electrical hazard. Try to ensure that the area is not wet; however, a wet surface is not an absolute contraindication to defibrillation. Defibrillation can be performed on ice and wet pavement.

Finally, defibrillation of an occult or false asystole or a very fine VF not detectable because of paddle or electrode position may be considered but is not recommended.¹³ Fine VF can occasionally masquerade as ventricular standstill or asystole. This may be a function of perpendicular electrode orientation with respect to the wavefront of depolarization. When evaluating the rhythm of a patient, if there is any doubt or confusion regarding the type of rhythm present, make sure that several leads are checked and rotate the paddles 90 degrees from their

original position to ensure that asystole is indeed present before abandoning the possibility of defibrillation. If fine VF is unmasked, consider providing aggressive CPR before defibrillation. In addition, place the controls on the ECG monitor on maximal gain to ensure adequate amplification of weak signals.

CONDUCTIVE MATERIAL

Use of conductive material is important to lower the impedance or resistance to flow of current at the electrode–chest wall interface.^{16–18} Multiple factors affect the range of impedance (e.g., body weight, chest size, chest hair, moisture on the skin surface of the patient, paddle size [diameter], paddle contact pressure, phase of respiration, and type of conductive material used). High impedance or resistance to flow of current can compromise the amount of current actually delivered to the myocardium and lead to a failed first shock. Inappropriate use of conductive material can result in current bridging or a short circuit and arcing of electrical current secondary to streaking of the material across the chest. This can produce sparks and unnecessary burns on the patient's skin. In addition, arcing of electricity can become a possible explosion hazard, depending on the circumstances. Conductive material needs to be used with the handheld electrodes. Various electrode gels are available on the market and should be kept in the proximity of the defibrillator, on the prearranged cart ready to use (Fig. 12.9A).

Self-adhesive pad electrodes now have a resistance-reducing, conductive material incorporated into the adhesive, thus rendering the use of a gel or other conductive material unnecessary. Firmly applying the self-adhesive electrode pads to the skin will usually be sufficient to minimize impedance, allow adequate ECG acquisition, and if indicated, defibrillate (see Fig. 12.9B).

PROCEDURE

Witnessed Sudden Cardiac Arrest (Figs. 12.10 and 12.11)

When confronted with a patient who has just become unresponsive, prepare for immediate defibrillation (Fig. 12.12). As soon as the defibrillator is available and the patient is connected to the monitor, assess the rhythm. In the interim, turn on the defibrillation equipment, place the paddles or electrodes on the chest, begin assessment of the patient, and initiate the steps in CPR by applying the CAB principle.⁷

Cardiopulmonary Resuscitation

Perform a pulse check (<10 seconds; see Fig. 12.11, step 1). If a pulse is definitely present, provide 1 breath for 1 second every 5 to 6 seconds or 8 to 10 breaths/min. The breaths can be delivered with either a bag-valve-mask (BVM) or some type of barrier device. Observe the patient for visible chest wall rise and fall so that the thorax does not become overinflated. Hyperinflation of the chest can lead to inadvertent pressurization of the esophagus, which can cause lower esophageal sphincter pressure to be exceeded. This can lead to retrograde flow of gastric contents into the esophagus with the potential for subsequent aspiration of acid and debris into the trachea if the airway is not adequately protected. Overventilation of the thorax can also lead to an increase in intrathoracic pressure and

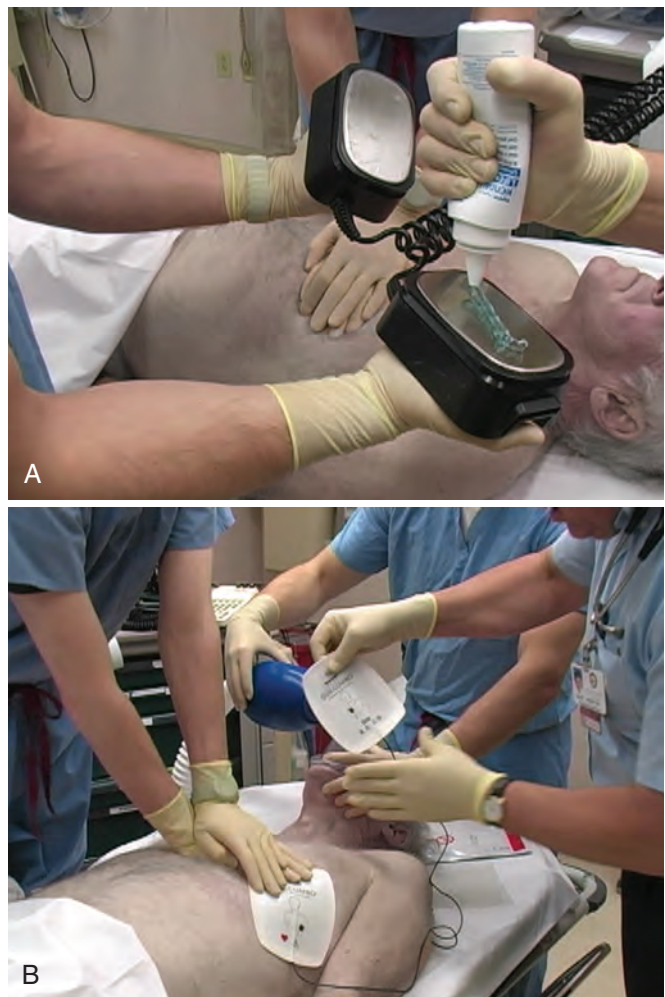

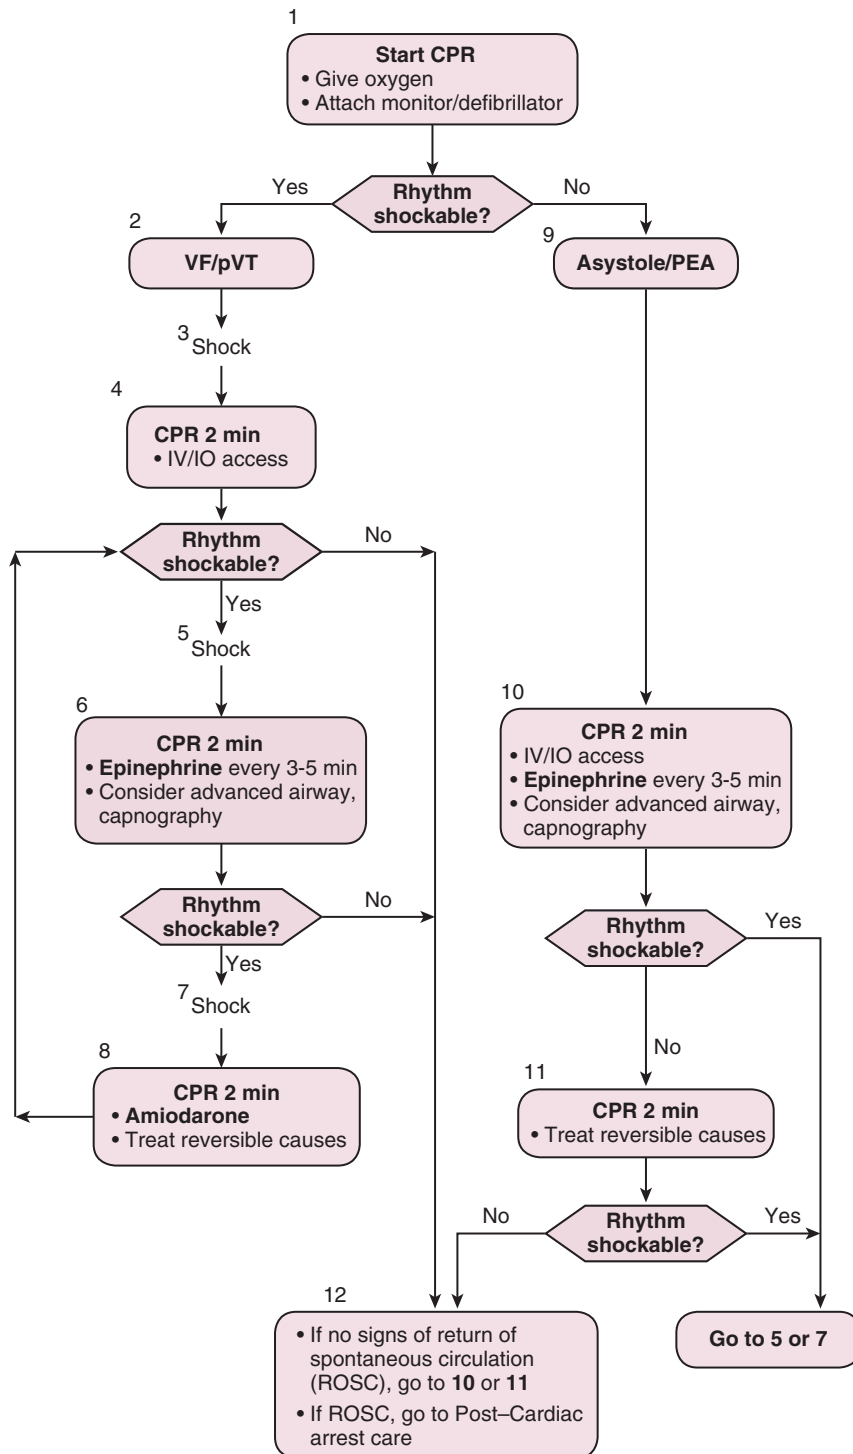

Figure 12.9 Use of conductive material is essential during defibrillation to lower the impedance to flow of current at the electrode–chest interface. **A**, If standard defibrillation paddles are being used, electrode gel *must* be applied before the procedure. **B**, Self-adhesive pad electrodes have conductive material incorporated into the adhesive. Use of gel with these pads is unnecessary. The use of self-adhesive pads is highly recommended.

impedance of blood flow to and from the heart, which should be avoided. Reassess the patient's pulse every 2 minutes.

If no pulse is present, begin a sequence of 30 chest compressions followed by 2 ventilations/breaths (see Fig. 12.11, step 2). Keep your hands on the lower half of the sternum and compress it at least 2 inches (5 cm) at a rate of at least 100 compressions/min. The time allotted for compression should be 50%/50% for compression and relaxation of the chest. Watch for full chest recoil to allow adequate ventricular filling and do not lean on the chest, before the next compression. When the defibrillator or AED arrives, continue the 30:2 ratio of compressions to ventilations during CPR, attach the patient to the defibrillator via electrodes, pads, and paddles applied to the patient's chest, and initiate the rhythm check (see Fig. 12.11, step 3). Every attempt should be made to minimize interruption of compressions.

Rhythm Assessment

Once the defibrillator is at the bedside, turn on the defibrillator/monitor and place electrodes on the patient's chest in the form

**CPR quality**

- Push hard (at least 2 inches [5 cm]) and fast (100-120/min) and allow complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 30 : 2 compression-ventilation ratio.
- Quantitative waveform capnography
 - If $PETCO_2 < 10$ mm Hg, attempt to improve CPR quality.
- Intraarterial pressure
 - If relaxation phase (diastolic) pressure < 20 mm Hg, attempt to improve CPR quality.

Shock energy for defibrillation

- **Biphasic:** Manufacturer recommendation (e.g., initial dose of 120-200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug therapy

- **Epinephrine IV/IO dose:** 1 mg every 3-5 minutes
- **Amiodarone IV/IO dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions.

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Abrupt sustained increase in $PETCO_2$ (typically ≥ 40 mm Hg)
- Spontaneous arterial pressure waves with intraarterial monitoring

Reversible causes

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

Figure 12.10 Adult cardiac arrest algorithm. *Note:* The use of epinephrine and its safety and beneficial effects for an improved cardiac arrest outcome has recently been questioned. A worsened final outcome, possibly from prolonged cerebral vasoconstriction, has been associated with the use of epinephrine during resuscitation. Only two medications, epinephrine and amiodarone, are currently recommended for cardiac arrest; however, *no ACLS drug has been proved to improve long-term survival.* CPR, Cardiopulmonary resuscitation; ET, endotracheal; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; $PETCO_2$, end-tidal CO_2 ; pVT, pulseless ventricular tachycardia; VF, ventricular fibrillation. (©2015 American Heart Association.)

DEFIBRILLATION

1 Assess patient responsiveness, breathing, and circulation. Check for a pulse for <10 seconds. Call for help and have the code cart delivered to the bedside.

2 If there is no pulse, begin CPR at a rate of >100 compressions per minute with a ratio of 30 compressions to 2 ventilations. Avoid interruptions in CPR, PUSH HARD, and PUSH FAST.

3 Apply the electrodes to the patient's chest. Place the sternal electrode below the clavicle, to the right of the sternum. Place the apical electrode in the midaxillary line at the fifth intercostal space.

4 Check the rhythm on the monitor. If there is a shockable rhythm (i.e., VF or pulseless VT), prepare for immediate defibrillation.

5 Select the appropriate energy for the initial shock. For biphasic defibrillators, a default energy of 200 J is appropriate (see text for details). For monophasic machines, use 360 J. Make sure that "SYNC" is turned off.

6 Once the energy has been selected and the decision to defibrillate confirmed, press the "CHARGE" button on the defibrillator.

7 As the "CHARGE" button is depressed, loudly announce "I'm clear, you're clear, everybody's clear!" and make sure that no caregivers are in contact with the patient.

8 Check once again to make sure that everyone is clear, and then depress the "SHOCK" button to defibrillate the patient.

9 Resume CPR *immediately* and continue for 5 cycles/2 minutes. Additional interventions such as IV/IO access and airway management may be pursued but should not interfere with continuous CPR.

10 After 2 minutes of CPR, reassess the patient and the rhythm. Refer to the text and algorithms in this chapter for additional information.

Figure 12.11 Defibrillation. CPR, Cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; VF, ventricular fibrillation; VT, ventricular tachycardia.

Figure 12.12 All resuscitation equipment should be kept on a “code cart” equipped with the monitor/defibrillator, airway supplies, emergency medications, and other essentials.

of either quick-look paddles or the multifunctional electrode pads that can acquire ECG signals and be used concomitantly to defibrillate the patient. To decrease chest wall impedance, apply a gel or saline pads to the contact surface of the handheld electrode paddles to function as conductive material.

The correct position for placement of either the handheld quick-look paddle electrodes or the self-adhesive pads is illustrated in [Fig. 12.13](#). Frequently, the pads are labeled with a diagram as a guide to placing the electrodes on the chest wall. Using the patient’s right side for orientation, place the sternal electrode just below the clavicle and just to the right of the sternum. Place the apical electrode in the midaxillary line around the fifth or sixth intercostal space. Once the electrodes or pads are in position, set the selector dial or switch on the defibrillator monitor to the appropriate position to acquire the ECG signal from the input source, either the handheld quick-look paddles or the multifunctional electrode pads. Errors sometimes occur when the selector switch is in the position for the patient cable and electrode pads whilst the operator is attempting to use the handheld paddles. This could lead to misinterpretation of the rhythm, with the operator perceiving that the patient is in asystole, whereas in reality, VF, pulseless VT, or some other rhythm is actually present. Be familiar with the operation of the switches. In addition, adjust the controls for gain of the ECG signal to increase the sensitivity or gain of the ECG amplifier to ensure that fine VF is not interpreted as asystole. As the ECG rhythm appears on the monitor, make a diagnosis of the type of rhythm or

Figure 12.13 Electrode positioning for defibrillation. **A**, Sternal-apical placement. Place the sternal electrode just to the right of the sternum, underneath the clavicle. Place the apical electrode in the mid-axillary line at the 5th–6th intercostal space. **B**, Anterior-posterior placement. Place the anterior pad just to the left of the sternum, and the posterior pad directly behind it, approximating the position of the heart.

lack thereof (see [Fig. 12.11](#), *step 4*). If a shockable rhythm such as VF or pulseless VT is present, defibrillation is indicated. Proceed to select the appropriate energy level for the anticipated defibrillation.

Energy Selection

As noted previously, two major types of defibrillators are available: biphasic and monophasic ([Fig. 12.14](#)). Currently, the biphasic defibrillator, which is more likely to be found in the clinical setting, produces either a biphasic rectilinear waveform or a biphasic truncated exponential (BTE) waveform. However, there are still monophasic defibrillators present that usually produce an MDS waveform. Current data do not support one waveform over another, but biphasic defibrillators appear to be more efficient in achieving defibrillation with the first shock.

Therefore the following recommendations are made: In general, a defibrillator using the biphasic rectilinear waveform should be set to an energy level of 120 J. If a BTE defibrillator waveform is being used, energy levels of 150 to 200 J are suggested for the first shock. If the type of waveform of the biphasic defibrillator is unknown or unavailable, a consensus default energy level of 200 J is suggested.

If the defibrillator is an older monophasic model using the MDS waveform, use 360 J for the first shock.

Figure 12.14 Biphasic and monophasic defibrillator waveforms. Most machines encountered in clinical practice today will be of the biphasic variety.

Mode Selection

Before defibrillation, check to make sure that the defibrillator is set to the unsynchronized mode. Most defibrillators default into the unsynchronized mode between shocks. Nonetheless, this control should be checked to make sure that it is in the unsynchronized mode; otherwise, the defibrillator may not discharge when the shock buttons are depressed because it is looking for the QRS complex, which is not present in VF. This is discussed in more detail in the section on [Cardioversion](#) later.

Defibrillate

Continue CPR until the defibrillator is charged and ready to defibrillate. Once the energy level has been selected and the decision made to defibrillate, clear the patient for defibrillation by loudly stating “I’m clear, you’re clear, everybody’s clear,” and then activate the button to charge the defibrillator (see [Fig. 12.11](#), steps 6 and 7). Once the defibrillator has been charged and everyone is clear, apply firm pressure to the defibrillation paddles (25 lb) to increase contact and deflate the lungs to the end-expiration state. This will decrease impedance at the paddle–chest wall interface. Subsequently, depress the defibrillation controls and deliver the shock (see [Fig. 12.11](#), step 8). This will usually be followed by a perceptible whole-body muscle twitch in the patient. If no obvious response or twitch of the patient is seen, check the defibrillator controls to make sure that it is in the unsynchronized mode and that the paddles are activated. If using the multifunctional pads, no pressure is needed.

Resume Cardiopulmonary Resuscitation

Once the shock has been delivered, resume resuscitation with immediate chest compressions (see [Fig. 12.11](#), step 9). Continue chest compressions for approximately 5 cycles of 30 compressions to 2 ventilations, or approximately 2 minutes of CPR. This facilitates the transition from SCA to ROSC after the heart has been stunned by the defibrillation and may not be functioning at optimal contractility for a few minutes after the shock. If additional monitoring devices are in place, such as arterial lines or Swan catheters, modify this step accordingly as dictated by the resuscitation team leader.

Continue CPR for approximately 2 minutes. If the rescuers become fatigued, rotate the compressor and ventilator.

Reassess the Patient: Management of the Airway and Intravenous Access

After 2 minutes of CPR (5 cycles at a 30:2 ratio of compressions to ventilations), check the patient’s perfusion status or carotid pulses. If there is no palpable pulse, resume compressions *immediately* and prepare for delivery of a second defibrillatory shock.

As preparation for the second shock begins, other members of the resuscitation team can work on securing the airway via endotracheal intubation, a laryngeal mask airway, or another appropriate device. Proceed with blood drawing and intravenous (IV) line placement, or intraosseous (IO) if applicable, but do not interfere with chest compressions. The goal is to maintain uninterrupted chest compressions and to avoid any unnecessary interruptions.

Changes in Cardiopulmonary Resuscitation

Once an advanced airway has been secured, the compression and ventilation cycles are no longer delivered as described. Now, the compressor will continue to deliver compressions at a rate higher than 100 compressions/min *continuously*, without pausing for interposition of ventilation. Ask an assistant to deliver the ventilations at a rate of 8 to 10 breaths/min. Be careful to not overinflate the chest or to use too much force during ventilation because this can overpressurize the airways and esophagus, potentiate reflux, and impede venous return to the heart.

Energy and Mode Selection for the Second Shock

The energy for the second shock can be the same as that used before, but a higher energy level can be chosen at the discretion of the resuscitation leader. Check the mode selector again to be certain that it is in the unsynchronized position.

Second Defibrillation

Once the energy level has been selected, charge the defibrillator. When the defibrillator is ready to shock, halt CPR, clear the patient as discussed earlier, and deliver the second shock.

Resume CPR immediately after delivering the second shock. This step can be modified at the discretion of the resuscitation team leader, if there is clinical evidence of ROSC, or if devices are being used to monitor circulatory status (e.g., central venous pressure monitor, Swan-Ganz catheter, or direct arterial line).

If the patient does not have a shockable rhythm, proceed to the appropriate algorithm for VT, PEA, or asystole. Regarding airway management, consider using a supraglottic airway or endotracheal intubation without causing any significant interruption in chest compressions. In addition, initiate end-tidal carbon dioxide measurements (capnography) to determine the adequacy of CPR and ROSC when applicable.⁷

It is now believed that when SCA occurs in a presumably nonhypoxic heart, there is enough oxygen in the functional residual capacity (FRC) of the lungs ($FRC = ERV$ [expiratory reserve volume] + RV [residual volume]) that with compressions only, blood will be oxygenated in the lungs for a short period. Therefore airway management is not as urgent as when restoring circulation that has totally ceased. Additionally, there is no need to overventilate the patient because hyperinflation of the lungs will cause an increase in intrathoracic pressure and compromise venous return to the right side of the heart.

Unwitnessed Arrest

When encountering a patient who is unresponsive and has been down for an unknown amount of time, assess the patient, summon help, and initiate CPR immediately, if indicated. Perform CPR until the defibrillator or AED is brought to the patient's side. As preparations are being made for defibrillation, consider performing 5 cycles of 30:2 compressions to ventilations before performing defibrillation.

Automated External Defibrillator Application

The availability of AEDs or semi-automated defibrillators in hospitals has increased, especially in non-critical care areas (Fig. 12.15). Although AEDs are designed for lay public use, application of these devices may also occur in the clinical setting. As in the algorithm, assess the patient, summon help, and apply the AED. Operation of the AED is guided by voice and visual prompts. Turn the device on, apply the patient electrodes in the appropriate positions, analyze the rhythm, and deliver a shock if a shockable rhythm is present. The AED will determine the rhythm and choose the energy level. Integrate CPR with the shocks to enhance the potential outcome of SCA resuscitation.

Figure 12.15 Automated external defibrillator (AED).

Medication

As per the 2010 AHA guidelines, there are insufficient data to demonstrate that any drugs or mechanical CPR devices improve long-term outcome after cardiac arrest. There is now some concern that epinephrine, a long-time universally recommended adjunct to CPR, may actually worsen outcomes in patients with SCA. The routine use of medications has been deemphasized, but not abandoned, in the current recommendations for resuscitation of SCA, VF, and pulseless VT (Box 12.1). Whether increased long-term survival from cardiac arrest can be expected with the use of any medications during CPR remains uncertain.

Complications

Complications of defibrillation include soft tissue injury, myocardial injury, and cardiac dysrhythmias. The availability of multifunctional electrode pads and better applicators for electrode gel has decreased the potential for soft tissue injuries such as chest burns.¹⁹ In fact, many clinicians now prefer to use the multifunctional electrode pads for ECG acquisition and for defibrillation.

The development of new, energy-efficient biphasic defibrillation waveforms, such as the BTE and the rectilinear biphasic waveform, has increased first-shock success and decreased the incidence of dysrhythmias after defibrillation.⁸ As a result, fewer shocks are needed to defibrillate the myocardium and less current is applied to the myocardium, which results in less electrical damage to myocytes.

Use of AEDs in public access defibrillation programs has not been reported to have produced any significant mishaps or adverse outcomes.²⁰

Some older recommendations, such as use of the precordial thump, have been retracted. This procedure has been reported

BOX 12.1 Defibrillation Equipment

LIST OF MATERIAL FOR DEFIBRILLATION

- Defibrillator/ECG monitor
- Handheld defibrillation electrode “quick-look” paddles
- Patient interface cables; multifunctional for ECG monitoring and defibrillation
- Electrodes and pads for ECG signal acquisition and defibrillation
- Conductive gel (*not* ultrasound gel)

ADDITIONAL “EQUIPMENT” (PERTINENT TO VF/VT)*

ACLS Medications

- Epinephrine
- Vasopressin
- Amiodarone
- Lidocaine
- Magnesium sulfate
- Procainamide
- Atropine

MISCELLANEOUS

- IV access equipment, central line kits, etc.

*List of suggested equipment and medications for a code cart.

ACLS, Advanced cardiac life support; ECG, electrocardiographic; VF, ventricular fibrillation; VT, ventricular tachycardia.

to have caused asystole or complete heart block (or both) when applied.²¹

In addition, the use of procainamide, though not a complication, has fallen out of favor because of long infusion times and mixed results regarding the efficacy of its effects during the acute phase of VF and pulseless VT resuscitation.²²

PEDIATRIC DEFIBRILLATION

Cardiac arrest in infants and children should initially be considered to be secondary to respiratory arrest. SCA, VF, and pulseless VT are much less likely to occur in children than in adults. However, 5% to 15% of pediatric and adolescent SCA events demonstrate VF in the prehospital setting. In in-hospital arrests, a 20% occurrence of VF at some point during the resuscitation is reported. Nonetheless, rapid intervention and defibrillation improve outcomes from SCA. Causes of SCA, VF, and pulseless VT are more diverse in pediatric patients.²² Cardiac arrest does not usually occur as a result of a primary cardiac cause. Therefore the approach to resuscitation of a pediatric patient in VF or pulseless VT may differ depending on the cause of the arrest.

Ventricular Fibrillation in Children

VF is much less common in children than in adults. The etiology of VF and SCA in children is most likely to be sudden infant death syndrome, respiratory compromise, sepsis, neurologic disease, or injuries from motor vehicle crashes, burns, accidental firearm discharge, and drowning, many of which are preventable.^{23,24} The most common terminal rhythms reported in children younger than 17 years are PEA, bradycardia, and asystole.²⁵ The etiology of these pediatric arrhythmias is most often hypoxemia, hypotension, hypoglycemia, and acidemia. In addition, focal electrical ectopy is less likely to initiate VF in a young heart. A significant myocardial mass must be unstable and fibrillating before VF becomes established. In children (from birth to 8 years old) with nontraumatic arrest, only 3% of the dysrhythmias are reported to be VF. In victims aged 8 to 30 years, the number of patients with VF increases by almost sixfold (17%).²³ Several subpopulations of pediatric patients at various ages with cardiomyopathy or myocarditis or who have undergone heart surgery are at increased risk for a primary dysrhythmia.

As noted previously, the incidence of VF in cardiac arrest rhythms of pediatric patients is reported to range from 7% to 20%.²⁶ Patients with rhythms who have been defibrillated from VF have been reported to have a higher survival-to-discharge rate than do children who sustained asystole or PEA.²⁷ Therefore there is a definite indication for early defibrillation in the pediatric population.

Procedure and Technique

The procedure for pediatric defibrillation is similar to the algorithm for adult defibrillation (Fig. 12.16). However, a few differences must be addressed. These guidelines do not apply to children younger than 1 year.

Pediatric Sudden Cardiac Arrest

When cardiac arrest occurs in a child, it is usually a terminal event associated with respiratory compromise or shock. The

probability of SCA resulting from a primary cardiac cause is extremely low.²³ Nonetheless, it can and does occur. If resuscitation is prompt, the potential for a positive outcome, including preservation of the patient's neurologic integrity, is quite high. To enhance the outcome of SCA resuscitation, defibrillation and CPR must be effectively integrated. The pediatric resuscitation guidelines incorporated findings from a comprehensive review of the data.²⁸ Revised steps for the recommended resuscitation sequence are described in the following sections.

Equipment. To perform pediatric defibrillation, a defibrillator monitor capable of adjustments in energy appropriate for children is needed. If an AED is to be used, it should have an energy attenuator for adjusting the energy to the appropriate level for a child (Fig. 12.17A). In addition, the quick-look electrode paddles (see Fig. 12.17B) should have adapters attached to the adult paddles to ensure appropriate contact with the chest wall in a child without causing the electrodes to overlap. If adhesive pads are used, choose the appropriate size that will not overlap (see Fig. 12.17C). Use gels as in adults while being careful to prevent bridging across the chest wall from streaks of conductive material that may have been carelessly applied to the chest.

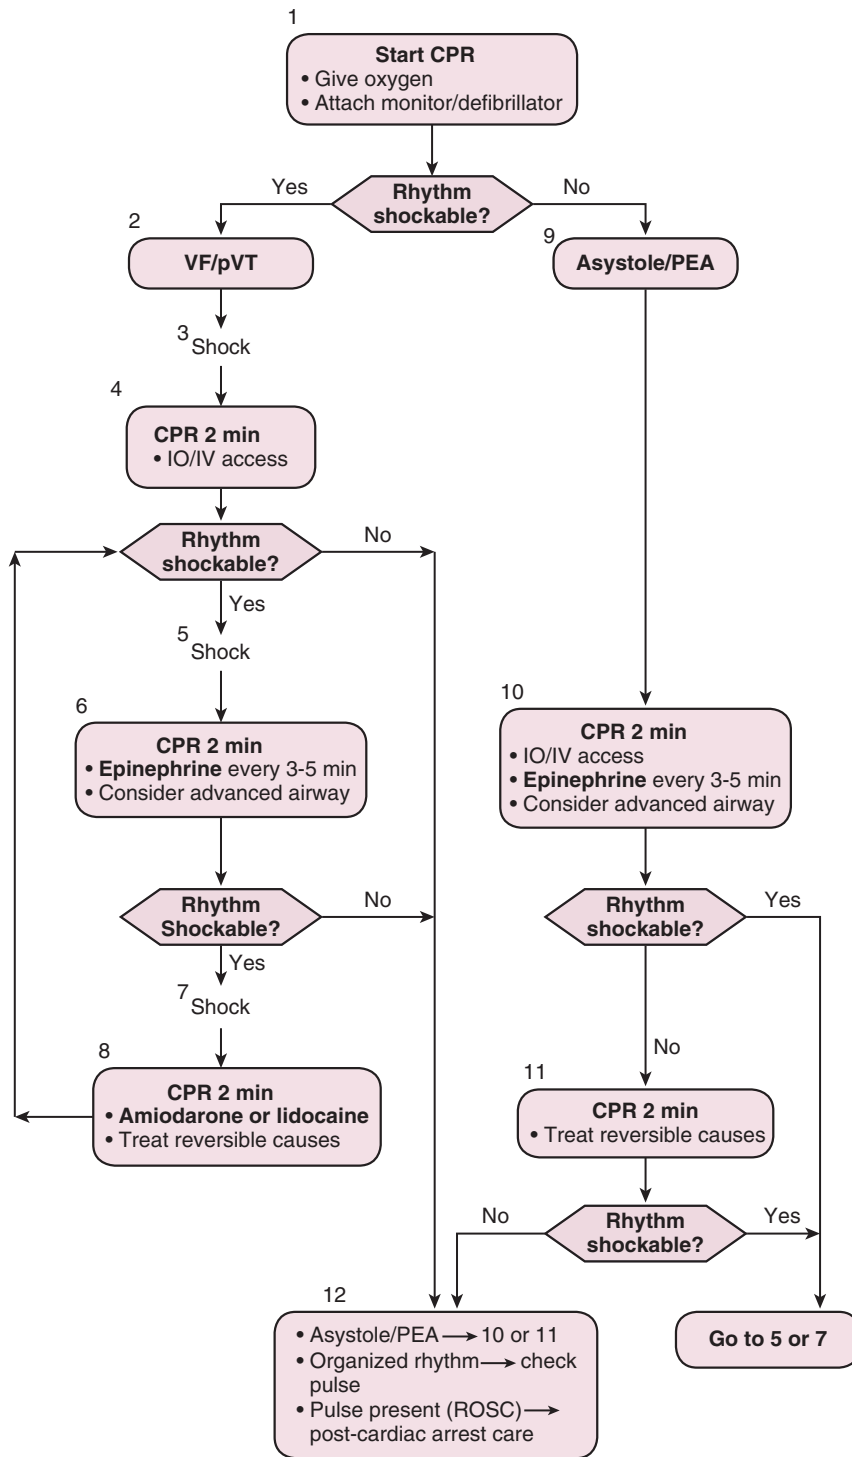

Paddle and Pad Application and Use of Conductive Material.

To acquire the electrical rhythm and subsequently administer an effective defibrillatory shock, place the appropriate-sized pads and paddles correctly on the chest. Use of the appropriate size and placement of paddles or pads will ensure that the appropriate current density is delivered across the myocardium to effectively defibrillate the myocytes. Furthermore, appropriate pad or paddle size—the largest surface area possible without direct electrode-to-electrode contact—will decrease transthoracic impedance and enhance defibrillation.²⁹ To accomplish this, use infant paddles for children weighing less than 10 kg. However, use larger paddles if they do not contact each other. If contact is made between the paddles, an electrical arc or short circuit could occur.³⁰ In children who weigh more than 10 kg (mean age, 1 year), use adult pads or paddles (8 to 10 cm in diameter).²⁹ Use a conductive agent to enhance skin contact and decrease transthoracic impedance. Never use dry paddles because the resistance to flow of current will be very large. However, refrain from using saline-soaked pads in children because they may cause arcing as a result of the proximity of the pads on the chest. Remember that electricity will take the path of least resistance and that the current from defibrillation will travel across the chest if there is a saline bridge between the electrodes. In addition, the use of ultrasound gel and alcohol pads is discouraged because of poor electrical conductivity and potentially high impedance.³⁰

Apply the paddles or pads firmly to the chest, one to the right of the sternum, just below the clavicle, and the other to the left of the left nipple, over the ribs and the apex of the heart (see Fig. 12.13A). An option when using self-adhesive pads is to place one pad just to the left of the sternum and the other over the back so that they approximate the position of the heart (see Fig. 12.13B).

Procedure in an Unresponsive Child

When confronted with an unresponsive child, immediately summon assistance and start the CABs of CPR. Bring equipment

CPR quality
<ul style="list-style-type: none"> • Push hard ($\geq\frac{1}{3}$ of anteroposterior diameter of chest) and fast (100-120/min) and allow complete chest recoil. • Minimize interruptions in compressions. • Avoid excessive ventilation. • Rotate compressor every 2 minutes, or sooner if fatigued. • If no advanced airway, 15 : 2 compression-ventilation ratio.
Shock energy for defibrillation
First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥ 4 J/kg, maximum 10 J/kg or adult dose.
Drug therapy
<ul style="list-style-type: none"> • Epinephrine IO/IV dose: 0.01 mg/kg (0.1 mL/kg of 1:10 000 concentration). Repeat every 3-5 minutes. If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration). • Amiodarone IO/IV dose: 5 mg/kg bolus during cardiac arrest. May repeat up to 2 times for refractory VF/pulseless VT. • Lidocaine IO/IV dose: Initial: 1 mg/kg loading dose. Maintenance: 20-50 mcg/kg per minute infusion (repeat bolus dose if infusion initiated >15 minutes after initial bolus therapy).
Advanced airway
<ul style="list-style-type: none"> • Endotracheal intubation or supraglottic advanced airway • Waveform capnography or capnometry to confirm and monitor ET tube placement • Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

for resuscitation expediently to the patient's side. If no help is immediately available, first perform approximately 2 minutes of CPR before leaving the patient's side. Remember that the arrest may have been the result of respiratory compromise and that performance of CPR may ameliorate the condition.

If the victim is unresponsive to verbal and tactile stimuli, begin chest compressions immediately (30:2) at a rate greater than 100/min. Open the airway by using the head-tilt/chin-lift method. If a spinal cord injury is suspected, use the jaw-thrust maneuver without head tilt. The team can initiate other actions. Next, determine breathlessness. If there is no perceivable evidence of breathing, provide two slow rescue breaths (1 breath/sec) that make the chest rise. Do not use excessive force when ventilating because this could cause regurgitation or aspiration, impede venous return to the heart, and decrease coronary blood flow as a result of increased intrathoracic pressure. After interposing the breaths, proceed to assess the circulation by checking for a pulse in either the carotid or femoral artery (<10 seconds). If there is no palpable pulse or a very slow pulse less than 60 beats/min in very young children after 10 seconds of attempting to feel a pulse, initiate chest compressions. Compress the lower half of the sternum while avoiding the xiphoid process. Compress the chest to approximately one-third to one-half the depth of the chest. The rate of compressions should be at least 100 compressions/min. If a single rescuer is performing the compressions and ventilations, the compression-to-ventilation ratio should be 30:2. If two rescuers are available, the compression-to-ventilation ratio should be 15:2. Try to avoid interruption of the chest compressions.

If an adequate pulse is present, interpose 12 to 20 breaths/min (1 breath every 3 to 5 seconds). Once a defibrillator monitor or an AED is available, prepare for rhythm analysis and defibrillation.

Rhythm Assessment. Once the defibrillator or monitor is at the patient's side, turn it on and place the electrodes on the patient's chest. The positions of the electrodes on a child correspond to the positions used in an adult (see Fig. 12.13). If quick-look paddles are used, carefully apply the conductive gel to the electrodes' surface. If self-adhesive multifunctional electrode pads are used, there is no need to use conductive gel. Make sure that the input selector switch is reading from the appropriate source (i.e., paddles or pads). Adjust or increase the gain or sensitivity of the monitor so that fine VF is not

missed because of low amplitude. As the ECG rhythm appears on the monitor, assess and diagnose the rhythm. If VF or pulseless VT is present, proceed to select the appropriate energy level for the anticipated defibrillation.

Energy Selection. As mentioned earlier in the adult section of the chapter, two types of defibrillators are available: biphasic and monophasic. As of this writing, there is no specific, detailed differentiation between energy levels to be used by either type of defibrillator. However, the caveat that biphasic shocks are at least as effective as monophasic shocks and that they are less damaging to the myocardium still applies.

Based on a review of adult and pediatric animal data, when a manual defibrillator is used for the first shock attempt, an energy level of 2 J/kg should be used with either a biphasic or a monophasic defibrillator. If a second or subsequent defibrillation is indicated, 4 J/kg should be used with either type.^{7,27}

Mode Selection. Before defibrillation, check to make sure that the defibrillator is set to the unsynchronized mode. Most defibrillators default into the unsynchronized mode between shocks. Nonetheless, this control should be checked to make sure that it is in the unsynchronized mode; otherwise, the defibrillator may not discharge when the shock buttons are depressed because it is looking for the QRS complex, which is not present in VF (this is discussed in more detail in the later section on [Cardioversion](#)).

Defibrillate. Once the energy level has been selected and the decision made to defibrillate, simultaneously clear the patient for defibrillation by loudly stating "I'm clear, you're clear, everybody's clear," while the button is activated to charge the capacitor. Continue CPR until ready to shock. Once the defibrillator has been charged and the patient cleared, apply firm pressure to the defibrillation paddles (25 lb) to increase contact and deflate the lungs to the end-expiration state. This will decrease impedance at the paddle-chest wall interface. Subsequently, depress the defibrillation controls and deliver the shock. This will usually be followed by a perceptible whole-body muscle twitch by the patient. If no obvious response or twitch of the patient is seen, check the defibrillator controls to make sure that it is in the unsynchronized mode and that the paddles are activated. No pressure is needed if adhesive multifunctional pads are used.

Resume Cardiopulmonary Resuscitation. Once the shock has been delivered, resume resuscitation with immediate chest compressions. Continue the compressions for approximately 5 cycles of 30 compressions to 2 ventilations or approximately 2 minutes of CPR. If two rescuers are available, use a 15:2 ratio and switch compressors when the first compressor fatigues. This is done to facilitate the transition from SCA to ROSC after the heart has been stunned by the defibrillation and may not be functioning at optimal contractility for a few minutes after the shock. If additional monitoring devices are in place in the hospital setting, modify this step accordingly as decided by the resuscitation team leader. Continue CPR for approximately 2 minutes.

Reassess the Patient, Manage the Airway, and Gain Intravenous Access. After 2 minutes of CPR, 5 cycles of 30:2, check the patient's perfusion status or carotid pulses. If no pulse is palpable, resume compressions immediately and prepare to deliver a second defibrillatory shock.

While the operator is preparing for the second shock, other members of the resuscitation team can work on securing the airway via endotracheal intubation, a laryngeal mask airway, or another appropriate device. Blood draws and IV-line placement (or IO if applicable) should proceed but not interfere with chest compressions. The goal is to maintain chest compressions and avoid any unnecessary interruptions.

Change in Cardiopulmonary Resuscitation. Once an advanced airway has been secured, compression and ventilation cycles are no longer delivered. Now, the compressor will continue to deliver compressions at a rate of 100/min continuously without pausing for interposition of ventilations. When delivering the ventilations, provide 8 to 10 breaths/min, but be careful to not overinflate the chest or use too much force during ventilation to avoid overpressurizing the airways and esophagus and potentiating reflux. Lesser force also decreases the possibility of compromising CO as a result of elevated intrathoracic pressure.

Second Shock: Energy Selection and Mode. The second shock, if indicated, should occur after 2 minutes of CPR. The energy level for the second shock should be 4 J/kg. Be sure to check that the defibrillator or monitor is in the unsynchronized mode.

Immediately after the second shock, resume CPR and continue for approximately 2 minutes. If assessment of the rhythm and circulatory status shows continued VF or pulseless VT and no ROSC, continue CPR and consider medications such as a vasopressor (e.g., epinephrine).

Medications. The same caveats concerning the lack of proven benefit of any medications to improve long-term survival in adults also applies to children.

Automated External Defibrillators in Children

As mentioned previously, the incidence of VF and pulseless VT in children is low. Nonetheless, the presence of VF or pulseless VT is an indication for using an AED or defibrillator. The age range for use of an AED or defibrillator is 1 to 8 years. No recommendations for the use of a defibrillator or AED in children younger than 1 year have been provided as of this writing.³¹ A pediatric energy dose attenuator (see Fig.

12.17A) should be used to prevent the delivery of too much current to the myocardium. If a pediatric dose attenuator is not immediately available, a standard defibrillator should be used at the lowest appropriate setting.

Use of the AED entails bringing the AED to the patient's side, turning the device on, following the voice or visual prompts, and connecting the electrodes to the patient. Once the pads are applied to the patient, the AED will initiate the rhythm analysis automatically or the rescuer will be prompted to press a button to activate the "analyze mode" of the AED. Subsequently, the AED will diagnose the rhythm and advise a shock if indicated. The energy level and mode are all preprogrammed into the AED electronics.

CARDIOVERSION

Introduction and Physiology

Cardioversion is the application of a direct current (DC) "shock" across the chest or directly across the ventricle to normalize the conduction pattern of a rapidly beating heart. This shock is delivered during the absolute refractory period of the ECG QRS; it is synchronized to the peak of the R wave.

A patient with significant tachycardia may be asymptomatic or may complain of chest pain or discomfort, light-headedness, or shortness of breath. These symptoms are the result of altered cardiovascular physiology. Rapid cardiac rhythms allow less time for ventricular filling and thereby result in reduced preload and hypotension. The reduced preload, as well as the increased ventricular work caused by the rapid HR, may also result in ventricular ischemia. Pulmonary capillary wedge pressure may also rise despite the shortened filling time because of reduced ventricular compliance secondary to ventricular ischemia. Elevated pulmonary capillary wedge pressure can then lead to pulmonary edema.

Termination of rapid rhythms to alleviate or prevent these symptoms must occur quickly to prevent further deterioration. Persistently poor CO because of a rapid HR results in the development of lactic acidosis, which further compromises cardiac function and makes cessation of the dysrhythmia even more difficult. Unchecked myocardial ischemia may lead to infarction with its attendant sequelae. Carotid sinus massage drug therapy, rapid cardiac pacing, and cardioversion are the methods available to terminate tachydysrhythmias.

In many cases, DC cardioversion has specific advantages over drug therapy. Although it may require more preparation than drug therapy, the effectiveness of electrical cardioversion enhances its usefulness in the ED setting. Cardioversion is effective almost immediately, has few side effects, and is often more successful than drug therapy in terminating dysrhythmias. In addition, the effective dose of many anti-dysrhythmic medications is variable, and there is often a small margin between therapeutic and toxic dosages. Although they can often suppress an undesirable rhythm, drugs may also suppress a normal sinus mechanism or may create toxic manifestations that are more severe than the dysrhythmia being treated.

In the clinical setting of hypotension or acute cardiopulmonary collapse, cardioversion may be lifesaving, and is preferred over drug therapy. Key concepts in the use of this procedure include understanding the indications for its use,

the equipment involved, the importance of adequate sedation, and the concerns for health worker safety.

Indications and Contraindications

All decisions regarding the need for cardioversion are best made at the bedside by the clinician assessing the given scenario. There are no firm guidelines on exactly what defines an unstable clinical situation, and definitions are relative terms that lend themselves to real-time clinical decision making and clinician interpretation. Cardioversion is often indicated whenever a reentrant tachycardia is causing chest pain, pulmonary edema, light-headedness, or hypotension. This excludes tachydysrhythmias that are known to be caused by digitalis toxicity, as well as a known sinus tachycardia. It is also indicated in less urgent circumstances when medical therapy has failed. In elderly patients, in whom a prolonged rapid heartbeat can be anticipated to cause complications (e.g., clots, thrombi) related to cardiac ischemia or dysfunction, early intervention with cardioversion may also be beneficial.

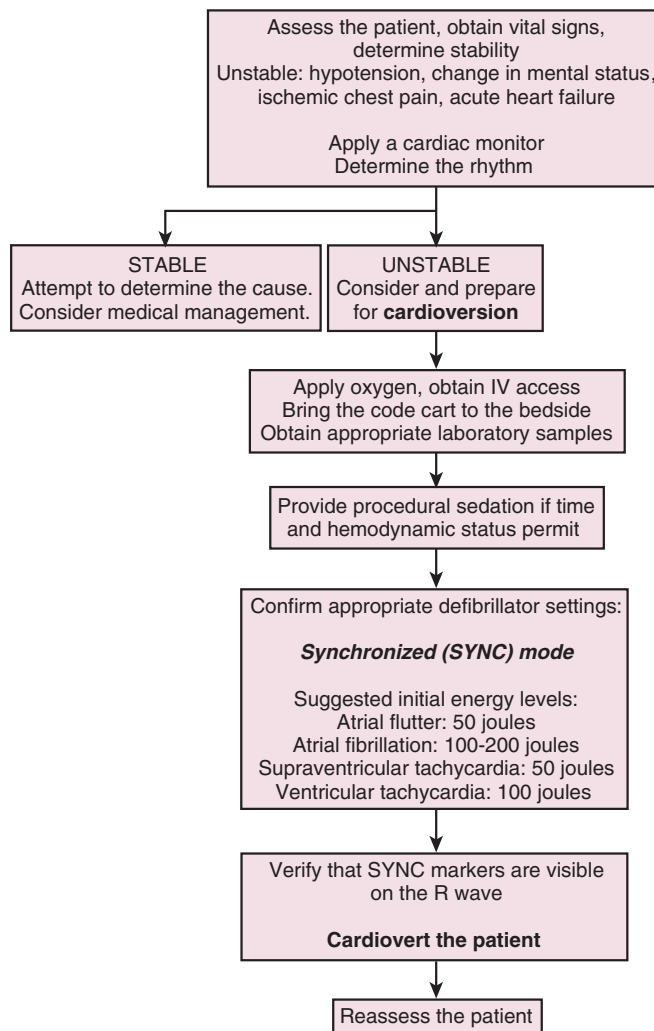

A reentrant tachydysrhythmia should be suspected when a sudden change in HR occurs within a few beats. Unless the dysrhythmia is noted whilst the patient is being monitored, it can be inferred only from the patient's history of a sudden onset of symptoms. In the unusual case of sinus node reentrant tachycardia, rapid onset and offset may be the only clues.³² Other clues to the presence of a reentrant dysrhythmia are a history of Wolff-Parkinson-White (WPW) syndrome or another known accessory pathway syndrome. Ventricular rates in excess of those predicted for age strongly suggest an accessory pathway.

Dysrhythmias caused by enhanced automaticity *will not* be terminated by uniformly depolarizing myocardial tissue because a homogeneous depolarization state already exists. Enhanced automaticity is the cause of most cases of digitalis toxicity-induced dysrhythmia, sinus tachycardia, and multifocal atrial tachycardia. Although cardioversion will not work in these cases, medications that suppress automaticity, including potassium and magnesium, may be useful.

In digoxin toxicity, not only is cardioversion ineffective, but it is also associated with a higher incidence of post-shock VT and VF.³³ However, in a patient with a therapeutic digoxin level, the risk associated with cardioversion is now thought to be no different from that of other patients. Digoxin is still generally withheld for 24 hours before cardioversion as a precaution against inadvertently elevated levels. Pregnancy at any stage is not a contraindication to cardioversion.¹⁵

Treatment

Therapy is dictated by the specific wide-complex tachycardia and the patient's clinical findings (Fig. 12.18). The initial approach must always be led, and modified if necessary, by the patient's signs and symptoms and subsequent changes. Synchronized monophasic or biphasic cardioversion is the appropriate first choice of treatment for unstable patients.¹¹ In patients deemed to be stable, the therapeutic options are more diverse. Stable, wide-complex tachycardia can always be considered VT and treated according to current VT algorithms.³⁴ A reasonable treatment protocol for stable patients may be the use of adenosine, procainamide, lidocaine, and finally, cardioversion. Amiodarone is effective for most SVTs, and its use for stable unknown wide-complex SVT is both appropriate and safe.⁷

See AHA 2010 guidelines for more information.

Figure 12.18 Cardioversion algorithm. IV, intravenous.

Equipment and Setup

The critical components of preparation for cardioversion are IV access, airway management equipment, drugs for sedation, monitoring, and DC delivery equipment (cardioverter) (Fig. 12.19, step 1).

Secure IV access is essential for delivery of sedatives, antidysrhythmics, fluids, and possibly paralytic agents. Although many of these drugs are not used routinely, if they are needed, timing is likely to be critical. A large-bore IV catheter should be inserted and firmly taped to the patient's skin.

A significant and preventable complication of procedures involving sedation is hypoventilation leading to hypoxia. Airway management equipment includes the secure IV catheter discussed previously, working suction with a tonsil-tipped device attached, BVM apparatus, oxygen, and appropriately sized laryngoscope and endotracheal tube. A pulse oximeter is generally recommended for patients undergoing conscious sedation. Another adjunct is continuous monitoring of carbon dioxide pressure (PCO₂). A rising PCO₂ level will be an earlier clue to hypoventilation secondary to sedation because oxygen saturation may remain normal for several minutes, especially if the patient has been preoxygenated.

CARDIOVERSION

1 Obtain IV access, administer oxygen, and place the patient on cardiac, pulse oximetry, and end-tidal CO₂ monitors. Anticipate and prepare sedative and antidysrhythmic medications.

2 Administer procedural sedation if time and the clinical scenario permit.

3 Push the "SYNC" button to select the synchronized mode. Check to see that the machine is correctly identifying the R wave of the complexes (arrow).

4 Select the appropriate energy level. This will depend on the rhythm being cardioverted. See text and the cardioversion algorithm for details.

5 Once the energy has been selected and the decision to cardiovert confirmed, press the "CHARGE" button on the defibrillator.

6 As the "CHARGE" button is depressed, loudly announce "I'm clear, you're clear, everybody's clear!" and make sure that no caregivers are in contact with the patient.

7 Check once again to make sure that everyone is clear, and then depress the "SHOCK" button to cardiovert the patient.

8 After delivery of the energy, reassess the patient and heart rhythm.

Figure 12.19 Cardioversion.

Sedative medications should be ready for use in labeled syringes, along with a prefilled saline syringe for flushing the catheter. Antidysrhythmic medications for ventricular dysrhythmias (e.g., amiodarone, lidocaine) and for unexpected bradycardia (e.g., atropine) should be readily accessible.

Technique

If time permits, metabolic abnormalities such as hypokalemia and hypomagnesemia should be corrected before attempting cardioversion. At a minimum, hypoxia should be corrected

with supplemental oxygen. If a patient has metabolic acidosis, compensatory hyperventilation after endotracheal intubation may be indicated before cardioversion. Respiratory acidosis should always be treated before the use of sedative drugs.

Sedation

Cardioversion may be extremely painful or terrifying, and patients must be adequately sedated before its use (see Fig. 12.19, step 2). Patients who are not adequately sedated may experience extreme anxiety and fear.³⁵ Several IV medications are available for sedation of patients before cardioversion,

TABLE 12.1 Commonly Available Intravenous Medications Used for Sedation in Cardioversion

DRUG	DOSE	COMMENTS
Midazolam	0.15 mg/kg	Most commonly used Induction occurs in approximately 2 min Small drop in blood pressure Flumazenil antagonist available
Methohexital	1 mg/kg	Quicker onset than midazolam Shorter duration than midazolam Small drop in blood pressure Rare complication of laryngospasm
Etomidate	0.15 mg/kg	No drop in blood pressure Painful IV infusion
Propofol	1.5 mg/kg	Small drop in blood pressure Painful IV infusion
Thiopental	3 mg/kg	Painful IV infusion
Fentanyl	1.5 µg/kg	An opiate Added for more sedation Can cause respiratory depression
Ketamine	1.5 mg/kg	Will not cause hypotension May be combined with reduced-dose propofol (0.5 mg/kg) or a full-dose benzodiazepine

IV, Intravenous.

including etomidate (0.15 mg/kg), midazolam (0.15 mg/kg), methohexital (1 mg/kg), propofol (0.5–1.0 mg/kg), and thiopental (3 mg/kg). In addition, IV ketamine (1.5 mg/kg), with or without a benzodiazepine or slightly reduced-dose propofol, and IV fentanyl (1.5 µg/kg), a synthetic opioid analgesic, may be administered 3 minutes before induction (Table 12.1).

Midazolam is probably the most commonly used agent, with induction occurring approximately 2 minutes after a dose of approximately 0.15 mg/kg, or at least 5 mg for an average-sized adult. Although induction with midazolam takes slightly longer than with the other medications, it has the advantage that a commercial antagonist, flumazenil, is available for reversal if necessary. Small additional doses of fentanyl (1 to 1.5 µg/kg) may be added for more profound sedation. Fentanyl can cause respiratory depression, but its action can be reversed with naloxone. Methohexital has the advantage of quick onset and a somewhat shorter duration of action than midazolam does, but it has a rare association with laryngospasm. All the drugs except etomidate and ketamine may cause a small drop in blood pressure, and infusion of propofol and etomidate is painful. Ketamine is a reasonable choice in patients with borderline hypotension.

In elderly patients, the pharmacodynamics and kinetics are altered by coexisting illness and polypharmacy rather than by any intrinsic effect of old age.³⁶ Drug doses should be reduced in these patients.

Administer the anesthetic agent or agents intravenously over a period of approximately 30 seconds and wait until the patient is unable to follow simple commands and loss of the eyelash reflex is noted. Administering the agent too quickly may result in hypotension; administering it too slowly may not allow blood levels to reach a therapeutic range if the agent has a rapid rate of metabolism.

Cardioverter Use

Selection of the synchronized or nonsynchronized mode is the next critical step (see Fig. 12.19, step 3). In the synchronized mode, the cardioverter searches for a large positive or negative deflection, which it interprets as the R or S wave. It then automatically discharges an electric current that lasts less than 4 msec, thereby avoiding the vulnerable period during repolarization when VF can easily be induced. Once the cardioverter is set to synchronize, a brief delay will occur after the buttons are pushed for discharge as the machine searches for an R wave. This delay may be disconcerting to an unaware operator.

If concern exists about whether the R wave is large enough to trigger the electrical discharge, the clinician can place the lubricated paddles together and press the discharge button. Firing should occur after a brief delay. When the R- or S-wave deflection is too small to trigger firing, change the lead that the monitor is reading or move the arm leads closer to the chest.

If there is no R or S wave to sense, as in VF, the cardioverter will not fire. Always turn off “synchronization” if VF is noted.

Electrode Position: Same as for Defibrillation

Electrode paddles may be positioned just as they are for defibrillation. Safety is a key concern in the performance of cardioversion. Any staff member acting as a ground for the electrical discharge can be seriously injured. The operator must announce “all clear” and give staff a chance to move away from the bed before discharging the paddles. Care must be taken to clean up spills of saline or water because they may create a conductive path to a staff person at the bedside.

Energy Requirements

The amount of energy required for cardioversion varies with the type of dysrhythmia, the degree of metabolic derangement, and the configuration and thickness of the chest wall (see Fig. 12.19, step 4). Obese patients may require a higher energy level for cardioversion, and the anteroposterior paddle position is sometimes more effective in these patients. If patients are shocked while in the expiratory phase of their respiratory cycle, energy requirements may also be lower.

VT in a hemodynamically stable patient should be treated with amiodarone, 150 mg intravenously, and this can be repeated as needed up to a dose of 2.2 g/24 hr. If unsuccessful, cardioversion is then performed. Cardioversion with 10 to 20 J is successful in converting VT in more than 80% of cases. Cardioversion will be accomplished with 50 J in 90% of cases, and conversion should initially be attempted at this energy level.⁷ Cardioversion should be synchronized unless the T wave is large and could be misread as the R wave by the cardioverter. If the initial attempts at electrical cardioversion

are unsuccessful, the energy level should be doubled, and doubled again if necessary, until a perfusing rhythm is restored. Immediately after conversion of VT, antidysrhythmic medications should be given to prevent recurrence.

Patients with pulseless VT should be initially shocked with 200 J, followed by 300 J if the first shock is not successful. Reentrant SVTs generally respond to low energy levels. Atrial flutter, for example, usually requires less than 50 J for conversion.⁷ Cardioversion of atrial flutter in the emergency department (ED) is indicated when the ventricular rate is not slowing in response to pharmacologically enhanced AV node blockade or if the patient is unable to tolerate the aberrant rhythm.

The majority of patients with paroxysmal atrial tachycardia respond to adenosine. If they do not, or if urgent conversion is needed because of a high ventricular rate, an electrical countershock should be administered in the synchronized mode at 50 J and doubled if necessary.

In patients with AF, the response to cardioversion is dependent on the duration of the AF and its underlying cause. Most patients with AF do not require cardioversion in the ED unless their ventricular response is high because of a bypass tract, as in WPW syndrome. They may also require cardioversion when sequelae of rapid ventricular contraction are present or anticipated and the ventricular rate is not responding to drug therapy aimed at slowing AV node conduction. Conversion of AF generally requires more energy than reentrant SVTs do (≈ 100 J in most cases).⁷

Complications

Complications of cardioversion may affect the patient, particularly those with a cardiac pacemaker, as well as health care personnel at the bedside. Injuries to health care personnel during cardioversion or defibrillation include mild shock and burns.

Patient complications are dose related and may involve the airway, heart, or chest wall, or they may be psychological. Hypoxia may develop in patients if sedation is excessive or the airway becomes compromised. With proper preparation and precautions, airway complications can be minimized. Respirations may also be depressed by any of the anesthetic agents, and the adequacy of tidal volume must be continually assessed by either direct observation or end-tidal CO₂ monitoring. If another clinician is available, that clinician should be placed in charge of monitoring the patient's airway. Routine supplemental oxygen is suggested for all patients undergoing sedation.

Chest wall burns resulting from electrical arcing are generally superficial partial-thickness burns, although deep partial-thickness burns have occurred.³⁷ They are preventable by adequate application of conductive gel and firm pressure on the paddles. Paddles should not be placed over medication patches or ointments, especially those containing nitroglycerin, because electrical discharge may cause ignition and result in chest burns.³⁸

Cardiac complications after cardioversion are proportionate to the energy dose delivered. In the moderate energy levels used most commonly, the hemodynamic effects are small. At higher energy levels, however, complications include dysrhythmias, hypotension, and rarely, pulmonary edema, which may occur several hours after the countershock.

The dysrhythmias occurring after high-dose (≈ 200 J) DC shocks include VT and VF, bradycardia, and AV block, in addition to transient and sustained asystole.³⁸ Sustained VT or VF was reported following 7 of 99 shocks in a study of patients undergoing electrophysiologic study and requiring cardioversion for VT, VF, or AF. These episodes occurred only in patients with prior VT or VF. Patients with ischemia or known coronary artery disease appear to be at much higher risk for significant post-shock bradycardia, with rate support pacing being required after 13 of 99 shocks in the aforementioned study. Asystole requiring pacing occurred only once in 99 countershocks. Therefore the proclivity for dysrhythmias is greater with high-dose cardioversion of an ischemic heart.

Conclusion

Cardioversion is a safe and effective method of quickly terminating reentrant tachycardia. Complications related to psychological trauma, respiratory depression, and unintentional shock in health care workers can be avoided with proper precautions. Adequate sedation is essential. Synchronized shock should be administered after close scrutiny of the lead used for sensing to be sure that the R or S wave is significantly larger than the T wave. Be prepared for post-shock VT or VF, and if VF occurs, switch the cardioverter to "nonsynchronized" and defibrillate. Atropine and temporary pacing equipment should be available to treat post-shock bradycardia, especially in patients with myocardial ischemia or infarction.

Pediatric Cardioversion

Pediatric cardioversion is similar to adult cardioversion. As described previously, the purpose of the procedure is to depolarize the myocytes completely at the most opportune time, during the peak of the R wave so that VF is not precipitated, and allow a slower perfusing rhythm to resume. However, the energy levels for pediatric cardioversion are different from those for adults. In the pediatric procedure, the initial recommended energy dose is 0.5 to 1 J/kg with the defibrillator in the synchronized mode. If needed, repeated cardioversion may be attempted at 2 J/kg, again while the defibrillator is in the synchronized mode. Remember to resynchronize the defibrillator after each cardioversion attempt and look for the appropriate markers on the monitor to ensure that the current is delivered at the appropriate phase of the cardiac cycle. If medication is needed, amiodarone at a dose of 5 mg/kg intravenously over a 60-minute period or procainamide at a dose of 15 mg/kg over a 60-minute period can be used (do not give these drugs together).

Assessment of Implantable Devices

James A. Pfaff and Robert T. Gerhardt

Patients with implanted pacemakers or automatic implantable cardioverter defibrillators (AICDs) are commonly seen in the emergency department (ED). Fortunately, the increased reliability of these devices has precluded a marked increase in patients with true emergencies related to device malfunction, but such patients clearly have serious underlying medical problems that must be considered. Pacemaker complications are not uncommon, with rates ranging from 2.7% to 5%. Many pacemakers fail within the first year. AICD complication rates, including inadvertent shocks, occur in up to 34% of patients with the device. The basic evaluation and treatment of patients with cardiac complaints are not substantially different in patients with pacemakers and AICDs than in those without. However, a general knowledge of the range of problems, complications, and techniques for evaluating or inactivating pacemakers or AICDs is important for emergency clinicians. These devices are complicated and emergency physicians are not expected to be experts in all complications; therefore appropriate consultation is often necessary depending on the clinical situation.

PACEMAKER CHARACTERISTICS

In essence a pacemaker consists of an electrical pulse-generating device and a lead system that senses intrinsic cardiac signals and then delivers a pulse. The pulse generator is hermetically sealed with a lithium-based battery device that weighs approximately 30 g and has an anticipated lifetime of 7 to 12 years. A semiconductor chip serves as the device's central processing unit. The generator is connected to sensing and pacing electrodes that are inserted into various locations in the heart, depending on the configuration of the pacemaker. Newer models are programmable for rate, output, sensitivity, refractory period, and modes of response. They can be reprogrammed radiotelemetrically after implantation.

Pacemakers are classified according to a standard five-letter code developed by the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group (Table 13.1). Known as the NBG code, it consists of five positions or digits. The first letter designates the chamber that receives the pacing current; the second, the sensing chamber; and the third, the pacemaker's response to sensing. The fourth letter refers to the pacemaker's rate modulation and programmability, and the fifth describes the pacemaker's ability to provide an antitachycardia function. Whereas standard pacemakers generally do not have an antitachycardia function, AICDs do have this capability and overdrive pacing is the device's first response to tachycardia. In normal practice, only the first three letters are used to describe the pacemaker (e.g., VVI or DDD).

Pacemaker wires are embedded in plastic catheters. The terminal electrodes, which may be unipolar or bipolar, travel from the generator unit to the heart via the venous system. In a unipolar system, the lead electrode functions as the negatively charged cathode, and the pulse generator case acts as the positively charged anode into which electrons flow to complete the circuit. The pulse generator casing must remain in contact with tissue and be uninsulated for pacing to occur. In the case of bipolar systems, both electrodes are located within the heart. The cathode is at the tip of the lead, and the anode is a ring electrode roughly 2 cm proximal to the tip. Bipolar leads are thicker, draw more current than unipolar leads, and are commonly preferred because of several advantages, including a decreased likelihood of pacer inhibition as a result of extraneous signals, and decreased susceptibility to interference by electromagnetic fields.

The typical entry point for inserting the leads is the central venous system, which is generally accessed via the subclavian or cephalic vein. The terminal electrodes are placed either in the right ventricle or in both the right ventricle and the atrium under fluoroscopic guidance. Proper lead placement, sensing, and pacing thresholds are assessed with electrocardiograms (ECGs). The typical radiographic appearances of implanted pacemakers and implantable cardioverter-defibrillators to include an example of lead fracture are depicted in Fig. 13.1A–E.

The pacemaker is typically programmed to pace at a rate of 60 to 80 beats/min. A significantly different rate usually indicates malfunction. When the battery is low, the rate generally begins to drop and gets slower as the battery fades. Sensing of intracardiac electrical activity is a combination of recognizing the characteristic waveforms of P waves or QRS complexes while discriminating them from T waves or external interfering signals, such as muscle activity or movement. The pacing electrical stimulus is a triphasic wave consisting of an intrinsic deflection, far-field potential, and an injury current, which typically delivers a current of 0.1 to 20.0 mA for 2 msec at 15 V.

Pacemakers have a reed switch that may be closed by placing a magnet over the generator externally on the chest wall; this inactivates the sensing mechanism of the pacemaker, which then reverts to an asynchronous rate termed the *magnet rate*. Essentially, the magnet turns the demand pacemaker into a fixed-rate pacemaker. The magnet rate is usually, but not always the same as the programmed rate.

Several innovations in rate regulation have been incorporated into some pacemakers. When present, the hysteresis feature causes pacing to be triggered at a rate greater than the intrinsic heart rate. When the hysteresis feature is used in a single-chamber ventricular pacemaker, it is designed to maintain atrioventricular (AV) synchrony at rates that are lower than what would be normal for a ventricular-paced rhythm alone. To illustrate, were the hysteresis feature of the pacemaker set at 50 beats/min, an intrinsic rate lower than 50 beats/min would trigger ventricular pacing. Unlike a standard ventricular pacemaker, the hysteresis feature might be set to offer a ventricular pacing rate at 70 beats/min or greater once the pacer is triggered.

Rate modulation by sensor-mediated methods is an additional feature triggered and mediated by a sensed response to various physiologic stimuli. The primary application for this rate modulation feature is in patients with pacemakers who continue to engage in vigorous physical activity. When present, the rate regulation feature is engaged and modulated through motion sensors installed within a pulse generator device, with

TABLE 13.1 North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group Generic Pacemaker Code (NBG Code)

a corresponding increase or decrease in the pacing rate depending on the degree of motion sensed by the pacemaker device. Other physiologic sensors that may be installed as part of the pacemaker system include those designed to sense minute ventilation, the QT interval, temperature, venous oxygen saturation, and right ventricular contractions. The latter sensors generally require that additional leads be placed.

One of the newest innovations in cardiac pacing is cardiac resynchronization therapy (CRT), also known as *biventricular pacing*.¹ In addition to a conventional right ventricular endocardial lead, CRT also employs a coronary sinus lead for left ventricular pacing. A right atrial lead may also be included. The primary objective of CRT is to restore left ventricular synchrony, primarily in patients with dilated cardiomyopathy and widened QRS complex. This condition results primarily from the presence of a left bundle branch block. In such situations CRT may improve left ventricular function, and thus cardiac output.

Characteristics of AICDs

The basic components of an AICD, including sensing electrodes, defibrillation electrodes, and a pulse generator (Fig. 13.2), can be seen on a chest radiograph. Transvenous electrodes have obviated the previous need for surgical placement. They are inserted into the pectoralis muscle. Many transvenous systems consist of a single lead containing a distal sensing electrode and one or more defibrillation electrodes in the right atrium and ventricle.² Leads are inserted through the subclavian, axillary, or cephalic vein into the right ventricular apex. The left side is preferred because of a smoother venous route to the heart and a more favorable shocking vector.² In an effort to improve the efficiency of defibrillation, an additional defibrillation coil may be used.² Various placements of AICDs are demonstrated in Fig. 13.3.

The pulse generator is a sealed titanium casing that encloses a lithium–silver–vanadium oxide battery. It has voltage converters and resistors, capacitors to store charge, microprocessors and integrated circuits to control analysis of the rhythm and delivery of therapy, memory chips to store electrographic data, and a telemetry module.² Although a pacemaker can draw the voltage required for function from its component battery, the energy needed for defibrillation requires a battery that is prohibitively large. To circumvent this problem, an AICD contains a capacitor that maximizes the voltage required by transferring energy from the battery before discharge. To achieve the energy required, AICDs use capacitors that are

charged over a period of 3 to 10 seconds by the battery and then release this energy rapidly for defibrillation.² The maximal output is 30 J in most units and 45 J in higher-energy units. This energy is high enough that a discharge is very obvious and often distressing to the patient.

Most AICDs use a system in which the pulse generator is part of the shocking circuit, often described as a “can” technology, and most of them have a dual-coil lead with a proximal coil in the superior vena cava and a distal coil in the right ventricle.² Current flows in a three-dimensional configuration from the distal coil to both the proximal coil and the generator.² This dispersion of the electrical field increases the likelihood of depolarizing the entire myocardium at once, thereby leading to successful defibrillation.²

AICDs may have the same programming capabilities as pacemakers and can be single chambered, dual chambered, or used with the aforementioned CRT.² Single-chamber devices have only a right ventricular lead. They often have difficulty identifying atrial arrhythmias, which can result in inappropriate defibrillation of atrial tachycardias. Dual-chamber AICDs have right atrial and right ventricular leads and improved ability to discriminate rhythms. In most studies, dual devices have been found to offer improved discrimination between ventricular and supraventricular arrhythmias, thus decreasing inappropriate shocks as a result of rapid supraventricular rhythms or physiologic sinus tachycardia.² Of AICDs implanted annually 27% are single chamber, 32% dual chamber, and 41% are CRT systems.³ In patients requiring both AICD and pacemaker functions, both these devices are placed together. The advent of technology has allowed placement of a single device that can perform both pacemaker and defibrillator functions.

AICDs use a combination of antitachycardia pacing, low-energy cardioversion, defibrillation, and bradycardiac pacing in a combination also known as *tiered therapy*. They are programmed with specific algorithms that identify and treat specific rhythms. Ventricular arrhythmias may initially be converted (or undergo attempts at conversion) with antitachycardiac pacing as opposed to immediate defibrillation. This *overdrive pacing* may terminate the rhythm without the need for electrical defibrillation in up to 90% of events. It is most successful for terminating monomorphic ventricular tachycardia with a rate of less than 200 beats/min. Overdrive pacing is better tolerated by patients than cardioversion and reduces the risk for inducing atrial fibrillation. These events may be silent, not felt by the patient, and discovered only by interrogating the device.

If unsuccessful, the next intervention may be low-energy cardioversion (<5 J). The device may be programmed to very

low levels of electricity that are better tolerated by the patient. This works best for ventricular rates higher than 150 and lower than 240 beats/min. This may be followed by a high-energy defibrillation. Traditionally, the energy level of the first shock is set at least 10 J above the threshold of the last defibrillation measured. If the first shock fails a backup shock may be required, but this may induce or aggravate ventricular arrhythmias (see

the later section on [Pacemaker-Mediated Tachycardia](#)). Unlike the proarrhythmic effects of medication, these arrhythmias are almost never fatal, although they may be associated with increased morbidity. Currently used biphasic waveforms have improved defibrillation thresholds.

This tiered approach obviates the need for unnecessary energy requirements. The devices also have antibradycardiac

Figure 13.1 A, Various radiographs of an implanted pacemaker and automatic implantable cardioverter-defibrillator showing battery and lead wires. Posteroanterior (PA; **A1**) and lateral (**A2**) chest radiographs demonstrate a biventricular pacing system. There are three leads—the first is positioned in the right atrium, the second is in the right ventricular apex, and the third courses posteriorly in the coronary sinus and into the posterolateral cardiac vein. **B**, PA chest radiographs of a dual-chamber pacemaker. **B1**, The ventricular lead is passing through an atrial septal defect into the left ventricle. **B2**, The lead is repositioned in the right ventricular apex. **C**, A dual-chamber implantable cardioverter-defibrillator with active fixation leads has been implanted via a transvenous approach to place the atrial lead in the systemic venous atrium and the ventricular lead across the baffle into the morphologic left ventricle.

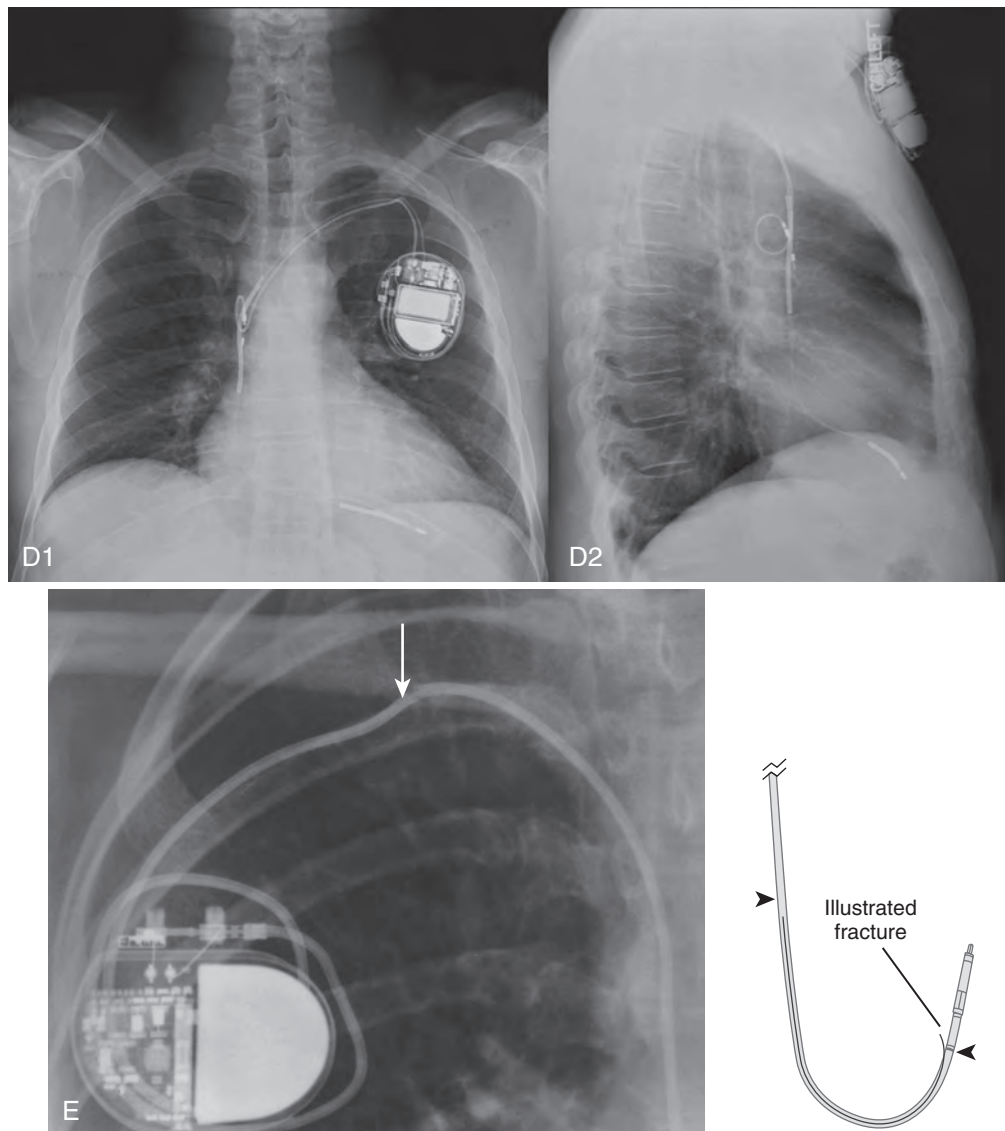

Figure 13.1, cont'd **D**, PA chest radiograph of a patient with a dual-chamber pacemaker (**D1**). The atrial lead, originally positioned in the right atrial appendage, is clearly no longer positioned in the right atrial appendage. A lateral view (**D2**) also shows definite dislodgement of the atrial lead. **E**, Close-up view of a portion of the PA chest radiograph of a patient with a single-chamber pacemaker. The lead has fractured (a subtle finding) at the point where it passes below the clavicle (*arrow*). The device showed intermittent ventricular failure to capture and intermittent failure to output on the ventricular lead. Impedance was intermittently measured at more than 9999 Ω . *Inset*, Diagram of the fracture site. (**E inset**, Courtesy Teletronics Pacing Systems, Englewood, CO.)

pacing that allows these patients to have one device instead of separate units. Additional complications associated with AICDs that have antibradycardiac pacing algorithms include a tendency toward oversensing, increased current drain, potential detection problems, and an increased incidence of hardware and software design problems. At the time of insertion, the amount of energy required for various AICD functions, such as the defibrillation threshold, is determined for any given patient, and output and sensing functions can be adjusted by reprogramming as needed.

In 2012 the Food and Drug Administration approved the use of a subcutaneous defibrillator. This consists of a subcutaneous lead with a shock coil flanked by two sensing electrodes; this coil is tunneled along the parasternal margin from the pulse generator that is implanted in a subcutaneous pocket. It

is placed by anatomic landmarks and as such no fluoroscopy is required.⁴ It delivers an 80-J biphasic shock across the precordium. Fig. 13.4 is a radiograph of a patient with a subcutaneous defibrillator.

The subcutaneous implantable device may be an alternative to patients who have difficult vascular access or who are at risk for transvenous complications. These could include the pediatric populations, patients with congenital disease, complicated vascular anatomy, patients at high risk for infection, or patients on dialysis.^{5,6} The notable limitations of the subcutaneous internal defibrillator when compared with conventional devices is the inability to provide long-term bradycardia pacing or antitachycardiac pacing.⁶ Patients that need resynchronization therapy are also unsuitable candidates.⁷

Left Ventricular Assist Devices

As the management of heart failure continues to evolve, emergency physicians may encounter patients who have surgically implanted ventricular assist devices (VADs). VADs are implanted pumps used to assist a failing ventricle. Although they have been used in the right ventricle and for biventricular support, they are primarily used as a left ventricular assist

device or LVAD. The first-generation of these devices utilized a pulsatile flow pump. The second and third devices provide continuous flow through the use of axial flow or centrifugal pumps. These devices are smaller and more durable, with higher energy efficiency than the first generation models, which are no longer in use.⁸

Initially used as a bridge to heart transplantation, they are now also being used as a bridge to recovery of heart function (such as in patients with myocarditis) and for permanent (destination) therapy. The LVAD consists of an inflow cannula that is placed in the apical part of the ventricle and allows blood to flow to a pump. The pump is attached to the outflow cannula, which is placed in the ascending aorta. The device is connected through a percutaneous lead or driveline to batteries located outside the body. Figs. 13.5 and 13.6 demonstrate the components of a left ventricular device.

INDICATIONS FOR PLACEMENT OF IMPLANTABLE PACEMAKERS AND AICDS

The most common indication for placement of a cardiac pacemaker is for the treatment of symptomatic bradyarrhythmias.

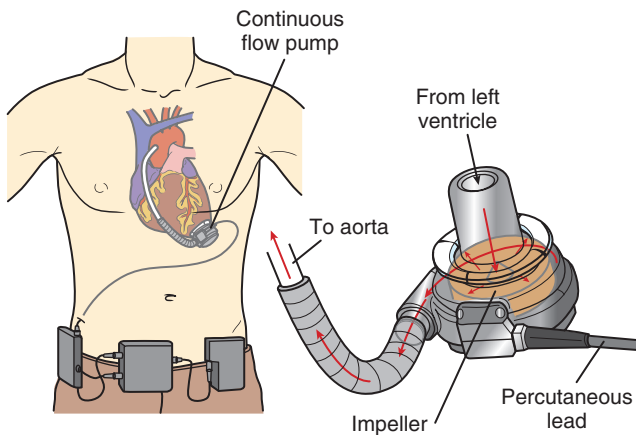

Figure 13.5 HeartWare left ventricular device basic components and function.

Figure 13.6 The HeartMate II continuous flow device receives blood from the left ventricular apex and returns to the ascending aorta. The pump is connected with a percutaneous lead to an external controller and batteries worn by the patient.

Roughly 50% of pacemakers are placed in such patients for the treatment of sinus node dysfunction (sick sinus syndrome). Other diagnoses include symptomatic sinus bradycardia, atrial fibrillation with a slow ventricular response, high-grade AV block (including Mobitz type II and third-degree AV block), tachycardia-bradycardia syndrome, chronotropic incompetence, and selected prolonged QT syndromes. Though not classified as absolute indications, pacemakers are sometimes placed for the treatment of severe refractory neurocardiogenic syncope, paroxysmal atrial fibrillation, and hypertrophic or dilated cardiomyopathy.

In recent years, CRT has emerged as a primary approach for patients with severe diastolic dysfunction and a low left ventricular ejection fraction (LVEF). Commonly such patients

manifest low-grade AV blocks and left bundle branch block. The resultant delay in left ventricular conduction often results in corresponding biomechanical delays in ventricular contraction, which in turn cause a further decrement in cardiac output and worsening congestive heart failure. Such prolongation may occur in as many as 33% of patients with advanced heart failure. This electromechanical “dyssynchrony” has been associated with increased risk for sudden cardiac death.

CRT comprises atrial-synchronized, biventricular pacing, which overcomes the atrial and ventricular blocks while optimizing both preload and LVEF. Clinical trials and systematic reviews have confirmed the efficacy of CRT, with decrements in mortality of 22% to 30%, in addition to improved LVEF and quality of life. It is therefore likely that emergency physicians will see the CRT configuration with increasing frequency in patients with implanted pacemakers and AICDs.

AICD technology is used principally for both primary and secondary prevention in patients at risk for sudden death. Primary prevention is an attempt to avoid a potentially malignant ventricular arrhythmia in patients identified as being at high risk. Secondary prevention is for patients who have already had a ventricular arrhythmia and are at risk for further events. In addition, AICDs are implanted for a number of other congenital or familial cardiac conditions.

PACEMAKER AND AICD RESPONSE TO MAGNET PLACEMENT

In the clinical setting, placement of a magnet over the pulse generator of a pacemaker is a technique that can be used either diagnostically or therapeutically by the emergency clinician. Application of a magnet is used to suspend antitachyarrhythmia detection and therapy of an AICD without changing pacing mode, or to produce asynchronous (fixed rate) pacing of a pacemaker. Hence, a magnet may change a demand pacemaker (synchronous) to a fixed rate (asynchronous) pacemaker. However, it is important to note that each pacemaker is programmed to respond in a specific fashion to a magnet as determined by the manufacturer. The response to magnet placement may not only vary by manufacturer, but also by model and by the particular mode in which the pacemaker is currently operating. Some devices (Boston Scientific, St. Jude, Biotronic devices) may be programmed to disable the magnet function and hence not respond to magnet application. Some leadless pacemakers do not initiate asynchronous pacing in response to a magnet application. In most cases manufacturers set the asynchronous (fixed rate) baseline pacing rate in a range approximating 70 beats/min. An indicator of aging of the pacemaker and weakening of the battery is that this asynchronous baseline pacing rate will decrease over time as the battery approaches the point at which replacement is required.

Keeping these provisions in mind, there are standard responses that the provider might expect to see in most circumstances. In the case of single-chamber ventricular pacemakers, the response will most likely be asynchronous pacing (V00). In the case of dual-chamber pacemakers, placement of a magnet usually results in dual-chamber asynchronous pacing (D00). In either case, it is important for the clinician to note that placement of a magnet over the pacemaker pulse generator will not turn the pacemaker off.

Placing a magnet over any of the currently available AICD models will temporarily disable tachyarrhythmia intervention

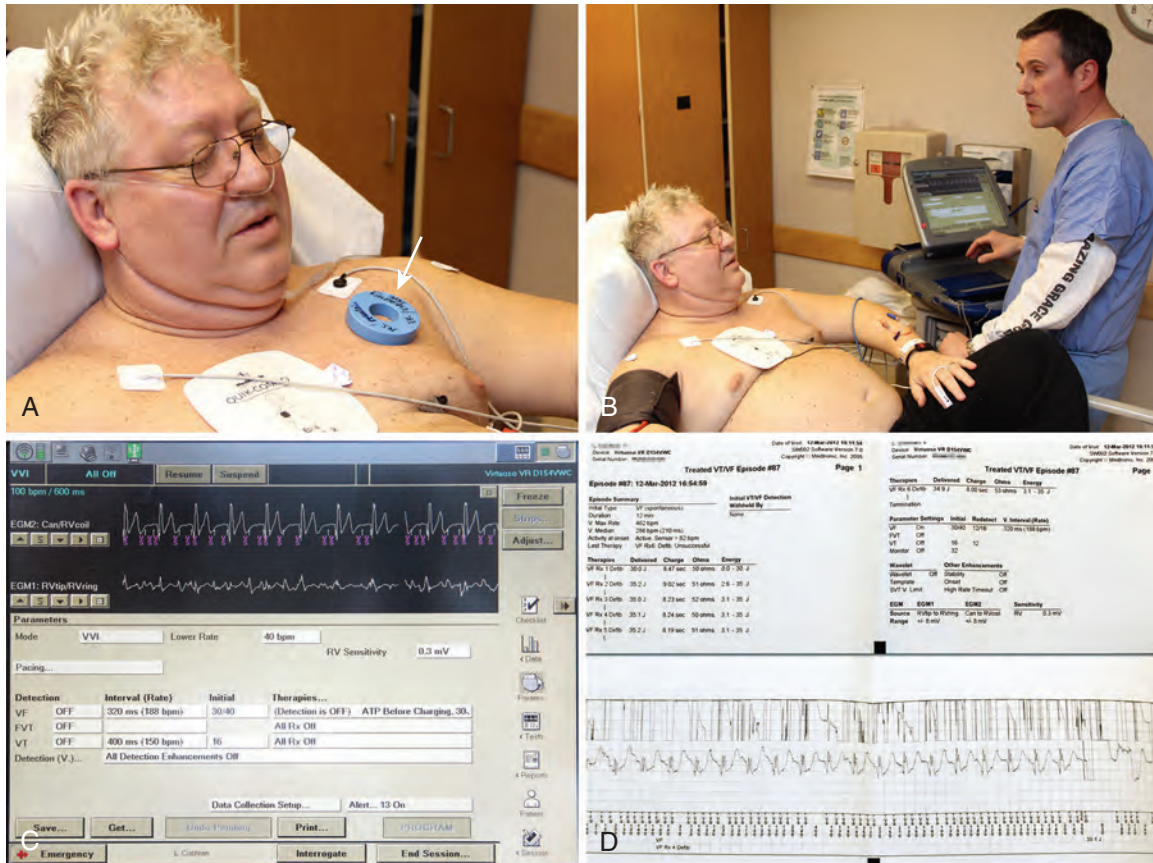

Figure 13.7 **A**, This patient suffered from 13 discharges of his automatic implantable cardioverter-defibrillator over the course of 1 hour. In the emergency department, he was noted to have a discharge while in sinus rhythm, and a magnet (*arrow*) was placed over the device to deactivate it. **B**, An electrophysiology specialist came to the emergency department to interrogate the device. Note that newer devices can communicate wirelessly. **C** and **D**, Interrogation and intracardiac electrocardiograms were consistent with fracture of the right ventricular lead. The device was deactivated and replaced shortly thereafter.

(Fig. 13.7). An ECG should be obtained before and after magnet placement for comparison (Fig. 13.8). Most commercially available pacemaker magnets are 7 cm in size and can be used with most implantable devices. Each of the present models may have a slightly different response to the magnet. The magnetic field closes a reed switch in the generator circuit that will disable recognition of tachyarrhythmias and subsequent firing of the device. There may be a variety of tones (continuous, intermittent, or silent) during activation or inactivation with the magnet, which are dependent on the manufacturer. Some devices may be programmed to not respond at all. After the desired effect is obtained, the magnet should be secured to maintain inactivation.

Pacemaker and AICD patients should carry an identification card that includes information regarding manufacturer, model type, and lead system, in addition to a 24-hour emergency number to allow rapid identification of the model when it is necessary to inactivate the device. In lieu of the availability of a device identification card, the general type, polarity, and number of ventricles involved with the implanted device may be inferred accurately by viewing an overpenetrated anteroposterior chest radiograph.

If a patient with an AICD has a ventricular arrhythmia, the assumption should be made that the device is inoperable and

standard advanced cardiac life support (ACLS) protocols should be used to stabilize the patient.

Of further note, in some obese patients or those with heavily developed chest wall musculature, the magnetic field emitted by a single magnet device may not be strong enough to elicit the desired effect on the implanted device. In such cases the clinician may find greater efficacy by using two magnets, one on top of the other.

CLINICAL EVALUATION OF PATIENTS WITH IMPLANTED PACEMAKERS AND AICDS

History

Although patients who go to the ED because of implantable pacemaker-related issues may have one or more of several complaints, those with AICD-related issues are generally seen because their device has discharged. They will often describe a sensation of being kicked or punched in the chest, and the sensation is not subtle. In fact, some patients live in fear of the shock after having experienced it previously, and this is one reason for removal of the device. Ask the patient about the number of discharges and associated symptoms, including

Figure 13.8 **A**, Electrocardiogram (ECG) of a patient with a nonfiring pacemaker. The intrinsic cardiac rate is 80 beats/min, and no pacemaker activity is seen. **B**, ECG of the same patient with a magnet applied over the pacemaker, which produced a paced rhythm. Pacer spikes are evident (*arrows*), and the magnet rate is 85 beats/min. Note the left bundle branch bundle typical of a pacer lead in the right ventricle.

chest pain, shortness of breath, lightheadedness, palpitations, syncope, extremity edema (raising concern for congestive heart failure or lower extremity deep vein thrombosis), or dyspnea on exertion. In addition, elicit general symptoms such as fever, chills, nausea, or vomiting, which could be indicative of infection. Inquire about medication history. Ask about the specific implanted device that they possess. Most pacemaker and AICD patients should have an identification card on their person that will identify the manufacturer, model number, lead system, and a 24-hour emergency contact number. Sophisticated information and the prior electrical events and settings of the device can be ascertained in the ED by simply placing an external interrogating device over the unit.

When a patient with an LVAD arrives in the ED, the provider should identify who the patient's cardiologist and cardiothoracic surgeon are. In most instances contact should be made with these providers and the patient may need to be transferred to a center with expertise in these devices.

Physical Examination

First, assess for airway patency, adequate ventilation, and cardiovascular status. The patient's mental status may also be an important clue to the severity of the symptoms. Perform an appropriate physical examination with emphasis on examining the heart and lung to seek murmurs, pericardial friction rubs, and evidence of pulmonary effusion or other abnormalities. Inspect the pacemaker or AICD site for erythema or edema. Palpate the skin for evidence of obvious lead abnormalities. Examine the extremities for evidence of edema or erythema.

There are several unique characteristics to consider in patients with ventricular assist devices. On physical exam, the provider should listen to the chest to determine if an audible "hum" is present. Patients lack a palpable pulse given the device's continuous flow and because their cardiac function at baseline is poor. The blood pressure should be obtained by using a Doppler on either the radial or brachial artery. Inflate the cuff until you can't hear flow. The cuff pressure should then be released, listening for the presence of flow.⁹ There is some degree of controversy about whether this is mean arterial pressure (MAP) or systolic pressure, however.^{10,11} When in

doubt, an arterial line would be the most accurate method to identify MAP. MAP is usually kept between 70 to 80. Pulse oximetry is also unreliable and a true measurement should be obtained with an arterial blood gas or arterial line.

Radiography

The imaging modality of choice, at least initially, in a patient with complaints related to an implanted pacemaker or AICD is the plain chest radiograph. If the patient's stability is in question, obtain a portable anteroposterior film. In addition to the standard cardiac, pulmonary, vascular, and skeletal evaluation, this study will probably confirm the location of the pulse generator case, as well as the current location of any leads. Survey the radiograph for evidence of lead fracture or displacement (see Fig. 13.1E). Compare with previous chest films. If the patient does not have a device identification card in immediate possession, take an overpenetrated radiograph to look for a radiopaque marker identifying the model type. Fig. 13.9 demonstrates a radiograph of a patient with an LVAD.

Electrocardiography

Perform an ECG to seek evidence of pacing, ectopy, and ST-segment or T-wave abnormalities. A comparison ECG may be helpful. If an AICD shock has been delivered, the shock itself can cause transient electrocardiographic changes, and waiting for several minutes to repeat the ECG may identify whether the changes are caused by the discharge or an ongoing disease process.

Cardiopulmonary Resuscitation, ACLS Interventions, and External Cardiac Defibrillation in Patients With Implanted Pacemakers or AICDs or LVADs

In general, ACLS interventions may be performed safely and effectively in patients with pacemakers and AICDs when indicated. Cardiopulmonary resuscitation (CPR) can usually be performed in standard fashion. If an AICD is present,

Figure 13.9 Heart-Mate II model of left ventricular assist device (LVAD) appearance in **A**, posterior-anterior and **B**, lateral chest X-ray, **C**, computerized tomography, and **D**, ultrasound examination. ICD, Implantable cardioverter defibrillator; LV, left ventricle; LA, left atrium.

rescuers may notice mild electrical shocks while performing CPR; these shocks are harmless to the rescuer. If the AICD shocks are impeding rescuer performance of CPR, or if supraventricular tachycardias are noted during resuscitation, disable the AICD by applying a magnet over the corner of the device from which the leads emerge. This location is generally found easily by palpation but may be located blindly by slowly relocating the magnet until AICD activity ceases.

External cardiac defibrillation may be performed safely in patients with pacemakers and AICDs with the standard expected efficacy; however, it is recommended that external paddles or defibrillator pads be placed at a location approximately 10 cm distant from the pulse generator if possible. A transcutaneous cardiac pacemaker may also be used in similar fashion with a recommendation that the pacing pads be placed in anatomically appropriate locations but preferably at a distance of 10 cm from the pulse generator.

Placing the external defibrillation or transcutaneous pacemaker pads in an anteroposterior configuration is advised because this configuration may circumvent energy shunting and shielding. Every attempt should be made to avoid application of the defibrillators directly over the device. Use of the lowest possible energy setting for cardioversion or defibrillation is recommended. If available, biphasic cardioverter defibrillators

are further suggested. In the event of successful resuscitation and return of spontaneous circulation, the pacemaker or AICD should be interrogated expeditiously by a cardiologist or electrophysiologist to ensure that no damage was sustained as a result of the resuscitation effort.

Regarding pharmacologic adjuncts, amiodarone has been reported to be more effective for the treatment of potentially lethal arrhythmias in the setting of implanted devices. Antiarrhythmic medications may be required for a resistant malignant rhythm when the AICD is functioning properly but the arrhythmia persists (Fig. 13.10G).

Several additional considerations are unique to the setting of ACLS in patients with a pacemaker or AICD. In cases of acute myocardial infarction involving areas of the myocardium in contact with the pacemaker leads, the implanted pacemaker may experience operative failure. Therefore, maintain a high level of suspicion for the potential requirement for supplemental transcutaneous or transvenous cardiac pacing.

LVAD patients that go into cardiac arrest offer some unique challenges. Ensure that the machine is connected, the battery charged, and the machine has an audible hum. The lack of peripheral pulses also make the use of ACLS problematic. In the case of arrest, follow the standard Advanced Cardiac Life Support algorithms. There is concern that standard CPR may

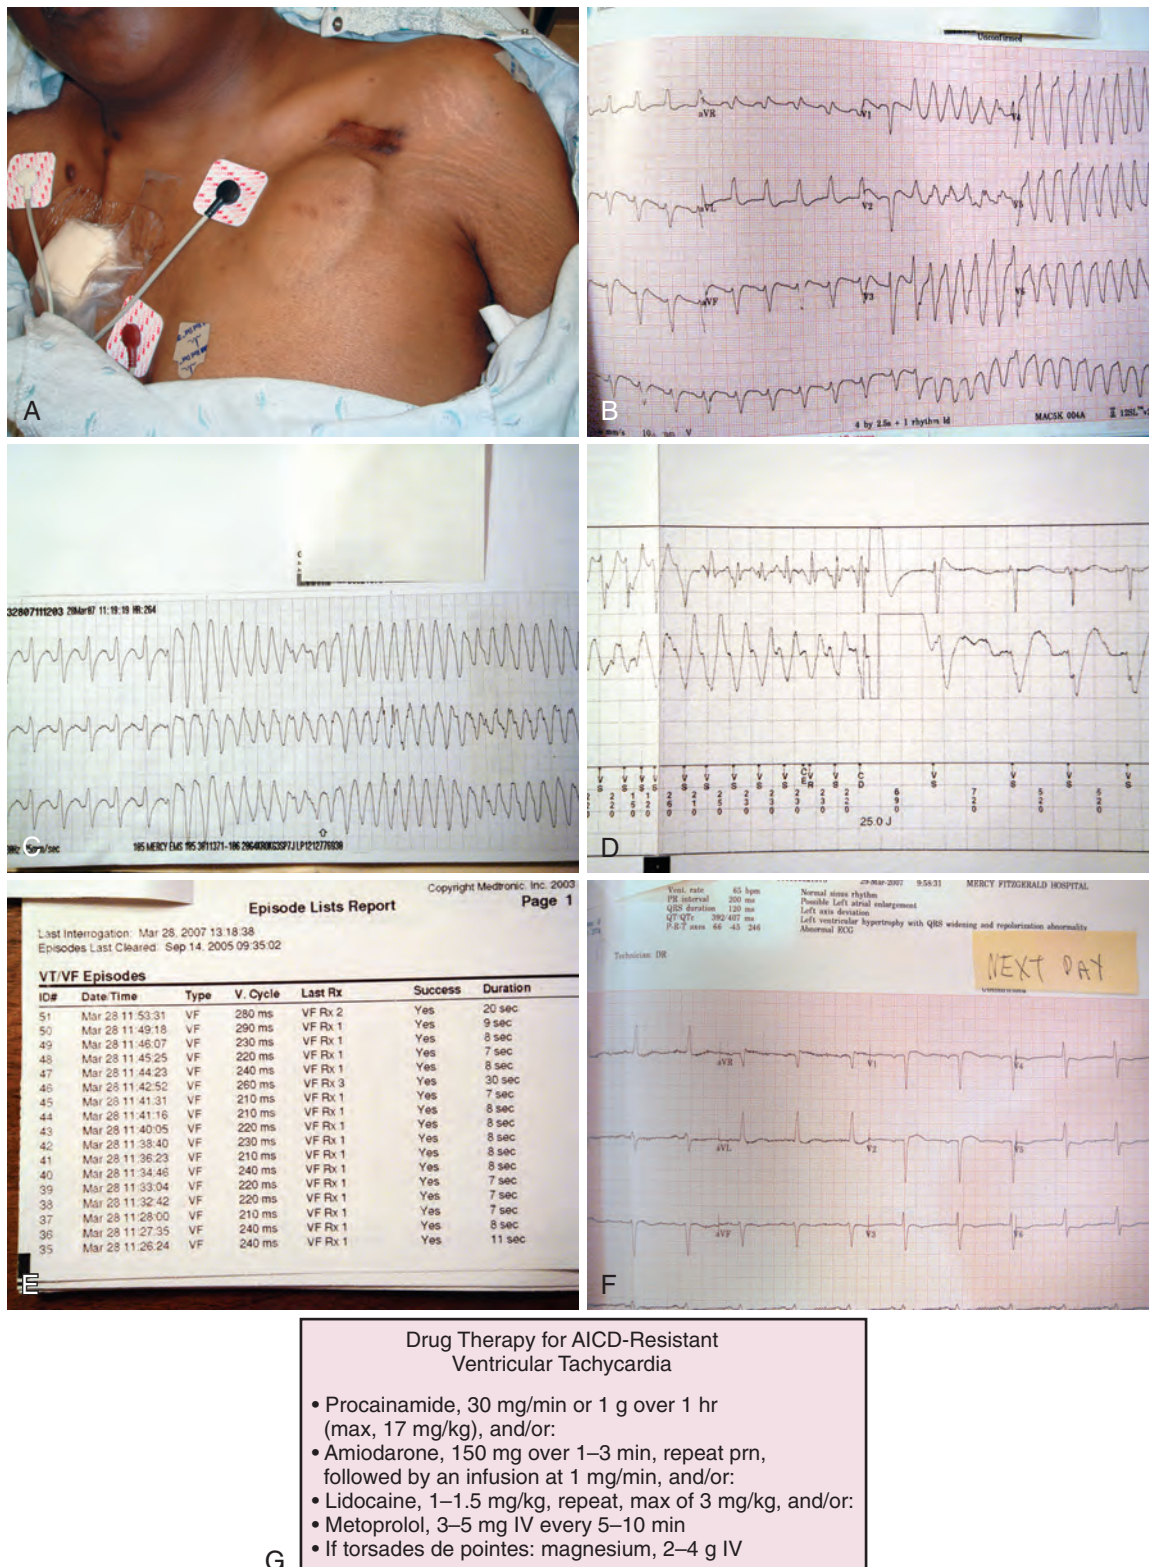

Figure 13.10 A, Patient with an automatic implantable cardioverter defibrillator (AICD) who experienced multiple discharges from an AICD because of recurrent ventricular tachycardia (VT). B, Electrocardiogram (ECG) of VT in the presence of an underlying tachycardia as the possible cause. C, A rhythm strip demonstrates persistent polymorphic (torsades de pointes) VT. D, After attempts at overdrive pacing failed, the AICD appropriately discharges with temporary termination of VT. E, Interrogation of the device uncovers a history of more than 20 episodes of recurrent VT within 30 minutes. *This patient was terrified of a subsequent shock because he could sense the VT and knew of the impending shock. In addition to antiarrhythmic medication, a quiet dark room and aggressive sedation are suggested to reduce catecholamine levels.* F, ECG after medical therapy with multiple medications, including magnesium. *Metoprolol seemed to be the deciding factor in terminating the VT in this case.* G, Current suggested medical therapy for VT in the presence of an appropriately functioning AICD.

dislodge the cannula or damage the unit's outflow conduit, but there have also been reports that this is not as harmful as previously thought.^{12,13} There was also a report of an emergency physician who replaced the driveline connections in a patient who had cut the wires resulting in subsequent resumption of the pump function.¹⁴

In the postresuscitation setting involving a patient with an implanted pacemaker or AICD, it is important to maintain a higher index of suspicion for device lead fracture or disruption resulting from CPR. Finally, in the postresuscitation phase the clinician should closely watch for the development of pneumothorax, hemothorax, pericardial effusion, or other aforementioned pathophysiologic processes that could adversely affect the function of the implanted device.

COMPLICATIONS AND MALFUNCTION OF IMPLANTED PACEMAKERS

Complications associated with pacemakers are listed in [Box 13.1](#). In addition, patients with previously implanted and otherwise stable pacemakers may experience complications related to direct or indirect trauma affecting the pulse generator or leads. Major complications of pacemaker placement or those caused by subsequent injuries that the emergency clinician might encounter include: local or systemic infections resulting from pacemaker placement, thrombophlebitis involving the transvenous route of the pacemaker leads, a venous thromboembolic event, pneumothorax or hemothorax, pericarditis, air embolism, localized hematoma interfering with pacemaker operation or sensing, lead dislodgement, cardiac perforation, hemopericardium with possible progression to cardiac tamponade, and development of the phenomenon known as *pacemaker syndrome*. This condition is often seen in patients with single-chamber ventricular pacemakers who have an underlying component of congestive heart failure. It is believed to be a consequence of the loss of AV synchrony resulting from the ventricular pacing, and may be manifested as vertigo, syncope, hypotension, and signs specific to the exacerbation of congestive heart failure.

In addition to the complications associated with initial pacemaker placement, malfunctions of these devices may occur in the short-, intermediate-, and long-term phases of their functional life spans. Most malfunctions result from one or a combination of three primary problems: failure of the pace generator to provide output, failure to capture, or failure to sense the intrinsic cardiac rhythm.

Pacemaker Output Failure

Pacemaker generator output failure is present when no pacing "spike" is noted on the ECG despite an indication for pacing. This condition may result from battery failure, fracture or loss of insulation in the pacer leads, oversensing of extraneous signals resulting in pacer inhibition, disconnection of the leads from the pacer generator, or in the case of a dual-chamber pacer, erroneous sensing of the pacemaker's atrial signal by a ventricular sensor. The latter phenomenon is commonly referred to as *crosstalk*.

Given that the reason for pacemaker implantation in most cases was for the treatment of an underlying bradycardia condition, initial clinical management of patients with some degree of pacer output failure will usually focus on pharma-

BOX 13.1 Complications of Permanent Pacemakers

FAILURE TO PACE (NO PACEMAKER ACTIVITY PRESENT)

- Lead fracture
- Lead disconnection
- Battery depletion
- Component failure
- Oversensing
- External interference

FAILURE TO SENSE (CONSTANT PACEMAKER SPIKES DESPITE ONGOING INTRINSIC CARDIAC ELECTRICAL ACTIVITY)

- Lead dislodgement
- Lead fracture
- Fibrosis around the tip of the lead
- Battery depletion
- Pacer in asynchronous mode
- External interference
- Low-amplitude intracardiac signal

FAILURE TO CAPTURE (PACEMAKER SPIKES BUT NO SUBSEQUENT CARDIAC ACTIVITY)

- Lead dislodgement, including perforation
- Lead fracture
- Lead disconnection
- Poor lead position
- Fibrosis around the tip of the lead
- Battery depletion
- Metabolic abnormalities
- Medications

INAPPROPRIATE PACEMAKER RATE (RUNAWAY PACEMAKER)

- Pacemaker reentrant tachycardia
- Resetting from external interference
- Battery depletion

OTHER

- Infections: pocket, wires
- Lead displacement: cardiac perforation, tamponade, pericarditis, vascular perforation
- Vascular complications: thrombosis, superior vena cava syndrome
- Psychiatric: anxiety, panic attacks

logic management aimed at restoring an acceptable intrinsic heart rate. Subsequently, a transcutaneous or transvenous pacemaker may be required to ensure stabilization of the patient. Once stabilization has been accomplished, further ED management should include a thorough secondary survey, 12-lead electrocardiography and continuous cardiovascular monitoring, portable chest radiograph to assess the condition of the pacemaker leads and identify related pathology, and any other pertinent diagnostic studies. At this point the clinician should seek to identify the type and model of the pacemaker and should consult an available cardiologist or electrophysiologist. Final disposition of the patient depends on the results of the stabilization, diagnostic studies, and cardiology consultation, and admission is often required.

Failure to Capture

In the case of failure to capture, pacemaker spikes are present on the ECG. However, some or all the spikes are not followed by atrial or ventricular complexes as appropriate for the pacemaker model in question. Failure to capture may result from: deterioration of lead insulation; fracture or dislodgement of the leads; electrolyte disturbances, including hyperkalemia or hypocalcemia; a new condition requiring an elevated pacing threshold; acid-base disturbance; direct damage to the myocardium, which is in contact with the pacer lead's tip (such as myocardial infarction or direct trauma); or dysfunction of the microcircuitry of the pulse generator. In addition, flecainide, a class IC antiarrhythmic medication, has been identified as an acute cause of the rise in ventricular capture thresholds in patients with implanted pacemakers. Likewise, all class I antiarrhythmic agents (sodium channel antagonists) may affect pacer capture thresholds and should therefore be identified as potential etiologic agents in patients suffering failure to capture.

Failure to Sense

Failure of an implanted cardiac pacemaker to sense the patient's intrinsic cardiac rhythm may be subdivided into conditions related to oversensing or undersensing. *Oversensing* is present when the pacemaker erroneously identifies extrinsic electrical signals, such as those from skeletal muscle potentials or electromagnetic interference (EMI), and is inhibited from delivering an appropriate pacemaker pulse. For additional information on extrinsic EMI, refer to the section on [Electromagnetic Interference and Implantable Devices](#) later in this chapter.

Management of pacemaker failure to sense will be driven largely by the patient's clinical condition. A prudent clinician will order cardiovascular monitoring, intravenous access, and a portable chest radiograph, with additional measures as dictated by the patient's condition. In the event of symptomatic bradycardia, placement of a magnet over the pacemaker pulse generator may be indicated because this maneuver will usually place the pacemaker in an asynchronous ventricular pacing mode and thereby restore a stable and regular paced ventricular rhythm while a consulting cardiologist or electrophysiologist is summoned.

Undersensing is said to occur when the pacemaker fails to identify intrinsic cardiac depolarization and delivers a pacing signal. This condition may result from damage or dislodgement of the pacemaker leads, myocardial infarction, direct cardiac trauma, failure of the pacemaker's power source, and even the application of a magnet. Initial ED management of this condition is similar to that performed in the case of oversensing. Magnet placement may also be appropriate in this setting because it will restore a stable, regular, and normal cardiac rhythm until the pacemaker and its leads may be more thoroughly examined.

Runaway Pacemaker Syndrome

This condition is seen almost exclusively in older pacemaker models particularly as they approach the end of their battery life, or when the pulse generator is damaged by exposure to radiation or direct impact. The hallmark of runaway pacemaker syndrome is uncontrolled tachycardia resulting in ventricular rates approaching 300 to 400 beats/min. In addition to initial

attempts at stabilization, magnet placement may be attempted. However, this is often ineffective. If the patient is hemodynamically unstable in the setting of runaway pacemaker syndrome, it may be necessary to disconnect the pulse generator. To do this, identify the location of the pacer leads by physical examination or a portable chest radiograph. Dissect through the skin and subcutaneous tissue and then sever the leads with a wire cutter or similar tool.

Pacemaker-Mediated Tachycardia

In some circumstances patients with implanted pacemakers or AICDs may be seen in the ED because of symptomatic tachycardias resulting specifically as a complication of their pacemaker devices. This condition, referred to as *pacemaker-mediated tachycardia*, and alternatively as *pacemaker-induced tachycardia*, results most often from one of three clinical scenarios. In patients with dual-chamber pacemakers, one of the pacemaker leads may function as a pathway for either antero- or retrograde conduction and result in what is referred to as *endless loop syndrome* and thus a tachycardiac arrhythmia, which may often become hemodynamically unstable. In general, patients suffering from endless loop syndrome will not have a ventricular rate greater than the maximum tracking rate of the pacemaker device. Consequently this condition will rarely be manifested as hemodynamic instability. One caveat, however, is that patients with underlying coronary artery disease and endless loop syndrome may experience coronary ischemia. In such a case or in a patient who is hemodynamically unstable because of the increased ventricular rate, application of a magnet will terminate the syndrome in most cases. Once stabilized, this condition may be prevented or at least mitigated by reprogramming of the pacemaker's atrial sensor lead by an electrophysiologist.

A second scenario in patients with dual-chamber pacemakers occurs under the circumstance in which the patient experiences an intrinsic atrial tachycardia, at which point the implanted pacemaker begins to continuously discharge at its maximum preprogrammed ventricular rate. This condition may continue until the underlying atrial tachycardia is terminated by intervention.

A third instance of pacemaker-mediated tachycardia occurs in patients with AICD units that have backup antibradycardia pacing capability. It appears that if this pacemaker feature is switched on in such patients and an ectopic ventricular stimulus is delivered after a sudden pause in the intrinsic ventricular depolarization cycle, a ventricular tachyarrhythmia may be triggered.

DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION IN THE PRESENCE OF A PACED CARDIAC RHYTHM

Patients undergoing active ventricular pacing from an implanted pacemaker device will normally have ECGs that resemble a left bundle branch block pattern. As a result, electrocardiographic diagnosis of acute ischemic changes is equally challenging in both populations. Sgarbossa and colleagues published a series of criteria in 1996 that offer some utility in the interpretation of ECGs in patients with active ventricular pacing in whom acute coronary syndromes are suspected. These criteria are depicted in [Table 13.2](#).

TABLE 13.2 Criteria for Electrocardiographic Diagnosis of Acute Myocardial Infarction in the Setting of a Ventricular Paced Rhythm

ELECTROCARDIOGRAPHIC CRITERION	SENSITIVITY (%)	SENSITIVITY (%)	P
Discordant ST-segment elevation >5 mm	53	88	0.025
Concordant ST-segment elevation >1 mm	18	94	NS
ST-segment depression >1 mm in precordial leads V ₁ –V ₃	2	82	NS

NS, Not significant.

AUTOMATIC IMPLANTABLE CARIOVERTER DEFIBRILLATORS—UNIQUE MALFUNCTIONS

Issues with sensing problems, lead migration, and battery failure are similar to pacemaker complications, and most occur within 3 months after implantation. There is some data that a dual chamber device is associated with a higher risk of device-related complications but a similar 1-year mortality compared to a single-chamber device.¹⁵ A large metaanalysis put the incidence of in-hospital adverse events between 2.8% to 3.6%.¹⁶ Complications related to the insertion include cardiac injury, lead dislodgement, infection, hemorrhage, and pneumothorax. A potential malfunction unique to AICDs is an inappropriate defibrillation or lack of defibrillation of the device.

The AICD may not terminate ventricular arrhythmias, which may or may not be the result of malfunction of the device. AICD malfunction may be a result of battery depletion, component failure, failure-to-sense, or lead malfunction. Failure to cardiovert or defibrillate occurring in the setting of a functioning AICD system may be caused by inappropriate cutoff rates, failure to satisfy multiple detection criteria, completion and exhaustion of therapies, and cross-inhibition by a separate pacemaker. The advent of AV or dual-chamber AICD devices has improved the sensitivity of detecting arrhythmias and thus prevents the delivery of inappropriate shocks.

Inappropriate AICD-delivered shocks occur in 20% to 25% of patients and are the most common adverse events observed in AICD patients. The main causes are atrial arrhythmias, sinus tachycardia, nonsustained ventricular tachycardia, lead fracture or EMI, or *electrical storm*. By definition this phenomenon occurs when three or more shocks are delivered in a 24-hour period, occurs in 10% to 20% of AICD patients, and constitutes a medical emergency. AICD patients who experience this phenomenon may have end-stage cardiac failure and increased long-term mortality. Specific causes of electrical storm are unclear, but it is associated with ventricular tachycardia in the setting of LVEF lower than 30%, and occurs more frequently in patients with demonstrated coronary artery disease, who have not as yet undergone revascularization procedures. Suggested initial treatment includes the administration of amiodarone and β_2 -adrenergic antagonists to pharmacologically suppress the arrhythmias, and urgent cardiology consultation

BOX 13.2 Outcome of Automatic Implantable Cardioverter Defibrillator Placement: Estimated Events Over a 5-Year Period After Placement for Current Criteria

For every 100 patients in whom an AICD is placed:
 30 patients will die anyway because of underlying disease.
 7–8 patients will be saved by AICD.
 10–20 will have a shock delivered that is not needed.
 5–15 will have an ICD complication.
 The rest will not experience the device firing.
 Some will ask to have it removed to allow natural death.

**Left ventricular ejection fraction less than 30% to 35% and anticipated survival with good functional capacity beyond 1 year.*

AICD, Automatic implantable cardioverter defibrillator; ICD, implantable cardioverter defibrillator.

for possible pacemaker interrogation, overdrive pacing, or even catheter ablation.

The AICD may discharge inappropriately in response to rapid supraventricular rhythms such as atrial fibrillation, supraventricular tachycardia, or even sinus tachycardia. Multiple shocks may be a manifestation of inefficient termination of tachycardia, such as inappropriately low-energy delivery at the first shock, increased defibrillation thresholds, and migration or dislodgement of the defibrillation lead system, or failure of the defibrillator system. Shocks that occur every few minutes may suggest that recurring ventricular tachyarrhythmias are being terminated appropriately (see Fig. 13.10).

AICD discharges in the setting of chest pain may be a result of myocardial ischemia-induced tachyarrhythmias. As noted earlier, any electrocardiographic abnormalities noted immediately after shocks should be interpreted with caution because ST elevation or depression can occur immediately after a shock. If the patient receives shocks in association with chest pain, ischemia is suggested, but other causes, including hypokalemia, hypomagnesemia, drug-induced proarrhythmia, or drugs that can prolong the QT interval (such as phenothiazines), should also be considered as underlying causes.

In some settings the AICD may fail to sense sustained ventricular tachycardia or fibrillation. Such failure may be caused by an intrinsic arrhythmia rate below the programmed detection rate, usually as a result of concurrent pharmacologic therapy. If the patient is hemodynamically stable, it may be advantageous for the cardiologist to interrogate the pacer before initiating further antiarrhythmic therapy. If unsuccessful or if the patient is experiencing a nonperfusing ventricular arrhythmia, other pharmacologic interventions include procainamide or amiodarone. Box 13.2 depicts the outcome of AICD placement in a general population.

Subcutaneous defibrillators have some of the same complications as the venous AICDs including hematoma, infection, lead displacement, and inappropriate shocks.

LVAD Complications

In patients with LVAD, infection is the second most common cause of death after cardiac failure.¹⁷ Ventricular assist device infections can be divided into three categories: VAD-specific infections including the pump, pocket, and driveline; VAD-related

infections such as bloodstream infections, endocarditis, and mediastinitis; and non-VAD infections such as pneumonia, urinary tract infection, or cholecystitis.¹⁸ Infections can involve any portion of the LVAD including the surgical site, pocket, pump, and most commonly the driveline. The patient may have nonspecific symptoms, or have fever, localized erythema, or wound drainage. Infections occur most commonly within the first three months of device implantation with the risk of severe infection and sepsis peaking at 1 month.¹⁹ Most infections are caused by gram-positive organisms such as *Staphylococcus aureus*. *Enterococcus* is also common, as are gram-negative organisms, most commonly *Pseudomonas*. Treatment includes broad spectrum antibiotics, though localized infection may be treated for gram-positives alone. LVAD-associated endocarditis has a high mortality rate,²⁰ and can range from minimal symptoms to fever and systemic emboli in a presentation similar to prosthetic valve endocarditis.

Given that most patients are on both antiplatelet therapy and anticoagulant therapy, bleeding is another frequent adverse event in LVAD patients. The increase in bleeding susceptibility is thought to be related to the development of acquired von Willebrand syndrome secondary to polymer deformation by the second- and third-generation LVADs resulting in deficiency of von Willebrand factor.²¹ Second- and third-generation LVADs have also led to nonsurgical gastrointestinal bleeding secondary to arterial venous malformations. It is thought that reduced pulse pressure from continuous infusion results in hypoperfusion of the gastrointestinal mucosa and neovascularization that, with friable vessels, is prone to bleeding.²¹ These patients need endoscopy and possibly agent reversal with the use of fresh frozen plasma or prothrombin complex concentrates.

LVAD thrombosis is a potentially devastating complication occurring in 2% to 13% of continuous flow LVAD patients.²² Thrombosis can occur throughout the device resulting in thrombotic stroke, thromboembolism, LVAD malfunction, and failure, resulting in life-threatening hemodynamic impairment, cardiogenic shock, and death. The patient may have very mild and nonspecific symptoms such as tea-colored urine to decompensated heart failure. Useful laboratory tests include coagulation studies to check for patient compliance, and tests for hemolysis to include a urinalysis and lactate dehydrogenase (a level of 3 times normal indicates hemolysis).²¹ Chest x-ray may reveal malposition of the outflow cannula and chest CT angiography may diagnose inflow malposition or outflow obstruction.²³ These patients need to be urgently transferred to a center with mechanical support because the definitive therapy is removal of the device and cardiac transplantation.²²

Dysrhythmias are a common problem in patients with advanced stages of cardiomyopathy, but they are also at risk from placement of the device. Atrial arrhythmias should be treated in the same manner as the heart failure population by initially controlling the rate with β -blockers.²⁴ LVAD patients are also at risk for ventricular arrhythmias and most of them will have an AICD in place before their placement. Patients with persistent ventricular arrhythmias, in spite of the AICD discharges, may require IV β -blockers in addition to reprogramming the device.²⁵

Resuscitation of these patients can be challenging given their sensitivity to both preload and afterload. A decrease in systemic volume may result in collapse of the left ventricular wall, which may crowd the inflow cannula leading to obstruction of blood flow (also known as a *suction effect*), and subsequent clinical deterioration.²⁶ Uncontrolled increase in MAP higher

BOX 13.3 Method for Inactivation of an Automatic Implantable Cardioverter Defibrillator

1. Determine the orientation of the device in the abdominal pocket radiographically or by palpation.
2. Place a ring magnet over the upper right-hand corner of the device.
3. A beeping tone will sound that corresponds to the sensing of QRS complexes.
4. Leave the magnet in place for at least 30 seconds.
5. When the beeping changes to a continuous tone, the device is inactivated.
6. Remove the magnet.

than 90 mm may reduce LVAD outflow, cardiac output, and distal perfusion. These patients are at risk for cerebral vascular events and should be treated promptly with afterload-reducing medications.^{9,11}

Use of a Magnet for AICD

A patient who is experiencing inappropriate AICD discharges in the ED can be treated by inactivation of the device with a magnet, similar to the approach described earlier for pacemaker patients. If the patient is experiencing recurrent rhythms that require activation of the AICD, do not inactivate the device because it is functioning as required.

Technique

The method for inactivating an AICD device is outlined in Box 13.3. The orientation of the device in the abdominal pocket should be determined, with the lead connections normally being cephalad. A ring magnet is then placed over the corner adjacent to the lead connections (usually the upper right-hand corner of the device). A series of beeping tones will sound that correspond to the sensed QRS complexes. In the absence of organized QRS activity, random beeps will sound. When the magnet is left in place for 30 seconds, a continuous beep is heard. This indicates that the AICD is inactivated. The magnet should then be removed, and the AICD will remain inactivated. The AICD may be reactivated by applying the magnet for 30 seconds and removing it when the steady beep changes to intermittent beeping. Note that unlike a pacemaker, in which a magnet will turn a demand pacemaker to a fixed-rate pacemaker, a magnet will not affect the pacing function of an AICD.

“Twiddler’s Syndrome”

In some cases, patients with implantable pacemakers choose to “twiddle” with the device: they manipulate the pulse generator case within its physiologic pocket under the skin in the chest. Note that a generator may also be placed in the abdominal wall (Fig. 13.11). This practice of twiddling may result in coiling, dislodgement, or disconnection of the pacemaker leads (Fig. 13.12). It may even lead to actual displacement of the pulse generator case. At a minimum, it may result in physical discomfort and may, in fact, precipitate cardiac arrhythmias or other complications local to the site of pacemaker placement.

Figure 13.11 Pacemakers and automatic implantable cardioverter defibrillators may be implanted in the abdominal wall, in addition to the more common pectoralis muscle.

Figure 13.12 Twiddler's syndrome. Note the twisting of the pacemaker leads as they exit the device (*arrow*). This twisting is a direct result of the patient "twiddling" with the device and may result in dislodgement or disconnection of the pacemaker leads.

After initial stabilization of the complaint, these patients may require readjustment or replacement of their pacemaker devices. As part of their care, pacemaker patients should be educated to avoid manipulating their pacemakers.

Mental Health Issues Related to Implanted Pacemakers and AICDs

Patients with these devices may manifest a number of anxiety-related complications including adjustment disorder, panic attacks, depression, imaginary shock; and defibrillator dependence, abuse, or withdrawal.²⁷ These patients may benefit from psychiatric referral either as an outpatient or as part of the admission evaluation if applicable.²⁸ The conditions may be severe enough that the device is removed by patient request.

Implantable Pacemaker and AICD Recalls

Since 1990, more than 60 device or lead advisories have been announced, affecting more than one million device patients.²⁹ These advisories were issued as a result of unanticipated failure

of devices identified after release of the product and widespread clinical use.³⁰ The decision to remove a device is complex, and there has been difficulty reaching consensus on the optimal management of patients with these recalled devices. The decision to replace them should be multifactorial and take into consideration the estimated malfunction rate of the device, anticipated consequences of failure of the device, the individual center's procedural risk for complications resulting from generator replacement, and patient preferences and desired level of risk tolerance.

Electromagnetic Interference and Implantable Devices

Given the plethora of new technologies there is always concern about the interaction of EMI with pacemakers and AICDs. The sources of EMI comprise a significant spectrum and may involve radiated and conducted sources.

The most common response of implanted devices to EMI is inappropriate inhibition or triggering of pacemaker stimuli, reversion to asynchronous pacing, and spurious detection of tachyarrhythmias by the AICD. Reprogramming of operating parameters and permanent damage to the circuitry of the device or the electrode-tissue interface can also occur but is much less frequent. Additional adverse effects that may occur include inhibition of bradycardia pacing, inadvertent delivery of a shock, or antitachycardia pacing.

The use of hermetic shielding in metal cases, filtering, interference rejection circuits, and bipolar sensing have helped mitigate most of this interference.³¹ Nonetheless, the clinician should be familiar with common sources of EMI that may affect pacemakers and AICDs.^{32,33}

It has been estimated that patients with pacemakers and AICDs have a 50% to 75% chance of developing an indication for magnetic resonance imaging (MRI) over the lifetime of the device.³³ MRIs are still considered a strong contraindication and the benefits of imaging should outweigh the risk.³⁴ Several specialty societies have published position statements emphasizing patient specific selection and the need to have the study at an experienced center with close coordination between cardiology and radiology services.³⁴

Several caveats will help to avoid the deleterious effects of EMI on implantable devices. Cell phones should not be kept in a pocket over the device. When in use they should be held at least 6 inches away from the device. When hands-free headphones are used, these devices should be placed in the ear opposite the implanted pacemaker or AICD. In addition, patients should be advised to not linger in theft detection areas or airport metal detectors. [Box 13.4](#) identifies different devices and the corresponding potential EMI that can occur with pacemakers and AICDs.

Out-of-Hospital Discharge of AICD

Patients are told to adhere to standard advice defining an appropriate response to out-of-hospital discharges of the AICD ([Box 13.5](#)). However, many come to the ED for evaluation after every shock. There is no standard ED intervention mandated by historical information, and clinical decisions are made on an individual basis corresponding to the current scenario. Options include prolonged ED observation, consultation, cardiac monitoring, laboratory testing (such as electrolytes and cardiac enzymes), or interrogation.

BOX 13.5 Follow-Up of Patients With an AICD

Follow-up assessments of patients with an AICD are made on a routine basis, every 3 to 6 months, and when discharge of the device occurs. Analysis of any previous clinical event and testing of defibrillation function are readily accomplished. Internet-based remote follow-up systems may replace some office follow-up. Follow-up can occur remotely with vendor-specific equipment to interrogate and upload data. Remote follow-up, however, permits only device interrogation and retrieval of diagnostic data, not threshold testing or reprogramming. Device interrogation includes the following:

- Determination of pacing and sensing thresholds.
- Analysis of recorded episodes of arrhythmia detection and AICD activation, including pacing and delivered shocks. Data include the date and time of each episode and a stored electrocardiogram from the event.
- Battery status.

DEFIBRILLATOR DISCHARGE

An appropriate shock is delivered in approximately 50% of patients by 2 years after implantation. Patients may not sense antitachycardiac (overdrive) pacing to terminate arrhythmias. Not all episodes of defibrillator discharge require immediate medical

evaluation, although many patients go to the ED immediately. Patients with a first shock may be seen on an urgent or elective basis to ascertain the specifics of the event and to determine whether the device is functioning properly. Discharges that are accompanied by changes in cognition (syncope, seizure, or loss of consciousness) require ED evaluation.

Per guidelines, patients who have had a single AICD discharge with immediate return to baseline clinical status and no associated symptoms (e.g., chest pain, shortness of breath, light-headedness) may have the device interrogated within 1 to 2 days.

Delivery of frequent shocks or clusters of shocks is either appropriate (because of recurrent VT) or inappropriate (because of atrial fibrillation, supraventricular tachycardia, or device malfunction). Such patients generally require emergency evaluation and hospital admission to determine the cause. Additional therapy (such as an antiarrhythmic drug or catheter ablation) may be required.

AICD, *Automatic implantable cardioverter defibrillator*; ED, *emergency department*; VT, *ventricular tachycardia*.

Disposition Criteria

In most cases, patients seen in the ED with pacemaker complications or malfunctions will be symptomatic. Accordingly, and regardless of the clinical requirement for admission, they will probably require device interrogation and possible recalibration or replacement by a cardiologist. In most cases this will be accomplished during hospital admission.

With regard to AICD malfunctions and disposition, patients who have had a single shock and no other specific complaints or comorbidity can be discharged with follow-up in 24 to

48 hours. Patients with symptoms concerning for ischemia, potentially lethal arrhythmias, or symptomatic illness should be admitted and specialty consultation obtained expeditiously. Patients who have had multiple shocks will need admission for observation and interrogation of their AICD device. Interrogation reveals significant information about the device such as why it fired, the rhythm history, and an accurate assessment of the underlying problem.

Basic Electrocardiographic Techniques

William J. Brady, Richard A. Harrigan, and Theodore C. Chan

INTRODUCTION

The electrocardiogram (ECG) is a graphic recording of the electrical activity of the heart. The standard ECG is obtained by applying electrodes over the chest and limbs to record the electrical activity of the cardiac cycle. Developed over 100 years ago, the ECG remains the most important initial diagnostic tool for the evaluation of patients presenting with chest pain, dyspnea, syncope, cardiac arrest, and toxicologic exposures, among many other clinical symptoms.

Electrocardiography is performed widely throughout the health care field, including ambulances, ambulatory clinics, emergency departments (EDs), and in-patient hospital units. Standard electrocardiography machines are small, self-contained, and portable, thus allowing them to be used in virtually any setting.

BACKGROUND

In 1903, Dutch physiologist Willem Einthoven¹ first published his recordings of the cardiac cycle with a new device, the string galvanometer, an early version of today's electrocardiogram.² Although others had previously recorded cardiac electrical activity, Einthoven's instrument laid the basis for modern clinical electrocardiography. He used bipolar leads, established standards for recording rate and amplitude, and initially described the deflections using the now familiar *P*, *Q*, *R*, *S*, and *T*, descriptors.^{3,4}

Thomas Lewis visited Einthoven's laboratory and recognized the potential clinical utility of the electrocardiography machine. Lewis became the leading authority on electrocardiography in the early 1900s and was instrumental in the development and clinical application of this new technology.² His electrocardiographic description of atrial fibrillation demonstrated the clinical potential of this technology. In the early 1930s, Francis Wood and Charles Wolferth first reported the use of ECGs to differentiate cardiac and noncardiac chest pain.² Along with Frank Wilson, their work also led to development of the unipolar "exploring" electrode, which measured electrical activity anywhere in the body with a zero-potential central terminal as a reference. These electrodes could be placed directly over the chest and formed the basis for the standard precordial leads.⁵

In 1938, the American Heart Association in conjunction with the Cardiac Society of Great Britain established the standard six precordial chest lead positions (V_1 to V_6).⁶ These precordial leads, along with Einthoven's original bipolar limb lead system (I, II, III) and the augmented unipolar limb leads developed by Emmanuel Goldberger (aVR, aVL, and aVF) in 1942, make up the standard 12-lead ECG used today.

INDICATIONS

The most frequent indication for electrocardiography in the ED is the presence of chest pain; other common complaint-based indications include dyspnea, syncope, and palpitations. Beyond complaint-based reasons for ECG performance, one can consider diagnostic investigations of suspected illness (cardiac arrest, acute coronary syndrome [ACS], pulmonary embolism, and toxic ingestion) and system considerations ("rule out myocardial infarction [MI]" protocol, sedations monitoring, admission purposes, and operative clearance).⁷ The ECG is used to help establish a diagnosis, select appropriate therapy, determine the response to treatment, assist in correct disposition of the patient, and help predict risk for both cardiovascular complications and death.

The initial 12-lead ECG obtained in the ED can be an important tool for determination of cardiovascular risk and accordingly, the choice of in-hospital admission location. Brush and coworkers⁸ classified the initial ECG into high- and low-risk groups. The low-risk electrocardiographic group had normal ECGs, nonspecific ST-T-wave changes, or no change when compared with a previous ECG. High-risk ECGs had significant abnormalities or confounding patterns, such as pathologic Q waves, ischemic ST-segment or T-wave changes, left ventricular hypertrophy, left bundle branch block, or ventricular paced rhythms. Patients with initial ECGs classified as low risk had a 14% incidence of acute myocardial infarction (AMI), a 0.6% incidence of life-threatening complications, and a 0% mortality rate. Patients with initial ECGs classified as high risk had a 42% incidence of AMI, a 14% incidence of life-threatening complications, and a 10% mortality rate.⁹ Another approach to risk prediction involves simple calculation of the number of electrocardiographic leads with ST-segment deviation (elevation or depression), with an increasing number of leads being associated with higher risk. Along similar lines, the clinician is also able to predict risk with a summation of the total millivolts of ST-segment deviation; once again, higher totals are associated with greater risk.⁹

The limitations of the ECG must be recognized. The ECG is widely reported to have a sensitivity for AMI of only approximately 55%; in one study of 1000 patients with ischemic symptoms, sensitivity improved to 68% with serial ECGs and monitoring of ST-segment trends.¹⁰ In another series, the sensitivity of the ECG for AMI ranged from 43% to 65% over a 12-hour period after the onset of ischemic symptoms, yet the negative predictive value of a normal ECG (defined as normal or with nonspecific changes or isolated fascicular blocks) for AMI did not improve above 93% during this period.¹⁰ In a large series of more than 10,000 patients evaluated for ACS, 19 (2%) patients—ultimately found to have an AMI—were inappropriately discharged from the ED. A nonischemic ECG emerged as one of five risk factors for that inappropriate disposition decision.¹¹

BASIC EQUIPMENT

The 12-Lead ECG

Although there is variability depending on the workplace, most ECGs in use today are three-channel recorders with computer memory. Such multichannel systems, which record electrical events in several leads concurrently, offer advantages over the

antiquated single-channel recorder systems as follows: capturing transient events on multiple leads simultaneously; banking the data in computer memory for storage, comparison, and transmission; and allowing presentation of data on a single sheet of paper.¹² The electrocardiographic tracing is printed in a standardized manner on standardized paper by the electrocardiograph, which has default settings regarding the speed at which the paper moves through the machine, in addition to the amplitude of the deflections to be made on the tracing (Fig. 14.1A). Electrocardiographic paper is divided into a grid with a series of horizontal and vertical lines; the thin lines are 1 mm apart, and the thick lines are separated by 5 mm. At the standard paper speed of 25 mm/sec, each vertical thin line thus represents 0.04 second (or 40 msec), and the thick vertical lines correspond to 0.20 second (or 200 msec). Recordings from each of the 12 leads are typically displayed for 2.5 seconds by default setting; the leads appearing horizontally adjacent to each other are separated by a small vertical hash mark to represent lead change.

Figure 14.1 A, Standard electrocardiographic (ECG) tracing. By convention, the thick lines are 5 mm apart, and the thin lines (barely visible on this reproduction) are 1 mm apart. At the standard paper speed of 25 mm/sec, each vertical thin line represents 0.04 sec (40 msec) and each vertical thick line represents 0.20 sec (200 msec). (The inset represents one “big box,” which is outlined by thick lines 5 mm apart.) B, Standard 12-lead ECG machine. Note the color coding of the leads.

The standard ECG includes 12 leads derived from 10 electrodes placed on the patient; each is color-coded and represented by a two-character abbreviation (Table 14.1; see also Fig. 14.1B). Distinction is made between the terms *lead* and *electrode* with the former referring to the electrical view or perspective and the latter the actual wire attached to the patient. Placement of limb leads includes on the left and right arms (LA and RA, respectively) and on the left and right legs (LL and RL, respectively). Caution is advised as to the correct anatomic placement of the leads; incorrect lead placement produces electrocardiographic findings which can mimic illness with resultant unnecessary clinical interventions and further diagnostic testing; please refer to the section on **Electrode Misplacement and Misconnection** later in this chapter for a more complete discussion of this important issue.

Standard 12 Leads

The standard 12-lead ECG depicts cardiac electrical activity from 12 points of view, or leads, that can be grouped according to planar orientation. Six leads (I, II, III, aVR, aVL, and aVF) are oriented in the frontal, or coronal, plane, and are derived from the four limb electrodes. The six precordial leads (V₁, V₂, V₃, V₄, V₅, and V₆) are oriented in the horizontal, or transverse, plane, with each representing cardiac electrical activity from that perspective. Leads I, II, and III are termed *limb leads* and are bipolar in that they record the potential difference between two electrodes (Fig. 14.2). The fourth electrode located on the right leg serves as an electrical ground. The positive poles of these bipolar leads lie to the left and inferior, a position approximating the major vector forces of the normal heart. This early convention was established so that the tracing would feature primarily upright complexes. In contrast, augmented leads aVR, aVL, and aVF are unipolar leads with the positive electrode located at the respective extremities. These augmented leads serve to fill the “electrical gaps” between leads I, II, and III. Lead aVR stands alone with a polarity and resultant orientation opposite that of the other limb and augmented leads because of the fact that its positive electrode is located in the opposite direction (superior and to the right) of the major vector force of the normal heart (inferior

TABLE 14.1 Conventional Electrodes for the 12-Lead ECG

LOCATION	NOTATION	COLOR
Right arm	RA	White
Left arm	LA	Black
Left leg	LL	Red
Right leg	RL	Green
Precordial leads	V ₁	Brown/red
	V ₂	Brown/yellow
	V ₃	Brown/green
	V ₄	Brown/blue
	V ₅	Brown/orange
	V ₆	Brown/violet

Figure 14.2 Bipolar limb leads. Leads I, II, and III are shown as a triangle, known as *Einthoven's triangle*. Left arm (LA), right arm (RA), and left leg (LL) placement is shown. Orient these bipolar leads so that the positive poles lie inferiorly and to the left (given that the bottom apex of the triangle is directed toward the left leg), as does the major electrical vector of the heart.

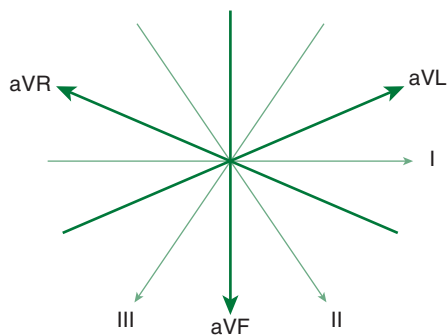

Figure 14.3 Hexaxial system of limb and augmented leads in the frontal plane. Each lead is separated by 30 degrees in this frontal-plane representation of the limb and augmented leads. Augmented leads are shown in boldface. Arrows denote positive polarity. Note that the inferior leads (II, III, aVF) logically lie at the bottom of this figure and the lateral leads (I, aVL) lie on the left side of the figure, where the lateral aspect of the heart is located if this were superimposed on a patient.

and to the left); thus its complexes usually appear “opposite” those in most or all of the other leads.

Merging of the vector axes of the limb and augmented leads around a central axis yields a hexaxial system representing cardiac electrical activity in the frontal plane (Fig. 14.3). The six precordial leads, oriented in the horizontal plane, represent six unipolar electrodes with vector positivity oriented toward the chest surface and the central terminal of the hexaxial system serving as a negative pole. In contrast to the frontal-plane leads, the angles between each of the precordial leads in the horizontal plane are not equal. They can vary depending on electrode placement and body habitus.

Electrode Placement

The four limb electrodes are conventionally placed on the extremities as follows: RA on the right wrist, LA on the left wrist, RL on the right ankle, and LL on the left ankle. Electrodes may be affixed more proximally on the limbs if necessary

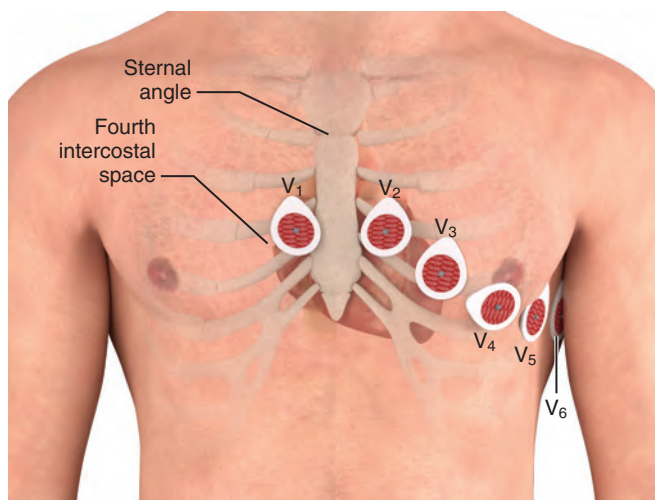

Figure 14.4 Normal precordial (V_1 – V_6) lead placement for the standard 12-lead electrocardiogram. If multiple or repeated electrocardiographic tracings are anticipated, mark the original lead placements on the patient's chest wall or leave stick-on leads in place after the electrocardiographic wires are removed.

(e.g., amputation, severe injuries), ideally with a notation made on the ECG.¹³ Others note that the electrodes may be placed on any part of the arms or legs provided that they are distal to the shoulders or inguinal/gluteal folds, respectively.¹⁴

Mason-Likar electrode placement is commonly used by hospital staff and paramedics; this approach does not alter precordial electrode placement but instead moves the limb electrodes to the torso. Originally described in 1966, the Mason-Likar configuration differs from standard electrode placement in that the arm electrodes are relocated to the infraclavicular fossae (medial to the borders of the deltoid muscles and 2 cm below the clavicles), and the leg electrodes are positioned along the anterior axillary lines (halfway between the costal margins and the iliac crests). Actual torso positioning may differ in practice because of individual variation or an attempt to simulate limb electrode placement. A rightward frontal-plane access shift has been described when torso electrode placement is used for the limb electrodes instead of standard positioning on the extremities. Mason-Likar positioning has also been associated with diminution of inferior Q waves, thus making detection of inferior MI more difficult.¹⁵ An alternative electrode configuration is the Lund system, in which the arm electrodes are placed laterally on the left and right arms at the level of the axillary folds, and the leg electrodes are positioned laterally on the greater femoral trochanters. The Lund system has been found to more directly approximate the electrocardiographic recordings obtained with conventional positioning than the Mason-Likar configuration does.^{16,17}

The precordial electrodes should be placed as follows: V_1 —right sternal border, fourth intercostal space; V_2 —left sternal border, fourth intercostal space; V_3 —midway between V_2 and V_4 ; V_4 —left midclavicular line, fifth intercostal space; V_5 —left anterior axillary line, same horizontal level as V_4 ; and V_6 —left midaxillary line, same horizontal level as V_4 and V_5 (Fig. 14.4). Note that V_4 to V_6 are placed at the same horizontal level, not all in the fifth intercostal space. If V_5 and V_6 are situated so that they follow the contour of the intercostal space rather than being on the same horizontal level, they will be superiorly displaced as the ribs curve around the side of

the thorax. Minor changes in the position of the precordial leads will alter the ECG tracing, so it is important to keep the adhesive leads in place throughout the ED stay so that lead placement is identical during serial ECG comparisons.

Intercostal space number can be determined by first palpating the sternal angle (angle of Louis), which is the junction of the manubrium and body of the sternum (see Fig. 14.4). This transverse bony ridge is located about 5 cm caudal from the sternal notch in adults. Immediately lateral and inferior to it is the second intercostal space; two spaces farther down lies the fourth intercostal space, where V_1 and V_2 should be placed. Alternatively, one can count down from the medial aspect of the clavicle; beneath the clavicle lies the first rib, below which is the first intercostal space. The precordial electrodes should not be simply “eyeballed” by the technician because as little as 1 to 2 cm of electrode displacement can result in significant morphologic alteration in the precordial QRS complexes.^{17,18}

If the patient's body habitus or pathologic process precludes placement of a precordial electrode as just described, it is permissible to attach it within the radius of the width of one interspace of the recommended position, with appropriate notation on the tracing. If the situation demands further displacement, it is recommended that the lead be omitted, with appropriate documentation on the tracing.¹³

Preformatted lead placement is used by some clinicians. For instance, the use of disposable, prewired electrodes in a manner similar to Mason-Likar positioning allows for more rapid placement, 20% faster compared to standard lead placement. The quality of the resultant ECG tracing is excellent, with lower rates of artifact and minimal impact on standard electrocardiographic structures.¹⁹ These preformatted lead placement systems are more expensive, however, as compared to standard lead placement wiring.²⁰

Pediatric Electrode Placement

In addition to the standard 12-lead tracing, leads V_4R and V_3R should also be recorded; these are mirror images of their left-sided counterparts (see section on [Additional Leads](#) later in this chapter). The chest of a tiny infant may not accommodate all the precordial electrodes; in such cases the following array is recommended: V_3R or V_4R , V_1 , V_3 , and V_6 . Limb electrode placement is the same as in adults.²¹

FEATURES OF THE ECG

Information Provided by the Computer

In addition to the patient demographic data entered by the operator, the tracing will often feature computations regarding rate, intervals, and axes along the top of the paper. On some tracings, a computer-generated interpretation, or “reading,” will also be displayed at the top of the tracing. These interpretations are not infallible. A sample of nine of these programs was compared with the readings of eight cardiologists; the gold standard in this study was clinical diagnosis made independently of the interpretations of these tracings based on other objective data (e.g., echocardiography, cardiac catheterization). The performance of the programs was good, with correct interpretations in a median of 91% of cases, but the cardiologists were significantly better (median of 96% correct).¹⁹ The

computer programs demonstrated a median sensitivity for anterior and inferior MI of only 77% and 59%, respectively.²² Of note, this study did not evaluate interpretation of acute ischemia and cardiac rhythm disturbance, other critical issues in electrocardiographic interpretation. Others have found both the computer programs and clinicians to be lacking in their ability to exclude cardiac disease with the ECG, with a negative predictive value for each of between 80% and 85%.²³ When diagnosing atrial fibrillation, both general practitioners (sensitivity, 80%; specificity, 83%) and computer software (sensitivity, 83%; specificity, 99%) are flawed; when combined, diagnostic accuracy improves but is still imperfect (sensitivity, 92%; specificity, 91%).²⁴

It is worthwhile to read and consider the computer reading of the ECG, but the emergency clinician should not be beholden to it. The properly trained and experienced clinician provides more accurate electrocardiographic interpretation, as compared with the machine's computer algorithm.

Adjustable Features

A notation of electrocardiographic paper speed (in millimeters per second), calibration (in millimeters per millivolt), and the frequency response (in hertz) is displayed, usually in the left lower corner of the recording. *Paper speed* is usually set at a default of 25 mm/sec. It may be manipulated for purposes of deciphering a dysrhythmia, as described later (see section on [Alteration in Amplitude and Paper Speed](#)).

Calibration, or standardization, refers to the amplitude of the waveforms on the tracing. It is usually set at a default value of 10 mm/mV and is graphically depicted by a plateau-shaped waveform that appears at the extreme left side of the tracing, in front of the first complex (Fig. 14.5A). This calibration can be modified by the operator or by the computer itself, as was the case in Fig. 14.5B, in which the patient appeared to have acquired voltage criteria for left ventricular hypertrophy when in reality the tracing was unchanged from his baseline (see Fig. 14.5A). Increasing the calibration to 20 mm/mV is helpful when trying to decipher P-wave morphology. Decreasing the calibration to 5 mm/mV is helpful in cases in which the amplitude of the QRS complex (usually in the precordial leads) is so large that it encroaches on those of adjacent leads. Standardization may not be uniform throughout a given tracing. At times calibration will be automatically adjusted by the computer based on the waveform amplitudes that it perceives. For example, it is possible to have normal calibration (10 mm/mV) in the limb and augmented leads, with half-standard calibration in the precordial leads (5 mm/mV). This may occur in instances of marked left ventricular hypertrophy. In this case the calibration pulse at the left-hand side of the paper will have a downward stairstep appearance.

It is important that the clinician examine all electrocardiographic tracings for standardization and paper speed parameters before rendering an interpretation.

ADDITIONAL ELECTROCARDIOGRAPHIC LEADS

Though not performed routinely and not an ED standard of care, additional electrocardiographic leads may be used in the evaluation of a patient with possible ACS. These leads can be considered in a patient with a presentation consistent with

Figure 14.5 **A**, Normal 10-mm/mV calibration. Note the box-shaped mark to the left of the complexes (arrows); this is a graphic representation of the calibration for the tracing. Routinely note this parameter before interpretation of the electrocardiogram (ECG). Note the change in **B**. **B**, Abnormal 20-mm/mV calibration. The calibration in this tracing was (inexplicably and unexpectedly) changed to 20 mm/mV by the computer, not by the operator. When compared with a baseline ECG it appeared that voltage criteria had developed for left ventricular hypertrophy and ST-segment elevation. **A** was recorded minutes later with correction of calibration to the standard 10 mm/mV and was unchanged from baseline tracings.

ACS yet demonstrating an unrevealing or nondiagnostic 12-lead ECG. These additional, or nontraditional, leads include posterior leads (V_7 , V_8 , and V_9), right ventricular leads (especially V_4R), and procedural leads (transvenous pacemaker wire placement and pericardiocentesis). Acute posterior and right ventricular MIs are likely to be underdiagnosed because the standard 12-lead ECG does not assess these areas directly. The standard ECG coupled with these additional leads constitutes the 15-lead ECG, the most frequently used extra lead ECG in clinical practice.

15-Lead ECG—Posterior and Right Ventricular Leads

Several different investigations have explored the use of the 15-lead ECG.^{7,25,26} In a study of all ED patients with chest pain, Brady and associates⁷ reported that the 15-lead ECG provided a more accurate description of myocardial injury in patients with AMI, yet failed to alter rates of diagnosis or use of reperfusion therapies or to change disposition locations. Looking at a more select population of ED patients, Zalenski and colleagues²⁶ investigated use of the 15-lead ECG in patients with chest pain and a moderate to high pretest probability of AMI, who were already identified as candidates for hospital admission. In this 15-lead ECG study, the authors reported a 12% increase in sensitivity with no loss of specificity (i.e., no increase in false-positive findings) for the diagnosis of ST-segment elevation AMI (STEMI). They further suggested that in the diagnosis of posterior AMI, leads V_8 and V_9 are superior to reliance on detecting the reciprocal ST-segment depression seen in leads V_1 to V_3 . Aql and colleagues used balloon inflation during coronary angiography for ostial or proximal left circumflex disease to simulate proximal left circumflex STEMI; they found that the posterior leads were significantly more accurate at detecting simulated STEMI when this vessel was occluded. Interestingly, 11% of their 53 patients had 1-mm or greater ST-segment elevation in a posterior lead with no ST-segment elevation or depression in any other lead.²⁵

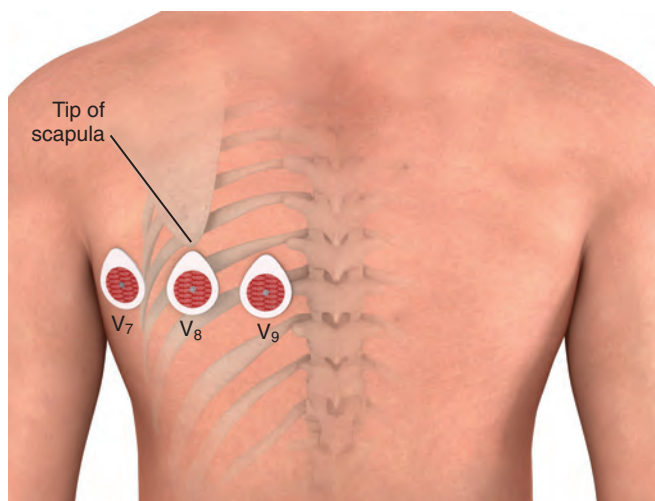

Figure 14.6 Posterior lead placement. Place leads V_7 , V_8 , and V_9 on the same horizontal plane as V_6 , with V_7 at the posterior axillary line, V_8 at the tip of the left scapula, and V_9 near the border of the left paraspinous muscles.

Potential indications for 15-lead ECGs in patients with suspected ACS include the following: (1) ST-segment depression in leads V_1 through V_3 , (2) STEMIs involving the inferior or lateral regions, (3) isolated ST-segment elevation in lead V_1 , or (4) high clinical suspicion for AMI without electrocardiographic evidence of STEMI on a 12-lead ECG (i.e., to detect “occult” left circumflex STEMI).

The posterior electrodes V_8 and V_9 are placed on the patient’s back, V_8 at the tip of the left scapula and V_9 in an intermediate position between lead V_8 and the left paraspinous muscles. An additional electrode, V_7 , may also be used and is placed on the posterior axillary line equidistant from electrode V_8 (Fig. 14.6). The degree of ST-segment elevation in the posterior leads is often less pronounced than the ST-segment elevation

Figure 14.7 Right-sided lead placement. Place right-sided leads V_1R to V_6R on the chest as a mirror image of the standard precordial leads. This alteration in lead placement is used to investigate the possibility of a right-sided acute myocardial infarction that may not be appreciated with normal lead placement.

seen in the standard 12 leads in patients with STEMI. This diminution in posterior lead ST-segment elevation results from both the relatively greater distance of these leads from the posterior surface of the heart and the presence of air and soft tissue between the epicardium and the electrocardiographic electrodes. It has been suggested that the threshold criterion for intervention be lowered from the standard 1 mm of ST-segment elevation to 0.5 mm when evaluating the posterior leads for STEMI.²⁷

The right ventricular electrocardiographic electrodes are placed across the right side of the chest in a mirror image of the standard left-sided electrodes and are labeled V_1R to V_6R ; alternatively, RV_1 to RV_6 is another commonly used nomenclature for this electrode distribution (Fig. 14.7). Lead V_4R (right fifth intercostal space, midclavicular line) is the most useful lead for detecting ST-segment elevation associated with right ventricular infarction and may be used solely for the evaluation of possible right ventricular infarction. The ST-segment elevation that occurs in association with right ventricular infarction is frequently quite subtle because of the relatively small muscle mass of the right ventricle; at other times the ST-segment elevation is quite prominent, similar in appearance to the ST-segment changes seen with the standard 12 leads (Fig. 14.8).

Invasive Procedural Leads

Patients with severely compromising bradydysrhythmia may require a transvenous pacemaker. In such instances, it may be necessary to place the pacing wire without the benefit of fluoroscopy. In such cases the recommendation is to advance the wire under electrocardiographic guidance with the patient connected to the limb leads of a grounded electrocardiographic machine and the pacing wire connected to the V lead (see Chapter 15). As the electrode enters the superior vena cava and high right atrium the P wave and QRS complex will be negative. While traversing the atrium, the P wave and QRS complex will become positive, and the latter will become larger as the

Figure 14.8 Right-sided precordial leads. This alteration in lead placement is used to investigate the possibility of a right-sided acute myocardial infarction (MI) that may not be appreciated with normal lead placement. This tracing displays the right-sided precordial leads in an elderly man with chest pain, and they are consistent with acute coronary syndrome. There is ST-segment elevation that is somewhat subtle in the inferior leads (II, III, and aVF), which together with the reciprocal ST-segment depression seen in lead aVL is consistent with a diagnosis of acute inferior MI. Leads V_1 to V_6 are in actuality leads V_1R to V_6R —right-sided precordial leads. The convex upward ST-segment elevation seen in leads V_3R to V_6R is indicative of concomitant right ventricular infarction. This patient was found to have a subtotal proximal occlusive lesion of his right coronary artery at cardiac catheterization.

ventricle is approached. If a balloon-tipped flotation catheter is used, deflate the balloon once it is in the right ventricle. Next, advance it until contact is made with the endocardium and the ventricle is captured. Ventricular wall contact will be indicated by marked ST-segment elevation. (See Chapter 15 for additional information on this procedure)

For patients with suspected pericardial effusion who are undergoing urgent pericardiocentesis, an electrocardiographic lead may be placed on the syringe needle. This form of monitoring will assist in correct positioning of the catheter in the pericardial space. Monitor the ST segments while advancing the needle. A sudden appearance of ST-segment elevation indicates that the needle has moved too far internally (i.e., beyond the pericardial space) and has made contact with the epicardium. (See Chapter 16 for additional information on this procedure.)

Body Surface Mapping

An emerging electrocardiographic tool, body surface mapping uses numerous leads to provide a more detailed electrical description of the heart than possible with the 12-lead ECG. The body map ECG that is most commonly used is based on an 80-lead ECG with 64 anterior and 16 posterior leads. This more detailed imaging of the myocardium allows potentially greater diagnostic accuracy in the early detection of STEMI, in addition to detection of infarction in more traditionally electrocardiographic “silent” areas of the heart.^{28–30} The body map ECG should not replace the typical 12-lead ECG in patients with chest pain. It should be used only as a second-tier tool in the evaluation of patients with intermediate to high clinical suspicion for ACS and an unrevealing initial 12-lead ECG. In this instance the clinician is in search of STEMI in electrocardiographically silent areas, namely, the far inferior and lateral walls, the posterior wall, and the right ventricle. The use of body mapping does increase the rate of ACS diagnosis as noted in the Optimal Cardiovascular Diagnostic Evaluation Enabling Faster Treatment of Myocardial Infarction (OCCULT MI) trial; the OCCULT MI study group obtained simultaneous 12-lead and 80-lead ECGs in patients suspected of having ACS. The 80-lead ECG improved the rate of diagnosis

of STEMI by an incremental 27.5% when compared with the embedded 12-lead ECG.³¹

PREHOSPITAL ECG

Early treatment, primarily reperfusion therapy, is an important goal in the management of ACS, particularly STEMI. Early treatment is made possible by early STEMI diagnosis, which is achieved by earlier application of the diagnostic tools, namely the 12-lead ECG. Emergency medical services (EMS) systems and strategies that optimize STEMI care include early application of the ECG, which reduces the time to initiation of reperfusion therapy.³²⁻³⁴

Many studies have demonstrated benefits of prehospital ECGs in decreasing door-to-fibrinolytic treatment and door-to-percutaneous coronary intervention (PCI) times in patients with STEMI.³⁵⁻⁴⁰ Other studies have shown even further reductions in time to revascularization when cardiac catheterization laboratories are activated prior to patient arrival at the hospital.³⁷⁻⁴⁰ The early acquisition, interpretation, and transmission of a prehospital ECG can dramatically decrease the time to treatment for a patient with ACS, particularly STEMI. Importantly, this reduction in time to management is seen in urban, suburban, and rural settings, regardless of the transport time or type of reperfusion strategy selected for the particular patient.

Beyond establishing the diagnosis of STEMI prior to ED arrival, the prehospital 12-lead ECG can impact EMS management strategies and hospital-based diagnosis in several ways, including the following:³⁴ more aggressive and focused EMS-based therapies; change of destination hospital (i.e., a PCI-capable facility); rapid transport to hospital (i.e., helicopter) if transport time is significantly prolonged; and the detection of ACS-related changes that resolve prior to the patient's arrival at hospital.

It must also be pointed out that minimal prolongation in EMS scene time is acceptable when one considers the vital information provided by the ECG and its impact on overall time-to-therapy considerations. The prehospital ECG can be obtained within as little as 2 to 3 minutes; furthermore, it can be obtained while en route to the hospital. The significant reduction in time to definitive therapy for STEMI more than compensates for any small transport delay.

ALTERNATIVE TECHNIQUES FOR ASSESSMENT OF RHYTHM

Electrocardiographic rhythm assessment depends on a clear signal of both atrial and ventricular electrical activity over a period. Although continuous 12-lead electrocardiographic rhythm monitoring has the advantage of recording cardiac activity over multiple leads (thus maximizing atrial and ventricular monitoring), it is often impractical. Moreover, correct identification of the cardiac rhythm on an ECG can be difficult, depending on the clinical setting. Rapid atrial or ventricular rates, especially those above 150 beats/min, often lead to simultaneous or nearly simultaneous deflections that can alter the usual waveforms or cause smaller deflections to be buried within larger ones (such as P waves buried within the QRS complex). In addition, rapid rates result in smaller, narrower waveforms, which makes visual recognition on the ECG challenging. Finally, assessment of atrial activity in general is more

difficult because of the smaller electrical impulse and resulting electrocardiographic waveform generated by the atria.

Lead V₁ is generally considered the most appropriate lead for detecting the P wave, followed by lead II. In a study of 62 measurements in 28 patients, lead V₁ demonstrated the tallest P wave 53% of the time, followed by lead II (29%), lead I (7%), and lead III (3%).⁴¹ A number of alternative techniques have been developed to improve assessment of rhythm, including alterations in the standard 12-lead ECG, as well as the addition of nonstandard leads to monitor cardiac and, in particular, atrial rhythm activity.

Alteration in Amplitude and Paper Speed

Most 12-lead electrocardiography machines today allow alteration of both amplitude and paper speed from the basic 10-mm/mV and 25-mm/sec standards, respectively. Increasing the amplitude to double the standard or 20 mm/mV, can increase the prominence of smaller deflections such as the P wave, and can improve recognition of the atrial rhythm (Fig. 14.9). In addition, clinicians have also used photocopy enlargements of the standard ECG to visually enhance smaller deflections.⁴²

Increasing the paper speed to double the standard or 50 mm/sec, has the effect of artificially slowing the rhythm. This technique is most advantageous when assessing patients with marked atrial or ventricular tachycardia. Increasing the paper speed exaggerates any existing irregularity (such as in atrial fibrillation) and can improve recognition of smaller deflections, such as P waves, in the presence of a significant tachycardia. Faster paper speeds also make it possible to measure short electrocardiographic intervals (such as PR or R-R) more accurately (Fig. 14.10). Accardi and coworkers⁴³ found that overall diagnostic accuracy improved when clinicians were provided ECGs recorded at the faster 50-mm/sec paper speed, as opposed to a standard 12-lead ECG, in patients with narrow-complex tachycardia.

Alternative Leads

Assessment of rhythm often requires electrocardiographic monitoring over a longer and continuous period; such a need is not met by the 12-lead ECG. A number of alternative lead systems requiring fewer electrodes have been described. Many of these systems use the limb bipolar leads (RA, LA, LL) in alternative positions over the chest. Leads I, II, or III are then recorded depending on the positions of the positive and negative electrodes. Although various alternative leads provide additional information to the clinician, there are no standard guidelines mandating the use of any alternative leads in the ED.

Lewis Leads

In 1910, Thomas Lewis first described alternative positions for the RA and LL leads to enhance detection of atrial fibrillation. The RA lead was placed over the right second costochondral junction, whereas the LL lead was placed in the right fourth intercostal space 1 inch to the right of the sternum, with the LA and RL leads left in their usual positions. Madias compared standard ECG leads to the "Lewis lead,"⁴¹ noting enhancement of atrial activity when the RA served as the negative electrode and LL as the positive electrode (lead II) in this new configuration. Other alternative lead placements to enhance detection of atrial activity have also been described⁴⁴⁻⁴⁶ (Table 14.2 and Fig. 14.11).

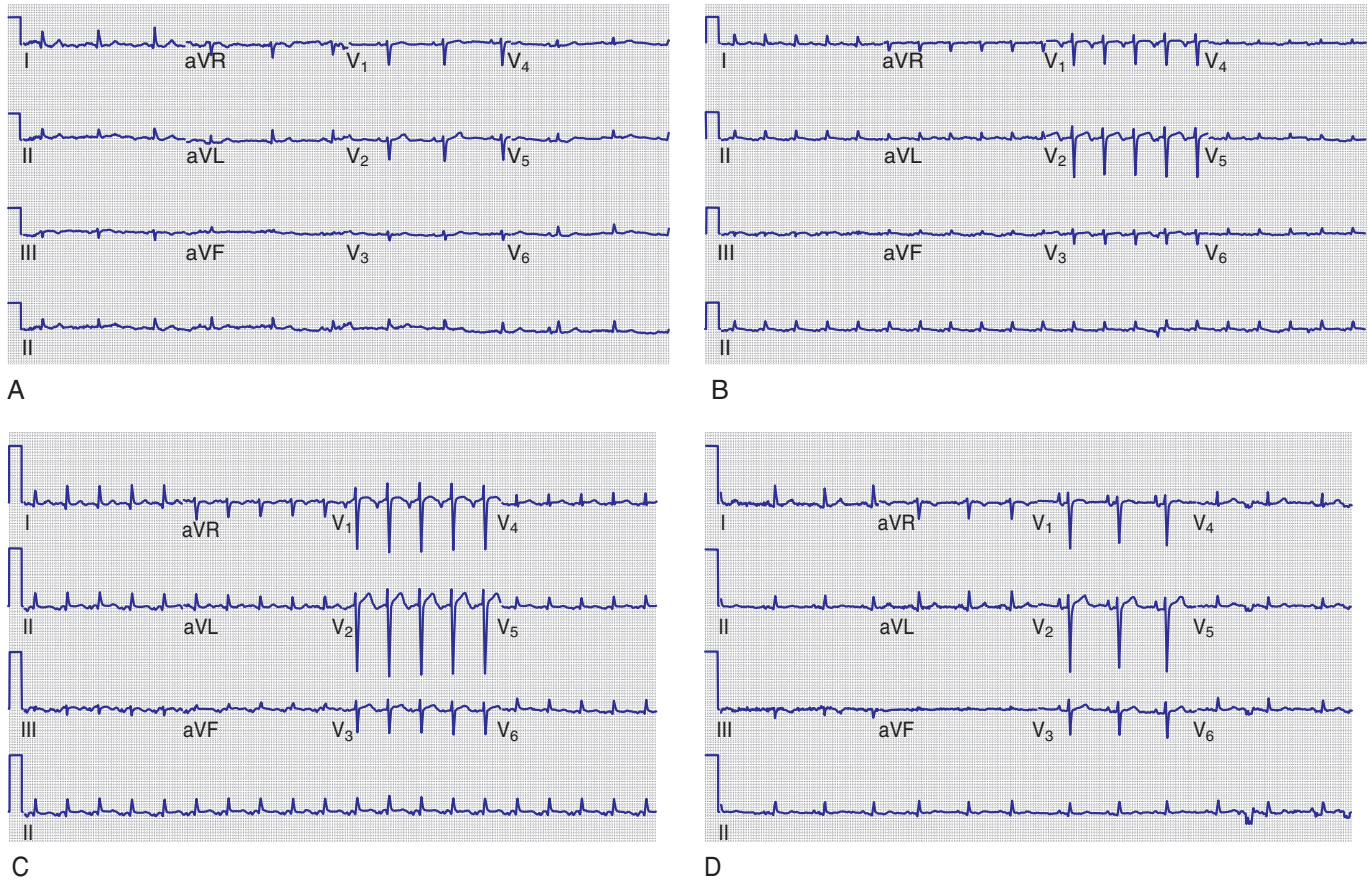

Figure 14.9 A, Baseline electrocardiogram (ECG) of a patient before the development of an abnormal rhythm (10 mm/mV). Note the P-wave morphologies, especially in leads I, II, and V₁. B, ECG during ectopic atrial tachycardia (10 mm/mV). Note the change in P-wave morphology, especially in lead V₁. C, ECG during ectopic atrial tachycardia (20 mm/mV). The P waves are now easier to see in all leads. D, ECG after reversion to a normal atrial focus (20 mm/mV). Contrast these accentuated P waves with those in C.

Figure 14.10 A, Electrocardiogram (ECG) with tachycardia at normal paper speed (25 mm/sec). Because of the rapid rate, the actual P waves are difficult to discern, thus making determination of the rhythm difficult. The computerized interpretation is sinus tachycardia with a first-degree atrioventricular (AV) block. B, ECG with tachycardia at double paper speed (50 mm/sec). With increased paper speed, atrial P-wave activity is accentuated, and atrial flutter with a 2:1 AV block is demonstrated. Carotid sinus massage may have slowed the rhythm and also revealed P waves.

TABLE 14.2 Alternative Leads for Assessment of Rhythm

Lead I ^a	RA = negative electrode	LA = positive electrode
Lead II ^a	RA = negative electrode	LL = positive electrode
Lead III ^a	LA = negative electrode	LL = positive electrode
Alternative Lead	Negative Electrode Position	Positive Electrode Position
Lewis ^b	Right second costochondral junction	Right fourth intercostal space, 1 inch right of the sternum
Drury	Second right costochondral junction, Center of the sternum	Seventh right costal cartilage, Inferior angle of the scapula 2 inches right of the spine
Schoenwald	Third intercostal space along the right sternal border, Third intercostal space along the R sternal border	Left leg, Right arm
Lu	First intercostal space directly above V ₁	Approximately 3 inches directly below V ₄
Vertical sternal (“Barker leads”)	Below the suprasternal notch at the manubrium	Xiphoid process
MCL ₁	Left shoulder (1 cm inferior to the left midclavicle)	V ₁ (fourth intercostal space, right sternal border)
MCL ₆	Left shoulder (1 cm inferior to the left midclavicle)	V ₆ (≈sixth rib, midaxillary line)

^aFirst, set the electrocardiographic machine to record the rhythm strip with this lead. If the recording rhythm strip is lead I, the RA wire becomes the negative electrode, which is placed as noted in the table, and the LA wire becomes the positive electrode, which is placed as noted in the table. If lead II or lead III is the lead that is set to record the rhythm strip, the positive and negative electrodes will vary.

^bExample: One way to record the Lewis lead is to set the electrocardiographic machine to record lead I, use the RA wire as the negative electrode, and place it in the right second costochondral junction. Use the LA wire as the positive electrode and place it in the right fourth intercostal space, 1 inch to the right of the sternum. The Lewis lead may also be recorded on lead II and lead III, but the wires that serve as the positive and negative electrodes will vary.

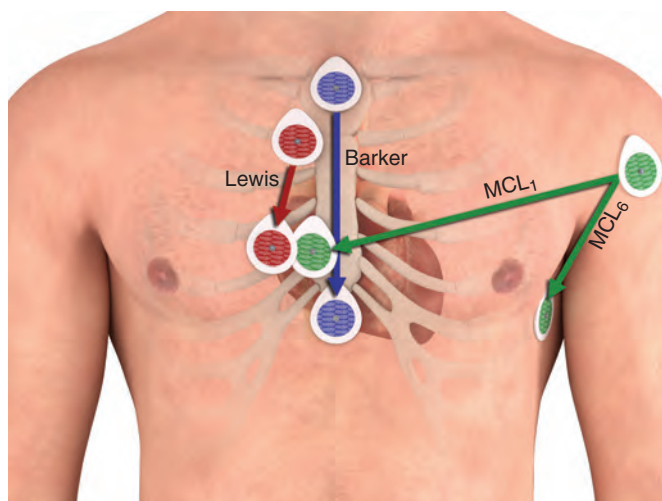

Figure 14.11 Alternative leads. Three of the more commonly used alternative lead strategies for clarification of the atrial rhythm (Lewis leads [red], vertical sternal or Barker leads [blue], and modified bipolar chest lead 1 [MCL₁]) and monitoring of the ST-T wave (MCL₆) are shown. For the Lewis leads, designed to further evaluate for atrial fibrillation, the RA lead was placed over the right second costochondral junction, whereas the LL lead was placed in the right fourth intercostal space 1 inch to the right of the sternum, with the LA and RL leads left in their usual positions. See text for further explanation of other leads.

Vertical Sternal “Barker” Leads

In this alternative lead system the positive electrode is placed at the xiphoid process and the negative electrode is placed just below the suprasternal notch on the manubrium. Herzog and associates⁴² reported that vertical sternal leads produce a larger

P wave than other systems do, including the Lewis leads. In addition, the vertical sternal leads are placed over bone, which may reduce artifact caused by muscle activity on recordings (see Fig. 14.11).

Limb-Precordium Leads

A sequential pattern of bipolar leads on the chest, termed limb-precordium leads, has been proposed in combination with the original Einthoven limb leads. In this system standard limb leads are placed on the patient. The RA electrode is then repositioned sequentially at the fourth intercostal space just to the right of the sternum, the fourth intercostal space just to the left of the sternum (low parasternal), the first intercostal space just to the left of the sternum, and the first intercostal space just to the right of the sternum (high parasternal). During this sequential mapping, tracings are recorded for leads I and II until atrial activity is identified. Brenes-Pereira⁴⁷ reported that this mapping system allowed the identification of P waves in a majority of patients when none were detected initially on the standard 12-lead ECG.

Modified Bipolar Chest Leads

Modified bipolar chest leads (MCLs) are the most commonly used leads for monitoring cardiac rhythm. The positive electrode is placed on the chest at a precordial position (V) concordant with the MCL desired (e.g., the V₁ position for MCL₁). The negative electrode is placed on the left shoulder. On standard electrocardiographic machines, the LA electrode is placed at V₁, RA at the left shoulder, LL at V₆, and RL at a remote location on the chest to serve as ground. Lead I would then reflect MCL₁ and lead II, MCL₆. MCL₁ may be useful in distinguishing atrial activity; MCL₅ and MCL₆ more commonly

in monitoring of the ST-T wave; and both MCL₁ and MCL₆ in evaluating wide-complex tachycardias⁴⁸ (see Fig. 14.11).

Esophageal Leads

The esophageal lead (E) was first described by Brown in the 1930s.⁴⁹ Since that time both unipolar and bipolar esophageal leads have been developed.⁵⁰ Because of its posterior location, this lead is often superior in detecting atrial deflections and recording the activity of the posterior surface of the left ventricle. The electrode, which is connected to the ECG by thin wires, is either swallowed or passed through the nares into the esophagus. Once in the esophagus, the location of the electrode is determined either by fluoroscopy or by making a series of low to high esophageal recordings. The position of the electrode in the esophagus is adjusted by slowly pulling the electrode wire out the nares or mouth. In normal adults, leads E₁₅₋₂₅ (the electrode is located in the esophagus 15 to 25 cm from the nares) generally records atrial activity; E₂₅₋₃₅, activity of the atrioventricular groove; and E₄₀₋₅₀, activity of the left ventricular posterior surface. The E lead should be recorded through lead channel I simultaneously with lead channel II and the other surface channels.

Central Venous Catheter Intracardiac Leads

For patients in whom a central venous catheter was placed for vascular access (or for other reasons such as cardiac pacing, hemodialysis, or Swan-Ganz monitoring) that catheter, when filled with saline, can be used as a modified intracardiac electrode for recording of atrial activity. Once filled with saline, a needle was then left in a side access port of the catheter and attached via an alligator clip to lead V₁. With this method, the distal port of the saline-filled central venous catheter demonstrated significantly larger P waves than the standard 12-lead ECG and the Lewis lead did.⁴¹

ELECTRODE MISPLACEMENT AND MISCONNECTION

Limb Electrode Reversal

Although the limb electrodes are not often misplaced, the cables that link them to the ECG are at times improperly connected, resulting in “electrocardiographic changes” that are, in actuality, artifact. A multitude of possibilities for misconnection of the limb electrodes exists; some of the most likely are summarized here. It is helpful to categorize these possibilities into those that are easily recognizable without comparison to an old ECG versus those that are not. Failure to recognize limb electrode reversal may lead to misattribution of ECG “changes” to a disease that is actually caused by technical misadventure. Even though the incidence of electrode reversal in the ED has not been quantified, it has been observed to occur in an intensive care unit setting in 4% to 5% of tracings.^{51,52}

Easily Recognizable without an Old ECG

The most common of all misconnections is reversal of the LA and RA electrodes⁴⁸ (Fig. 14.12). The hallmark is a negative P wave and a primarily negative QRS complex in lead I, which creates a right or extreme axis deviation (depending on the principal vector of the QRS complex in lead aVF). Dextrocardia

Figure 14.12 Arm electrode reversal (LA ↔ RA). The most common of limb electrode reversals, the clues lie in leads I and aVR. Lead I features a negative P wave, as well as a principally negative QRS complex and T wave. This could suggest dextrocardia, but the precordial leads demonstrate a normal transition, which is not consistent with dextrocardia. Note also the unusual appearance of aVR in this tracing.

should also be considered with such findings; the pattern of precordial lead transition will differentiate between dextrocardia and arm electrode reversal, however, with dextrocardia featuring progressive diminution in QRS amplitude as the eye moves from lead V₁ (right sided) toward lead V₆ (left sided). Moreover, lead aVR is actually aVL in this circumstance, and thus lead aVR may feature both an upright P wave and QRS complex; the former does not occur in normal sinus rhythm, and the latter is clinically unusual as the QRS vectors in leads aVR and V₆ are usually opposite unless the heart has a superior frontal-plane axis.⁵³ A further clue to arm electrode reversal is the resultant discrepancy in the major QRS vectors of leads I and V₆. Because the vectors of these two leads are leftward, the QRS complexes are expected to point in similar directions when the ECG is performed properly. These two leads will feature discordant QRS vectors when the arm electrodes are reversed (see Fig. 14.12). Transposition of the RA and LL cables is also easily recognized; all leads are upside down in comparison to the usual patterns with the exception of aVL, which is unchanged.^{54,55}

Anytime that the RL electrode is transposed with another extremity lead, one of the limb leads will appear as virtually a straight line and thus is easily recognized if this finding is not incorrectly ascribed to poor electrode contact or function. The most common is RA/RL reversal, which causes a nearly flat line in lead II (Fig. 14.13). An exception to this rule is if the leg electrodes are reversed (RL ↔ LL), in which case the ECG is virtually identical to one with correct placement of the limb electrodes. Reversal of the leg electrodes is largely insignificant in that the potentials at the left and right legs are essentially the same.

Not Easily Recognizable Without an Old ECG

One limb electrode reversal that is not readily recognizable without comparison to a previous tracing is transposition of the LA and LL electrodes. This causes transposition of lead I with lead II on the tracing in addition to lead aVL with aVF. In effect, two inferior leads (II and aVF) have become the lateral leads (I and aVL) and vice versa, thus making this misconnection difficult to detect at times without a baseline ECG for comparison. Furthermore, lead III will be upside

Figure 14.13 Right-sided electrode reversal (RA \leftrightarrow RL). **A**, In this tracing, the nearly flat line in lead II (*arrow*) suggests that the right leg electrode has been switched with the right arm electrode. The trivial voltage in lead II reflects the expected lack of potential difference between the two legs (the right leg electrode is in the right arm position; lead II normally runs from the right arm to the left leg, but now it effectively runs from the right leg to the left leg). **B**, The second tracing was acquired with correct electrode placement.

Figure 14.14 **A**, Left-sided limb electrode reversal (LA \leftrightarrow LL). A patient with a history consistent with acute coronary syndrome was brought to the emergency department after this electrocardiogram was recorded in a clinic. Leads I and aVL suggest an acute high lateral infarction, but surprisingly there are no corresponding changes in leads V₅ and V₆. The deep T-wave inversions in III and aVF were at first thought to be inferior ischemia or reciprocal changes (see also **B**). **B**, Correction of electrode reversal (LA \leftrightarrow LL). After the electrodes were reconnected, this tracing reveals an acute inferior wall myocardial infarction (MI) and deep T-wave inversion in aVL, a harbinger of acute inferior MI. In comparing this tracing with that in **A**, note the following: lead I \leftrightarrow lead II, lead aVL \leftrightarrow aVF, and lead III is inverted. Thus, inferior changes become lateral, and lateral changes become inferior, the hallmark of LA \leftrightarrow LL reversal.

down (although a negative QRS complex in lead III is not unusual), and aVR will be unchanged (**Fig. 14.14**). Suspect LA/LL reversal when comparing two ECGs with changes that do not make clinical sense; if the P-QRS-T-wave morphologies in lead III in the two tracings are mirror opposites, repeat the ECG with close attention to correct electrode connection. Clues to limb electrode reversal are summarized in **Table 14.3**.

Precordial Electrode Misplacement and Misconnection

Unlike the limb electrodes, the precordial electrodes are more prone to misplacement, especially when variations in body habitus (e.g., obesity, breast tissue, pectus excavatum, chronic lung disease) make proper electrode placement more difficult. This may cause some variability in the amplitude and morphology of the complexes in the precordial leads. However, these

changes are not usually grossly abnormal and therefore can be difficult to detect. Variation often becomes evident when comparing the current tracing with an old ECG. In such cases, it is useful to go to the bedside and examine where the electrodes were positioned relative to the recommended placement (see section on **Electrode Placement** earlier in this chapter). One cannot ensure, however, that the baseline ECG was done with proper electrode placement. When comparing the precordial leads on the current ECG with a baseline tracing, ST-segment and T-wave changes should be viewed in the context of the relative morphologies of the associated QRS complexes. If a marked difference is noted between the two tracings in the amplitude or polarity of the QRS complex in a given precordial lead—the R/S ratio for that QRS complex—the corresponding ST-T-wave changes may be the result of variability in electrode placement, although cardiac ischemia cannot be completely excluded as the cause.

TABLE 14.3 Clues to Improper Limb Electrode Connections

REVERSED LEADS	NEED OLD ECG FOR DETECTION?	KEY FINDINGS
LA ↔ RA	No	P-QRS-T waves upside down in lead I Precordial leads normal (not dextrocardia)
LA ↔ LL	Yes	III upside down from baseline I ↔ II, aVL ↔ aVF, no change in aVR
LA ↔ RL	No	III is a straight line
RA ↔ LL	No	P-QRS-T waves upside down in all leads except aVL
RA ↔ RL	No	II is a straight line
LL ↔ RL	Cannot detect change	Looks like normal electrode placement
LA ↔ LL + RA ↔ RL	No	I is a straight line, aVL and aVR are the same polarity and amplitude, and II is upside down III

LA, Left arm; LL, left leg; RA, right arm; RL, right leg.

B

Figure 14.15 A and B, Precordial electrode reversal ($V_2 \leftrightarrow V_3$). Note that the usual precordial progression of R-wave growth in leads V_2 and V_3 is disrupted in the tracing displayed in A. B shows a return to a normal V_3 transition zone.

Some studies have reported that placement of chest electrodes by more than 20 to 25 mm from the standard positions can be associated with clinically significant changes on the ECG. It has been observed that leads V_1 and V_2 are typically placed too high and that the lateral leads are placed too laterally and too low. McCann and colleagues⁵⁶ demonstrated a high degree of variability between experienced clinicians in identifying anatomic landmarks for precordial electrocardiographic electrode placement. There was frequently a large difference in the measured distance from the actual to the “standardized” electrode position that ranged between 0 and 105 mm in the vertical direction (mean, 14 mm; median, 10 mm), and between 0 and 120 mm in the horizontal plane (mean, 17 mm; median, 10 mm). Overall, 20.8% of the paired measurements in the vertical direction and 26.6% of those in the horizontal plane differed by more than 25 mm.

Misconnection of the precordial cables is usually easy to detect. The expected progression of P-, QRS-, and T-wave morphologies across the precordium will be disrupted (Fig. 14.15). An abrupt change in wave morphology evolution—followed by a seeming return to normalcy in the next lead—is a good clue to misconnection of the precordial electrodes.

ARTIFACT

Electrocardiographic artifact is commonly encountered yet not always easy to recognize. It can be attributed to either physiologic (internal) or nonphysiologic (external) sources; the former includes muscle activity, patient motion, and poor electrode contact with the skin. Tremors, hiccups, and shivering may produce frequent, narrow spikes on the tracing and simulate atrial and ventricular dysrhythmias (Fig. 14.16). A wandering baseline featuring wide undulations in addition to other “noise” on the ECG can often be traced to patient movement and high skin impedance, which leads to inadequate contact of the electrode with the skin. Minimizing skin impedance and artifact may be achieved by: (1) avoiding electrode placement over bony prominences, major muscles, or pulsating arteries; (2) clipping rather than shaving thick hair at electrode sites; and (3) cleaning, and most importantly, drying the skin surface before reapplying the electrode if the tracing features substantial artifact. Nonphysiologic artifact is most often caused by 60-Hz electrical interference, which is ascribable to various other sources of alternating current near the patient. This will be manifested as a wide, indistinct isoelectric baseline.

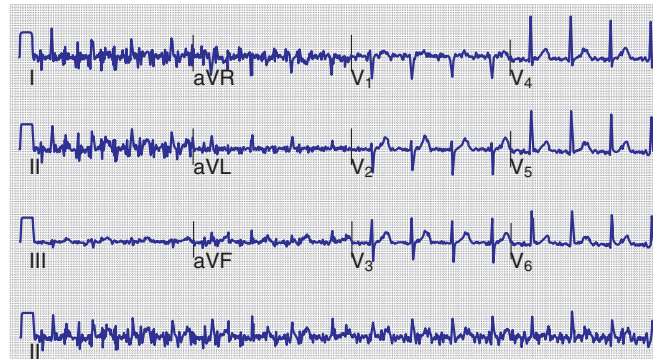

Figure 14.16 Artifact secondary to a physiologic cause. The patient's monitor was alarming because of a perceived heart rate greater than 200 beats/min, and the computerized alert system called this ventricular tachycardia. The patient, who has Parkinson's disease, was without complaint. The electrocardiogram demonstrates a marked artifact that is giving the appearance of atrial flutter in lead V₁.

Figure 14.17 Artifact secondary to rigors. This tracing features a pseudodysrhythmia. The intrinsic RR interval can be traced back through the "dysrhythmia" and reveals an underlying sinus rhythm. As a clue to the artifact, the patient was clinically stable and asymptomatic during the event, except for his rigors.

Electrocardiographic artifact should be considered when the clinical picture indicates stability, and status quo and coincident procedures are in progress (e.g., hemodialysis, blood warmer, bronchoscopy) or devices are in use (e.g., nerve stimulators); the list of causative equipment is long and varied.⁵⁵ Other sources of nonphysiologic artifact include those attributable to the monitoring equipment: loose connections, broken monitor cables, and mechanical issues with the machine (e.g., broken stylus, uneven paper transport). The 60-Hz artifact caused by electrical current interference can be minimized by shutting off nonessential sources of current in the vicinity, and also by straightening the lead wires so that they are parallel to the patient's body in the long axis.

Differentiation of artifact from true electrocardiographic abnormality is intuitively important; moreover, clinical consequences have been reported that are directly attributable to

confusion of artifact with disease. Unnecessary treatment and procedures—including cardiac catheterization, electrophysiologic testing, and even implantation of a pacemaker and an automatic defibrillator—have been reported.⁵⁷ Characteristics that may aid in differentiating artifact from dysrhythmia include the absence of hemodynamic instability during the event (or even absence of any symptoms), normal QRS complexes occurring during the "dysrhythmia," instability of the baseline on the tracing during and immediately after the "dysrhythmic" event, association with body movement, and observance of "notches" amid the complexes of the pseudo-dysrhythmia that "march out" with the normal QRS complexes that precede and follow the disturbance^{58,59} (Fig. 14.17).

Emergency Cardiac Pacing

Edward S. Bessman

The purpose of cardiac pacing is to restore or ensure effective cardiac depolarization. Emergency cardiac pacing may be instituted either prophylactically or therapeutically. Prophylactic indications include patients with a high risk for atrioventricular (AV) block. Therapeutic indications include symptomatic bradyarrhythmias and overdrive pacing. Pacing for asystole has very minimal success but it has been used for this condition. Several approaches to pacing can be taken, including transcutaneous, transvenous, transthoracic, epicardial, endocardial, and esophageal. Transcutaneous and transvenous pacemakers are the two techniques most commonly used in the emergency department (ED). Because it can be instituted quickly and noninvasively, transcutaneous pacing is the technique of choice in the ED when time is of the essence. Transvenous pacing should be reserved for patients who require prolonged pacing

or have a very high (>30%) risk for heart block. Transcutaneous pacing is generally a temporizing measure that may precede transvenous cardiac pacing. Although it is not an expectation that all emergency clinicians will be adept at placing temporary transvenous cardiac pacemakers, many have mastered the techniques and are often the only clinicians available to perform this lifesaving procedure.

EMERGENCY TRANSVENOUS CARDIAC PACING

The transvenous method of endocardial pacing is commonly used and is both safe and effective. In skilled hands, the semifloating transvenous catheter is successfully placed under electrocardiographic (ECG) guidance in 80% of patients.¹ The technique can be performed in less than 20 minutes in 72% of patients and in less than 5 minutes in 30% (Videos 15.1–15.3). However, in some instances, anatomic, logistic, and hemodynamic impediments can prohibit successful pacing by even the most skilled clinician. As with other medical procedures, it should not be performed without a thorough understanding of its indications, contraindications, and complications.²

Because this procedure is essentially performed in a blind manner, sometimes it will not be successful. This may be because the condition is not amenable to pacing (e.g., asystole, drug overdose) or because of technical difficulties inherent with the procedure.

Transvenous Cardiac Pacing

Indications

Bradycardias

- Symptomatic sinus node dysfunction
- Second- and third-degree heart block
- Atrial fibrillation with a slow ventricular response
- With myocardial infarction: new left bundle branch block, bifascicular block, alternating bundle branch block
- Malfuction of an implanted pacemaker

Tachycardias

- Supraventricular dysrhythmias
- Ventricular dysrhythmias

Contraindications

- Prosthetic tricuspid valve
- Severe hypothermia

Complications

- Inadvertent arterial puncture
- Venous thrombosis/thrombophlebitis
- Pneumothorax/other anatomic injury
- Ventricular arrhythmia
- Misplacement of the pacing catheter
- Myocardial/pericardial perforation
- Entanglement of the pacing catheter

Equipment

The contents of a typical transvenous pacemaker kit are shown here. Additional equipment required for insertion of the sheath introducer is reviewed in Chapter 22. Individual kits may vary by manufacturer; be familiar with the equipment available at your institution before performing the procedure.

Background

The ability of muscle to be artificially depolarized was recognized as early as the 18th century. Initial efforts focused on the transcutaneous approach (see later in this section). Over the succeeding years several scattered experiments were reported, and in 1951 Callaghan and Bigelow first used the transvenous approach to stimulate asystolic hearts in hypothermic dogs.³

Furman and Robinson demonstrated the transvenous endocardial approach in humans in 1958.⁴ They treated two patients with complete heart block and Stokes-Adams seizures, thus reconfirming that low-voltage pacing could completely control myocardial depolarization. The catheter remained in the second patient for 96 days without complication. Other early clinical studies also demonstrated the utility of transvenous pacing.⁵ Fluoroscopic guidance was used for placement of the pacing catheter in all these studies.

In 1964 Vogel and coworkers demonstrated the use of a flexible catheter passed without fluoroscopic guidance for intracardiac electrocardiography.⁶ One year later, Kimball and Killip used this technique to insert endocardial pacemakers at the bedside.⁷ They noted technical problems in 20% of their patients, including intermittent capture, difficulty passing the catheter, and catheter knotting. During the same year, Harris and colleagues confirmed the ease and speed with which this procedure could be accomplished.⁸

Before 1965 all intracardiac pacing was done asynchronously, which meant that the pacing catheter could cause electrical stimulation during any phase of the cardiac cycle. Asynchronous pacing frequently resulted in the pacemaker firing during the vulnerable period of an intrinsic depolarization; this occasionally caused ventricular tachycardia or fibrillation. In 1967 a demand pacemaker generator that sensed intrinsic depolarizations and inhibited the pacemaker for a predetermined period was used successfully by Zuckerman and associates in six patients.⁹ Since then there has been steady progress in the design and functionality of pacemakers. Table 15.1 summarizes the four-letter code that is used to describe modern pacemakers (there is a fifth letter for combined pacemaker-cardioverter/defibrillators). The most commonly used emergency transvenous pacemaker is represented by the code VVI: the ventricle is paced, the ventricle is sensed, and when a native impulse is sensed, the pacemaker is inhibited. Dual-chamber pacing (DDD or DDDR) is the preferred methodology for permanent pacing but is rarely used on an emergency basis because of the increased complexity of the procedure.

Rosenberg and coworkers introduced an improved pacing catheter known as the Elecath semifloating pacing wire.¹ The Elecath was stiffer than the Flexon steel wire electrode that was in prevailing use. Rosenberg and coworkers¹ achieved pacing in 72% of their patients with an average procedure time of 18 minutes. They also noted that 30% of their patients were paced in 5 minutes or less. In 1970, Swan and Ganz introduced the technique of heart catheterization with a flow-directed balloon-tipped catheter.¹⁰ Schnitzler and colleagues successfully used this method for placement of a right ventricular pacemaker in 15 of 17 patients.¹¹

In 1981 Lang and associates compared bedside use of the flow-directed balloon-tipped catheter with insertion of a semirigid electrode catheter in 111 perfusing patients.¹² These researchers found a significantly shorter insertion time (6 minutes 45 seconds versus 13 minutes 30 seconds), a lower incidence of serious arrhythmias (1.5% versus 20.4%), and a lower incidence of catheter displacement (13.4% versus 32%) with the balloon-tipped catheter. They concluded that the balloon-tipped catheter was the method of choice for temporary transvenous pacing.

Although placing temporary transvenous pacemakers has long been considered a core skill in the ED, it has not been well studied. Birkhahn and coworkers retrospectively compared the experience of emergency physicians with that of cardiologists in placing transvenous pacemakers under ECG guidance.¹³ They reported a 13% risk for major complications in both groups of specialists. They concluded that pacemaker placement by emergency physicians under ECG guidance without fluoroscopy had success and complication rates that were comparable to those of their cardiology colleagues. In a retrospective review of 43 ED patients in whom emergency transvenous pacemaker placement was attempted, there was a 95% success rate and no immediate or delayed complications.¹⁴

Indications

The purpose of cardiac pacing is to stimulate effective cardiac depolarization. In most cases the specific indications for cardiac pacing are clear; however, some areas are still controversial. The decision to pace on an emergency basis requires knowledge of the presence or absence of hemodynamic compromise, the cause of the rhythm disturbance, the status of the AV conduction system, and the type of dysrhythmia. The clinician caring for the patient is in the best position to decide on the value or nonvalue of pacing, based on nuances of the clinical scenario that are not possible to unravel by any theoretical

TABLE 15.1 Four-Letter Pacemaker Code

O = None	O = None	O = None	C = Communicating O = None

discussion. Controversy exists throughout the literature, and this discussion is not meant to set a standard of care for individual circumstances.

In general, the indications can be grouped into those that cause either tachycardias or bradycardias (see [Review Box 15.1](#)). Transcutaneous cardiac pacing (TCP) has become the mainstay of emergency cardiac pacing and is often used pending placement of a transvenous catheter or to determine whether potentially terminal bradysystolic rhythms will respond to pacing.

Bradycardias

Sinus Node Dysfunction

Sinus node dysfunction may be manifested as sinus arrest, tachybrady (sick sinus) syndrome, or sinus bradycardia. Although symptomatic sinus node dysfunction is a common indication for elective permanent pacing, it is seldom cause for emergency pacemaker insertion.

Seventeen percent of patients with acute myocardial infarction (AMI) will experience sinus bradycardia.¹⁵ It occurs more frequently with inferior than with anterior infarction and has a relatively good prognosis when accompanied by a hemodynamically tolerable escape rhythm. However, sinus bradycardia is not a benign rhythm in this situation; it has a mortality rate of 2% with inferior infarction and 9% with anterior infarction.¹⁶ Sinus node dysfunction frequently responds to medical therapy but requires prompt pacing if such therapy fails.

Asystolic Arrest

Transvenous pacing in an asystolic or bradysystolic patient has little value and is not recommended.¹⁷ In a study of 13 patients who had suffered cardiac arrest, capture of the myocardium was noted in 4 patients, but there were no survivors.¹⁸ Transvenous pacing alone may also not be effective for post-countershock pulseless bradyarrhythmias.¹⁹ This failure of pacing has likewise been demonstrated with transcutaneous pacemakers, thus suggesting that failure of effective pacing is primarily related to the state of the myocardial tissue.¹⁸ Cardiac pacing may be used as a “last-ditch” effort in bradysystolic patients but is rarely successful and is not considered standard practice. Early pacing is essential when done for this purpose if success is to be achieved²⁰ (see later in this section). Most importantly, given the continued emphasis on the importance of maximizing chest compressions during cardiopulmonary resuscitation (CPR), interrupting CPR to institute emergency pacing is not recommended.²¹

AV Block

AV block is the classic indication for pacemaker therapy. In symptomatic patients without myocardial infarction (MI) and in asymptomatic patients with a ventricular rate lower than 40 beats/min, pacemaker therapy is indicated.²²

In patients with AMI, 15% to 19% progress to heart block: first-degree block develops in approximately 8%, second-degree block in 5%, and third-degree block in 6%.²³ First-degree block progresses to second- or third-degree block 33% of the time, and second-degree block progresses to third-degree block approximately one-third of the time.²⁴

AV block occurring during anterior infarction is believed to result from diffuse ischemia in the septum and infranodal conduction tissue. Because these patients tend to progress to high-degree block without warning, a pacemaker is often placed prophylactically. Some patients are prophylactically

paced on a temporary basis, even in the absence of hemodynamic compromise.

During inferior infarction, early septal ischemia is the exception and typically block develops sequentially from first-degree to Mobitz type I second-degree and then to third-degree AV block. These conduction abnormalities frequently result in hemodynamically tolerable escape rhythms because of sparing of the bundle branches. A hemodynamically unstable patient who is unresponsive to medical therapy should be paced promptly. Whether and when stable patients should be paced is unclear, but placing a transcutaneous pacer is one option that can be attempted before placing a transvenous pacing catheter.

Trauma

Pacing is not a standard intervention in traumatic cardiac arrest, but in selected cases it may be considered. Several rhythm and conduction disturbances have been documented in patients with nonpenetrating chest trauma. In these patients, traumatic injury to the specialized conduction system may predispose to life-threatening dysrhythmias and blocks that can be treated by cardiac pacing.²⁵

Hypovolemia and hypotension can cause ischemia of conduction tissue and cardiac dysfunction.²⁶ Marked bradyarrhythmias that persist even after vigorous volume replacement may rarely respond to cardiac pacing in patients with such trauma.²⁷

Bundle Branch Block and Ischemia

Bundle branch block occurring in AMI is associated with a higher mortality rate and a greater incidence of third-degree heart block than is an uncomplicated infarction. Atkins and colleagues noted that 18% of patients with MI had a bundle branch block.²⁸ Of these patients, complete heart block developed in 43% who had right bundle branch block (RBBB) and left axis deviation, in 17% who had left bundle branch block (LBBB), in 19% who had left anterior hemiblock, and in 6% who had no conduction block. The investigators concluded that RBBB with left axis deviation should be paced prophylactically.

A study by Hindman and associates confirmed the natural history of bundle branch block during MI.²⁹ In their study, the presence or absence of first-degree AV block, the type of bundle branch block, and the age of the block (new versus old) were used to determine the relative risk for progression to type II second-degree or third-degree block ([Table 15.2](#)).

Because of the increased risk, consider pacing for the following conduction blocks: new-onset LBBB, RBBB with left axis deviation or other bifascicular block, and alternating bundle branch block.²⁹ Though controversial, one authority recommends prophylactic pacing for all new bundle branch blocks when MI is evident.³⁰

Whether to place a transvenous pacemaker prophylactically in patients with LBBB before insertion of a flow-directed pulmonary artery catheter (PAC) remains controversial. Some researchers strongly advocate this procedure because of the risk for transient RBBB and life-threatening complete heart block associated with PAC placement.³¹ One study noted that this risk is low in patients with previous LBBB but continued to recommend temporary catheter placement for all cases of new LBBB.³² One solution to this problem is to place a transcutaneous pacemaker before catheterization as an emergency measure should heart block develop. In these cases a temporary transvenous pacemaker can be placed in a

Indications of temporary and permanent pacemaker insertion*, *Circulation* 58:690, 1978.

semi-elective manner when needed.³³ In any event, the trend toward decreased PAC use, particularly outside the critical care setting, makes it unlikely that this will be an issue in the ED.³⁴

Most of the studies investigating temporary pacing in the setting of AMI were done in the era before the use of thrombolytic agents or percutaneous coronary intervention. Nonetheless, whereas modern treatment of AMI has reduced the frequency of emergency transvenous pacemaker insertion, the indications are essentially unchanged and it remains a potentially life-saving intervention.^{35,36}

Tachycardias

Hemodynamically compromising tachycardias are usually treated with medications or electrical cardioversion. Since 1980 there has been increasing interest in pacing therapy for symptomatic tachycardias. Supraventricular dysrhythmias, with the exception of atrial fibrillation, respond well to atrial pacing. By “overdrive” pacing the atria at rates 10 to 20 beats/min faster than the underlying rhythm, the atria become entrained, and when the rate is slowed the rhythm frequently returns to normal sinus. A similar procedure is done for ventricular dysrhythmias.³⁷ Overdrive pacing is especially useful for arrhythmias with recurrent prolonged QT intervals, such as those seen with quinidine toxicity or torsades de pointes.³⁸ Though an attractive

thought, there is no reported experience with these techniques in the ED. Transvenous pacing is also useful in patients with digitalis-induced dysrhythmias, in whom direct current cardioversion may be dangerous, or in patients in whom there is further concern about myocardial depression with drugs.³⁹

Cardiac Pacing for Drug-Induced Dysrhythmias

Significant dysrhythmias can be caused by excessive therapeutic medication (often in combination therapy) and overdose of cardioactive medications. Because these drugs have direct effects on cells of the myocardial pacemaker and conduction system, cardiac pacing is usually of little therapeutic value. Both bradycardias and tachycardias may result. Tachycardic rhythms from amphetamines, cocaine, anticholinergics, cyclic antidepressants, theophylline, and other drugs do not benefit from cardiac pacing. Drug-induced torsades de pointes may theoretically be overdriven by pacing, but data on this technique are lacking. Any drug that affects the central nervous system (e.g., opiates, sedative-hypnotics, clonidine) may produce bradycardia. Uncommon causes of toxin-induced bradycardia include organophosphate poisoning, various cholinergic drugs, ciguatera poisoning, and rarely, plant toxins. Cardiac pacing is not used for bradycardias from these sources; rather, the underlying central nervous system depression is addressed.

Severe bradycardia and heart block often accompany overdose of digitalis preparations, β -adrenergic blockers, and calcium channel blockers. Although intuitively attractive, cardiac pacing is not generally effective for serious toxin-induced bradycardias, even though there have been rare case reports of success.³⁰⁻⁴³ In β -blocker overdose, pacing may increase the heart rate but rarely benefits blood pressure or cardiac output. Worsening of blood pressure may occur as a result of loss of atrial contractions with ventricular pacing. Likewise, calcium channel blocker overdose and digitalis-induced bradycardia and heart block rarely benefit from cardiac pacing. Pharmacologic interventions, such as digoxin-specific Fab, glucagon, calcium, inotropic medications, and vasopressors, remain the mainstay in the treatment of drug-induced dysrhythmias. Given the lack of success of pacing, possible downsides, and the greater effectiveness of specific antidotes, it is not standard to routinely attempt transvenous cardiac pacing in the setting of drug overdose. However, as a last resort, cardiac pacing can be supported.⁴⁴

Contraindications

The presence of a prosthetic tricuspid valve is generally considered to be an absolute contraindication to transvenous cardiac pacing.⁴⁵ In addition, severe hypothermia will occasionally result in ventricular fibrillation when pacing is attempted. Because ventricular fibrillation under these conditions is difficult to convert, caution is advised when considering pacing severely hypothermic and bradycardic patients. Rapid and careful rewarming is often recommended first, followed by pacing if the patient's condition does not improve.

Equipment

Several items are required to insert a transvenous pacemaker adequately. Like most special procedures, a prearranged tray is convenient. The usual components required to insert a transvenous cardiac pacemaker are depicted in [Review Box 15.1](#).

Figure 15.1 Pacemaker energy source: controls and connections.

Pacing Generator

Many different pacing generators are available, but in general they all have the same basic features. The controls will frequently have a locking feature or cover to prevent the generator from being switched off or reprogrammed inadvertently. An amperage control allows the operator to vary the amount of electrical current delivered to the myocardium, usually 0.1 to 20 mA. Increasing the setting increases the output and improves the likelihood of capture. The pacing control mode is determined by adjusting the gain setting for the sensing function of the generator. By increasing the sensitivity, one can convert the unit from a fixed-rate (asynchronous mode) to a demand (synchronous mode) pacemaker. The typical pacing generator has a sensitivity setting that ranges from approximately 0.5 to 20 mV. The voltage setting represents the minimum strength of the electrical signal that the pacer is able to detect. Decreasing the setting increases the sensitivity and improves the likelihood of sensing myocardial depolarization. In the fixed-rate mode, the unit fires despite the underlying intrinsic rhythm; that is, the unit does not sense any intrinsic electrical activity. In the full-demand mode, however, the pacemaker senses the underlying ventricular depolarizations, and the unit does not fire as long as the patient's ventricular rate is equal to or faster than the set rate of the pacing generator. A sensing indicator meter and a rate control knob are also present.

Temporary pacing generators are battery operated, and thus it is always good practice to install a fresh battery whenever pacing is anticipated. An example of a pacing generator is shown in [Fig. 15.1](#).

Pacing Catheters and Electrodes

Several sizes and brands of pacing catheters are available. In general, most range from 3 to 5 Fr in size and are approximately 100 cm in length. Lines are marked along the catheter surface at approximately 10-cm intervals and can be used to estimate catheter position during insertion. Pacing catheters differ with respect to their stiffness, electrode configurations, floating

Figure 15.2 Balloon-tipped pacing catheter.

characteristics, and other qualities. For emergency pacing, the semifloating bipolar electrode catheter with a balloon tip is used most frequently ([Fig. 15.2](#)). The balloon holds approximately 1.5 mL of air, and the air injection port has a locking lever to secure balloon expansion. Before insertion, check the balloon for leakage of air by inflating and immersing it in sterile water. The presence of an air leak is noted by a stream of bubbles rising to the surface of the water. An inflated balloon helps the catheter “float” into the heart, even in low-flow states, but is not advantageous in the cardiac arrest situation.

For all practical purposes, temporary transvenous pacing is accomplished with a bipolar pacing catheter. The terms unipolar and bipolar refer to the number of electrodes in contact with the portion of the heart that is to be stimulated. All pacemaker systems must have both a positive (anode) and a negative (cathode) electrode; hence, all stimulation is bipolar. In the typical bipolar catheter used for temporary transvenous pacing, the cathode (stimulating electrode) is at the tip of the pacing catheter. The anode is located 1 to 2 cm proximal to the tip, and a balloon or an insulated wire separates the two electrodes. The distinction between unipolar and bipolar pacing catheters is that a bipolar catheter has both electrodes in relatively close proximity on the catheter and both may contact the endocardium. In a bipolar catheter, the electrodes are usually stainless steel or platinum rings that encircle the pacing catheter. When properly positioned, both electrodes will be within the right ventricle so that a field of electrical excitation is set up between the electrodes. With a bipolar catheter, the cathode does not need to be in direct contact with the endocardium for pacing to occur, although it is preferable to have direct contact.

A unipolar system is also effective but is used infrequently for temporary transvenous pacing. In a unipolar system, the cathode is at the tip of the pacing catheter and the anode is located in one of three places: in the pacing generator itself, more proximally on the catheter (outside the ventricle), or on the patient's chest. A bipolar system may be converted to a unipolar system by simply disconnecting the positive proximal connection of the bipolar catheter from the pacing generator and running a new wire from the positive (pacing generator) terminal to the patient's chest wall. Such a conversion may be required in the unlikely event of failure of one lead of the bipolar system.

ECG Machine

An ECG machine can be used to record the heart's inherent electrical activity during insertion of the pacer and to aid in localization of the tip of the catheter without fluoroscopy. The ECG machine must be well grounded to prevent leakage of alternating current, which can cause ventricular fibrillation. Such leakage should be suspected if interference of 50 to 60 cycles per second (Hz) is noted on the ECG tracing.

The ECG machine should be placed in a manner that allows easy visibility of the rhythm during insertion. One method is to place the machine near the level of the patient's midthorax, facing the operator, on either side of the patient as logistics and operator preference allow (Fig. 15.3). Note that the operator stands at the head of the patient during passage of the catheter through the internal jugular or subclavian vein and at the midabdomen for insertion through the femoral or brachiocephalic vein. Newer patient monitors may be equipped with suitable ECG connections to allow their use in place of a stand-alone ECG machine. Because these patients will already be attached to a monitor, it may prove convenient to use the same piece of equipment to assist in insertion of the pacemaker.

Introducer Sheath

An introducer set or sheath is required for venous access (see Chapter 22). Some pacing catheters are prepackaged with the appropriate equipment, whereas others require a separate set. The introducer set is used to enhance passage of the pacing catheter through the skin, subcutaneous tissue, and vessel wall. The sheath must be larger than the pacing catheter to allow it to pass. The size of the pacing catheter refers to its outside diameter, whereas the size of the introducer refers to its inside diameter. Thus, a 5-Fr pacing catheter will fit through a 5-Fr introducer. Introducer sheaths are available with a perforated elastic seal covering the opening through which the pacing

catheter is passed (pacer port). The seal allows the catheter to be manipulated while preventing blood from escaping or air from entering the vein. A side port allows the sheath to be used for central venous access. A makeshift sheath can be fashioned with an appropriately sized intravenous (IV) catheter. For a 3-Fr balloon-tipped catheter, a 14-gauge 1.5- to 2-inch IV catheter is suitable. A 4-Fr balloon-tipped catheter will also fit through a 14-gauge catheter or needle. However, without a seal over the hub, blood will leak from the end of the IV catheter.

Overall, the key to success with this procedure is preparation. In a typical ED there are often a variety of vascular access kits and devices, not all of which will work well, if at all, for passing a pacing catheter. It is imperative that one examine all the components of the tray before starting the procedure to ensure that all wires, sheaths, dilators, and syringes fit as expected. Ideally, all the equipment and accessories needed for emergency pacemaker insertion should be kept together in a designated location.

Procedure

A checklist for the preparation and initial setup of a pacing generator is shown in Box 15.1. It may be useful to have a copy of this checklist or a similar list stored with the pacemaker, to have on hand in emergency situations.

Patient Preparation

Patient instruction is an extremely important aspect of any procedure. Frequently, there is not enough time to give patients a detailed explanation or to obtain written informed consent. Nonetheless, sufficient information should be provided so that the patient feels at ease. It is always prudent to obtain and document informed consent from the patient, if possible, before any invasive procedure or to document that the circumstances

Figure 15.3 Position of operator and electrocardiographic device during insertion of a pacemaker catheter through the left subclavian vein (a preferred site).

BOX 15.1 Checklist for a Temporary Transvenous Pacing Generator

- Insert a new battery.
- Turn the pacemaker ON.
- Set the RATE (80 beats/min), OUTPUT (5 mA), and SENSITIVITY (3 mV).^b
- Connect the patient cable to the pacemaker.
- Open both connector terminals on the patient cable.
- Insert the PROXIMAL (+) pin of the pacing catheter into the POSITIVE (+) connector terminal on the patient cable.
- Tighten the connection firmly.
- Use alligator clips to connect the DISTAL (-) pin of the pacing catheter to lead V₁ of the electrocardiographic machine.
- When the catheter is in position, remove the DISTAL (-) pin from V₁ and insert it into the NEGATIVE (-) connector terminal on the patient cable.
- Tighten the connection firmly.

^aAdjust pacemaker settings as needed to achieve proper capture and sensitivity (see text).

^bGuidelines only. Follow the recommendations of the device's manufacturer if different.

TABLE 15.3 Advantages and Disadvantages of Pacemaker Placement Sites

VENOUS CHANNELS	ADVANTAGES	DISADVANTAGES
Brachial	Very safe route Vessel easily accessible, either by cutdown or a percutaneous approach Compressible	Often requires a cutdown Easily displaced and poor patient mobility Not reusable if a cutdown technique is performed The catheter is more difficult to advance than in central or larger vessels
Subclavian	Direct access to the right side of the heart (especially via the left subclavian) Rapid insertion time Good patient mobility	Pneumothorax and other intrathoracic trauma are possible Noncompressible
Femoral	Direct access to the right side of the heart Rapid insertion time Compressible	Increased incidence of thrombophlebitis Can be dislodged by leg movement Poor patient mobility Infection
Internal jugular	Direct access to the right side of the heart (especially via the right internal jugular) Rapid insertion time Compressible	Possible carotid artery puncture Dislodgment with movement of the head Thrombophlebitis

did not allow informed consent. Patients should be assured that they will feel no discomfort after the venipuncture site has been anesthetized and that they will feel better when the catheter is in place and is functional. Continued reassurance is required during the procedure because patients are usually facing away from the operator and their faces are often covered; thus, they may be unsure of what is occurring. Sedation and analgesia should be considered when appropriate.

All operators should wear surgical masks, caps, gloves, and gowns to decrease the risk for infection before catheter placement. Patients should be prepared and draped in the usual sterile fashion. This aseptic precaution should also be explained to the patient.

Site Selection

The four venous channels that provide easy access to the right ventricle are the brachial, subclavian, femoral, and internal jugular veins (Table 15.3). The route selected is often one of personal or institutional preference. The right internal jugular and left subclavian veins have the straightest anatomic pathway to the right ventricle and are generally preferred for temporary transvenous pacing (Fig. 15.4). In some centers a particular site is preferred for permanent transvenous pacemaker placement and, if possible, this site should be avoided for temporary placement.

The subclavian vein can be accessed through both an infraclavicular and a supraclavicular approach; the infraclavicular approach is most commonly reported for all temporary transvenous pacemaker insertions. This route is preferred because of its easy accessibility, close proximity to the heart, and ease in catheter maintenance and stability. The supraclavicular approach has been described in the literature for several years and has gained popularity among some clinicians.^{46,47}

Figure 15.4 The right internal jugular and left subclavian veins have the straightest anatomic pathway to the right ventricle and are generally preferred for temporary transvenous pacing.

The left subclavian vein is preferred because of the less acute angle traversed than with the right-sided approach, but either side may be used.^{46,47}

The internal jugular approach may also be used. In this case, the right internal jugular vein is preferred because of the direct line to the superior vena cava. Problems with this approach include dislodgment of the pacemaker with movement of the head, puncture of the carotid artery, and thrombophlebitis.

During CPR, use of the right internal jugular vein and the left subclavian vein for pacemaker insertion has been demonstrated to result in the highest rates of proper placement

in the right ventricle.⁴⁸ The right internal jugular vein is the more direct route of the two and may be the most appropriate site.

Femoral veins, like neck veins, are compressible and easily catheterized. Problems include easy dislodgment, infection, and increased risk for thrombophlebitis.^{49,50}

Brachial vein catheterization is easy to perform but results in a high incidence of infection and vessel thrombosis.⁵¹ In addition, the catheter is easily dislodged with arm motion. This approach is seldom used in the emergency setting.

Although the left subclavian and right internal jugular veins are the preferred routes for access, in emergency situations clinicians should use the approach with which they are most experienced to minimize the time spent cannulating the vein and to reduce the potential for complications from the venipuncture.

Skin Preparation and Venous Access

Clean the skin over the venipuncture site twice with an antiseptic solution such as chlorhexidine or povidone-iodine. Prepare a wide area because of the tendency for guidewires and catheters to spring from the hands of an unsuspecting operator. Similarly, drape widely in the standard manner to maintain a sterile field and to allow clear visibility of the venipuncture site.

The infraclavicular approach is used in this chapter to illustrate venous access, although the mechanics are generally the same as for other vascular approaches.

Occasionally, a patient who already has a central venous line in place requires emergency placement of a pacing catheter. An existing central venous pressure (CVP) line can be used to place the pacing catheter if the lumen of the catheter is large enough to accept a guidewire. Withdraw the CVP line 3 to 5 cm to expose an area of sterile tubing. Transect the tubing through a sterile area while holding it firmly at skin level. Pass a guidewire through the tubing, and then withdraw the tubing so that only the wire is left in the vein. Never release the guidewire and the tubing because embolization may result.

With the guidewire in place, pass a dilator and introducer sheath together over the guidewire, as is done in the Seldinger technique. Remove the dilator and guidewire and pass the pacing catheter through the introducer sheath (Fig. 15.5, step 1). One key additional step to help preserve sterility while manipulating the pacing catheter is to attach an extensible sleeve on the end of the introducer before inserting the pacing catheter (see Fig. 15.5, steps 1 and 6). In this way the pacing catheter can be advanced and withdrawn multiple times without fear of contamination.

Bedside ultrasound (US) can be useful as an aid in securing central venous access, and its use in the setting of emergency transvenous pacing has been reported.^{52,53}

Pacemaker Placement Emergency Blind Passage

A transvenous pacemaker wire can be advanced blindly, or under ECG guidance. In an emergency, blind advancement is preferred. The right internal jugular route is preferred. Attach the pacer wire to the pacemaker energy source and turn it on at a rate of 80 beats/min, output at 20 mA of current, and set the asynchronous (fixed rate) mode. After the wire is blindly advanced to the 20-cm depth (two hash marks on the wire) inflate the pacing-wire balloon and advance the pacing wire while viewing the patient's cardiac monitor. When capture is seen on the ECG monitor by observing a pacer spike followed

by QRS ST segment elevation, the pacing wire is in the proper position. Deflate the balloon and secure the pacing wire at the skin. When time permits, or if the blind passage procedure is not successful, attach the pacing wire to the ECG V₁ lead with an alligator clamp. Turn on the ECG machine to monitor the V₁ lead and hence the position of the catheter tip. The following is a detailed summary of that ECG-guided procedure.

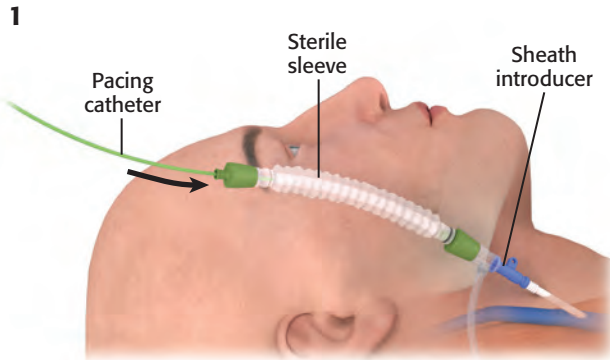

ECG Guidance

Connect the patient to the limb leads of an ECG machine, and turn the indicator to record the chest (V) lead.

With newer ECG machines, the pacemaker may be attached to any of the V leads (usually V₁ or V₅) that are displayed during rhythm monitoring. The distal terminal of the pacing catheter (the cathode or lead marked "negative", "-", or "distal") must be connected to the V lead of the ECG machine by a male-to-male connector or by an insulated wire with an alligator clip on each end. Some prepackaged kits contain an alligator clamp that can be connected to the lead with an adapter pin (see Fig. 15.5, step 2). The pacing catheter is thus an exploring electrode that creates a unipolar electrode for intracardiac ECG recording. The ECG tracing recorded from the electrode tip localizes the position of the tip of the pacing electrode. Because the tracing on the ECG machine may be slightly delayed, advancement of the catheter after initial insertion must be evaluated carefully. If a balloon-tipped catheter is used, inflate the balloon with air after the catheter enters the superior vena cava (≈ 10 to 12 cm for a subclavian or internal jugular insertion) (see Fig. 15.5, step 3). The inflation port should be locked and the syringe left attached.

Advance the pacing catheter both quickly and smoothly. Monitor the ECG V lead, and observe the P wave and QRS complex to ascertain the location of the tip of the pacing catheter (see Fig. 15.5, step 4). Use of electrocardiography to guide placement of a pacing catheter is based on two concepts. First, the complex will vary in size depending on which chamber is entered. For example, when the tip of the pacing catheter is in the atrium, one will see large P waves, often larger than the corresponding QRS complex. Second, the sum of the electrical forces will be negative if the depolarization is moving away from the catheter tip and positive if the depolarization is moving toward the catheter tip. Therefore if the tip of the catheter is above the atrium, both the P wave and QRS complex will be negative (i.e., the electrical forces of a normally beating heart will be moving away from the catheter tip). As the tip progresses inferiorly in the atrium, the P wave will become isoelectric (biphasic) and will eventually become positive as the wave of atrial depolarization advances toward the tip of the catheter. The ECG tracing resembles an aVR lead initially when in the left subclavian vein (Fig. 15.6A) or the midportion of the superior vena cava (see Fig. 15.6B). At the high right atrial level, both the P wave and QRS complex are negative. The P wave is larger than the QRS complex and is deeply inverted (see Fig. 15.6C and D). As the center of the atrium is approached, the P wave becomes larger and biphasic (see Fig. 15.6E). As the catheter approaches the lower atrium (see Fig. 15.6F), the P wave becomes smaller and upright. The QRS complex is fairly normal. When striking the right atrial wall, an injury pattern with a P-Ta segment is seen (see Fig. 15.6G). As the electrode passes through the tricuspid valve, the P wave becomes smaller and the QRS complex becomes larger (see Fig. 15.6H). Placement in the inferior vena cava may be recognized by a change in the morphology of the P

Emergency Transvenous Cardiac Pacing

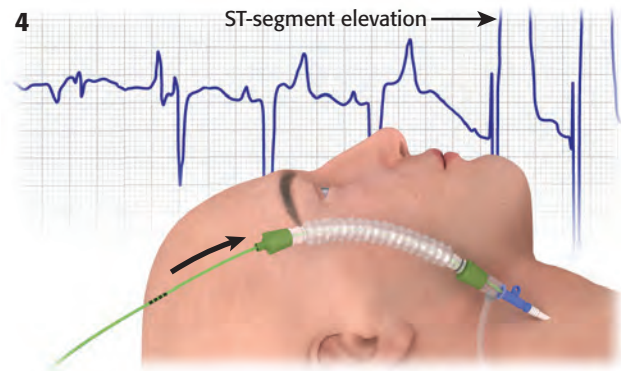

1 Establish a sheath introducer in the selected vein. Attach the still-compressed sterile sleeve to the introducer hub. Check the balloon for integrity and then advance the catheter into the sleeve. (Full sterile drapes should be used but are not depicted here.)

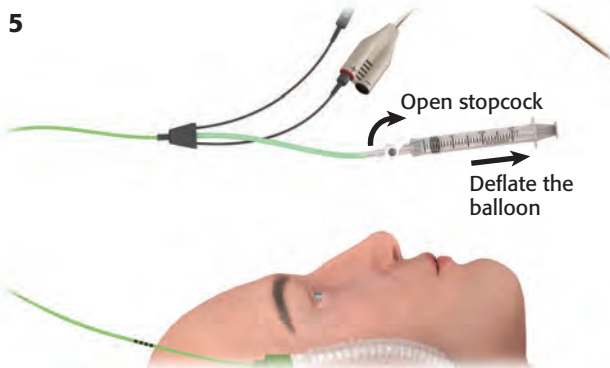

2 Instruct an assistant to make the following nonsterile connections. Attach the proximal (+) lead to the positive terminal of the connecting cable and the distal (-) lead to the V₁ lead of an ECG machine with an alligator clamp. (Alternatively, an insulated wire with an alligator clip on each end may be used.)

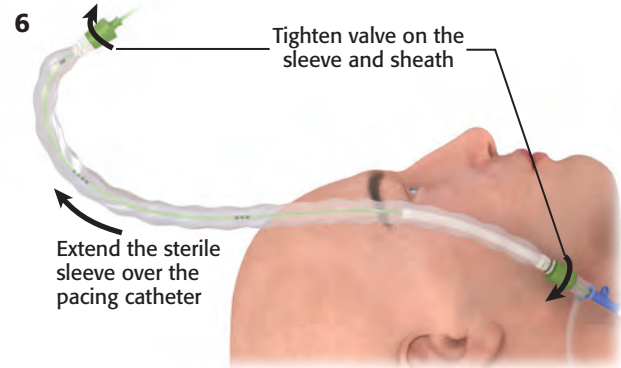

3 Advance the catheter approximately 10 to 12 cm so that the tip lies within the superior vena cava. Then inflate the balloon with 1.5 mL of air. Close the stopcock valve to keep the balloon inflated.

4 Advance the pacing catheter quickly and smoothly. Monitor the V lead on the electrocardiogram to ascertain the location of the tip of the pacing catheter. The P wave and QRS complex will vary in size depending on which chamber the tip is in, and the sum of the electrical forces will be negative if depolarization is moving away from the catheter tip and positive if depolarization is moving toward it. ST-segment elevation will occur when the tip contacts the endocardium.

5 When the pacing catheter is in the desired position, deflate the balloon by unlocking the stopcock and allow the syringe to spontaneously refill with air.

6 Extend the sterile sleeve so that it fully covers the pacing catheter. If your sheath and sleeve have valves, close them by turning clockwise to keep the wire and sleeve in place.

Figure 15.5 Emergency transvenous cardiac pacing. Note that by attaching the pacing catheter to the electrocardiographic (ECG) machine (step 2) and observing the V₁ ECG tracing, the negative lead now becomes an exploring lead that tells the operator the position of the tip of the pacing catheter in the body (see Fig. 15.6).

Emergency Transvenous Cardiac Pacing, CONTINUED

Figure 15.5, cont'd

wave and a decrease in the amplitude of both the P wave and the QRS complex (see Fig. 15.6J).

Once the pacing catheter is in the desired position, deflate the balloon by unlocking the port, observe that the syringe refills with air spontaneously, and then remove the syringe (see Fig. 15.5, step 5). Avoid drawing back on the syringe because this may rupture the balloon. If the syringe does not refill spontaneously, the balloon might be ruptured. Do not inflate the balloon. Withdraw the pacing catheter, and check the balloon for leaks. If a leak is found, use a new pacing catheter.

After successful passage of the catheter into the right ventricle, advance the tip until contact is made with the endocardial wall. When this occurs, the QRS segment will

show ST-segment elevation (see Fig. 15.6J). Ideally, the tip of the catheter should be lodged in the trabeculae at the apex of the right ventricle; however, pacing may also be successful if the catheter is in various other positions within the ventricle or outflow tract.

If the pacer enters the pulmonary artery outflow tract, the P wave again becomes negative, and the QRS amplitude diminishes (see Fig. 15.6K). If the catheter is in the pulmonary artery, withdraw the pacing catheter into the right ventricle and readvance it. Sometimes a clockwise or counterclockwise twist of the catheter will redirect its path in a more favorable direction. If catheter-induced ectopy develops, withdraw the catheter slightly until the ectopy stops, and then readvance

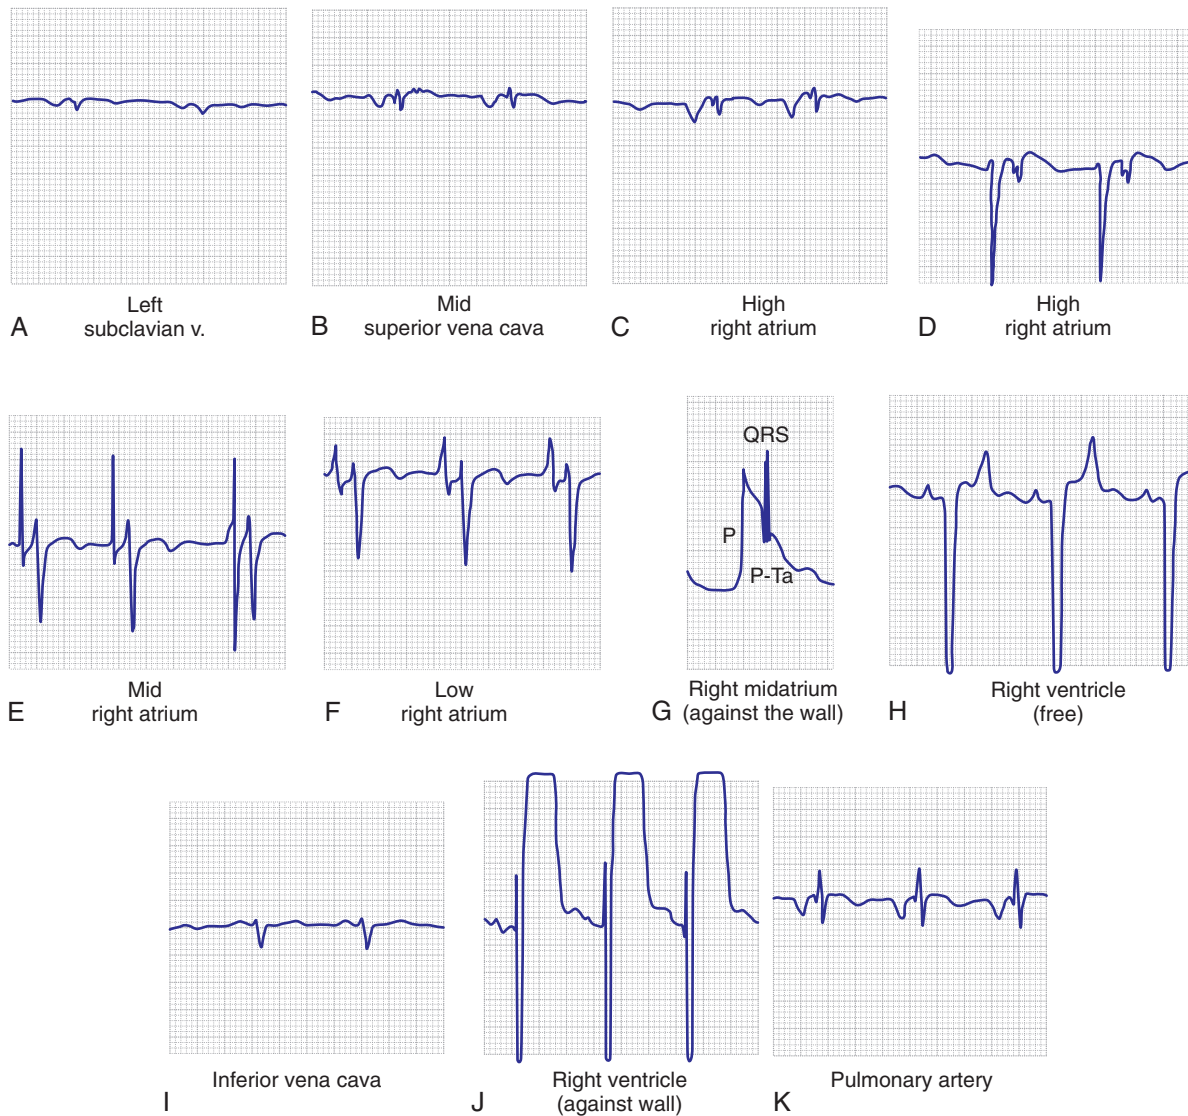

Figure 15.6 For pacemaker placement with electrocardiographic (ECG) guidance, connect the patient to the limb leads of an ECG machine, and turn the indicator to record the chest (V) lead. With newer ECG machines, the pacemaker may be attached to any of the V leads (usually V₁ or V₅) that are displayed during rhythm monitoring. The distal terminal of the pacing catheter (the cathode or lead marked “negative”, “-” or “distal”) must be connected to the V lead of the ECG machine by a male-to-male connector or by an insulated wire with an alligator clip on each end. As one advances the pacing catheter and records the ECG complex that is obtained from the distal electrode (the exploring lead), the location of the tip of the pacing wire can be ascertained. **A-C**, Left subclavian vein, mid superior vena cava, and high right atrium, respectively. **D**, With the tip of the pacer in the high right atrium, above the sinoatrial node, the P waves are large and negative which indicates that the cardiac forces are moving away from the tip of the catheter. **E**, Mid right atrium. **F**, With the exploring electrode in the low right atrium the P waves are now positive because the sinus depolarization is now coming toward the tip of the electrode. **G**, Right midatrium. **H**, With the recording electrode tip free in the right ventricle positive P waves and large QRS complexes are seen. **I**, Inferior vena cava. **J**, When lodged against the ventricular wall the current of injury denotes proper pacer tip placement. **K**, Pulmonary artery. (*A-F and H-K*, From Bing OH, McDowell JW, Hantman J, et al: *Pacemaker placement by electrocardiographic monitoring*, N Engl J Med 287:651, 1972; *G*, from Goldberger E: *Treatment of cardiac emergencies*, ed 3, St. Louis, 1982, Mosby p 252.)

it. Occasionally, an antidysrhythmic drug such as lidocaine may be needed to desensitize the myocardium. Once ventricular endocardial contact is made, disconnect the catheter from the ECG machine and connect the distal lead to the negative terminal on the pacing generator (see Fig. 15.5,

step 7). Set the pacing generator at a rate of 80 beats/min or 10 beats/min faster than the underlying ventricular rhythm, whichever is higher. Select the full-demand mode with an output of approximately 5 mA. Then turn on the pacing generator.

Assess the patient for electrical and *mechanical capture*. Electrical capture will be manifested on the ECG monitor as a pacer spike followed by a QRS complex (see Fig. 15.5, step 8). If a pacer spike is seen but no QRS follows, capture is not occurring. Mechanical capture means that a pacer spike with its corresponding QRS triggers a myocardial contraction. This can be assessed by checking that a palpable pulse is present and equal to the rate set on the pacemaker. If complete capture does not occur or if it is intermittent, the pacer will need to be repositioned. When proper capture occurs, assess the pacer for optimal positioning. This is done by testing the thresholds for pacing and sensing, and by physical examination, electrocardiography, and chest radiography.

Catheter Placement in Low-Flow States

If cardiac output is too low to float a pacing catheter or if the patient is in extremis, there may not be enough time to advance a pacing catheter via the previously described techniques. Such a situation would be asystole or complete heart block with malignant ventricular escape rhythms (although one can make a case for TCP in such conditions). In such emergency situations, connect the pacing catheter to the energy source, turn the output to the maximum amperage, and select the asynchronous mode (see earlier section on [Emergency Blind Passage](#)). Advance the catheter blindly in the hope that it will enter the right ventricle and pacing will be accomplished. Rotate, advance, withdraw, or otherwise manipulate the pacing catheter according to clinical response. The right internal jugular approach is the most practical access route in this situation.

US Guidance

As bedside US has become more widely available in the ED, new uses have been discovered. One promising technique involves using US to assist in the placement of emergency transvenous pacing catheters.⁵⁴⁻⁵⁶ US may also help demonstrate whether mechanical capture has been achieved. The advantages of US over fluoroscopy are: no exposure to ionizing radiation, lower rates of complications, and faster times to pacemaker insertion.^{57,58} Further experience will be necessary to confirm its utility ([Ultrasound Box 15.1](#)).

Testing Threshold

The threshold is the minimum current necessary to obtain capture. Ideally, it is less than 1.0 mA, and usually it is between 0.3 and 0.7 mA. If the threshold is in this ideal range, good contact with the endocardium can be presumed.

To determine the threshold, set the pacing generator to maximum sensitivity (full-demand mode) at 5-mA output and a rate of approximately 80 beats/min (or at least 10 beats/min greater than the patient's intrinsic rate) (see Fig. 15.5, step 9). Reduce the current (output) slowly until capture is lost. This current is the threshold. Carry out this maneuver two or three times to ensure that this value is consistent. Increase the amperage to 2.5 times the threshold to ensure consistency of capture (usually between 2 and 3 mA).

Testing Sensing

Test the sensing function in patients who have underlying rhythms. Set the rate at approximately 10 beats/min greater than the endogenous rhythm, place the pacemaker in asynchronous mode (minimum sensitivity, which is the maximum setting on the sensitivity voltage control), and ensure that

there is complete capture (see Fig. 15.5, step 10). Then adjust the sensitivity control to its midposition or approximately 3 mV, and gradually decrease the rate until pacing is suppressed by the patient's intrinsic rhythm. The sensing indicator on the pacing generator should signal each time a native beat is sensed and should be in synchrony with each QRS complex on the ECG monitor. If the pacer fails to sense the intrinsic rhythm, increase the sensitivity (decrease the millivolts) until the pacer is suppressed. Conversely, if the sensing indicator is triggered by P or T waves or by artifact, decrease the sensitivity until only the QRS complex is sensed. Once the sensitivity threshold is determined, set the millivoltage to approximately half that value.

Securing and Final Assessment

After the pacemaker's position has been tested for electrical accuracy, it must be secured in place. If a sealed introducer sheath was used, the hub should be fixed firmly to the skin with suture (e.g., 4-0 nylon or silk). A fastening suture should be sewn to the skin and the hub tied securely in place. If a plain introducer was used, withdraw it to prevent leakage and suture the catheter in place. In either case, coil the excess pacing catheter and secure it in a sterile manner underneath a large sterile dressing. Assess pacemaker function again, and take a chest film to ensure proper positioning. Ideal positioning of the pacing catheter is at the apex of the right ventricle (Fig. 15.7).

A 12-lead ECG tracing should be obtained after placement of the transvenous pacemaker. If the catheter is within the right ventricle, an LBBB pattern with left axis deviation should be evident in paced beats (Fig. 15.8). If an RBBB pattern is noted, coronary sinus placement or left ventricular pacing secondary to septal penetration should be suspected (Fig. 15.9).

With a properly functioning ventricular pacemaker, large cannon waves may be noted on inspection of the venous pulsations at the neck. When the pacemaker achieves ventricular capture, there may be times when the atria contract against a closed tricuspid valve and a cannon wave results. On auscultation of the heart a slight murmur may be evident, secondary to tricuspid insufficiency as a result of the catheter interfering with the tricuspid valve apparatus.⁵⁹ Following each pacemaker impulse a clicking sound may be heard during expiration; this is believed to represent either intercostal or diaphragmatic muscular contractions caused by the pacemaker.⁶⁰ Note that this can also be a sign of cardiac perforation.⁶¹ On auscultation of the second heart sound, paradoxical splitting may be noted. This represents a delay in closure of the aortic valve because of delayed left ventricular depolarization.

As in any procedure, assess the patient for improvement in clinical status. Evaluate vital signs, mentation, congestive symptoms, and urinary output. In addition, look for complications secondary to the procedure and treat as needed.

Complications

The complications associated with emergency transvenous cardiac pacing are numerous and represent a compendium of those related to central venous catheterization,^{13,62} those related to right-sided heart catheterization, and those unique to the pacing catheter itself. Overall rates of adverse events using modern flexible, balloon-tipped catheters are in the range of 20%.^{13,63} However, the majority of complications are a result of obtaining venous access, and when US guidance is used the rate is markedly decreased.¹⁴

ULTRASOUND BOX 15.1: Transvenous Cardiac Pacing

by Christine Butts, MD

Using ultrasound to guide placement of a transvenous pacemaker (TVPM) gives the physician the advantage of direct visualization of the tip of the pacemaker and the ability to directly maneuver it into the correct position to obtain capture. Although placement of a TVPM is a relatively rare procedure in the emergency department, the use of ultrasound has been described to facilitate the procedure.^{1,2} Ultrasound can also be used to evaluate placement in cases in which blind attempts at transvenous pacing are unsuccessful. Additionally, ultrasound is useful in achieving the central venous access necessary to introduce the pacemaker.

Equipment

A low-frequency (2 to 5 mHz) transducer offers the optimum depth to evaluate the heart. A phased-array or microconvex transducer is ideal for this purpose because its small footprint enables the sonographer to "see" between the patient's ribs. In the absence of a phased-array or microconvex transducer, a curvilinear transducer may be adequate. Although insertion of a TVPM is a sterile procedure, the transducer does not need to be sterile if it is used away from the field. If the transducer will be used near or on the field, it can be placed inside a sterile cover or a sterile glove.

Image Interpretation

The subxiphoid view of the heart is the optimum view for this procedure (Fig. 15.US1). It enables the operator to view all four chambers of the heart at once. The subxiphoid view is obtained by placing the transducer just inferior to the xiphoid process with the indicator pointing toward the patient's right side (Fig. 15.US2). A hand should be placed on top of the transducer to enable the sonographer to push downward into the epigastric area. The transducer can then be aimed toward the left side of the chest until the four-chambered view of the heart is seen. In this view the left lobe of the liver is seen at the top of the image. Deep to this is the heart, with the right atrium and ventricle abutting the liver.

Figure 15.US1 Ultrasound subxiphoid image of the heart. In this ultrasound the liver is seen at the top of the image. The heart is seen below, with the right ventricle (RV), right atrium (RA), and left atrium (LA) abutting the left lobe of the liver. The left ventricle (LV) and atria are deep to the right side at the bottom of the image.

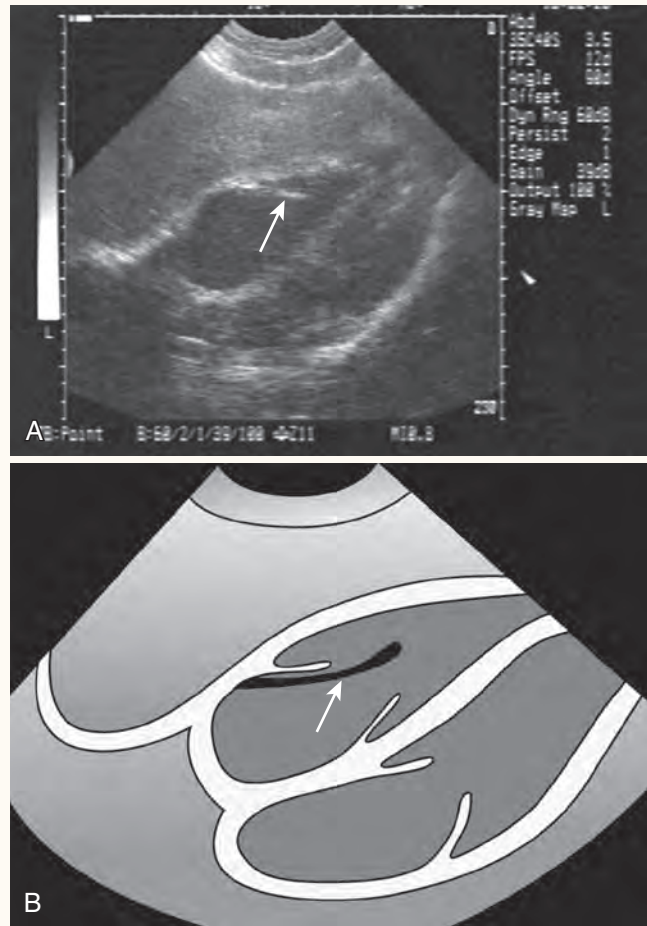

Figure 15.US3 Pacing wire within the right ventricle (arrows). **A**, Sonographic image. **B**, Schematic representation. The right ventricle is seen through the subxiphoid window, which provides excellent views of the heart without interfering with placement of the pacemaker line. The pacemaker wire is seen as a brightly echogenic structure within the right ventricle.

ULTRASOUND BOX 15.1: Transvenous Cardiac Pacing—cont'd

Procedure and Technique

To guide placement of the pacemaker, the procedure should begin in the usual fashion (as described earlier). Once the pacer wire has been inserted, the sonographer should begin observing the right atrium. The wire will appear as a hyperechoic (white) linear echo as it enters the right atrium and it can be seen to advance in real time (Fig. 15.US3). The wire should be followed as it enters the right ventricle. This can be observed simultaneously with the electrical readings on the monitor. Capture of the pacemaker can be confirmed

by visualization of coordinated, rhythmic contractions of the myocardium at the set rate. The monitor can also be evaluated for signs of electrical capture.

Problems Related to Central Venous Catheterization

Inadvertent arterial puncture is a well-known complication of the percutaneous approach to the venous system.⁶⁴ This problem is usually recognized quickly because of the rapid return of arterial blood. Firm compression over the puncture site will almost always result in hemostasis in 5 minutes or less.

Venous thrombosis and thrombophlebitis are also potential problems with central venous catheterization. Thrombophlebitis, which occurs early after insertion, is an uncommon complication. Thrombosis of the innominate vein is also a rare problem, with pulmonary embolism being an even more uncommon event.⁶⁵ Femoral vein thrombosis, however, appears to be a much more common event associated with femoral vein catheterization.^{49,66} Studies using noninvasive techniques have shown a 37% incidence of femoral vein thrombosis, with 55% of these patients having evidence of pulmonary embolism on ventilation-perfusion scans.⁶⁶ At least one study suggests that the use of low-dose enoxaparin is safe and effective in reducing pacemaker-related femoral vein thrombosis.⁶⁷

Pneumothorax is consistently a problem with the various approaches to the veins at the base of the neck. The decision to place a chest tube in patients with this complication depends on the extent of the air leak and the clinical status of the patient. In addition, laceration of the subclavian vein with

hemothorax,⁶⁸ laceration of the thoracic duct with chylothorax, air embolism, wound infections, pneumomediastinum, hydro-mediastinum, hemomediastinum,⁶⁹ phrenic nerve injury,⁷⁰ and fracture of the guidewire with embolization^{71,72} are all potential complications.^{38,68}

Complications of Right-Sided Heart Catheterization

A frequent complication of the pacing catheter is dysrhythmia, with premature ventricular contractions being a common occurrence. One study noted a 1.5% incidence of serious dysrhythmias with a balloon-tipped catheter inserted under ECG guidance, as opposed to a 32% incidence with insertion of a semirigid catheter under fluoroscopic guidance, thus suggesting that the balloon catheter was the preferred type of catheter.¹² Another study noted a 6% incidence of ventricular tachycardia during insertion.⁴⁹ An ischemic heart is more prone to dysrhythmias than a nonischemic heart.⁷³ Therapy for catheter-induced ectopy during insertion involves repositioning the catheter in the ventricle. This usually stops the ectopy; however, if after repeated attempts it is found that the catheter cannot be passed without ectopy, myocardial suppressant therapy may be used to desensitize the myocardium.

Misplacement of the pacing catheter has been well studied. Passage of the catheter into the pulmonary artery can be

Figure 15.8 Electrocardiographic pattern of a right ventricular pacemaker.

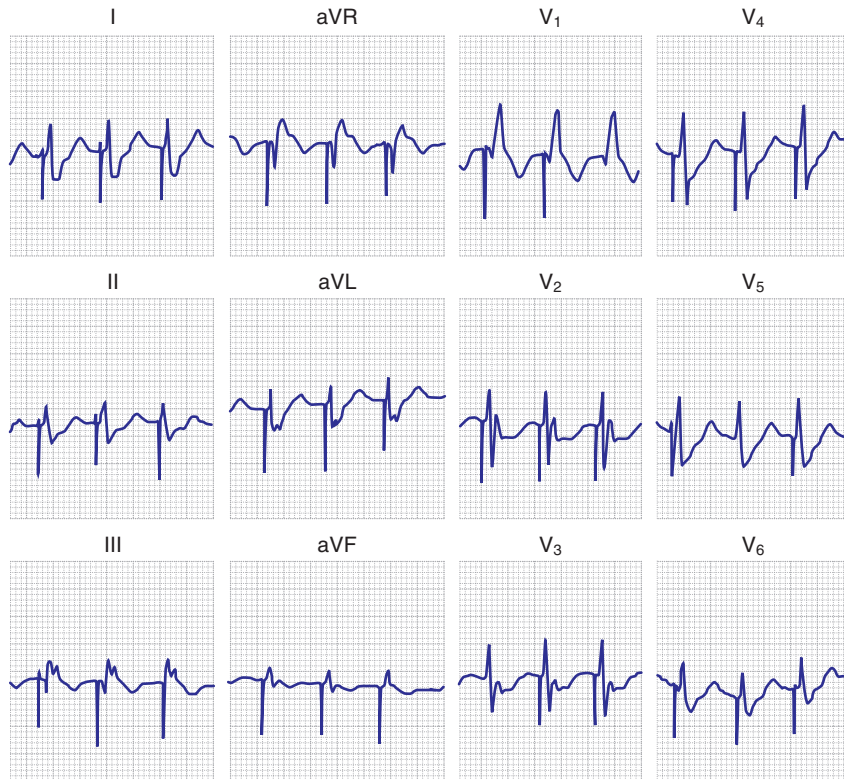

Figure 15.9 Coronary sinus pacing. Note the paced right bundle branch block pattern.

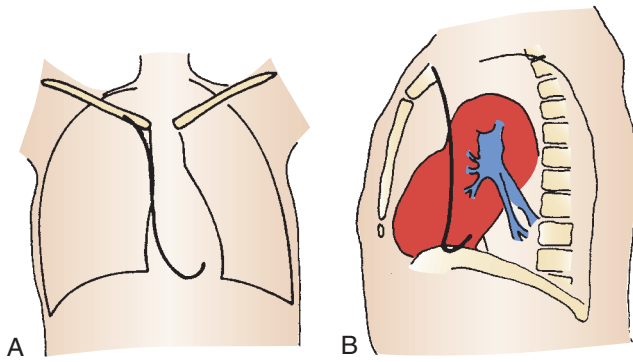

Figure 15.10 Coronary sinus position. **A**, Posteroanterior view. **B**, Lateral view. Normally, the tip of the catheter should point anteriorly toward the apex of the heart. With coronary sinus placement, the tip is displaced posteriorly and several centimeters from the sternum. (*A and B*, From Goldberger E: Treatment of cardiac emergencies, ed 3, St. Louis, 1982, Mosby.)

diagnosed electrocardiographically by observing the return of an inverted P wave and a decrease in the voltage of the QRS complex. Misplacement in the coronary sinus may occur and should be suspected in patients in whom a paced RBBB pattern on the electrocardiogram is seen with right ventricular pacing (see Fig. 15.9). Rarely, an RBBB pattern can be seen with a normal right ventricular position; therefore all RBBB patterns do not represent coronary sinus pacing.⁷⁴ Further evidence of coronary sinus location can be obtained by viewing the lateral chest film. Normally the tip of the catheter should point anteriorly toward the apex of the heart; however, with placement in the coronary sinus, the tip of the catheter is displaced posteriorly and several centimeters away from the sternum (Fig. 15.10). Other potential forms of misplacement include left ventricular pacing through an atrial or ventricular septal defect, septal puncture, extraluminal insertion, and arterial insertion.⁷⁵

Perforation of the ventricle is a well-described complication that can result in loss of capture,⁷⁶ hemopericardium, and tamponade.^{76a,77} Reported symptoms and signs of this problem include chest pain, pericardial friction rub, and diaphragmatic or chest wall muscular pacing.⁷⁸ At least one case of a postpericardiotomy-like syndrome and two cases of endocardial friction rub have been reported without perforation.^{79,80}

Pericardial perforation is suggested radiographically when the pacing catheter is outside or abuts the cardiac silhouette and is not in proper position within the right ventricular cavity (Fig. 15.11).⁸¹ ECG clues include a change in the QRS complex and T-wave axis or failure to properly sense. In suspected cases a two-dimensional echocardiogram usually demonstrates the catheter's extracardiac position. Simply pulling the catheter back and repositioning it in the right ventricle can usually treat uncomplicated perforation.

During insertion of a temporary pacing catheter when a nonfunctioning permanent catheter is in place, there is a small risk of entanglement or knotting.⁸² This potential also exists with other central lines and PACs. Even without the presence of other lines, the pacing catheter can become knotted.⁸³ Frequently, these lines can be untangled under fluoroscopy with the use of specialized catheters.

Local and systemic infection,⁵¹ balloon rupture, pulmonary infarction,⁸⁴ phrenic nerve pacing,⁸⁵ and rupture of the chordae tendineae are also potential complications.

Figure 15.11 A pacing catheter tip (arrow) that is outside or abuts the cardiac silhouette and is not properly positioned within the right ventricular cavity suggests myocardial perforation. (From Tarver RD, Gillespie KR: The misplaced tube, Emerg Med Clin North Am 20:97, 1988.)

Complications of the Pacing Electrode

Complications related to the pacing electrode can be separated into three groups: mechanical, organic, and electrical.

Mechanical failures include displacement, fracture of the catheter, and loose leads. Displacement can result in intermittent or complete loss of capture or improper sensing, malignant dysrhythmias, diaphragmatic pacing, or perforation. Displacement should be suspected with changes in amplitude, with changes of greater than 90 degrees in vector, or with a change in threshold.⁸⁶ Frequently, catheter fractures may be detected by careful review of the chest film or may be suspected because of a change in the sensing threshold. As with displacement, catheter fractures may result in intermittent or complete loss of capture.

Organic causes of pacemaker failure result in changes in the threshold or sensing function.⁸⁷ Progressive inflammation, fibrosis, and thrombosis may result in more than doubling of the original threshold.⁸⁸ However, this process takes several weeks and is of no concern in the setting of pacemaker placement in the ED.

Electrical problems with pacing in the past have included failure of the pacemaker generator, dysrhythmias, and outside interference. Modern devices are extremely reliable and resistant to outside interference. Although ventricular tachycardia and ventricular fibrillation have been reported to result from pacemakers, these dysrhythmias are rare. Therefore patients with such dysrhythmias should be evaluated for a non-pacemaker-induced cause.⁸⁹ Defibrillation and cardioversion are safe in patients who have temporary pacemakers.

EMERGENCY TCP

TCP is a rapid, minimally invasive method of emergency cardiac pacing that may temporarily substitute for transvenous pacing. Electrodes are applied to the skin of the anterior and posterior chest walls, and pacing is initiated with a portable pulse

Transcutaneous Cardiac Pacing

Indications

General indications are identical to those for transvenous pacing (see Review Box 15.1)
 Initial stabilization of patients requiring pacing while arrangements for transvenous pacing are being made
 Pacing in various environments (prehospital, hospital ward, etc.)
 Pacing in patients treated with thrombolytics or other anticoagulants

Contraindications

No absolute contraindications

Complications

Failure to recognize the presence of underlying treatable ventricular fibrillation
 Induction of ventricular fibrillation (rare)
 Soft tissue discomfort

Equipment

Review Box 15.2 Transcutaneous cardiac pacing: indications, contraindications, complications, and equipment.

generator. In an emergency setting, this pacing technique is faster and easier to initiate than transvenous pacing. Pulse generators are sufficiently portable to be used in EDs, hospital wards, intensive care units, and mobile paramedic vehicles.

In 1872, Duchenne de Boulogne reported successful resuscitation of a child by attaching one electrode to a limb while a second electrode was rhythmically touched to the precordium of the thorax.⁹⁰ Successful overdrive pacing of the human heart with a precordial electrode was reported by VonZiemssen in 1882.⁹¹

In 1952, Zoll introduced the first practical means of TCP. Using a ground electrode attached to the skin and a subcutaneous needle electrode over the precordium, he reported successful resuscitation of two patients in ventricular standstill.⁹² One patient was paced for 5 days and subsequently discharged from the hospital. Zoll later introduced a machine that delivered impulses lasting 2 msec through 3-cm diameter metal paddles pressed firmly against the anterior chest wall. This device was the first commercial transcutaneous cardiac pacemaker. During the 1950s, both Zoll and coworkers and Leatham and colleagues demonstrated the effectiveness of TCP in patients with bradycardia and asystole.⁹³⁻⁹⁶ Leatham and colleagues used larger electrodes (4 × 6 cm) and a longer pulse duration (20 msec) to successfully pace two patients with bradydysrhythmias.⁹⁶

Until the late 1950s, TCP was the only clinically accepted method of cardiac pacing. The original technique involving bare metal electrodes had adverse effects, including local tissue burns, muscle contraction, and severe pain.^{92,96} With the development of the first implantable pacemakers from 1958 to 1960, and the improvement in transvenous electrodes during the early 1960s, TCP was rapidly discarded.⁹⁷

Refinements in electrode size and pulse characteristics led to the reintroduction of TCP into clinical practice.^{98,99} Increasing the pulse duration from 2 to 20 msec or longer was found to decrease the current output required for cardiac capture.^{100,101} Longer impulse durations also make induction of ventricular fibrillation less likely.¹⁰⁰ Electrodes with a larger surface area

(80 to 100 cm²) decrease the current density at the underlying skin and therefore decrease pain and the possibility of tissue burns.⁹⁸

Indications and Contraindications

General indications for cardiac pacing were discussed earlier. TCP is the fastest and easiest method of emergency pacing. This technique is useful for initial stabilization of patients in the ED who require emergency pacing while arrangements or decisions about transvenous pacemaker insertion are being made. The equipment is readily mastered, the procedure is fast, and it is minimally invasive.^{99,102} Refinements in equipment have made TCP the emergency pacing procedure of choice. TCP is also widely used in the prehospital environment, as well as in the hospital in the cardiac catheterization laboratory, operating room, intensive care units, and on general medical floors.¹⁰³⁻¹⁰⁵ The technique may be preferable to transvenous pacing in patients who have received thrombolytic agents or other anticoagulants. No central venous puncture, with the attendant risk of hemorrhage, is required. Limited experience suggests that TCP may also be useful in the treatment of refractory tachydysrhythmias by overdrive pacing.¹⁰⁶⁻¹¹¹ Although small pediatric electrodes for TCP have been developed, experience with pediatric TCP has been limited.¹¹²⁻¹¹⁴

TCP is indicated for the treatment of hemodynamically significant bradydysrhythmias that have not responded to medical therapy. Hemodynamically significant implies hypotension, anginal chest pain, pulmonary edema, or evidence of decreased cerebral perfusion. This technique is temporary and is indicated for short intervals as a bridge until transvenous pacing can be initiated or the underlying cause of the bradydysrhythmia (e.g., hyperkalemia,¹⁰² drug overdose) can be reversed.¹¹⁵ Though generally unsuccessful, TCP may be attempted for the treatment of asystolic cardiac arrest. In this setting the technique is efficacious only if used early after the onset of arrest (usually within 10 minutes).^{116,117} TCP is not

indicated for the treatment of prolonged arrest victims with a final morbid rhythm of asystole.^{113,118–120}

Delay from the onset of arrest to the initiation of pacing is a major problem that limits the usefulness of TCP in prehospital care. Hedges and associates reported that the everyday availability of pacing increased the number of patients who underwent pacing within 10 minutes of hemodynamic decompensation and also increased long-term patient survival.¹¹⁷ Prehospital pacing may be most useful in the treatment of patients with a hemodynamically significant bradycardia who have not yet progressed to cardiac arrest (e.g., heart block in the setting of AMI) or in patients who arrest after the arrival of prehospital providers.^{116,117}

In conscious patients with hemodynamically stable bradycardia, TCP may not be necessary. It is reasonable to attach electrodes to such patients and to leave the pacemaker in standby mode against the possibility of hemodynamic deterioration while further efforts at treatment of the patient's underlying disorder are being made. This approach has been used successfully in patients with new heart block in the setting of cardiac ischemia.¹²¹ Generally, when a transvenous pacemaker becomes available it is preferred because of better patient tolerance.

Sedation/Analgesia

Most patients cannot tolerate TCP for prolonged periods because they will sense each depolarization spike. Hence, TCP is often rapidly replaced by transvenous pacing. Standard sedatives (such as benzodiazepines) and opioids (such as morphine) should be administered as needed to control anxiety and discomfort.

Equipment

Since their reintroduction, transcutaneous pacemakers have undergone rapid evolution and are now standard equipment in most EDs, as well as in other hospital settings and the prehospital environment. The pacemakers introduced in the early 1980s tended to be asynchronous devices with a limited selection of rate and output parameters. Units introduced more recently have demand mode pacing and more output options and are often combined with a defibrillator in a single unit. Combined defibrillator-pacers offer advantages in cost, ease, and rapidity of use when compared with stand-alone devices. An example of a combined unit is shown in [Review Box 15.2](#).

All transcutaneous pacemakers have similar basic features. Most allow operation in either a fixed rate (asynchronous) or a demand mode (VVI). Most allow rate selection in a range from 30 to 200 beats/min. Current output is usually adjustable from 0 to 200 mA. If an ECG monitor is not an integral part of the unit, an output adapter to a separate monitor is required to “blank” the large electrical spike from the pacemaker impulse and allow interpretation of the much smaller ECG complex. Without blanking protection, the standard ECG machine is swamped by the pacemaker spike and is uninterpretable. This could be disastrous because the large pacing artifacts can mask treatable ventricular fibrillation ([Fig. 15.12](#)). Pulse durations on available units vary from 20 to 40 msec and are not adjustable by the operator.

Two sets of patient electrodes are usually required for operation of the device. One set of standard ECG electrodes

is used for monitoring. The much larger pacing electrodes deliver electrical impulses for pacing. Newer combined defibrillator-pacemakers can use a single set of electrodes for ECG monitoring, pacing, and defibrillation. This approach makes the device simpler to use, although the ECG waveform and analysis may be suboptimal. Provisions are generally made for separate ECG monitoring electrodes for use as desired by the operator.

Along with the widespread use of TCP come problems arising from lack of standardization of equipment. Pacing electrodes placed on a patient before arrival at the hospital may be incompatible with the transcutaneous pacemaker used in the ED, and likewise, the equipment in the ED may differ from inpatient units. Efforts should be made to establish a single standard for pacing electrode connectors within an institution and out to the prehospital environment if possible.

To facilitate rapid setup, the pacing electrodes should be connected to the pacemaker at all times. With conventional packaging the leads are inside the packet with the pads, which means that the packet must be opened to allow connection to the pacing unit. However, exposure to air causes the electrodes to dry out and lose their conductivity, thus requiring continual replacement of the unused electrodes. Newer packaging leaves the connectors outside the packet, thus allowing connection to the pacemaker while preserving the shelf life of the pacing electrodes.

Technique

Pad Placement

The pacing electrodes are self-adhesive. Position them as shown in [Fig. 15.13](#). Take care to avoid placing the electrodes over an implanted pacemaker or defibrillator. Remove any transdermal drug delivery patches if they are in the way. Remove excessive hair if time permits. Place the anterior electrode (cathode or negative electrode) as close as possible to the point of maximal impulse on the left anterior chest wall. Place the second electrode directly posterior to the anterior electrode (see [Fig. 15.13A and B](#)). The posterior electrode serves as the ground. An alternative arrangement for the pacing electrodes is shown in [Fig. 15.13C](#). On females, place the electrode beneath the breast and against the chest wall. Because data regarding optimum electrode placement are scarce, selection can be based on the clinician's preference and the patient's habitus.^{122,123} Nonetheless, suboptimal capture as a result of poor electrode placement may be rectified with a small change in electrode position. Although the polarity of the electrodes does not appear to be important for defibrillation, at least one study has indicated that it may be important for pacing.¹²⁴ The electrodes are labeled by the manufacturer to indicate which one should be placed over the precordium, and it is prudent to observe this recommendation. ECG electrodes (if used) are placed on the chest wall or limbs, or both, as required and connected to the instrument cable. Some clinicians prophylactically apply pacing electrodes to all critically ill patients with bradycardia to facilitate immediate TCP should decompensation occur.

There is little risk for electrical injury to health care providers during TCP. The power delivered during each impulse is less than 1/1000 of that delivered during defibrillation.¹²⁵ Chest compressions (CPR) can be administered directly over the insulated electrodes while pacing.¹²⁶ Inadvertent contact with the active pacing surface results in only a mild shock.

Figure 15.12 A-C, The top three rhythm strips are taken from a standard wall-mounted electrocardiographic monitor. They all demonstrate large pacer spikes without capture (*arrows*). The underlying rhythm cannot be determined and could be treatable ventricular fibrillation. **D**, The bottom rhythm strip demonstrates a tracing on the same patient with the external pacer monitor (special dampening). Note that the pacing spikes are much smaller, and it is easy to see that the underlying rhythm is asystole, without pacer capture. The presence of a T wave after the QRS complex is a good indicator of ventricular capture.

Figure 15.13 Correct placement of transcutaneous pacemaker electrodes. **A** and **B**, Anteroposterior positions. **C**, Anterolateral positions (see text).

Pacing Bradycardic Rhythms

To initiate TCP, apply the pacing electrodes and activate the device (Fig. 15.14, steps 1 and 2). Slowly increase the output from minimal settings until capture is achieved (see Fig. 15.14, step 4). Rate and current (output) selections are adjustable.

Generally, a heart rate of 60 to 70 beats/min will maintain adequate blood pressure (by blood pressure cuff or arterial catheter) and cerebral perfusion.

Assess electrical capture by monitoring the ECG tracing on the filtered monitor of the pacing unit (see Fig. 15.14, steps

Emergency Transcutaneous Cardiac Pacing

Apply the pacing pads in either the anteroposterior or the anterolateral positions.

Excessive hair may be removed if time permits.

Turn the pacemaker on (long arrow), and check to make sure that the pacemaker is sensing the intrinsic rhythm (short arrows).

Select the pacing rate by using the Rate button.

Generally, a rate of 60 to 70 beats/min will maintain adequate blood pressure and cerebral perfusion.

Slowly increase the current output from minimal settings until capture is achieved.

Note the presence of pacer spikes (arrows) and the absence of subsequent QRS complexes.

Electrical capture has not been achieved and the current needs to be increased.

With higher current electrical capture has been achieved (QRS after every pacer spike, arrows).

Check for mechanical capture by palpating for a pulse.

Figure 15.14 Emergency transcutaneous cardiac pacing.

5 and 6). Assess mechanical capture by palpating the pulse as for transvenous pacing. Because of muscular contractions triggered by the pacer, carotid pulses may be difficult to assess, so palpating the femoral pulse may be easier. Additionally, bedside US may prove useful in determining ventricular capture.^{127,128} Ideally, continue pacing at an output level just above the threshold of initial electrical capture to minimize discomfort. One study involving 16 normal male volunteers who were paced without sedation noted cardiac capture at a mean current of 54 mA (range, 42 to 60 mA).¹²⁹ Most volunteers could tolerate pacing at their capture threshold; only one participant required discontinuation of pacing at 60 mA because of intolerable pain. Heller and coworkers compared subjective pain perception and capture thresholds in 10 volunteers paced with five different transcutaneous pacers.¹³⁰ Capture rates (40% to 80%), thresholds (66.5 to 104 mA), and subjective discomfort varied from pacemaker to pacemaker.

Failure to capture with TCP may be related to electrode placement or patient size. Patients with barrel-shaped chests and large amounts of intrathoracic air conduct electricity poorly and may prove refractory to capture. In one study, the scarring associated with thoracotomy was found to nearly double the

pacing threshold.¹³¹ A large pericardial effusion or tamponade will also increase the output required for capture.¹³² Failure to electrically capture with a transcutaneous device in these settings is an indication to consider immediate placement of a transvenous pacer.

Patients who are conscious or who regain consciousness during TCP will experience discomfort because of muscle contraction.^{121,129,130} Analgesia with incremental doses of an opioid agent, sedation with a benzodiazepine compound, or both, will make this discomfort tolerable until transvenous pacing can be instituted.

Overdrive Pacing

Overdrive pacing of ventricular tachycardia or paroxysmal supraventricular tachycardia is performed in patients who are stable enough to tolerate the brief delay associated with the preparation needed for this technique.^{106–111} Few data exist on the efficacy or use of this procedure in the ED. Sedate the patient as explained earlier, place pacing and monitoring electrode pads in the standard positions as detailed earlier, and initiate brief trains (6 to 10 beats) of asynchronous pacing. Set the pacer rate at approximately 20 to 60 pulses/min greater

than the dysrhythmia rate.¹³³ Generally, an impulse rate of 200 pulses/min is used for ventricular tachycardias (the rate is usually 150 to 180 beats/min), and a rate of 240 to 280 pulses/min is used for paroxysmal supraventricular tachycardias (the rate is commonly 200 to 250 beats/min).

Because rhythm acceleration is possible during overdrive pacing, it is essential to keep resuscitation equipment, including a defibrillator, at the bedside.

Complications

The major potential complication of TCP is failure to recognize the presence of underlying treatable ventricular fibrillation. This complication is primarily due to the size of the pacing artifact on the ECG screen, a technical problem inherent in systems without appropriate dampening circuitry.

A rare complication of TCP is induction of ventricular fibrillation. Studies of fibrillation thresholds using large precordial electrodes have shown that the longer impulse durations used in modern devices seem to decrease the chance of inducing ventricular fibrillation with TCP. Nonetheless, asynchronous TCP for tachydysrhythmias has been associated with acceleration in rhythm and the development of ventricular fibrillation.¹⁰⁹

If the patient has an implanted cardioverter defibrillator that is not delivering effective pacing, disable the defibrillator

by placing a magnet over it prior to initiating TCP. Failure to do so may trigger the device to administer an unnecessary shock to the patient.¹³⁴

Studies looking at prolonged TCP in humans have not been extensive. Zoll and colleagues reported 25 humans paced for up to 108 hours with impulses of 20-msec duration.⁹⁵ Pacer-induced dysrhythmias did not occur. Leatham and colleagues paced one patient for 68 hours with impulses 20 msec in duration.⁹⁶ The patient died 2 days after pacing was discontinued. Pathologic examination revealed no evidence of pacer-induced myocardial damage. Madsen and colleagues paced 10 healthy volunteers at threshold for 30 minutes and found no enzyme or echocardiographic abnormalities.¹³⁵ TCP appears unlikely to produce cardiac injury with short-term use in the ED.

Soft tissue discomfort with potential injury may still occur with current transcutaneous pacemakers. Most patients are able to tolerate the discomfort, especially after sedation and analgesia, which should be routine. Nonetheless, prolonged use may still induce local cutaneous injury, particularly in pediatric patients because of the use of smaller electrodes.^{136,137} Patients who cannot tolerate TCP or who will need long-term pacing are candidates for transvenous pacing.

Pericardiocentesis

Haney A. Mallema and Semhar Z. Tewelde

DEFINITION

Pericardial effusion, the presence of fluid within the pericardial space, has a number of causes. As fluid accumulates, a critical point is reached at which pericardial pressure negatively affects cardiac filling and causes circulatory insufficiency. This is called pericardial tamponade. Once compensatory mechanisms begin to fail, obstructive shock ensues and a failure to restore hemodynamics eventually leads to cardiac arrest. Only removal of fluid can stabilize hemodynamics at this point.

ANATOMY AND PHYSIOLOGY

Pericardium and Pericardial Space

The pericardium is a two-layered fibroelastic sac surrounding the heart.¹ The pericardium is avascular but well innervated, so inflammation induces pain. The visceral pericardium is a

single-cell layer that adheres to the epicardium. The outer parietal pericardium consists mostly of collagen with some elastin. These two layers create the pericardial space, which normally contains 15 to 50 mL of serous fluid and is under negative pressure to promote filling of the right ventricle (RV) during diastole.² Pericardial fluid provides lubrication for cardiac contractility and acts as a “shock absorber” for deceleration forces.

The pericardium is a tense structure, but it also has some elasticity. These properties limit the amount of cardiac dilation that is possible during diastole and enhance mechanical interactions between the atria and ventricles during systole.³ This semi-elastic property can also tolerate an acute (i.e., over a period of hours to days) accumulation of pericardial fluid (80 to 120 mL) without significantly increasing intrapericardial pressure, which is the flat portion of the pressure-volume curve for pericardial pressure (Fig. 16.1).^{4,5} Once a critical volume is reached, adding as little as 20 to 40 mL can double intrapericardial pressure (the steep portion of the pressure-volume curve [see Fig. 16.1]) and cause clinical decompensation from cardiac tamponade. Cardiac tamponade typically occurs with an intrapericardial pressure of 15 to 20 mm Hg.⁶

Slow and chronic accumulation of pericardial fluid (over a period of weeks to months) causes the pericardium to expand circumferentially, and it can accommodate several liters of fluid with minimal alteration in intrapericardial pressure. Patients with this condition may be asymptomatic despite large effusions. No specific pericardial volume predicts the hemodynamic consequences of an effusion; such consequences depend on the acuity of the accumulation of the fluid.

Pericardiocentesis

Indications

Diagnostic

Determining the cause of pericardial effusion

Therapeutic

Shock/hemodynamic instability

Cardiac arrest, pulseless electrical activity

Contraindications

Absolute

None (if hypotension or hypoperfusion is evident or if the patient is in cardiac arrest)

Relative

Coagulopathy

Prosthetic heart valve

Pacemakers and cardiac devices

Lack of direct visualization (e.g., ultrasound) during the procedure

Traumatic pericardium (thoracotomy preferred)

Complications

Dysrhythmias

Intra-abdominal injury (e.g., liver injury)

Air embolism

Fluid reaccumulation

Hemothorax

Pneumothorax

Pneumopericardium

Costochondritis

Suppurative pericarditis

Coronary artery injury (puncture or laceration)

Internal mammary artery injury

Intercostal vessel or nerve injury

Atrial or ventricular puncture or laceration

Equipment

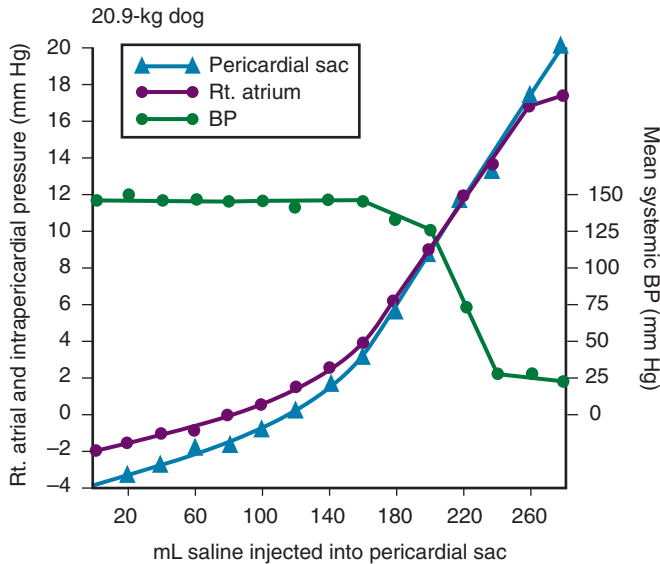

Figure 16.1 Production of cardiac tamponade by injection of saline into the pericardial sac. The pericardial space can accommodate the acute introduction of 80 to 120 mL of fluid without a significant increase in pericardial pressure, but with approximately 200 mL of saline, pressure increases steeply and rapidly (within minutes) and blood pressure (BP) drops. Once critical volumes are reached, very small increases cause significant hemodynamic compromise. (From Fowler NO: Physiology of cardiac tamponade and pulsus paradoxus. II: physiological, circulatory, and pharmacological responses in cardiac tamponade. *Mod Concepts Cardiovasc Dis.* 47:116, 1978. Reproduced by permission of the American Heart Association, Inc.)

Pathophysiology of Pericardial Tamponade

To generate an effective stroke volume, the left ventricle (LV) must be filled during diastole, and this process relies primarily on adequate filling of the RV. Normal inspiration makes the intrathoracic space more negative, which promotes RV filling by increasing venous return and causing dilation of the RV chamber secondary to a reduction in the tension in the RV free wall (Video 16.1).

Elevated intrapericardial pressure (i.e., early tamponade) first results in abnormal RV filling followed by abnormal LV filling. In this situation, the free wall of the RV cannot expand against the pericardial fluid during inspiration. To accommodate RV filling, the interventricular septum bows abnormally into the LV, which reduces its volume; this is also known as ventricular interdependence. LV filling, stroke volume, and ultimately distal tissue perfusion is reduced.⁷ This phenomenon is responsible for pulsus paradoxus (PP; described later in this chapter), which is sometimes observed with tamponade.⁸ LV filling is also reduced by the collapse of right-sided structures. After a critical volume is reached on the pressure-volume curve (see Fig. 16.1), the intrapericardial pressure is transmitted to the inferior vena cava (IVC) and right atrium. These thin-walled structures then become compressed and reduce filling of the RV.

The atria and pulmonary circulation are at much lower pressure than systemic arterial pressure and are also vulnerable to rising intrapericardial pressure (Fig. 16.2). Late in tamponade a “pressure plateau” occurs in which right atrial pressure, RV diastolic pressure, pulmonary artery diastolic pressure, and pulmonary capillary wedge pressure are virtually identical. This

Figure 16.2 Summary of physiologic changes in tamponade. *RV*, Right ventricle. Note the initial slow changes, then the rapid decrease in systolic pressures once critical pericardial volume and pressure are reached. (From Shoemaker WC, Carey JS, Yao ST, et al: Hemodynamic monitoring for physiological evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds, *J Trauma* 13:363, 1973; and Spodick D: Acute cardiac tamponade: pathologic physiology, diagnosis, and management, *Prog Cardiovasc Dis* 10:65, 1967. Reproduced by permission.)

equalization of chamber pressure leads to a reduction in venous return and the echocardiographic hallmark of tamponade: diastolic collapse of the RV (discussed later in this chapter). At this point, hemodynamic collapse is imminent, with severe hypotension, and potentially pulseless electrical activity (PEA) developing. Unless intrapericardial pressure is decreased immediately, cardiac arrest will ensue.⁹

Compensatory Mechanisms and Pericardiocentesis

To maintain a physiologic cardiac output early in tamponade, the sympathetic nervous system increases the heart rate, arterial vasoconstriction (to maintain mean arterial blood pressure), and venoconstriction (to maintain normal venous-atrial and atrioventricular filling gradients). Early in tamponade, these compensatory mechanisms are usually effective in maintaining adequate cardiac output.⁷

Compensatory mechanisms also preserve normal cardiac contractility and myocardial perfusion.^{10,11} However, when the pericardial pressure overwhelms the compensatory mechanisms, coronary perfusion is reduced, which leads to myocardial ischemia, systolic dysfunction, and ultimately a reduction in cardiac output. Experimental induction of severe tamponade

Figure 16.3 Relationship of intrapericardial pressure to volume of pericardial fluid. Pressure drops rapidly when a small amount of fluid is removed, hence the initial significant benefit of pericardiocentesis. (From Pories W, Gaudiani V. Cardiac tamponade: *Surg Clin North Am* 55:573, 1975. Reproduced by permission.)

demonstrated microscopic ischemic cardiac injury.¹² Lactic acidosis (resulting from reduced cardiac output and systemic hypoperfusion) also leads to further reduction in cardiac contractility and, ultimately, cardiac output.⁹

Removal of pericardial fluid (i.e., pericardiocentesis) reverses the pathophysiologic processes just described by improving coronary filling, cardiac filling, and hence cardiac output. Interestingly, the pressure-volume relationship of the pericardial space demonstrates hysteresis; that is, withdrawing a certain quantity of fluid reduces intrapericardial pressure more than addition of the same amount of fluid increases intrapericardial pressure. This effect, however, is not universal and may vary among patients and in various disease states (Fig. 16.3).²

Special Considerations in Patients With Pericardial Effusion and Tamponade

Under normal circumstances, positive pressure ventilation (e.g., mechanical ventilation) reduces venous return to the right side of the heart by increasing intrathoracic pressure. This could be detrimental for patients with tamponade because right-sided filling is already compromised and further reductions can lead to severe hemodynamic instability.¹³ Therefore positive pressure ventilation (i.e., noninvasive or invasive) should be avoided in patients with known or suspected tamponade unless it is absolutely necessary (e.g., respiratory failure).

Low-pressure pericardial tamponade is defined as a hemodynamically significant effusion with an intrapericardial pressure that is lower than expected.¹⁴ This category of tamponade occurs in patients with subacute or chronic effusions, but present with a superimposed hypovolemia (e.g., associated with long-term diuretic use, dehydration, or excessive dialysis).¹⁵ The diagnosis may be challenging because the classic symptoms and findings on physical examination (e.g., distended neck veins) may be absent.¹⁶ Ultrasound is most helpful in making the diagnosis in these patients. Fluid boluses may temporize

the hemodynamic compromise while pericardial decompression is being arranged.

EPIDEMIOLOGY

The major categories of pericardial effusion include infection, inflammation, malignancy, trauma, and metabolic abnormalities. Effusion may also be associated with aortic disease, connective tissue disease, or idiopathic causes. It is often difficult to report the exact incidence of each type of pericardial effusion because of variations in patient populations, local epidemiology, and the diagnostic protocols used during evaluation. The prevalence of a chronic effusion is also difficult to ascertain because it is often asymptomatic and underreported. General autopsy studies demonstrate an overall prevalence of 3.4%.¹⁷

CAUSES OF PERICARDIAL EFFUSION (BOX 16.1)

Acute Hemopericardium

Acute hemopericardium, or rapid accumulation of blood in the pericardial space, can have a traumatic or nontraumatic etiology. It is one of the most feared causes of tamponade because the semi-elastic pericardium cannot accommodate acute increases in pericardial fluid and clinical deterioration can be rapid. This diagnosis can be challenging to make because there may be little or no evidence during the initial evaluation (e.g., pericardial size might be normal on a chest radiograph). Common causes include trauma and aortic dissection retrograde into the pericardial sac.

Traumatic Hemopericardium Penetrating Trauma

Penetrating cardiac trauma can cause acute hemopericardium by either external forces (e.g., a stab wound to the heart) or internal forces (e.g., iatrogenic injury during placement of a pacemaker). Cardiac perforation can lead to rapid clinical deterioration and PEA.

External cardiac puncture is associated with stab wounds or projectile injuries (e.g., gunshot wounds). Tamponade develops in 80% to 90% of patients with cardiac stab wounds as opposed to 20% of those with gunshot wounds.^{18,19} Stab wounds cause tamponade more frequently because if the pericardial injury is small, it can reseal and trap blood within the pericardial space.²⁰ On the other hand, a gunshot typically produces both large myocardial and pericardial wounds that allow continuous drainage into the mediastinal and pleural space.²¹ Clinical deterioration is usually secondary to hypovolemia.²¹ Any penetrating injury to the chest, back, or upper part of the abdomen may injure the pericardium and cause tamponade.

Internal penetrating trauma is typically caused by invasive diagnostic or therapeutic procedures. The procedures most often associated with this injury are cardiac catheterization (angioplasty or valvuloplasty) and pacemaker insertion.^{22–24} Hemopericardium results from puncturing a cardiac chamber, a coronary artery, or a great vessel (e.g., the superior vena cava). Ironically, pericardiocentesis itself (treatment of a pericardial effusion) can cause hemopericardium if a coronary vessel or the myocardium is injured during the procedure.^{25,26}

Behçet's syndrome
Pancreatitis
Postpericardiotomy
Amyloidosis
Ascites

Data from Guberman BA, Fowler NO, Engel Pj, et al: Cardiac tamponade in medical patients, Circulation 64:633, 1981; and Porjes WJ, Caudiani VA: Cardiac tamponade, Surg Clin North Am 55:573, 1975.

Internal jugular and subclavian venous catheters (e.g., central venous or hemodialysis catheters) are commonly inserted in the emergency department (ED). During such procedures, hemopericardium results from perforation of the superior vena cava, right atrium, or RV. Hemopericardium can occur immediately or can be delayed for days subsequent to erosion of the catheter through myocardial or vascular tissue.^{27,28} Although this complication seldom occurs, it should always be considered when a patient experiences sudden hemodynamic deterioration following an invasive procedure.

Blunt Trauma

Major blunt chest trauma can cause hemopericardium with or without obvious signs of injury, from rupture of a cardiac chamber or, less commonly, damage to a coronary artery.²⁹ Myocardial rupture can be uncontained or contained.^{30,31} Patients with uncontained rupture do not typically survive long enough to reach the hospital.³² Contained rupture may be found soon after injury or may be a late finding.³³ Tamponade can also be caused by a deceleration mechanism of injury that

induces either aortic or vena caval disruption.³⁴ In one case series the incidence of tamponade following deceleration injury was found to be 2.3% (1 in 43 patients).³⁵

Miscellaneous Trauma

Chest compressions during cardiopulmonary resuscitation (CPR) can also cause hemopericardium from broken ribs or bleeding intercostal vessels.³⁶ Hemopericardium following CPR has been described in case reports^{37,38} but is unlikely to be significant, much less to cause tamponade.

Atraumatic Hemopericardium

Atraumatic hemopericardium is difficult to diagnose. Diagnosis is often delayed because it occurs spontaneously and the clinical findings can be less obvious than those of hemopericardium from traumatic causes. Maintain a high index of suspicion for this condition in patients with risk factors, such as certain malignancies (e.g., lung cancer) or tuberculosis within endemic areas. Common causes of atraumatic hemopericardium are discussed later.

Bleeding diathesis is an important cause of spontaneous hemopericardium and may be associated with the use of anticoagulants (reported incidence of 2.5% to 11%)²² or thrombolytic therapy (incidence <1%).³⁹ Patients who have undergone cardiac surgery are at increased risk because of the anticoagulative effects of the cardiopulmonary bypass machine and medications started postoperatively (e.g., clopidogrel, warfarin).⁴⁰ Fortunately, tamponade has a low incidence and is generally detected in the postoperative period before discharge.^{41,42} This complication is usually prevented by the intraoperative placement of mediastinal or pericardial drains.^{22,43}

Hemopericardium can develop following myocardial infarction (MI). Early after a transmural MI (1 to 3 days), the necrotic myocardium causes inflammation of the overlying pericardium and then effusions can form. Late-developing effusions (weeks after an MI) are caused by an autoimmune pericarditis called Dressler's syndrome.¹ Improved reperfusion techniques have drastically reduced the incidence of post-MI pericarditis and effusion.⁴⁴

Ascending aortic dissection causes rapid and usually fatal hemopericardium. The dissection may expand in a retrograde fashion by extending to the base of the aorta and into the pericardial sac. This is a very difficult diagnosis, and best visualized and confirmed by bedside ultrasound. Risk factors for aortic dissection include hypertension, atherosclerosis, vasculitis (e.g., giant cell arteritis, syphilis), collagen vascular disease (e.g., Marfan's syndrome), and the use of sympathomimetics (e.g., cocaine).⁴⁵⁻⁴⁷

Ventricular free-wall rupture is a rapidly fatal cause of acute hemopericardium that can occur after MI leading to cardiac failure and shock. This complication is less common today than in the past (<1%)³⁹ secondary to improved revascularization techniques, better therapeutic medications, and faster intervention times (shorter door-to-balloon times) for coronary ischemia. Despite a reduction in its overall incidence, 7% of all deaths related to MI are caused by this complication.^{48,49} Survival is theoretically possible with prompt recognition and treatment, but the prognosis is grim once tamponade occurs.^{50,51}

Nonhemorrhagic Effusions

Nonhemorrhagic pericardial effusions usually accumulate slower than acute hemopericardium does (over a period of weeks to months). Chronic fluid accumulation allows the pericardium to stretch circumferentially and accommodate up to 2000 mL of fluid without any hemodynamic compromise.⁵² Effusions that grow slowly allow the circulatory system to adapt to increased intrapericardial pressure, thereby further maintaining hemodynamic stability. Thus, asymptomatic patients with moderate to large effusions may not need emergency pericardiocentesis, in contrast to patients with acute hemopericardium.^{53,54}

Nonhemorrhagic effusions have several causes (see [Box 16.1](#)), and the exact one may not be obvious during the initial evaluation without diagnostic pericardiocentesis. Common causes of nonhemorrhagic effusions are discussed in the following sections.

Idiopathic Effusions

Most idiopathic effusions are believed to be viral in origin and most commonly caused by infection with coxsackievirus, echovirus, cytomegalovirus, or human immunodeficiency virus (HIV) (discussed later in the chapter). Idiopathic pericardial effusions may be asymptomatic or have an associated component

of pericarditis (e.g., positional pain or diffuse ST-segment changes on the electrocardiogram [ECG]).⁵⁵ These effusions are often labeled *idiopathic* because the diagnosis cannot be made noninvasively (i.e., based on the history, physical examination, or serum testing) and the risk associated with diagnostic pericardiocentesis often outweighs the risk of observation in asymptomatic adults who appear to be well.⁵⁶ Diagnostic pericardiocentesis may be recommended for idiopathic effusions that are persistent or symptomatic without a known cause.⁵⁷

Neoplastic Effusion

Tumors of the pericardium or myocardium may cause non-hemorrhagic effusions.^{54,58} Primary cardiac tumors are less common (0.001% to 0.003%) than metastases from another site (2% to 18%), but either may cause a malignant effusion.⁵⁹ Although no malignancy preferentially metastasizes to the heart, certain tumors commonly involve the heart when they metastasize; frequently implicated are lung cancer, breast cancer, mediastinal tumors, malignant melanoma, leukemia, and lymphoma.⁴⁶

Cardiac metastasis is usually a late finding in cancer, as other foci are generally evident first.⁴⁷ The classic signs and symptoms of tamponade (e.g., chest pain and dyspnea) may not be obvious with malignant tamponade. When present, they may be mistakenly attributed to the underlying malignancy.⁴⁶ Thus, in the relevant clinical scenario, consider screening patients with malignancy for pericardial effusion (e.g., ultrasound) before the clinical findings of tamponade appear.

Radiation

Pericardial effusions (secondary to radiation-induced pericarditis) can develop acutely during radiation therapy or may be delayed for years. Risk factors include the radiation dose, duration of exposure, and age of the patient. Patients treated with radiation for Hodgkin's disease have the highest association of radiation-induced pericarditis and subsequent effusions.²² These effusions can be serous, hemorrhagic, or fibrinous.⁵⁷

Congestive Heart Failure

Congestive heart failure (CHF) is a cause of pericardial effusion. Diagnosis may be difficult because of overlapping signs and symptoms with exacerbations of CHF (e.g., chest pain or dyspnea). Adding to the diagnostic complexity is that 12% to 20% of patients with CHF have a coexisting pericardial effusion.⁶⁰ Fortunately, treatment of CHF-associated pericardial effusion does not differ from that for an effusion from other causes: treat the underlying cause unless the patient has evidence of hemodynamic compromise.

HIV-Associated Effusions

HIV can cause nonhemorrhagic pericardial effusion and tamponade.^{61,62} The incidence has been reported to be approximately 11% in patients with HIV infection or acquired immunodeficiency syndrome, and 13% of cases are classified as moderate to severe. It is unclear whether antiretroviral therapy has affected these data.¹⁷

HIV-related effusions have been attributed to bacterial (e.g., *Staphylococcus aureus*), viral (e.g., cytomegalovirus), fungal (*Cryptococcus neoformans*), and mycobacterial causes (e.g., tuberculosis), which is the most common cause of HIV-related effusions worldwide.⁶³ Kaposi's sarcoma and lymphoma can cause noninfectious pericardial effusions in HIV patients.^{64,65}

Renal Failure and Uremia

Pericardial effusion develops in approximately 15% to 20% of dialysis patients, and tamponade may eventually occur in as many as 35% of those people.^{66,67} Up to 7% of chronic dialysis patients have effusions with volumes of 1000 mL or greater.⁶⁸ In many cases, effusions secondary to renal failure can be managed solely with aggressive dialysis without pericardiocentesis. Any sign of hemodynamic compromise, however, warrants strong consideration of pericardiocentesis.

Hypothyroidism

Hypothyroid patients are at risk for pericardial effusions (up to 30%), but the fluid accumulates gradually, so tamponade develops in only a few patients.⁵⁴ If a pericardial effusion is present, other areas of the body usually demonstrate serositis (e.g., pleural effusions). Medically managing the underlying hypothyroidism often reverses the effusion without the need for pericardiocentesis.

Special Considerations in Pericardial Disease

Pericardial tamponade is classically described as being secondary to circumferential effusion, which causes a generalized increase in pericardial pressure and compression of multiple cardiac chambers. Loculated effusions (caused by a local hematoma or an infectious process) or pericardial adhesions (from previous inflammation) can lead to tamponade by compressing one or more cardiac chambers and thus reducing both cardiac filling and cardiac output.^{69,70}

Constrictive pericarditis occurs following chronic pericardial inflammation, infection, or mediastinal irradiation. These processes cause scarring, fibrosis, or calcification, and the pericardium eventually becomes a nonelastic and “constrictive” sac around the heart. Myocardial relaxation and cardiac filling are impaired, and diastolic dysfunction ensues. Without echocardiography, constrictive pericarditis can be difficult to distinguish from pericardial tamponade.¹

Effusive-constrictive pericarditis is defined by the presence of both pericardial effusion and pericardial constriction. It may be quite difficult to differentiate between effusive-constrictive pericarditis and pericardial tamponade in stable patients because both are associated with effusions.⁷¹ Fortunately, distinguishing between these diagnoses is less important in hemodynamically unstable patients because they are treated identically (i.e., with pericardiocentesis).⁷²

Pneumopericardium is an interesting, though rare cause of cardiac tamponade. It is most commonly associated with pneumothorax caused by barotrauma (e.g., mechanical ventilation).⁷³ It also occurs spontaneously during acute asthma exacerbations,⁷⁴ and it can follow blunt chest injury.^{75,76} Although typically benign, tension pneumopericardium has been reported as a cause of life-threatening tamponade after blunt^{77,78} and penetrating chest trauma.^{79,80}

DIAGNOSING CARDIAC TAMPONADE

Diagnosis of pericardial effusions requires careful integration of the patient's history, findings on physical examination, and diagnostic testing. Unfortunately, even experienced clinicians may not initially consider pericardial effusion because the clinical findings are often vague and nonspecific. Nonspecific symptoms, such as chest pain and dyspnea, can be ascribed to

more common conditions (e.g., CHF or pulmonary pathology), so the diagnosis might be delayed until diagnostic testing is performed (e.g., computed tomography [CT] of the chest for pulmonary embolism),⁸¹ or until hypotension develops and bedside ultrasound is performed.⁸²

Acute pericardial tamponade (e.g., secondary to blunt chest wall trauma) is usually challenging to diagnose because the findings on physical examination may resemble those of other life-threatening conditions (e.g., tension pneumothorax, hemothorax, hypovolemia, pulmonary edema, severe contusion of the RV, aortic dissection, or pulmonary embolism).⁶⁷ In hemodynamically unstable patients, diagnostic (e.g., bedside ultrasound) and therapeutic (e.g., pericardiocentesis) interventions must be performed even with a paucity of findings on physical examination because rapid clinical deterioration and cardiac arrest can occur before a definitive diagnosis can be made.

Once a pericardial effusion is suspected (or diagnosed), the next step is to determine its size and hemodynamic significance and presence of underlying or associated diseases.⁸³ Specific therapies will hinge on this information and is discussed in the following sections.

History: Patient Profile and Symptoms

The historical features of pericardial effusions are nonspecific and the diagnosis may easily be overlooked. An astute clinician might be suspicious based on comorbid conditions (e.g., warfarin therapy or a history of myxedema) and the time course of the symptoms (e.g., free-wall rupture several days after MI, dyspnea in a patient with uremic pericarditis). Patients are likely to present with symptoms relating to the underlying disease rather than the pericardial effusion itself. [Box 16.2](#) lists important details to be ascertained from the history when pericardial effusion is suspected.⁸⁴

Physical Examination

Physical examination of patients with pericardial effusion (e.g., displaced point of maximal impulse, muffled heart sounds) lacks sensitivity and specificity. If the history suggests pericardial effusion, the physical examination should focus on determining the underlying cause (e.g., stigmata of hypothyroidism) to guide definitive diagnostic testing (e.g., echocardiography). Ironically, many pericardial effusions are not diagnosed from the history or findings on physical examination but are found incidentally during the evaluation for other diseases.

In 1935, Beck characterized the physical manifestations of tamponade with two triads, one for chronic and one for acute tamponade.⁸⁵ Beck's chronic triad consists of increased central venous pressure (CVP) (i.e., distended neck veins), ascites, and a small, quiet heart. *Beck's triad* is a classic description of acute cardiac compression, which includes increased CVP, decreased arterial pressure, and muffled heart sounds. Almost 90% of patients have one or more of these “acute” signs,⁸⁶ but only approximately 33% demonstrate the complete triad.^{9,87} The utility of this triad is further limited because all three signs are usually observed shortly before cardiac arrest.

It would be clinically desirable to identify patients in early tamponade, before hemodynamic collapse. Unfortunately, findings on physical examination in early tamponade are nonspecific and may be indistinguishable from those of other critical diseases (e.g., septic shock, right heart failure).⁵⁷ Patients

BOX 16.2 Information to Obtain from Patients When Pericardial Effusion Is Suspected**ONSET AND DURATION OF SYMPTOMS****Acute**

Trauma
 Recent cardiac surgery
 Recent myocardial infarction
 Acute aortic dissection
 Recent diagnostic or therapeutic intervention (e.g., catheterization)
 Recent upper thoracic vascular procedure (e.g., hemodialysis catheter, central line, peripherally inserted central catheter line, Mediport)
 Recent placement of a pacemaker or automatic implantable cardioverter-defibrillator

Subacute/Chronic

Metabolic (e.g., uremia)
 Endocrine (e.g., hypothyroidism)
 Infectious

- Viral (e.g., human immunodeficiency virus)
- Bacterial (e.g., *Staphylococcus*)
- Fungal (e.g., *Aspergillus*)

 Neoplastic

- Primary cardiac
- Metastatic

 Autoimmune disorders (e.g., lupus)
 Inflammatory

- Vasculitis

MEDICAL/SURGICAL HISTORY

Autoimmune disorders

- Lupus
- Mixed connective tissue disease
- Vasculitis

 Endocrine disease

- Hypothyroidism
- Ovarian hyperstimulation syndrome

 Metabolic diseases

- End-stage renal disease and uremia
- Thyroid disorders
- Coagulopathies

 Artificial cardiac valves

- Anticoagulation medications
- Risk for myocarditis

Cardiac disease

- Anticoagulation medications
- Pericarditis
- Aneurysm

Recent placement of a vascular catheter
 Recent cardiac surgery
 Recent cardiac intervention
 Recent thoracic radiation

MEDICATIONS

Anticoagulants

- Aspirin
- Warfarin
- Clopidogrel

Antiarrhythmic

- Procainamide (drug-induced lupus)

Tuberculosis therapy

- Isoniazid (drug-induced lupus)

COMMON SYMPTOMS

Altered mental status, confusion
 Fatigue
 Dizziness, light-headedness
 Orthostatic changes
 Exercise intolerance
 Hoarseness
 Hiccups
 Fever
 Chills
 Chest pain

- Substernal
- Pleuritic
- Positional
- Scapula (phrenic nerve irritation)
- Palpitations
- Cough
- Dyspnea
- Myalgia
- Arthralgia

initially seen in late tamponade also have nonspecific findings. They may be agitated, panic-stricken, confused, uncooperative, restless, cyanotic, diaphoretic, acutely dyspneic, or hemodynamically unstable. Such patients should undergo a brief and focused physical examination followed by a rapid hemodynamic assessment with bedside ultrasound because the time between initial evaluation and full arrest may be brief.

Some of the findings on physical examination associated with tamponade are described later. A more comprehensive list is presented in [Box 16.3](#).

Vital Sign Abnormalities

There are three sequential stages that are typically described to reflect the natural history of acute tamponade ([Table 16.1](#)).⁸⁸

The time course within each stage varies from patient to patient. Some patients are stable within a given stage for hours, whereas others proceed through all three stages and develop cardiac arrest within minutes.^{9,88} Grade I tamponade is characterized by normal blood pressure and cardiac output with an increase in the heart rate and CVP (measured invasively with a central venous catheter). Grade II tamponade is defined by normal or slightly reduced blood pressure; CVP and the heart rate remain increased. Grade III tamponade is identified on the basis of Beck's triad: hypotension, tachycardia, and elevated CVP.

Nearly all patients with tamponade present with sinus tachycardia, although its specificity is low.⁸⁹ The physiologic purpose of tachycardia is to maintain normal cardiac output

BOX 16.3 Physical Examination Findings Suggestive of Pericardial Effusion or Tamponade**VITAL SIGNS**

Normal vital signs
Tachycardia (tamponade)
Hypotension (tamponade)
Narrow pulse pressure
Pulsus paradoxus
Fever (if the cause is infectious or neoplastic)

APPEARANCE

Normal appearance
Anxiety
Sense of impending doom
Diaphoretic
Cold and clammy
Pallor
Altered mental status, confusion

NECK

Supraclavicular retractions
Distended neck veins (may be flat with hypotension)

CARDIOVASCULAR

Normal findings on examination
Tachycardia
Increased pain with a supine position, relieved by leaning forward

Muted, distant heart sounds
Pericardial friction rub (inflammatory pericarditis)
Displaced point of maximal impulse
Increased cardiac borders with percussion
Distended neck veins
Auscultatory dullness along the left scapular area

PULMONARY

Telegraphic speech
Respiratory distress
Supraclavicular retractions, abdominal breathing
Cough
Hoarseness
Clear breath sounds (may distinguish tamponade from congestive heart failure)

ABDOMINAL

Hepatomegaly
Splenomegaly

SKIN

Cool extremities
Clammy extremities
Dilated head and scalp veins
Peripheral edema
Anasarca

TABLE 16.1 Shoemaker System of Grading Cardiac Tamponade

GRADE	PERICARDIAL VOLUME (mL)	CARDIAC INDEX	STROKE INDEX	MEAN ARTERIAL PRESSURE	CENTRAL VENOUS PRESSURE	HEART RATE	BECK'S TRIAD
I	<200	Normal or ↑	Normal or ↓	Normal	↑	↑	Venous distention, hypotension, muffled heart sounds usually not present
II	≥200	↓	↓	Normal or ↓	↑ (≤12 cm H ₂ O)	↑	May or may not be present
III	>200	↓↓	↓↓	↓↓	↑↑ (30–40 cm H ₂ O)	↑	Usually present

From Shoemaker WC, Carey SJ, Yao ST, et al: Hemodynamic monitoring for physiologic evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds, *J Trauma* 13:36, 1973.

despite reductions in stroke volume from worsening tamponade. Exceptions to the pairing of tachycardia with tamponade usually relate to the underlying cause of the effusion (e.g., myxedema) or the concomitant use of certain medications (e.g., β -blockers).

Adding to the diagnostic complexity, not all patients in tamponade have a reduction in blood pressure. In fact, Brown and co-workers⁹⁰ described several tamponade patients with elevated blood pressure. These patients were previously hypertensive and paradoxically had reduced systolic blood pressure following pericardiocentesis.

Pulsus Paradoxus

PP is an exaggerated decrease in systolic blood pressure (>12 mm Hg) during inspiration secondary to reduced stroke

volume (Fig. 16.4A).^{30,91,92} Patients with moderate to severe tamponade typically demonstrate PP greater than 20 mm Hg.^{9,86,93} Unfortunately, PP is not pathognomonic for tamponade. It is observed in other conditions, such as hypotension associated with labored breathing (secondary to extreme reductions in intrathoracic pressure) (see Fig. 16.4B), severe emphysema, severe asthma, obesity, cardiac failure, constrictive pericarditis, pulmonary embolism, and cardiogenic shock.^{9,86,93}

The absence of PP does not rule out tamponade because it can occur with several conditions: atrial septal defects, aortic insufficiency, positive pressure ventilation, loculated pericardial effusions, and elevated left ventricular diastolic pressure (e.g., poor left ventricular compliance secondary to chronic hypertension).¹⁴ Finally, PP should be interpreted with caution in patients

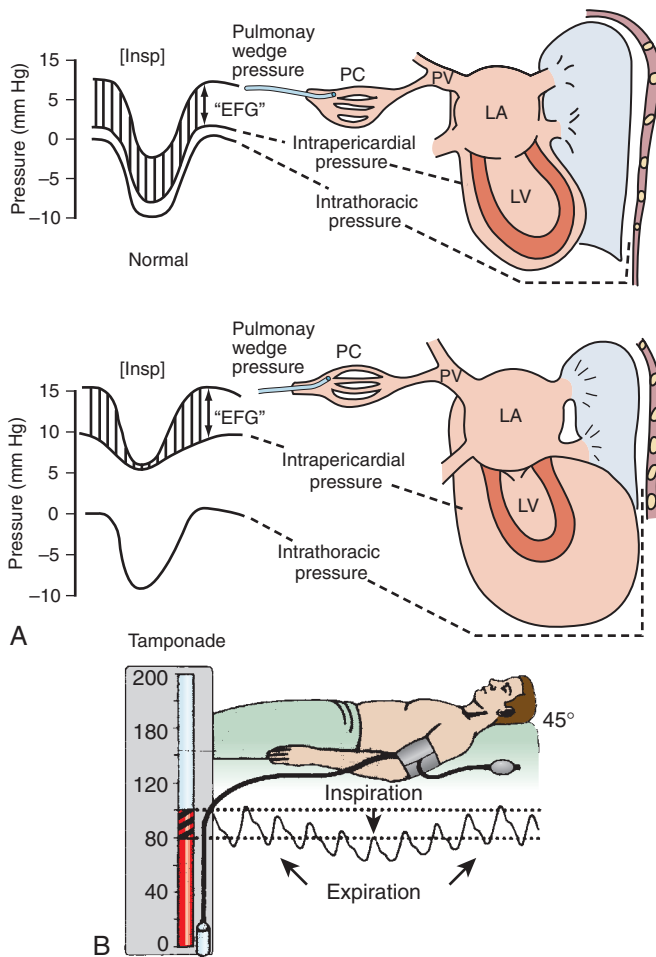

Figure 16.4 Pulsus paradoxus to diagnose pericardial tamponade. **A, Top**, The normal situation in which changes in intrathoracic pressure are transmitted to both the pericardial sac and the pulmonary veins. The effective filling gradient (EFG) changes only slightly during respiration. **Bottom**, Cardiac tamponade in which changes in intrathoracic pressure are transmitted to the pulmonary veins but not to the pericardial sac. The EFG falls during inspiration (Insp). *LA*, Left atrium; *LV*, left ventricle; *PC*, pulmonary capillaries; *PV*, pulmonary veins. **B**, Normally, systolic blood pressure drops slightly during inspiration. To assess for pulsus paradoxus, have the patient breathe normally while lying at a 45-degree angle. Inflate the blood pressure cuff well above systolic pressure and slowly deflate it. When the pulse is first heard only during expiration, this is the upper value. Deflate the cuff until the pulse is heard during both inspiration and expiration; this is the lower value. A difference of more than 12 mm Hg between the two values indicates pulsus paradoxus. (A, Adapted from Sharp JT, Bunnell IL, Holand JF, et al: Hemodynamics during induced cardiac tamponade in man, *Am J Med* 25:640, 1960.)

with traumatic tamponade because it may not be present.⁹⁴⁻⁹⁶ In a study of 197 patients with traumatic tamponade, only 8.6% had PP.⁹⁷

Measuring PP is useful only occasionally because it is difficult to perform, time-consuming, and not specific or sensitive for tamponade. Its description here is for historical value and for use in hemodynamically stable patients. When managing unstable patients, especially those in extremis, assessment for PP should not replace more definitive testing, such as bedside ultrasound.

Neck Vein Distention and Elevated CVP

Neck vein distention (a surrogate for measuring CVP) occurs late in tamponade, when right-sided chambers (e.g., the RV) collapse. Neck vein distention may be obvious on examination (Fig. 16.5A), but visualization of such distention is less accurate than measuring CVP by central venous catheter or evaluation of the IVC with ultrasound (Table 16.2). Patients with significant tamponade typically have a CVP of 12 cm H₂O or higher.⁹⁵ Finally, although initial CVP readings are useful and diagnostic when grossly elevated (e.g., 20 to 30 cm H₂O),^{95,98} upward trends in CVP can be a more sensitive diagnostic tool.⁹⁵

Overreliance on increased CVP and venous distention should be avoided because they do not always indicate tamponade. For example, increased intrathoracic pressure (as induced by positive pressure ventilation or Valsalva maneuvers) increases CVP and causes neck vein distention even without pericardial effusion. Conversely, hypovolemic patients may have reduced CVP and no neck vein distention despite having clinical tamponade. The absence of distended neck veins may also result from severe venoconstriction secondary to intrinsic sympathetic discharge, vasopressor use, or severe hypovolemia.^{9,88,93,95}

Diagnostic Testing

Diagnostic testing should be initiated when pericardial effusion or tamponade is suspected. Definitive diagnosis requires imaging, which may be done by CT but preferably is done by cardiac ultrasound (see Fig. 16.5B). Bedside ultrasound is the fastest and most reliable diagnostic tool because it is noninvasive, does not emit radiation, and can be performed at the bedside without transporting unstable patients outside the ED.

As discussed previously, pericardial effusions are occasionally discovered incidentally during evaluation for other disorders. For example, a chest x-ray and ECG performed on a patient being assessed for acute coronary syndrome (ACS) may suggest tamponade. If the clinical context supports pericardial effusion as the primary diagnosis rather than ACS, further workup for the effusion (e.g., bedside echocardiogram) should be ordered. If neither diagnosis is more likely than the other, dual workups may be necessary.

Chest Radiography

Chest radiographs are not diagnostically useful in patients with acute traumatic tamponade because the pericardium does not have sufficient time to change size or shape (see section on Pathophysiology of Pericardial Tamponade). Radiographs, however, may reveal other associated findings such as hemothorax, bullets in the thorax, or even pneumopericardium. Chest radiography may also be helpful when other diagnoses (e.g., CHF) have clinical findings similar to those of pericardial effusion. For example, a dyspneic patient with a clear chest film is less likely to have decompensated CHF than tamponade.

In patients with chronic pericardial effusions, chest films often demonstrate an enlarged, saclike, “water-bottle” cardiac shadow or a pleural effusion (see Fig. 16.5C). Unfortunately, it is difficult to differentiate a large effusion from myocardial enlargement (e.g., dilated cardiomyopathy) because radiographs demonstrate only the cardiac silhouette and do not reveal the physiologic differences between these two diagnoses.

Electrocardiography

Pericardial effusion secondary to acute pericarditis is suspected on the basis of typical changes on the ECG. Pericarditis has

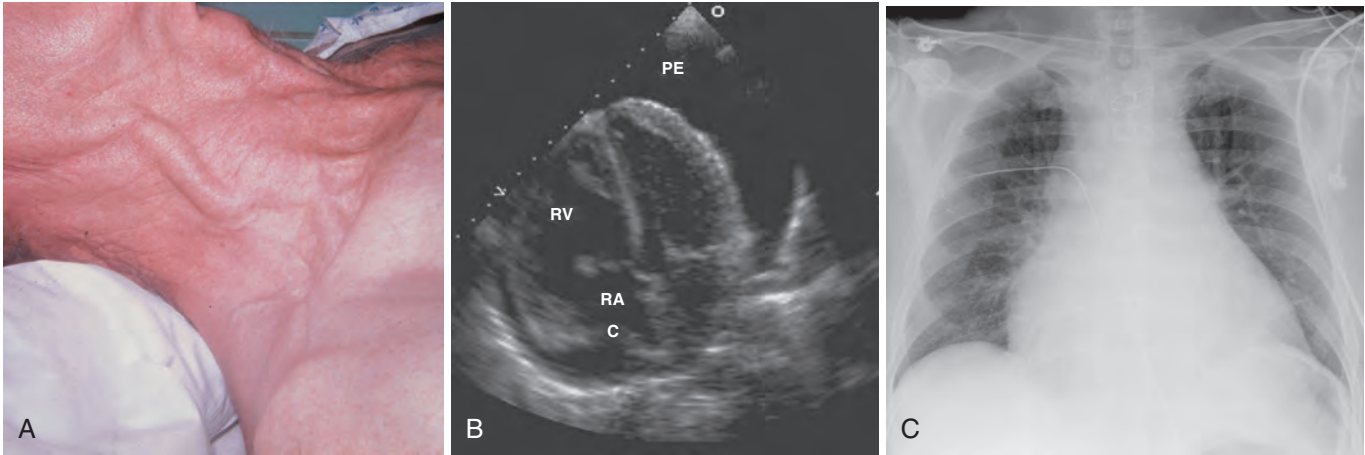

Figure 16.5 **A**, The neck veins might be markedly distended with cardiac tamponade, but this finding is not universal, especially in patients with hypovolemic trauma. **B**, Ultrasound. An apical view of a large pericardial effusion in early ventricular diastole reveals marked right atrial collapse. **C**, Chest radiograph showing an enlarged, globular cardiac silhouette (water-bottle heart) in a patient with tamponade caused by a malignant effusion. The chest film has minimal value in diagnosing tamponade but is usually abnormal when significant *chronic* effusions are present. *C*, Collapsed segment of the right atrial wall; *PE*, pericardial effusion; *RA*, right atrium; *RV*, right ventricle.

TABLE 16.2 Noninvasive Estimation of Right Atrial Pressure With Ultrasound

DIAMETER (cm) OF INFERIOR VENA CAVA	CHANGE IN DIAMETER WITH RESPIRATION	ESTIMATED RIGHT ATRIAL PRESSURE (mm Hg)
Normal (<2.1)	Decrease >50%	~3 (normal, 0–5)
Dilated (<2.1)	Decrease <50%	~8 (normal, 5–10)
Dilated (>2.1)	Decrease >50%	~8 (normal, 5–10)
Dilated (>2.1)	Decrease <50%	>15 (10–20)

Based on Rudski LG, Lai WW, Afilalo J, et al: Guidelines for the echocardiographic assessment of the right heart in adults: a report from the American Society of Echocardiography endorsed by the European Association of Echocardiography, a registered branch of the European Society of Cardiology, and the Canadian Society of Echocardiography. *J Am Soc Echocardiogr* 23:685, 2010.

four stages: (1) diffuse ST-segment elevation with PR depression, (2) ST- and PR-segment normalization, (3) diffuse T-wave inversion, and (4) normalization of T waves.⁹⁹

Electrocardiography has acceptable specificity but poor sensitivity^{93,100,101} in diagnosing pericardial effusion and tamponade. In a study of patients with pericardial effusion, electrocardiography had an overall sensitivity of 1% to 17% and a specificity of 89% to 100%.⁹³ Therefore an ECG may suggest but should never be the only means of diagnosing a pericardial effusion (Fig. 16.6). Furthermore, electrocardiography cannot reliably differentiate tamponade from effusion.¹⁰²

The four most commonly described electrocardiographic findings in pericardial effusion are sinus tachycardia, PR depression, low-voltage QRS complexes, and electrical alternans. PR-segment depression is defined as depression of 1 mV or greater in at least one lead other than aVR. Low-voltage QRS complexes (most frequently associated with moderate to large effusions) are defined by a QRS complex with an amplitude of 5 mm or less across all limb leads. Alternatively, low-voltage

ELECTRICAL ALTERNANS IN PERICARDIAL TAMPONADE

Figure 16.6 Electrical alternans may develop in patients with pericardial effusion and cardiac tamponade. Notice the beat-to-beat alternation in the voltage in the P-QRS-T axis; this is caused by the periodic swinging motion of the heart in a large pericardial effusion. Relatively low QRS voltage and sinus tachycardia are also present. Overall, the electrocardiogram has low sensitivity for pericardial effusion and tamponade. Note that electrical alternans may be more evident in the V leads.

QRS complexes can be identified by a sum of 10 mm or less for all precordial lead QRS amplitudes. Electrical alternans is a beat-to-beat alternation in QRS axis caused by the pendulum motion of the heart within the fluid-filled pericardial sac.¹⁰³ Alternans has been observed in 22% of medical patients with tamponade¹⁰⁴ and in 5% of patients with tamponade secondary to cancer.¹⁰⁵ Electrical alternans of P waves and QRS complexes (i.e., total electrical alternans) is a rare finding but, when seen, is pathognomonic of tamponade (see Fig. 16.6).^{93,106}

Echocardiography

Echocardiography is the best tool for diagnosing pericardial effusion or tamponade (Figs. 16.7–16.9 and the Ultrasound Box). It not only demonstrates the presence of a pericardial

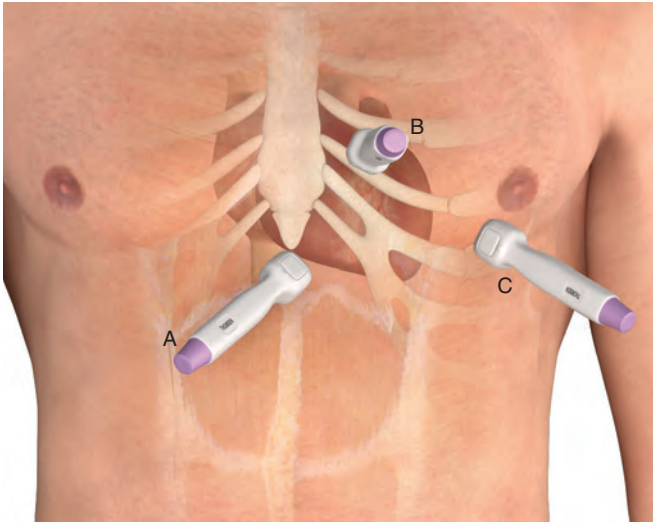

Figure 16.7 Areas of the chest to obtain basic echocardiographic windows: *A*, subxiphoid (subcostal) view; *B*, parasternal view; *C*, apical four-chamber view.

effusion but can also detect hemodynamic abnormalities. Ultrasonography (used interchangeably with *echocardiography* from here on) has the advantage that it is noninvasive, portable for use at the patient's bedside, and involves no ionizing radiation.⁹ Echocardiography is a very sensitive and specific tool for the diagnosis of pericardial effusion and tamponade,^{57,87,89} and its use in diagnosing pericardial effusions has been endorsed by several academic societies.¹⁰⁷⁻¹¹⁰

Diagnosing Pericardial Effusions and Tamponade

Fluid found within the pericardial space is not always pathologic as it normally holds 15 to 50 mL of fluid. Small effusions may be clinically insignificant. The sonographer/clinician should exercise caution to not over-read an effusion, particularly when the patient is hemodynamically stable.¹¹¹ Small effusions typically contain 50 to 100 mL with an echo-free space less than 10 mm

Figure 16.9 Examples of pericardial effusion. *A*, Small pericardial effusion (parasternal long-axis view). *B*, Moderate pericardial effusion (parasternal long-axis view). *C*, Large pericardial effusion (apical four-chamber view). *D*, Large pericardial effusion (subcostal/subxiphoid view). *LA*, Left atrium; *LV*, left ventricle; *PE*, pericardial effusion; *PL*, pleural effusion; *RA*, right atrium; *RV*, right ventricle.

in thickness between the visceral and parietal pericardium. Moderate effusions typically contain 100 to 500 mL with 10 to 20 mm of echo-free space. Large effusions contain more than 500 mL and have an echo-free space greater than 20 mm. Large effusions tend to have an echo-free space seen circumferentially around the heart.¹¹⁰ A loculated pericardial effusion can present in an atypical location and may be more difficult to appreciate compared to the non-loculated types described previously.

Once a pericardial effusion is discovered, the next step is to evaluate the patient for evidence of hemodynamic compromise. Echocardiographic signs include (1) diastolic collapse of the right atrium (highly specific and sensitive for tamponade, especially when the collapse occurs for more than a third of the cardiac cycle)¹¹²; (2) early diastolic collapse of the right ventricular free wall (less sensitive than right atrial collapse but specific for tamponade)¹¹³; (3) left atrial collapse (a very specific sign of tamponade)¹¹⁴; (4) a small, slit-like, hyperkinetic left ventricle; (5) dilation of the hepatic veins and IVC; (6) respiratory variations in the velocity of blood flow through the tricuspid and mitral valves; and (7) visualizing the heart swinging to and fro within the pericardial sac.¹¹⁵ The presence of any of these signs should alert the clinician to the possibility of hemodynamic instability. Obtain expert consultation if there is any uncertainty about the ultrasound findings.

Limitations of Ultrasound

Ultrasound is the best diagnostic tool for pericardial effusion and tamponade, but great care must be taken when it is used as the only diagnostic modality (Video 16.2). In a post-operative series of cardiac surgery patients, 60% of loculated effusions causing tamponade were missed on transthoracic echocardiography but were visualized with transesophageal echocardiography.¹¹⁶

There are several false positive findings for a pericardial effusion on ultrasound. Examples include pericardial thickening, large pleural effusions, atelectasis, and mediastinal lesions.¹⁷ Epicardial (or anterior) fat pads can also be misinterpreted as

ULTRASOUND BOX 16.1: Pericardiocentesis

by Christine Butts, MD

Pericardiocentesis has traditionally been performed blindly. This approach was associated with a low success rate and a high rate of complications, such as inadvertent puncture of the lung, ventricle, or epicardial vessels.¹ Using ultrasound to both diagnose and guide pericardiocentesis has resulted in increased success rates, as well as a lower rate of complications.^{2,3}

Bedside ultrasound may additionally allow the emergency physician to make a rapid diagnosis of pericardial effusion. Evidence of impending cardiac tamponade, including right ventricular collapse and distention of the inferior vena cava, can also be identified.

Equipment

The pericardium should be imaged with a low-frequency (2 to 4 mHz) transducer to achieve adequate depth. A phased-array or microconvex transducer is preferred for its smaller footprint, which enables the sonographer to image between the ribs. However, a curvilinear transducer may be used if that is what is available.

Image Interpretation

The initial step in the procedure is to evaluate the pericardium in multiple windows. This will allow identification and characterization of the effusion, as well as planning of the best approach for drainage. This chapter focuses primarily on the views most commonly used in this procedure, the subxiphoid and parasternal.

The subxiphoid view is best known to most emergency physicians as part of the focused abdominal sonography in trauma (FAST) examination. This view provides a four-chamber view of the heart and uses the left lobe of the liver as an acoustic window. To obtain this view, the transducer is placed just inferior to the xiphoid process in the midline. The indicator faces the patient's right side (Fig. 16.US1). To obtain the best image possible it is best to place the hand over the transducer and press down into the epigastric area. The transducer can then be aimed toward the left side of the chest until the heart comes into view. The depth may need to be adjusted to view all four chambers of the heart, as well as the pericardium.

In this view the left lobe of the liver can be seen at the top of the image. Deep to the liver, a four-chambered view of the heart should be seen, surrounded by the brightly echogenic (white) border of the pericardium (Fig. 16.US2). The right ventricle will abut the liver, with the left ventricle located deeper into the body. A pericardial effusion can be identified as an anechoic (black) or hypoechoic (dark gray) collection between the heart and pericardium (Fig. 16.US3). Although

Figure 16.US1 Placement of the ultrasound transducer to obtain a subxiphoid image of the heart.

fluid will typically collect at the most gravity-dependent area, loculated collections may not follow this rule.

The parasternal view is obtained by placing the transducer to the left of the patient's sternum in the fourth to fifth intercostal space. The indicator should be pointing toward the patient's right shoulder (Fig. 16.US4). Slight adjustments in angle may be needed to obtain the best image of the heart. If the patient's hemodynamic status allows, placing the patient in a left lateral decubitus position may improve this view by moving the heart closer to the anterior chest wall and displacing the air-filled lungs.

The parasternal view will demonstrate the left atrium, left ventricle, and a small portion of the right ventricle (Fig. 16.US5). The pericardium can be seen as an echogenic (white) border surrounding the heart. As in the subxiphoid view, an effusion will appear as an anechoic (black) or hypoechoic (dark gray) collection between the heart and pericardium (Fig. 16.US6).

Procedure and Technique

Once the views have been evaluated and an effusion has been identified, evaluate the pericardium in multiple views to determine the

Figure 16.US2 Normal subxiphoid view of the heart seen with ultrasound. The pericardium (arrow) can be identified as a bright white (hyperechoic) outline, typically best seen at the inferior aspect of the heart. The pericardium should directly abut the heart, as seen in this image.

Figure 16.US3 Subxiphoid view demonstrating a pericardial effusion. When comparing this image with the normal view, a black (anechoic) fluid collection (arrow) can be seen between the pericardium and the left ventricle.

ULTRASOUND BOX 16.1: Pericardiocentesis—cont'd

Figure 16.US4 Placement of the ultrasound transducer to obtain a parasternal long-axis view of the heart.

Figure 16.US5 Normal parasternal long-axis view of the heart. The pericardium can be seen as a bright white (hyperechoic) outline surrounding the heart (arrow). As with the subxiphoid image, the pericardium should directly abut the heart with no intervening fluid.

best area to attempt pericardiocentesis. Tsang and colleagues described the procedure for echocardiographically guided pericardiocentesis in detail in 1998.⁴ Ideally, the procedure should be attempted at the site at which the largest fluid collection is closest to the skin surface. Typically, the anterior chest wall is preferred because of its proximity to the pericardium and the absence of vital interfering structures such as the liver. The air-filled lung creates a scatter artifact that does not allow the ultrasound beam to pass. Therefore if the heart and pericardium can be viewed clearly, avoidance of the lung can be ensured. The sonographer should also attempt to approximate and avoid the location of the internal mammary artery, which lies 3 to 5 cm lateral to the sternum. Once the optimum site is identified, the practitioner should note the trajectory of the ultrasound beam. This is the trajectory that should be followed by the needle.

Sterilize the field. Anesthetize the area to be traversed with local anesthetic. Place the ultrasound transducer in a sterile covering. Take care to not reposition the patient after initial assessment because this will alter the position and trajectory. Use a 16-gauge catheter with a retractable needle to minimize potential injury to the underlying structures. After the field is prepared, attach the catheter to an attached syringe. Advance the needle in the predetermined location

Figure 16.US6 Parasternal long-axis view demonstrating a pericardial effusion. An anechoic (black) fluid collection can be seen on the right of the image (arrow), between the left ventricle and the pericardium. The right ventricle, at the top of the image (arrowhead), can be seen to “bow” inward from the pressure exerted by the effusion. This finding, right ventricular collapse, indicates that the effusion is causing hemodynamic compromise.

along the predetermined trajectory. This can be done blindly or can be guided directly by the transducer. Apply gentle continuous pressure to the syringe until the pericardial space is entered and fluid is obtained.

If there is any question of whether the needle tip is in the pericardial space, inject agitated saline through the catheter under direct ultrasound guidance. This will allow analysis of the location of the needle tip. Prepare saline echocardiographic contrast medium by using two 5-mL syringes, one with saline and the other air, connected via a three-way stopcock to the needle catheter sheath. Saline in one syringe is rapidly injected between the syringes and then injected into the sheath once it is agitated. Entrance of the agitated saline into the pericardial space will appear sonographically as a brightly echogenic area.

Complications

Complications may occur when a pericardial effusion is misdiagnosed. The most common factor causing misdiagnosis is the presence of a fat pad anterior to the heart. Unless the effusion is loculated, it should lie within the most dependent portion of the heart and should be circumferential, depending on its size. Considering these factors and evaluating the pericardium in multiple views will aid in decreasing this misdiagnosis. Additionally, take care when performing pericardiocentesis in stable patients, particularly when the effusion is small. Smaller effusions may be more difficult to access and therefore lead to increased complications.

pericardial effusions, although several details help distinguish between the two entities. First, epicardial fat pads tend to occur anteriorly, unlike circumferential effusions, which occur posteriorly. If a fat pad is suspected, multiple ultrasound views should be obtained to rule out a posterior effusion. Second, the echocardiographic appearance of an epicardial fat pad is isoechoic and homogeneous. This differs from blood in the pericardial space, which may look like fronds of clot waving within an anechoic (black) pericardial space. Third, an epicardial fat pad does not alter hemodynamics like tamponade does; it should not cause diastolic collapse of the right ventricular free wall, dilation of the IVC, or any signs indicating hemodynamic compromise. After careful examination, if doubt still exists regarding the presence of an effusion, hemodynamically stable patients should have a formal echocardiogram; consider CT scan if an echocardiogram is not available.

CT Scan

CT may be the only diagnostic option at institutions where ultrasound or formal echocardiography is not available in the ED. It is also helpful when concomitant diseases of the lung or mediastinum are considered. CT can demonstrate dilated hepatic veins, a plethoric IVC, and interventricular septal bowing.¹¹⁷ This modality is less desirable than bedside ultrasound because it requires patients to be transported to the radiology suite. Thus, patient safety and cardiopulmonary stability must be considered before the decision is made to transport the patient. Unstable patients should never be transported until they are fully stabilized.

For stable patients, CT is effective in defining the presence, severity, and extent of pericardial effusions (i.e., circumferential versus loculated). In certain circumstances, it even provides a more definitive diagnosis than echocardiography does because it may reveal the type of pericardial fluid (by differences in tissue density) and pericardial disease (e.g., constrictive pericarditis).¹¹⁸ In one series, eight equivocal echocardiograms were evaluated by follow-up CT.¹¹⁹ Two patients thought to have pericardial effusion by ultrasonography were found to have pleural effusions. Another patient in whom a pericardial effusion was diagnosed on ultrasonography was found by CT to have an epicardial lipoma. CT defined three loculated pericardial effusions not identified by ultrasonography. Finally, two patients had hemopericardium visualized by CT but not by ultrasonography.

Treating Pericardial Effusions and Tamponade

Treatment of pericardial effusions in the ED depends on the degree of hemodynamic compromise. Patients with stable effusions should be treated supportively while the underlying cause (known or suspected) is addressed. For example, stable patients with pericardial effusions secondary to uremia may best be treated with dialysis, observation, and serial echocardiograms.¹²⁰ Even when the diagnosis is unknown there may be no need to perform emergency pericardiocentesis if the effusion is small to moderate.¹²¹ Deferring diagnostic pericardiocentesis to the inpatient setting may be preferred because the cardiac catheterization laboratory or operating room is a more sterile and controlled environment than the ED.⁵⁷

Patients with evidence of tamponade need urgent pericardiocentesis (discussed in the next section). Even those with early tamponade who are stable can decompensate quickly

with little warning. Fluid boluses may improve hemodynamics temporarily, especially in patients with concomitant hypovolemia.⁸⁹ Administration of a vasopressor (e.g., norepinephrine) is a temporizing measure and should be initiated while preparing for emergency pericardiocentesis. Finally, positive pressure ventilation (e.g., mechanical ventilation) should be avoided if possible because, as discussed in the section on physiology, it can lead to hemodynamic collapse secondary to changes in intrathoracic pressure.

INDICATIONS FOR PERICARDIOCENTESIS

There are two indications for pericardiocentesis: (1) to diagnose the presence and cause of a pericardial effusion (diagnostic pericardiocentesis) and (2) to relieve tamponade (therapeutic pericardiocentesis). Diagnostic pericardiocentesis is an elective procedure. It is ideally performed under visual guidance (e.g., ultrasound or fluoroscopy). Therapeutic pericardiocentesis may be an urgent or emergency procedure based on patient hemodynamics. In the semi-stable patient, ultrasound guidance should be utilized for pericardial fluid aspiration; however, in the case of cardiovascular collapse or cardiac arrest, a blind approach may be warranted.

Diagnostic Pericardiocentesis

The use of pericardiocentesis to determine the cause of nonhemorrhagic effusions is common practice despite varying opinions on its utility.^{52,122,123} Recovery of pericardial fluid to assess for tumor, autoimmune, and biochemical markers in addition to bacterial and viral cultures with Gram stain can be valuable in making the diagnosis. Measurement of pericardial fluid pH can also be helpful because inflammatory fluid is significantly more acidotic than noninflammatory fluid.¹²⁴ When a specific cause is suspected, additional diagnostic testing may be useful (e.g., adenosine deaminase in patients with tuberculosis and carcinoembryonic antigen in those with suspected malignancy).¹²⁵

The diagnostic accuracy of pericardiocentesis is variable, and certain diagnoses are unlikely to be made from pericardial fluid. In one large series, fluid samples were obtained in 90% of aspirations, but the specific cause was determined from only 24% of those specimens.¹²⁶ Another series demonstrated false-negative cytologic results in certain cases of lymphoma and mesothelioma.¹²⁶ In some HIV patients, effusions secondary to Kaposi's sarcoma and cytomegalovirus infection have been diagnosed by pericardial biopsy following nondiagnostic fluid analysis.^{127,128} Nevertheless, pericardial biopsy is not routinely indicated and is considered only in cases of recurrent effusions, such as a neoplasm or granulomatous disease.¹²⁹ When a biopsy is obtained it is often during implementation of a subxiphoid pericardiotomy (pericardial window).

A pericardial window is typically employed to obtain both pericardial fluid and a pericardial biopsy specimen, because once a tissue sample is obtained, a definitive diagnosis is much more likely.¹³⁰ It is reserved for those with recurring episodes of tamponade.¹³⁰ This procedure can be performed safely in the operating suite without general anesthesia.¹³¹ In a prospective series of 57 patients who underwent subxiphoid pericardiotomy, a definitive diagnosis was obtained in 36%, a probable diagnosis in 40%, a possible diagnosis in 16%, and no diagnosis in 7%. It is uncertain whether this technique is safer than

ultrasound-guided pericardiocentesis, but published reports show low rates of complications in experienced hands.⁵⁸

The most valuable clinical predictors in diagnosis are size of the effusion (larger effusions and tamponade are more likely to yield a diagnosis) and signs of inflammation (e.g., fever, pericardial friction rub, ST-segment elevation).⁵⁸ Unfortunately, the only methods of making definitive diagnosis are pericardial fluid aspiration with analysis and pericardial biopsy.

Diagnostic pericardiocentesis has limited utility for hemopericardium secondary to traumatic causes. When used diagnostically after trauma to assess for the presence of pericardial bleeding, the procedure has a false-negative rate (i.e., no blood aspirated) of between 20% and 40%.^{95,132-134} The high false-negative rate is due to the fact that posttraumatic blood tends to clot within the pericardial space and therefore cannot be aspirated.¹⁹ Furthermore, pericardiocentesis should not delay emergency thoracotomy if cardiac tamponade is suspected.¹³⁵ If there is uncertainty about the presence of tamponade, the focused abdominal sonography in trauma (FAST) examination rapidly and noninvasively identifies pericardial fluid.¹³⁶⁻¹³⁸

Therapeutic Pericardiocentesis

The ultrasonographic finding of a large pericardial effusion (>20 mm) in a stable patient should lead to early cardiology or cardiothoracic surgery consultation for percutaneous drainage or placement of a pericardial window. Patients with a pericardial effusion who remain hypotensive despite fluid resuscitation require urgent therapeutic drainage. The decision to wait for consultants is best made by the emergency physician at the bedside and should be based on clinical judgment. Until recently, few algorithms existed to assist in the risk stratification of patients with pericardial effusions and who should undergo emergency versus delayed pericardiocentesis. In 2012, Halpern and colleagues introduced a scoring system based on effusion size, echocardiography derangements, and clinical criteria.¹³⁹ Similarly, Ristic and colleagues in 2014 created a system incorporating etiology, clinical factors, and diagnostic imaging.¹⁴⁰ Such tools can aid the emergency physician in identifying who would benefit most from ED pericardiocentesis and who could await consultant recommendations. (Fig. 16.10)

For patients in extremis, pericardiocentesis should be performed immediately even if consultation is unavailable. The clinician who performs the procedure should be the one who is most experienced in both sonography and pericardial fluid aspiration.

Tamponade of Uncertain Cause: Pulseless Electrical Activity

A major indication for emergency pericardiocentesis is a patient in cardiac arrest with PEA. Always consider cardiac tamponade in the differential diagnosis for PEA, especially if jugular venous pressure is elevated or a pericardial effusion is demonstrated on ultrasound. In a series of 20 patients with PEA, 3 had tamponade and another 5 had some degree of pericardial effusion.¹⁴¹ In this setting, blind (i.e., landmark method), ECG-guided, or ultrasound-guided pericardiocentesis can be lifesaving.

Tamponade Caused by Nonhemorrhagic Effusions

Most nonhemorrhagic effusions are liquid. They can be drained by pericardiocentesis with a small needle or by a catheter left in the pericardial space. Removal of even a small amount of fluid can cause immediate and dramatic improvement in blood

pressure and cardiac output. Pericardiocentesis relieves tamponade caused by nonhemorrhagic effusions in 60% to 90% of cases.^{54,126,142}

If aspiration with small-needle pericardiocentesis fails, the patient may have a purulent, malignant, or loculated effusion. Placement of a pericardial catheter is more useful in the long-term management of these patients. In Krikorian and Hancock's series,¹²⁶ 24% of patients were managed successfully with a single pericardiocentesis procedure, but 37% needed multiple aspirations or an indwelling catheter (39% required surgical drainage and 55% of these patients had traumatic hemopericardium). Therefore if time and patient stability permit, consider pericardiocentesis with a catheter to reduce the necessity for repeated aspirations.

Patients with renal failure and tamponade require urgent pericardiocentesis. Without signs of tamponade, however, these patients may be better managed by dialysis. In one series, 63% of renal failure patients were managed successfully with only dialysis.¹²⁶ There is some evidence that needle pericardiocentesis is a poor choice in patients who need pericardial drainage; in one series, 9 of 10 patients had serious complications following this procedure.⁶⁶ Consultation with specialists is advised when there is no evidence of hemodynamic collapse but pericardial drainage is still being considered.

An algorithm for the urgent management of nonhemorrhagic cardiac tamponade is presented in Fig. 16.11.

Pericardiocentesis in Patients With Hemorrhagic Tamponade

For hemorrhagic tamponade, pericardiocentesis is never the definitive treatment because this strategy has several drawbacks.^{143,144} Aspiration of a small quantity of fluid may cause a dramatic improvement in hemodynamics, but pericardial clots can prevent adequate drainage, so blood usually reaccumulates.^{93,106} Patients with traumatic pericardial hemorrhage ultimately require thoracotomy to explore and repair the cardiac injury. Pericardiocentesis simply delays this definitive procedure. A study investigating traumatic cardiac injury found that all patients who underwent surgery within 2 hours of the injury survived but the mortality rate was higher in patients who experienced longer operating room delays.¹⁴³

Sugg and associates documented a 43% mortality rate when pericardiocentesis was the sole treatment of traumatic tamponade, as compared with 16% in those who also underwent surgical intervention.¹³³ All patients managed by pericardiocentesis had repairable wounds at autopsy, thus suggesting that in this population, operative repair is preferable. The number of deaths from stab wounds has been decreasing over time in response to a shift in trauma philosophy in which early thoracotomy is supported rather than repeated pericardiocentesis.^{95,134,144,145}

In the austere setting where no surgeon is immediately available and hemopericardium is identified on FAST exam, pericardiocentesis can serve as a life-saving bridge until definitive surgical intervention is arranged (Fig. 16.12). A study of penetrating trauma patients with tamponade found that preoperative pericardiocentesis decreased the mortality rate from 25% to 11%.¹⁴⁶

CONTRAINDICATIONS

There are no absolute contraindications to pericardiocentesis in hemodynamically unstable patients. Relative contraindications

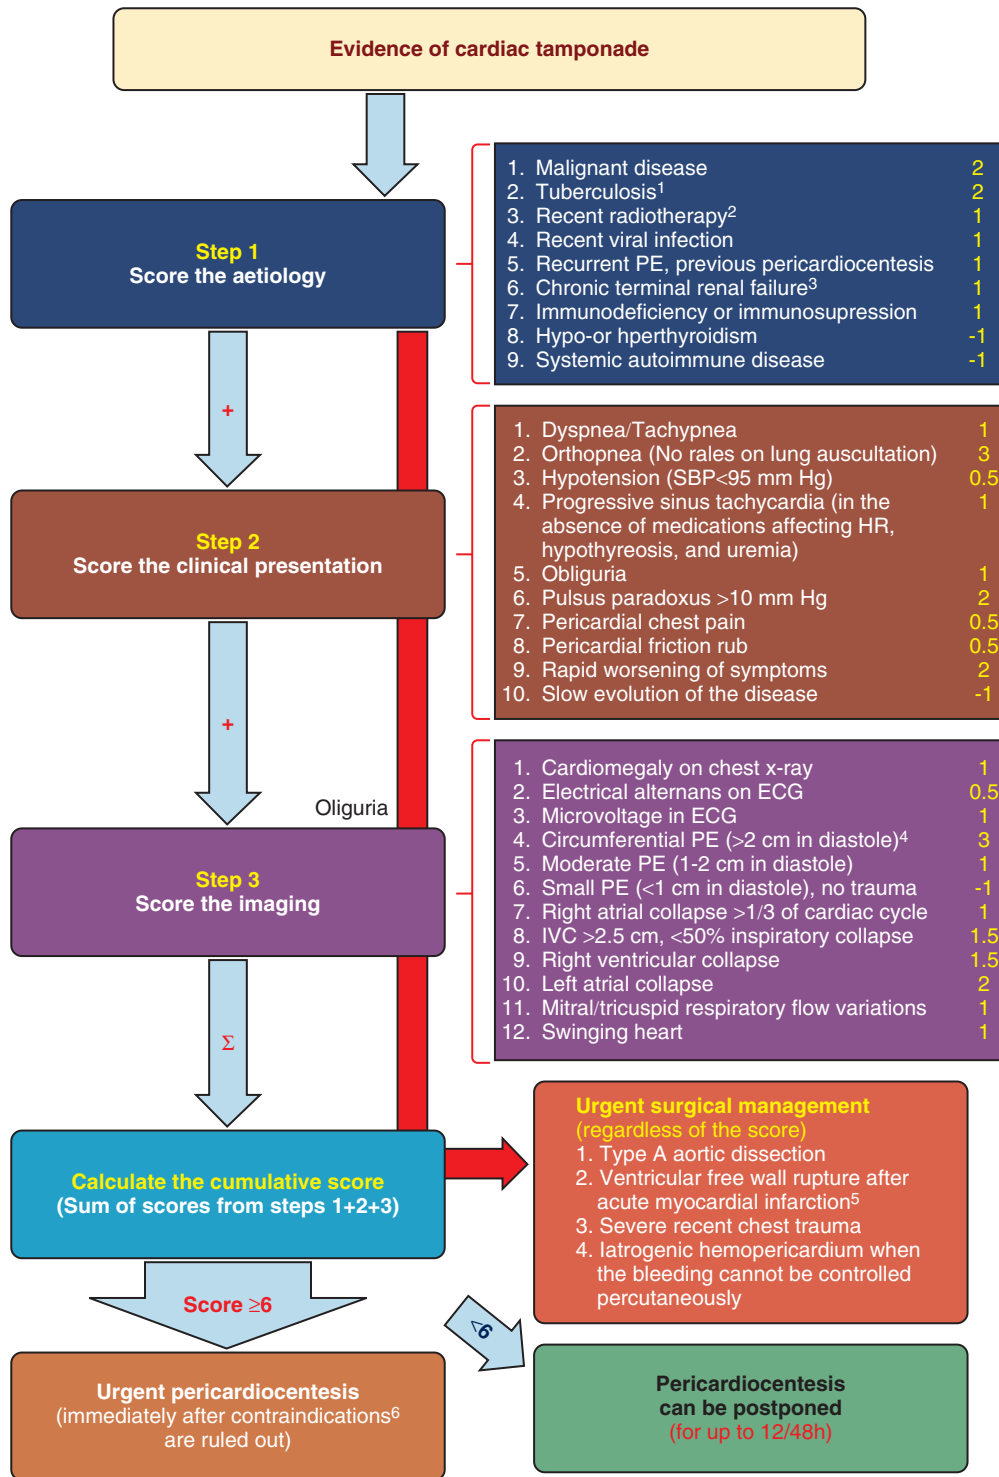

Figure 16.10 Three-step scoring system triage patients requiring urgent percutaneous or surgical drainage of pericardial effusion. Diagnosis of cardiac tamponade is based on clinical symptoms, signs, and echo findings. Total score ≥ 6 indicates urgent pericardiocentesis. *HR*, Heart rate; *IVC*, inferior vena cava; *PE*, pulmonary embolism; *SBP*, systolic blood pressure. (From Ristic A, Imazio M, Adler Y, et al: Triage strategy for urgent management of cardiac tamponade: a position statement of the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases, *Eur Heart J* 35:2279, 2014. Oxford University Press.)

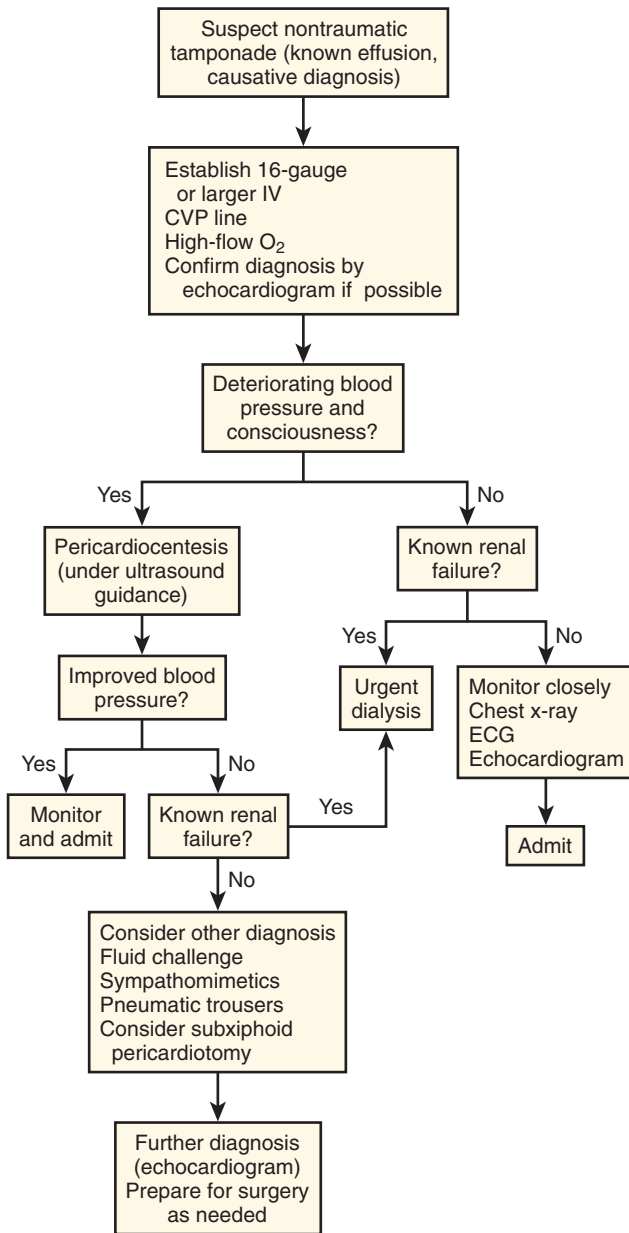

Figure 16.11 Management of nontraumatic cardiac tamponade. CVP, Central venous pressure; ECG, electrocardiogram; IV, intravenous line.

to pericardiocentesis include coagulopathy; previous thoracoabdominal surgery; the presence of prosthetic heart valves, pacemakers, or cardiac devices; inability to visualize the effusion with ultrasound during the procedure; and situations in which better treatment modalities are immediately available (e.g., thoracotomy for trauma patients).

Ideally, pericardiocentesis is performed in the cardiac catheterization laboratory under fluoroscopic or echocardiographic guidance. With the advent of bedside ultrasound and immediate visualization of large pericardial effusions, pericardiocentesis is being performed in the ED more frequently. Ultrasound can accurately identify the area of the heart with the greatest fluid accumulation and clarify its relationship to the body wall.^{40,147,148} This allows the physician to choose an entry site and angle of penetration with the greatest likelihood of obtaining fluid while avoiding vital structures.

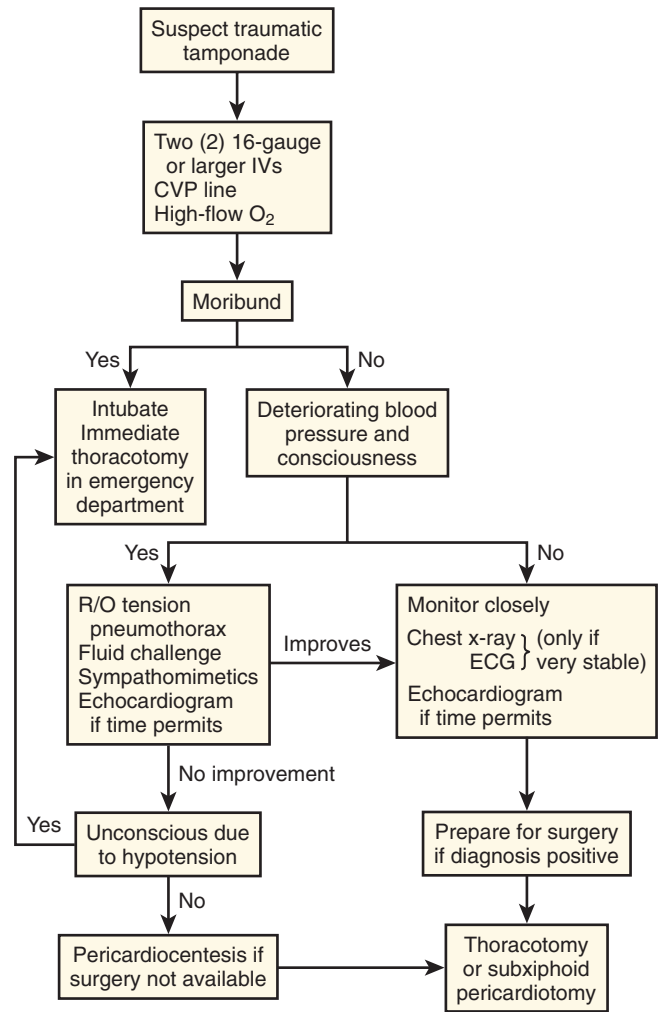

Figure 16.12 Management of traumatic cardiac tamponade. CVP, Central venous pressure; ECG, electrocardiogram; IVs, intravenous lines; R/O, rule out.

OVERVIEW OF TECHNIQUES AND EQUIPMENT

In an urgent situation (e.g., PEA arrest) with no adjunctive equipment available, pericardiocentesis can be performed with minimal equipment. Use a long 18-gauge spinal needle attached to a 10-mL syringe to withdraw fluid from the pericardial sac. Although the procedure can be done with these two simple devices, access to several others would be beneficial during the procedure. Of all the components, the most essential is an ultrasound machine, which first is used to determine whether a pericardial effusion is present and then assists in accurate needle placement. Ideally, use a probe with a small-footprint and a frequency of 2 to 4 MHz. If this type of probe is not available, use a 2- to 3.5-MHz curvilinear probe in the subxiphoid view, which will also provide excellent images of the heart.

Before the introduction of real-time sonography to guide needle placement, electrocardiographic monitoring was used to indicate appropriate needle placement. This is done by connecting the electrocardiographic machine to one of the precordial leads (e.g., V₁). That precordial lead is then attached to the distal end of a spinal needle with an alligator clamp

Figure 16.13 For emergency pericardiocentesis, a long 18-gauge spinal needle is connected to a V lead of an electrocardiographic machine via a cable with alligator clips.

(Fig. 16.13). The precordial lead can then be used as a rhythm strip to monitor the needle tip continuously.

Other tools that are desirable for urgent pericardiocentesis can be found easily in the ED or in a pericardiocentesis kit (see Review Box 16.1): a finder needle; Seldinger wire; dilator; flexible catheter guide; 6- to 8-Fr pigtail catheter; plastic drainage tube; extra syringes; sterile hat, gown, gloves, and drape; and local anesthetic.

PROCEDURE

Temporizing Measures

Cardiac tamponade is an emergency that requires urgent therapy. Therapy typically consists of either pericardial drainage by needle aspiration or placement of a pericardial window. These procedures are not classically performed in an ED, so temporizing methods are the mainstay of therapy unless the patient is unstable (e.g., in PEA arrest). The most common therapeutic procedures used as temporizing measures in the setting of tamponade are intravascular volume expansion with crystalloids and administration of vasopressors or inotropes.^{5,14,149} Although most textbooks and protocols encourage the use of these temporizing methods, they are backed by only sparse scientific evidence.^{150,151} Studies in animals have shown an increase in cardiac output and improvement in blood pressure with expansion of central blood volume; the validity of this in humans with cardiac tamponade is uncertain. Fluid resuscitation in a trauma patient with penetrating cardiac injury might cause deterioration. Animal experiments indicate that the response depends on whether fluid boluses produce recurrent bleeding from the cardiac wound.¹⁵² Despite the lack of evidence, judicious volume expansion with or without an adjunctive vasopressor before definitive therapy may be the only option for patients with tamponade.

Norepinephrine, isoproterenol, dopamine, and dobutamine have all been evaluated as the vasopressor or inotropes of choice in patients with cardiac tamponade. Norepinephrine and isoproterenol increased cardiac output in animal models of tamponade, but failed to increase it in humans.^{153,154} Dopamine and dobutamine increased cardiac output and improved hemodynamics in the setting of tamponade.^{33,151} Any of these

agents may be beneficial as a temporizing agent only, but theoretically, dobutamine is preferable because of its greater β -adrenergic activity.¹⁵⁴

Preparation

Before preparing for pericardiocentesis, place all resuscitation equipment at the bedside in anticipation of clinical deterioration. Most patients undergoing pericardiocentesis in the ED have already experienced hemodynamic collapse and are lying supine. If the patient is able to cooperate, elevate the chest 30 to 45 degrees to bring the heart closer to the chest wall. Sedation of stuporous patients is typically forgone because of the risk for further hemodynamic collapse. If the patient is awake and undergoing the procedure without obvious hemodynamic compromise, short-acting medications (e.g., ketamine, midazolam, or fentanyl) are preferred.

Every effort should be made to ensure aseptic technique. Prepare the chest and upper part of the abdomen with a chlorhexidine-based solution. Drape the patient and ensure that all care providers involved in the procedure are wearing a sterile hat, mask, gown, and gloves. If the patient is awake, anesthetize the skin and the proposed route with 1% lidocaine (see Review Box 16.1). Because the pericardium is extremely sensitive, it should be anesthetized.¹⁵⁵

The approach to pericardiocentesis depends on the clinical status of the patient, the availability of ultrasound, and the distribution of pericardial fluid. Pericardial fluid is not always distributed circumferentially in the pericardial sac, so ultrasound can quickly identify the maximal effusion pocket and demarcate the appropriate site for needle placement. Pericardiocentesis with ultrasound guidance is currently the safest and most reliable method for the diagnosis and treatment of pericardial effusion and tamponade.¹⁵⁶ Studies of echocardiography-directed pericardiocentesis have found that the apical approach is the best site for puncture.^{148,157,158} Cadaver studies have corroborated this finding and have demonstrated greater safety with an apical approach. However, these studies also revealed that an apical approach is associated with a greater incidence of pneumothorax than a traditional subcostal approach is. Before the advent of ultrasound guidance, the subxiphoid approach (discussed later in this chapter) was the preferred method of pericardiocentesis. It is still used frequently during cardiac arrest and when ultrasound is not readily available.

ECG Monitoring

If ultrasound is not readily available to guide needle placement, electrocardiographic monitoring can serve as a useful adjunct. Electrocardiographic monitoring is used to prevent puncture of the ventricle. When using this method, an assistant is essential to ensure sterile technique, observe for dysrhythmias, and make sure that the electrocardiographic machine is functioning properly.

After all equipment is sterile, attach an alligator clip from one of the precordial leads (e.g., V₁) to the distal end of the spinal needle. Record a rhythm strip of this lead (the “exploring electrode”) continuously. Advance the needle through the skin while remembering that any contact with the epicardium will cause a current-of-injury pattern that can be seen on the ECG. Typically, this is represented as a wide-complex premature ventricular contraction with an elevated ST segment (Fig. 16.14). When a current-of-injury pattern is seen, the needle

Figure 16.14 Current-of-injury. There is an obvious change in the electrocardiogram when the pericardiocentesis needle touches the epicardium. Following slight withdrawal (*arrow*), the ST-segment elevation diminishes. This is best seen when the needle is directly attached to the electrocardiographic V lead.

is probably touching the epicardium. Withdraw it several millimeters to prevent laceration of the myocardium or coronary vessels. After slight withdrawal, the needle should be within the pericardial space. Aspirate any fluid, but watch for changes on the ECG. Electrocardiographic monitoring is not infallible: if the patient has an abnormal myocardium from conditions such as a previous MI or the formation of scar tissue, no current-of-injury pattern will be generated on the rhythm strip.

Ultrasound-Guided Pericardiocentesis

Pericardiocentesis has traditionally been performed blindly. This approach was associated with a low success rate and a high rate of complications, such as inadvertent puncture of the lung, ventricle, or epicardial vessels. Using ultrasound to both diagnose and guide pericardiocentesis has resulted in increased success rates, as well as a lower rate of complications. The techniques are described in [the Ultrasound Box](#).

Subxiphoid/Subcostal Approach

As mentioned earlier, the traditional blind subxiphoid approach can still be used for pericardiocentesis in the ED (e.g., for patients in cardiac arrest and when ultrasound is not available). The technique is performed as follows: introduce the needle 1 cm inferior to the left xiphocostal angle at a 30-degree angle to the skin ([Fig. 16.15](#)). Because the heart is an anterior structure, angles greater than 45 degrees may lacerate the liver or stomach. Aim toward the left shoulder and advance the needle slowly while continuously maintaining negative pressure on the syringe to aspirate any fluid. Aspirate with an “in-and-out” vector only, not “side-to-side,” which may lacerate tissue. If no fluid is aspirated, withdraw the needle completely and redirect it in a deeper posterior trajectory. If no fluid is aspirated after redirecting the needle, withdraw the needle and redirect it, working from the patient’s left to right, until it is aimed at the right shoulder. Recommendations regarding needle trajectory vary widely, including toward the right shoulder, sternal notch, and left shoulder.^{149,155}

Apical Approach

The apical approach is occasionally used as an alternative to the subcostal approach to drain a pericardial effusion when ultrasound is available. Use ultrasound to identify the largest area of the apical effusion ([Fig. 16.16A](#)) or simply feel for the apex. If the apex cannot be palpated, it typically lies within the area of cardiac dullness, often between the fifth, sixth, or

seventh intercostal space, between the midclavicular and midaxillary lines. Introduce the needle 1 cm lateral to and into the intercostal space below the apical heartbeat. Advance the needle over the cephalad border of the rib and aim it toward the right shoulder to avoid the neurovascular bundle located caudal to the rib space. This area is close to the lingula and the left pleural space, thus making pneumothorax a frequent complication. Theoretically, this technique is used because the coronary vessels are small at the apex; therefore if a ventricle is entered, it is the thick-walled LV, which is more likely to seal off after ventricular injury. With echocardiographic guidance, the apical approach is used more commonly.¹⁵⁹

Parasternal Approach

The parasternal approach is an alternative approach to the previously described techniques. First, identify the largest area of the parasternal effusion on ultrasound if possible. If ultrasound is not available or if the effusion is not clearly identified on the ultrasound image, proceed by introducing the needle 1 cm lateral to the sternal border at the left fifth or sixth intercostal interspace. Advance the needle over the cephalad border of the rib to avoid the neurovascular bundle on the caudal aspect of the rib. Avoid going too far laterally from the sternal border because of potential injury to the internal mammary artery.¹⁶⁰ Occasionally, a right parasternal approach may be used when ultrasound predicts superior access to an effusion from this direction.

Tsang and co-workers¹⁶¹ described this technique for ultrasound-guided pericardiocentesis in 1998. The ideal site for skin puncture is where the largest area of fluid accumulation is closest to the skin surface. On ultrasound, this is indicated by a large anechoic (black) area at the top of the screen, usually corresponding to the left anterior chest wall (rather than the subcostal region). This approach also avoids injury to the liver (common with the subcostal approach). Inadvertent puncture of the lung is also prevented with this approach because air in the lung will not conduct sound waves and will prevent visualization of the heart when located immediately beneath the probe. Avoid choosing a site that could puncture the internal mammary artery, which lies 3 to 5 cm from either parasternal border, or the neurovascular bundle, which is located at the inferior border of the rib. Mark the best site with a sterile pen.

Procedure and Technique

Confirm the trajectory and depth of the needle before puncturing the skin. Be aware that repositioning the patient alters the position of the heart and pericardial sac within the chest, so reassessment will be necessary. Prepare the skin antiseptically and place a sterile cover over the ultrasound probe. If time permits, anesthetize the selected area with 1% lidocaine, with the superior border of the adjacent rib being used as a landmark. Select an 18-gauge spinal needle. Ideally, the needle should have a sheath that allows it to be withdrawn after the pericardial space is entered. This helps avoid injury to the heart and other vital structures. Attach a saline-filled syringe to the needle, and gently aspirate while slowly advancing the needle. Keep the ultrasound probe on the chest wall, immediately adjacent to the aspiration site.

Once the pericardial space is entered, inject agitated saline to confirm needle placement, particularly if the pericardial fluid is grossly bloody or if there is any question about needle

PERICARDIOCENTESIS (SUBXIPHOID APPROACH)

1

Examine the patient and identify the xiphoid process and the costal margin.

Prepare the area with antiseptic and administer local anesthetic.

2

Introduce the needle 1 cm inferior to the left xiphocostal angle at a 30-degree angle to the skin.

Aim toward the left shoulder.

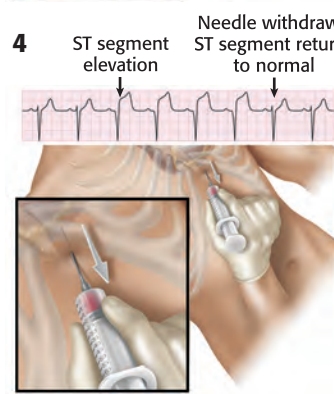

3

Aspirate during needle advancement and monitor for fluid return.

Stop advancing once fluid is returned.

4

Needle withdrawn
ST segment returns to normal

If using electrocardiographic monitoring, observe for current of injury during needle advancement, which indicates epicardial contact. If this occurs, withdraw the needle slightly.

5

Advance a J-tipped guidewire through the needle and into the pericardium.

6

Remove the needle, while leaving the guidewire in place in the pericardium.

7

Advance a 6- to 8-Fr dilator over the wire and then remove the dilator.

8

Advance a 6- to 8-Fr pigtail catheter over the wire and into the pericardium.

9

Remove the wire and drain the pericardial fluid.

Figure 16.15 Pericardiocentesis (preferred subxiphoid approach). (From Custalow CB: *Color atlas of emergency department Procedures*, Philadelphia, 2005, Saunders, p 123.)

Figure 16.16 Placement of a pigtail catheter in the pericardial space under ultrasound assistance: subcostal view of a small but hemodynamically significant pericardial effusion during pericardiocentesis. **A**, The effusion. **B**, After the injection of approximately 0.1 mL of agitated saline through the pericardiocentesis needle to confirm its position in the pericardial space. **C**, The shaft of the pigtail catheter (*arrowhead*, two discrete parallel echogenic lines reflect the catheter walls; the echo-free area represents the catheter lumen) lying in the pericardial space after the majority of fluid has been drained. *LI*, Liver; *PE*, pericardial effusion; *RV*, right ventricle; *SC*, saline contrast.

position (see Fig. 16.16B). Prepare a saline echocardiographic contrast medium by using two 5-mL syringes, one with saline and the other with air. Connect them via a three-way stopcock to the needle and catheter. Rapidly inject saline between the syringes and then inject it into the sheath. Monitor the entrance of the agitated saline into the pericardial space sonographically—it appears as a brightly echogenic stream. If the use of agitated saline proves to be inconclusive or suboptimal, use an echo-

cardiographic contrast agent (e.g., Definity) as a safe and successful alternative.^{162,163} Contrast agents contain gas microbubbles, which markedly enhance the fluid echo by introducing multiple liquid-gas interfaces. Inject this solution as a bolus. If the contrast material clears immediately after administration (as occurs with agitated saline) or persists temporarily within the cardiac chambers, an intracardiac location is suggested.

Fluid Aspiration and Evaluation

Removal of even a small amount of pericardial fluid (e.g., 30 to 50 mL) usually results in either return of spontaneous circulation or hemodynamic improvement. After any approach used for pericardiocentesis, place a temporary drain not only to ensure rapid access into the pericardial sac but also to allow more fluid to be removed quickly if hemodynamic collapse recurs. After needle placement is confirmed, a temporary drain can be placed by the Seldinger technique, described in Chapter 22.

Remove the syringe from the needle, advance a guidewire through the needle, and then remove the needle (see Fig. 16.15). Position a dilator (6 to 8 Fr Cordis) over the wire. If a dilator is not used, particularly with the subxiphoid approach, the pigtail catheter tip may get caught in the subcutaneous tissue and make placement of the catheter difficult. Remove the dilator and slide an introducer sheath dilator (6 to 8 Fr Cordis) over the wire. Remove the wire and the dilator while leaving the introducer sheath in place. Insert the pigtail angi catheter through the introducer sheath, and aspirate fluid to confirm placement.^{157,161} After the catheter is advanced into place, secure it with a suture to ensure that it does not migrate after the procedure. Apply an appropriate catheter dressing. Attach the catheter to a three-way stopcock and connect it to a water seal to drain by gravity. The pigtail catheter allows prolonged drainage and safe access into the pericardial sac without requiring the introduction of another needle.^{164,165} If drainage of pericardial fluid becomes sluggish, flush the catheter with a heparinized saline solution to ensure patency of the lumen.¹⁵⁵

Aspiration of blood during pericardiocentesis raises the possibility of cardiac puncture. Blood retrieved from the ventricle usually clots faster than bloody fluid aspirated from the pericardium. In general, hemorrhagic pericardial effusions have local fibrinolytic activity, which prevents clot formation. If the bleeding is brisk enough, however, blood may still clot and does not necessarily point toward ventricular puncture. The hematocrit of pericardial fluid should always be lower than that of a sample from the systemic vascular system, except in patients with aortic dissection or acute myocardial rupture. These circumstances aside, a hematocrit value similar to that for systemic blood should raise concern for an intracardiac needle location. Several other simple laboratory tests can differentiate normal from abnormal pericardial fluid, but they require the availability of a centrifuge system and time. Under normal conditions, pericardial fluid is less than 50 mL in volume and clear to pale yellow in color with no red or white blood cells, inflammatory markers, bacteria, or cancer cells and with a glucose concentration similar to that of blood.

Immediately following the procedure, obtain a chest film to ensure the absence of pneumothorax and free air under the diaphragm. Place the patient on continuous cardiac monitoring for 24 hours and watch for signs of reaccumulating fluid or

iatrogenic complications. Repeating the ultrasound examination in 24 hours is recommended. Diagnostic evaluation of non-hemorrhagic fluid is similar to that for pleural fluid (see Chapter 9).

Suture the pigtail catheter to the skin, but be careful not to occlude the catheter by tying it too tightly. Wrap the catheter in gauze at the skin and cover it with a sterile dressing. Attach the catheter to suction tubing and a drainage system.

COMPLICATIONS

Emergency physicians often perform pericardiocentesis under duress on a patient in PEA arrest. Many also perform the technique blindly because they have little or no time to gather adjunctive assistance or tools. It is critical for the emergency physician to be aware of both the traditional and contemporary methods of performing the procedure and the complications that can be associated with these methods (see Review Box 16.1).

With the advent of ultrasound- and CT-guided pericardiocentesis, the complication rate has been greatly reduced. Complication rates as low as 4% have been reported in large observational studies. Earlier studies of blind pericardiocentesis documented morbidity rates of 20% to 40% and mortality rates as high as 6%.¹⁶⁶ Because pericardiocentesis is performed in moribund patients, the likelihood of cardiac arrest and death is high. However, they are not usually a direct complication of pericardiocentesis but of poor cardiopulmonary reserve. Cardiac arrest and death are rarely associated with echocardiographically guided pericardiocentesis. When blind or electrocardiographically guided pericardiocentesis is performed, the patient is usually already in full arrest and attributing the cause of death to the procedure is nearly impossible. In a series of 52 patients the only death occurred in a patient in cardiogenic shock in whom pericardiocentesis was nonproductive and who was found to have severe arteriosclerotic heart disease, not tamponade, on postmortem examination.¹⁶⁷ In a series of 352 fluoroscopically guided pericardiocenteses, two deaths were documented.¹⁶⁸ Ultrasonographic or CT confirmation of effusion was used in all but 15 cases. The two deaths occurred during or after the procedure, but whether they could be attributed to the procedure is unclear. One patient with aortic rupture that penetrated into the pericardial space died of cardiac arrest immediately after the puncture. The other death, in a post-MI patient with a left ventricular aneurysm, was caused by ventricular fibrillation that occurred approximately 15 minutes after the procedure.

One of the most frequent complications is a dry tap, especially when a blind approach is used. A dry tap is often caused by blockage of the needle with clotted blood or a skin plug. With the parasternal approach, the needle can become blocked by vigorous probing of the anterior costal cartilage. The problem can be solved by repositioning or irrigating the needle, which allows the effusion to be aspirated unless it is loculated.

Preventricular contractions are frequently noted after the needle enters the pericardial sac; however, no serious dysrhythmias resulting in hemodynamic compromise have been mentioned in the literature. Several case series reported no dysrhythmias.^{54,67,157} Krikorian and Hancock¹²⁶ reported one episode of ventricular tachycardia and several “hypotensive vasovagal reactions” that were associated with bradycardia and

Figure 16.17 Air-fluid level (*arrow*) in the pericardial space immediately after pericardiocentesis. A minor pneumopericardium is inconsequential; a larger collection may cause tamponade.

responded to atropine and fluid loading. Duvernoy and associates¹⁶⁸ reported 1 case of ventricular tachycardia and 1 case of atrial fibrillation in 352 procedures. Maggiolini and co-workers reported transient third-degree heart block in a single patient.¹⁶⁹ The traditional subxiphoid approach carries a risk for liver laceration. Fortunately, inadvertent needle passage into the liver has not been reported to cause significant hemorrhage or death.¹⁷⁰

The parasternal and apical approaches have been documented as causing pneumothorax and pneumopericardium in several case series, but without any clinical consequence (Fig. 16.17). The pneumothoraces were treated with 100% oxygen or thoracostomy. There have also been infrequent reports of pneumopericardium after removal of a pericardiocentesis catheter. The cause of the pneumopericardium is thought to be the formation of a bronchopericardial fistula, but the exact mechanism is unclear. The mortality rate associated with tension pneumopericardium is approximately 50%, so consider pneumopericardium when patients complain of dyspnea and hypotension after removal of their catheter.¹⁷¹⁻¹⁷³

Very few studies have reported ventricular or coronary vessel laceration during pericardiocentesis. These complications occur more frequently during blind or electrocardiographically guided procedures. Most cardiac perforations occur in the RV, but punctures in the LV and atria have also been reported.²⁵ When these perforations occur, they tend to be silent and result in hemopericardium and death. In patients taking anticoagulants, it is important to check coagulation factors and monitor them closely after a seemingly insignificant pericardiocentesis because hemopericardium could develop just from the procedure itself.

In the series compiled by Krikorian and Hancock,¹²⁶ hemopericardium developed in 13 of 123 patients as a result of pericardiocentesis, one as a result of a lacerated coronary artery. One patient died of a punctured ventricle. Surgical control was necessary in four patients in whom tamponade developed, whereas it did not develop in eight patients with hemopericardium, and they were managed conservatively. Guberman and colleagues⁵⁴ reported three lacerations of the RV in 46 patients; one was fatal. Wong and colleagues¹⁶⁷ found five punctures of the RV, four in patients with nonproductive

pericardiocentesis, but none caused any adverse sequelae. In their series of 352 procedures, Duvernoy and associates¹⁶⁸ reported 23 penetrations. In two cases both the RV and LV had been perforated, and in all other cases the RV had been entered.

Researchers differ in their opinions regarding the adverse effects of ventricular puncture. Most ventricular punctures involve the lower aspect of the RV. The wall of the RV is thin and therefore vulnerable to laceration. However, pressure in the RV is low,² so a puncture should cause little bleeding. In a series of patients who underwent ultrasound-directed pericardiocentesis, ventricular puncture occurred in 1.5% but was without consequence.¹⁵⁷ In another study, laceration of the RV occurred in 1 patient despite the use of echocardiography; it resulted in tamponade and necessitated emergency surgery.¹²³ Of the 23 perforations in the series by Duvernoy and associates, 3 were considered major complications (2 patients required thoracotomy). Left ventricular pseudoaneurysm typically occurs as a complication of MI. It is rarely seen after surgery, trauma, or infection. Rare cases of severe left ventricular pseudoaneurysm after pericardiocentesis have been reported.^{174,175}

Even when pericardiocentesis has induced no physical injury, adverse events have been documented. Most have to do with the fact that during pericardiocentesis the stroke volume of the previously collapsed RV increases 75% after the first 200 mL of fluid is removed.⁷ In general, this increase in stroke volume is greater initially than that demonstrated by the LV. This imbalance can cause significant consequences for both right

and left ventricular function. Three of six patients in whom large effusions were removed by pericardiocentesis experienced right ventricular dilation and overload, abnormal septal motion, and either no increase or a decrease in the right ventricular ejection fraction.¹⁷⁶ These patients subsequently and slowly returned to normal hemodynamic status.

Pulmonary edema following pericardiocentesis has also been reported, presumably caused by a sudden increase in venous return to the LV when peripheral vascular resistance is still high from compensatory catecholamine secretion.¹⁷⁷⁻¹⁸¹ Supporting evidence for this explanation is that right ventricular stroke volume increases more than left ventricular stroke volume after relief of tamponade.¹⁰ Circulatory collapse with persistently low arterial blood pressure has been reported in a patient from whom 700 mL of clear fluid was drained at a rate of 100 mL/min.¹⁸² Thus, many authors recommend that the pericardial drainage rate not exceed 50 mL/min.

Cardiopulmonary Resuscitation and Artificial Perfusion During Cardiac Arrest

Benjamin S. Abella and Lance B. Becker

Cardiopulmonary resuscitation (CPR) can be lifesaving for a patient in cardiac arrest, particularly in conjunction with other therapies such as defibrillation or delivery of medications. In several large clinical studies, data have shown that prompt delivery of CPR serves as an important predictor of successful outcome and increases the chance of survival by up to twofold. Each minute without treatment, however, is associated with a 10% to 15% decrease in the probability of survival.^{1,2}

The quality of CPR is an important technical issue and has a direct effect on patient outcome. For example, shallow chest compressions have an adverse impact on the success of defibrillation.³ Because of these and related data, emphasis has recently been placed on improving the quality of CPR, and such priority has been codified in consensus CPR guidelines promulgated by the American Heart Association. These guidelines are formulated through a formalized data evaluation process and are updated every 5 years, last updated in 2015.⁴

Worrisome data have shown that the quality of CPR during actual resuscitation is endemically poor.^{5,6} Specifically, chest compressions are often administered too slowly with inadequate depth. In addition, pauses in chest compressions are too long, and hyperventilation of arrest patients is common. These deficiencies may be due to a variety of factors, including infrequent training, lack of awareness of the quality of CPR during resuscitation, and inadequate team leadership during resuscitation efforts.⁷

CONVENTIONAL CPR

Although CPR is widely taught to health care personnel and reassessed periodically, the importance of high-quality CPR cannot be stressed enough. High-quality CPR immediately before defibrillation increases the chance of successful restoration of circulation.^{3,8} Consensus opinion, based on a growing foundation of clinical data, is that early CPR and defibrillation (when appropriate) have a significant impact on patient survival and recovery.⁹⁻¹¹ Quality chest compression also increases the efficacy of drugs administered during resuscitation, whereas inadequate circulation leads to minimal effects from peripherally delivered drugs.¹² Hyperventilation is also widely prevalent and dramatically compromises hemodynamics. In animal studies, hyperventilation leads to reduced survival from arrest. In this section we review the key procedural aspects of manual CPR.

Compressions

The 2015 resuscitation guidelines emphasize the importance of quality chest compression⁴ by recommending that clinicians focus on maintaining proper chest compression depth and rate. Compress the sternum to a depth of between 2.0 and 2.4 inches with a rate of between 100 and 120 compressions/min. **Box 17.1** provides a summary of procedural recommendations for CPR. If possible, place a backboard under the victim to ensure appropriate thoracic compression. In addition, adjust the height of the bed or have the rescuer stand on top of a stepstool so that the entire weight of the rescuer above the waist is directed onto the patient's sternum (**Fig. 17.1A**). This enhances the depth of compressions and helps prevent leaning on the patient's chest between compressions, which is another key deficiency that has been widely observed. Extend the arms fully and place them perpendicular to the patient's chest while making sure to pull away from the chest sufficiently between compressions to allow full chest recoil. Rotate rescuers aggressively (approximately every 2 to 3 minutes) to avoid deteriorating quality of compressions because of exhaustion. Properly delivered compressions are highly fatiguing, and rescuer bravado often interferes with the realization of declining CPR quality over time.

Minimize pauses in chest compressions because even short pauses have profound effects on coronary perfusion pressure and outcomes.¹³ As stated earlier, long pauses in chest compressions before delivery of a shock are associated with failure of defibrillation.³ Do not stop CPR to deliver medications because the drugs can be administered at the same time as the compressions. Keep pauses in chest compressions to a minimum (e.g., for procedures such as intubation or pulse checks).

Ventilations

Deliver ventilations at a rate of 8 to 10 breaths/min (see **Fig. 17.1B**). Hyperventilation (e.g., ventilation rates greater than 30/min) is common during resuscitation. To prevent unwittingly hyperventilating the patient, one practical technique is to ask the rescuer who is providing ventilations to remove his or her hand completely off the bag-valve-mask apparatus between ventilations. The team leader should be vigilant in the observation of delivery of ventilations and should be ready to verbally prompt rescuers to ventilate the patient at the appropriate rate if hyperventilation is performed.

Pulse Checks

Pulse checks are generally performed too frequently during resuscitation efforts and take too much time. If a pulse cannot be readily felt within seconds, return to chest compressions as soon as possible. No studies have suggested that CPR is harmful to a patient with a very weak pulse, so use of a Doppler ultrasound device to detect the pulse is discouraged, as it is unnecessary and leads to increased pause times. If rescuers need ultrasound to find a pulse, the patient is at the very least markedly hypotensive and should probably be receiving CPR. Attempt pulse detection at the location of the carotid or femoral artery because peripheral pulse checks during profound shock or cardiac arrest states are notoriously unreliable. Frequently, a "pulse" can be detected during CPR itself; this phenomenon is often due to venous back pressure during compressions and does not indicate that compressions should be stopped, nor

BOX 17.1 Key Procedural Elements of Manual CPR

COMPRESSIONS

Between 100 and 120 compressions/min
Depth of between 2.0 and 2.4 inches/compression
Allow full chest recoil between compressions
Minimize pauses in compressions

VENTILATIONS

8–10 ventilations/min (avoid hyperventilation)
Minimize pauses in chest compression for intubation
Use of continuous capnography recommended for intubated patients

CPR, *Cardiopulmonary resuscitation.*

Figure 17.1 Conventional cardiopulmonary resuscitation (CPR). *Note:* no alternative technique or device in routine use has consistently been shown to be superior to conventional CPR. **A**, Compress the sternum to a depth between 2.0 and 2.4 inches at a rate between 100 and 120 compressions/min. Better CPR can be achieved by having the rescuer stand on a stepstool during compressions, rotating rescuers every 2 to 3 minutes, and minimizing pauses. **B**, Deliver ventilations at a rate of 8 to 10 breaths/min. Avoid hyperventilation during resuscitation.

does it necessarily suggest that the compressions are of adequate quality.

Monitoring end-tidal CO₂ pressure (PETCO₂) also affords an opportunity to detect a pulse during CPR. During ongoing resuscitation of a pulseless patient, capnography will generally remain low (often less than 20 mm Hg), which is indicative

of low blood flow. If the patient achieves return of spontaneous circulation (ROSC), a sharp increase in the PETCO₂ value (usually greater than 25 to 30 mm Hg) is consistent with return of adequate perfusion.¹⁴

Leadership and Teamwork

Cardiac arrest resuscitations are often crowded, chaotic events filled with stress and anxiety. To maximize calm and efficiency and to ensure quality of care, establish a team protocol. Designate someone to be the leader of the resuscitation, and make sure that all participants are clearly aware of this designation. The designated team leader should be responsible for monitoring the rhythm, for giving orders to initiate and terminate chest compressions, and for delivery of drugs and other therapies. The team leader should be situated either at the head of the bed or at a place where they can direct the resuscitation. It is important that the team leader does not actually perform compressions, ventilations, or other specific procedures unless absolutely necessary because they may quickly lose control of the resuscitation. As most rescuers are unable to detect when their own quality of compressions is diminishing, the team leader must observe CPR closely and order rescuer rotations throughout the duration of the resuscitation.¹⁵

Important Option for Layperson CPR: Chest Compression-CPR

Chest compression–only CPR (CC-CPR) has been shown in a number of investigations to be as effective as standard CPR in resuscitation efforts initiated by members of the lay public.^{16,17} Give compressions at a rate between 100 and 120 per minute, as with conventional CPR with interposed ventilations.

Because of its simplicity, CC-CPR minimizes pauses in chest compressions while maintaining proper rate and depth. Lay rescuers in the community may be less experienced with standard CPR and uncomfortable with the performance of mouth-to-mouth resuscitation. The simplicity of CC-CPR makes it relatively easy for first responders to initiate resuscitation efforts and for emergency medical dispatchers to guide lay rescuers remotely. Starting in 2010, and affirmed in 2015, the American Heart Association guidelines have shifted emphasis from “ABC” (“airway, breathing, compressions”) to “CAB” (“compressions, airway, breathing”) for lay rescuers. Their endorsement of “hands-only CPR” (a synonym for CC-CPR) educational programs reflects additional evidence that a focus on chest compressions during CPR may lead to an increase in bystander CPR, as well as improvements in patient outcomes.¹⁸ Recent investigations have shown that CC-CPR is associated with improved survival of patients with out-of-hospital cardiac arrest when performed by lay bystanders. A period of CC-CPR before intubation and rhythm evaluation also improves outcomes when used by emergency medical service (EMS) personnel.^{19,20} The EMS community is likely to see more widespread adoption and use of CC-CPR by lay public educational programs in the upcoming years.

ADJUNCTS TO IMPROVE THE QUALITY OF CPR

Numerous techniques and adjunctive devices have been investigated in attempts to improve long-term survival rates

with CPR. Data are conflicting and contrary, and as of this writing, no alternative technique or device in routine use has consistently been shown to be superior to conventional CPR. Unless breakthrough technology or new information on the parameters affecting the outcome of CPR emerge, this admonition will probably endure. Nonetheless, a variety of technologies have been developed to improve the quality of CPR. Some of these tools directly improve chest compressions, whereas others are less direct and aim to improve human performance or enhance hemodynamics during the delivery of chest compressions. This section describes some of these promising, intuitively useful, yet still unproven techniques.

Active-Compression Decompression CPR

Active compression-decompression CPR (ACD-CPR) is a variant of CPR in which the passive relaxation phase of CPR is converted into an active phase by means of a handheld or mechanical suction device, which can theoretically improve both myocardial and cerebral circulation when compared with traditional CPR.^{21,22} However, data on these devices are mixed; there have been studies on out-of-hospital cardiac arrest using this technique that did not find any improvements in either initial outcome or survival to discharge, and as with many devices, there are instances when its application is impractical.^{23,24}

Impedance Threshold Device

The impedance threshold device (ITD) optimizes chest compression hemodynamics via manipulation of intrathoracic pressure. From a practical standpoint, the ITD is a relatively simple device that is placed between the endotracheal tube and the bag-valve apparatus, much like a colorimetric PETCO₂ detector, which is familiar to most emergency department (ED) clinicians (Fig. 17.2). The ITD contains a valve that prevents air that is less than 10 cm H₂O in pressure from flowing through the device. During resuscitation, the ITD prevents air from entering the thorax during recoil of the chest wall after each compression by generating a small but hemodynamically significant negative pressure within the chest. In laboratory studies, this negative pressure enhances venous return to the heart and results in increased cardiac output with each subsequent chest compression.

The ITD can be used during resuscitation either with mask ventilation or via an endotracheal tube and is therefore appropriate for both basic life support care in the field and ED resuscitation. Apply the device and administer ventilations at a rate of 8 to 10 breaths/min as per standard resuscitation guidelines. The Res-Q-Pod ITD (Advanced Circulatory Systems, Inc., Roseville, MN) also has a flashing light timed to prompt the appropriate ventilatory rate. When using it with a face mask, it is important to continuously maintain a tight seal between the patient's face and the mask during CPR to maintain efficacy of the ITD. This is best accomplished with a two-person ventilation technique in which one person holds the face mask and the second person squeezes the bag. If a pulse is restored, remove the ITD from the respiratory circuit.

Current data are conflicting on whether ITDs improve clinical outcomes when used as an adjunct to resuscitation efforts. Numerous studies and clinical trials using one particular model of ITD (Res-Q-Pod, Advanced Circulatory Systems, Inc.) have demonstrated improved hemodynamics during CPR and have suggested that use of an ITD during resuscitation

Figure 17.2 Impedance threshold device (ITD). The ITD is placed in-line between the mask or endotracheal tube and the bag-valve apparatus. This is the Res-Q-Pod; the flashing light indicator is used to time the respiratory rate. (Courtesy Advanced Circulatory Systems, Inc., Roseville, MN.)

efforts may lead to improved survival and patient outcomes.^{25,26} However, the findings from randomized controlled trials of ITD use in patients suffering out-of-hospital cardiac arrest have offered opposing data, thus suggesting that there is not a significant improvement in patient outcomes when these devices have been used.²⁷

Monitoring and Feedback Devices

Emphasis on CPR quality and minimizing interruptions has spurred the development of devices to monitor the quality of chest compressions and ventilations and then provide audio or visual prompts to improve performance. These devices aim to improve human delivery of CPR and, unlike ACD-CPR or the ITD, do not enhance hemodynamics or patient physiology directly.

One method of monitoring chest compressions involves placing a relatively small external device on the patient's sternum and performing chest compressions on top of the device (Fig. 17.3). The device measures the quality of compressions via a force detector or accelerometer (or both) that determines the rate and depth of chest compressions. Different versions of these CPR quality-monitoring and feedback devices are on the market. Some are incorporated into defibrillators (MRx-QCPR, Philips Healthcare, Andover, MA; R series with Real CPR Help, Zoll Medical Corp., Chelmsford, MA), whereas others are stand-alone devices applied to the chest. In trials, use of such a defibrillator with CPR monitoring and feedback improved CPR performance and, in one out-of-hospital and one in-hospital investigation, improved the rate of initial resuscitation.^{28,29} Further research will be required to assess the magnitude of improvement in survival that these devices can offer and what training mechanisms can maximize team responses to feedback messages.

Figure 17.3 Cardiopulmonary resuscitation–sensing defibrillator. The chest compression pad with force detector and accelerometer is indicated (*arrow*). Several such devices are currently marketed; this is the MRx-QCPR (Philips Healthcare, Andover, MA).

Mechanical CPR Devices

The adjuncts described previously all rely on human performance of CPR. Another general approach to improve CPR quality is to provide compressions via a mechanical device that is independent of human fatigue or vagaries in performance. Such tools have been introduced in previous decades but fell out of favor because of unwieldy design and other practical considerations.

A newer generation of devices has brought the notion of mechanical CPR back to active consideration. One such device uses a “load-distributing compression band” (Autopulse, Zoll Medical Corp.). The Autopulse device works via a wide band that is attached to a backboard and battery-powered motor and is placed across the torso. Through cycles of constriction and relaxation, the band compresses the chest in a circumferential manner at a fixed rate and depth consistent with resuscitation guidelines. In this fashion, pauses are also minimized by eliminating rescuer switching. Such devices have a unique role in out-of-hospital arrest because compressions can be delivered while transporting a patient down stairs or into an ambulance.

Studies to determine the efficacy of the Autopulse have had mixed results. Although initial smaller investigations appeared promising, a large multicenter randomized trial was stopped early because patients in the manual CPR arm had survival equivalent to those receiving care via the Autopulse, with a trend toward worse outcomes in the Autopulse group.³⁰

A separate nonrandomized trial showed a marked improvement in survival when using the device.³¹ A 2007 randomized trial in Europe demonstrated the utility and feasibility of automated compression devices (in this case the Autopulse) in the resuscitation of out-of-hospital cardiac arrest patients.³² A 2015 pragmatic trial in the United Kingdom, evaluating a mechanical CPR device known as LUCAS (Physio-control, Redmond, WA), demonstrated equivalency between mechanical CPR and traditional manual CPR.³³ The LUCAS device (Fig. 17.4 and Video 17.1), in contrast to the band mechanism of the Autopulse, uses a piston/suction cup to compress the

Figure 17.4 The LUCAS-2 mechanical cardiopulmonary resuscitation device (Physio-control, Redmond, WA).

anterior aspect of the chest, much like during manual CPR, with the suction cup providing some degree of active compression-decompression, as described earlier in this chapter.

To highlight an intriguing opportunity available with mechanical CPR devices, there has been much discussion about the potential utility of these tools in clinical situations in which coronary angiography might be performed concurrently with ongoing resuscitation efforts.^{34,35} If clinical evidence suggests a major coronary event as the cause of the arrest, mechanical devices could be used to perform high-quality, continuous chest compressions as percutaneous coronary intervention is being performed. Case studies have demonstrated the feasibility of using the LUCAS device during intraarrest coronary angiography with good patient outcomes,^{36,37} but additional data will be necessary to draw clearer conclusions about clinical practices and patient outcomes in these situations.

Extracorporeal CPR

Extracorporeal CPR (E-CPR) is an emergency technique that has been investigated as a “last resort” for cardiac arrest patients who have failed to achieve ROSC despite ongoing resuscitation efforts (Fig. 17.5). Several clinical studies have demonstrated successful outcomes for patients in whom E-CPR was used (and thus indicate that E-CPR could be a feasible addition to resuscitation efforts).^{35–37} One prospective trial in Japan, which identified patients who failed to respond to other traditional resuscitation efforts, demonstrated a favorable neurologic outcome in patients who were able to undergo both emergency cardiac bypass and therapeutic hypothermia treatment; rapid initiation of E-CPR and attainment of the target temperature were associated with positive neurologic outcomes in this cohort.³⁸ The specialized training necessary to perform the procedure, as well as significant logistic issues surrounding rapid establishment of extracorporeal membrane oxygenation (Video 17.2) in the ED setting, raises concern about the widespread applicability of this intervention. Other investigations have highlighted the potential complications related to E-CPR in these critically ill patients.^{39,40} Additional research is needed on this topic, and more information will be necessary to clearly identify patients who are likely to benefit from E-CPR,

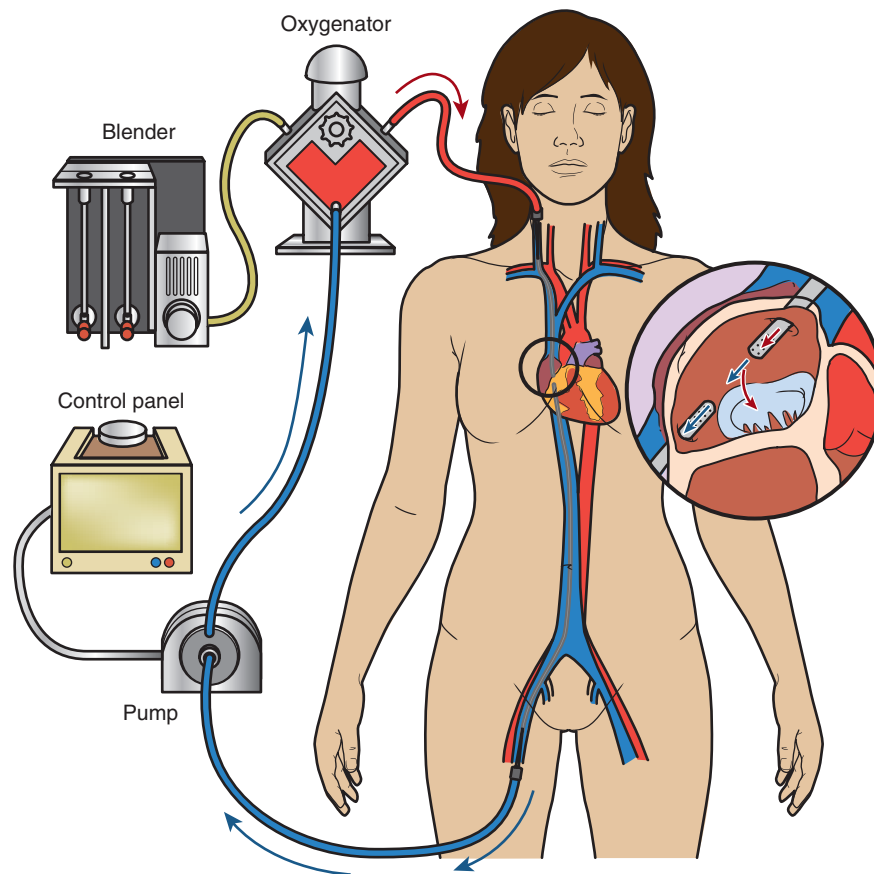

Figure 17.5 Extracorporeal cardiopulmonary resuscitation (E-CPR). Venous blood is withdrawn from a central vein (blue arrows), pumped through an oxygenator, and reinfused into a central vein (red arrow). Further research is required in this experimental procedure, which may benefit a select cohort of cardiac arrest victims. Currently E-CPR is restricted to institutions which have access to the highly trained personnel and equipment required to execute this complex procedure. (Modified from Abrams D, Combes A, Brodie D: Extracorporeal membrane oxygenation in cardiopulmonary disease in adults: *J Am Coll Cardiol* 2014;63(25_Pt A):2769–2778.)

examine the cost of such an intervention, and determine the impact of E-CPR on the survival of cardiac arrest victims.⁴¹

MONITORING DURING CPR

Overview of CPR

Despite extensive research and attempts to alter the outcome of cardiac arrest, it is discouraging to realize that at present, there are no reliable clinical criteria that clinicians can use to assess the efficacy of CPR. Although PETCO₂ serves as an indicator of the cardiac output produced by chest compressions and may indicate ROSC, there is little other technology available to provide real-time feedback on the effectiveness of CPR. Pulse oximetry is not helpful during arrest. Early defibrillation has been linked to better survival rates, but no medications have been shown to improve neurologically intact survival from cardiac arrest. Despite the widespread use of epinephrine and several studies of vasopressin, no placebo-controlled study has shown that any medication or vasopressor given routinely during human cardiac arrest (for any initial arrest rhythm) increases the rate of long-term survival after cardiac arrest.

Arterial blood gas monitoring during cardiac arrest is not a reliable indicator of the severity of tissue hypoxemia, hypercapnia (and therefore the adequacy of ventilation during CPR), or tissue acidosis. Current evidence in patients with ventricular fibrillation neither supports nor refutes the routine use of intravenous fluids. There is no evidence that any antiarrhythmic drug given routinely during human cardiac arrest increases survival to hospital discharge. There is insufficient evidence to recommend for or against the routine use of fibrinolysis for cardiac arrest.

No blood testing is considered routine or standard during the initial stages of cardiopulmonary arrest, although early serum potassium and blood glucose monitoring is prudent if resuscitation is successful.¹⁴

Capnography

Capnography measures respiratory CO₂, which is delivered to the lungs and expelled during exhalation (Fig. 17.6). The highest CO₂ levels occur at the end of each exhalation, called PETCO₂. During cardiac arrest, PETCO₂ falls abruptly at the onset of cardiac arrest, increases during the delivery of effective CPR, and returns to physiologic levels after ROSC. PETCO₂

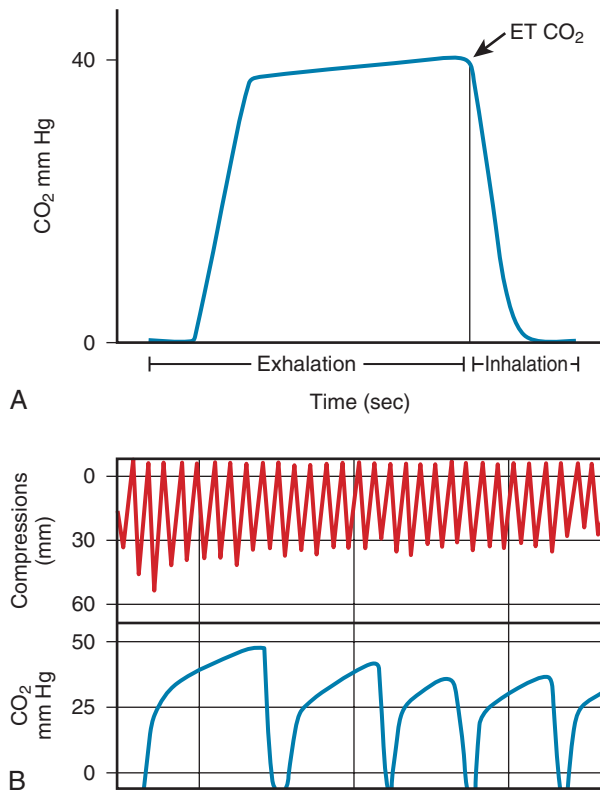

Figure 17.6 Waveform capnography during cardiac arrest. **A**, PETCO₂ diagram showing a typical ventilation cycle and CO₂ waveform. The point that represents PETCO₂ is marked with an *arrow*. **B**, PETCO₂ recording during cardiopulmonary resuscitation. This image demonstrates the use of capnography during ongoing resuscitation. The chest compression waveform is shown in red (*top panel*), and the PETCO₂ waveform is shown in blue (*bottom panel*). ET CO₂, End tidal CO₂.

correlates with cardiac output under low-flow states such as CPR.⁴² Because of this relationship with cardiac output, PETCO₂ has been regarded as a probable indicator of the quality of CPR. During effective CPR in animal trials, PETCO₂ positively correlates with cardiac output, coronary perfusion pressure, efficacy of cardiac compression, ROSC, and even survival. Research is currently being done to further understand the use of PETCO₂ during CPR. At the other end of the spectrum, PETCO₂ could be useful in determining when to terminate resuscitation efforts.⁴³

Although capnography is a common method of confirming correct endotracheal tube placement, it has also been regarded

as a potential method of measuring hemodynamics and perfusion during cardiac arrest, as well as for determining the outcome of resuscitation efforts (specifically, detection of ROSC). The 2015 resuscitation guidelines recommend continuous waveform capnography for all intubated patients during resuscitation efforts.¹⁴

Ultrasound Monitoring

With advances in ultrasound equipment, properly trained users can portably and accurately monitor cardiac function in real time. Preliminary studies have demonstrated that trained physicians can assess cardiac function and obtain adequate images rapidly by using a subcostal approach to standard echocardiography in the cardiac arrest setting.⁴⁴ If you are adequately trained in this technology, use it during resuscitation efforts to clinically diagnose conditions such as pulseless electrical activity (PEA) and to make a global assessment of cardiac motion during CPR and pulse restoration. Use ultrasound during arrest to rapidly diagnose and treat conditions such as cardiac tamponade. Get the ED ultrasound machine ready to use when preparing for an incoming cardiac arrest. Remember, however, that ultrasound is only a secondary diagnostic adjunct and should not interfere with the performance of high-quality CPR. Minimize interruptions to perform ultrasound and use it only during resuscitation for specific purposes (e.g., diagnosis of PEA versus hypotensive sinus rhythm). In most cases of arrest, ultrasound is probably of little value. Finally, there is ongoing research on the use of transcranial Doppler ultrasound to determine the prognosis after cardiac arrest. One preliminary study concluded that patients with severely disabling or fatal outcomes could be identified within the first 24 hours with this method.⁴⁵

CONCLUSION

Physicians and other health care workers have been performing CPR for more than 50 years, but only since the 1990s has the full importance of the quality of CPR become apparent through an evidence-based approach. Chest compressions and ventilations appear to be deceptively easy to the newly trained, but in fact they are highly complex skills and are difficult to perform well under stress. New technologies have been developed to assist in delivery of CPR, and use of these tools may improve the ability to save lives from cardiac arrest in the coming years.

Resuscitative Thoracotomy

Russell F. Jones and Emanuel P. Rivers

In the United States trauma is the leading cause of death in people aged 1 through 44.¹ Blunt trauma accounts for the majority of trauma mortality overall, but in urban settings penetrating trauma, including firearm-related injuries, accounts

for an increased proportion of trauma deaths. In 2013, more than 33,000 firearm-related deaths occurred in the United States,² with many victims arriving at the emergency department (ED) in extremis.

Severe traumatic injuries can be associated with a very high mortality rate. However, on rare occasions an aggressive approach involving the use of emergency department thoracotomy (EDT) leads to survival in patients with impending or recent traumatic arrest. EDT is a dramatic, heroic intervention performed outside the operating room and often in the absence of trained cardiothoracic or trauma surgeons. Though supported as a potential lifesaving procedure, EDT is not a mandated standard of care nor a procedure that is expected

Resuscitative Thoracotomy

Indications

Trauma victims with severe refractory instability or cardiac arrest
Nontraumatic hypothermic cardiac arrest

Contraindications

Blunt trauma cardiac arrest patients without signs of life
Trauma patients with obvious non-survivable injuries
Initial rhythm of asystole without signs of life
Signs of prolonged arrest including lividity or rigor

Complications

Phrenic nerve injury
Coronary artery injury
Infection
Injury/disease transmission to health care worker

Equipment

Review Box 18.1 Resuscitative thoracotomy: indications, contraindications, equipment, and complications.

to be performed in most EDs. The first successful thoracotomy was reported more than 100 years ago, and the first EDT was reported in 1966.³ Since then, multiple studies have reported outcomes, indications, techniques, and risks associated with the procedure. In 2003, the National Association of EMS Physicians Standards and Clinical Practice Committee and the American College of Surgeons Committee on Trauma (ACSCOT) proposed specific guidelines for EDT.⁴ Several other guidelines have been published without consensus guidelines on the ideal candidates for EDT.^{5,6}

Given the circumstances surrounding the procedure and the associated injuries, few patients survive. The poor overall survival rates, however, should not discourage performance of the procedure in the correct setting and when appropriate surgical backup is available for definitive care.

▶ EDT is not a simple procedure (Video 18.1). Identifying specific structures within a chest cavity filled with blood, coupled with a collapsed lung and an injured heart and major vessels, can be formidable. Localizing the injuries that can be reversed quickly and safely is even more difficult.

This chapter focuses on three major objectives: (1) identifying possible indications for and contraindications to EDT, (2) describing the technical aspects of the procedure and adjunctive maneuvers to repair specific injuries, and (3) recognizing the associated risks and complications.

Because of the controversies surrounding EDT, every institution should have guidelines for its appropriate use. An institutional plan for chest wound management and postprocedural care should also be established with the service that will provide backup when members of the surgical team cannot be on site at the time of resuscitation. Debate regarding who should perform EDT is not necessary because everyone who is licensed to perform resuscitative thoracotomy should be trained, competent, and prepared for the technical and initial critical care aspects of patient management. Patient care needs in the event of successful resuscitation should be considered in advance and the surgical and intensive care teams notified so that they can mobilize the appropriate supplies, equipment, and personnel.

INDICATIONS AND CONTRAINDICATIONS

In the ED the vast majority of thoracotomies are performed on penetrating trauma patients in cardiac arrest. Beall and coworkers initially proposed EDT for the treatment of penetrating cardiac injuries in 1966.³ Since then it has been expanded to include extrathoracic injuries, blunt trauma, and nontraumatic pathology. Studies show wide variation in survival rates and outcomes. Taking 50 years of collective EDT data into account, the survival rate of patients undergoing EDT for blunt trauma is nearly 2%, whereas that for penetrating trauma is nearly 10%,⁵ but these survival rates depend on many variables and are not applicable to every situation. There is a paucity of data concerning survival rates in patients with EDT performed for nontraumatic causes, and it is not recommended that this procedure be regularly used in these settings.

Make the decision to perform EDT quickly based on whether the patient is likely to benefit from the procedure, has a reasonable chance of survival, and cannot tolerate a delay in operative intervention. In addition, consider the risks associated with performing the procedure. Trauma researchers have identified

BOX 18.1 Factors Used to Determine Which Patients May Benefit From EDT

- Mechanism of injury
- Location of injury
- Initial cardiac rhythm
- Resuscitation (cardiopulmonary) time
- Signs of life

several factors that are considered crucial when determining who will benefit from EDT (Box 18.1).

The first assessment is made in the prehospital setting, where determination of the mechanism of injury and the presence or absence of a pulse is critical. Multiple guidelines recommend against EDT in patients without a pulse, blunt traumatic mechanisms, and without signs of life.⁴⁻⁶ Such patients do not survive, regardless of the intervention. In one of the largest EDT series to date, Branney and coworkers⁷ reviewed 868 consecutive patients over a 23-year period. They found that no blunt trauma patients survived EDT when they had no vital signs in the field, but that 2.5% of blunt trauma patients survived EDT when vital signs were present in the field. In 2000 Rhee and colleagues⁸ examined 4620 cases of EDT from 24 studies over a 25-year period. The overall survival rate after blunt trauma was just 1.4%, which led to EDT falling out of favor for this indication. Recent articles have challenged the idea of limiting EDT to those in cardiac arrest from penetrating injury only.^{5,6,9-11}

The survival rate of pulseless trauma patients sustaining penetrating injury is significantly higher than that of blunt trauma patients. Several penetrating injury subtypes have been studied as follows: firearm injuries, stab wounds, and penetrating explosive injuries. Thoracic stab wounds consistently show the highest rates of survival after EDT.^{5,7,12-14} This is theoretically as a result of the decreased amount of tissue damage related to the weapon and the ability to quickly identify anatomic structures and injuries. Penetrating firearm injuries are more likely to result in death because of increased tissue damage from the missile and concussive surrounding forces. Patients with firearm injuries are more likely to have multiple wounds, and the depth of penetration is increased in comparison to stab wounds. One published cohort of combat casualties from explosive penetrating injuries reported similar survival rates to those after firearm-related penetrating injuries.¹⁴

The location of the penetrating injury helps determine the futility of EDT. A trend toward increased survival rates in patients with thoracic injuries was found in historical data.^{4,5,14-23} Isolated cardiac wounds have the highest survival rate after EDT, with approximately 17% of patients surviving the procedure.⁵ Penetrating abdominal injuries have beneficial outcomes when EDT is performed to cross-clamp the aorta, with survival rates in the midteens.^{7,14,24,25} Extremity injuries rarely require EDT because the use of a tourniquet can control the hemorrhaging until the patient can be transported to the operating room. When EDT is used for traumatic extremity exsanguination survival rates range from 10% to 25%.¹⁴ Patients in cardiac arrest associated with head injuries, especially those with open cranial wounds, have dismal survival rates and are considered poor candidates for further resuscitative efforts, including EDT.^{5,9}

The type of cardiac electrical activity can be helpful in determining who may benefit from EDT. Battistella and colleagues²⁶ reviewed 604 patients undergoing cardiopulmonary resuscitation (CPR) for traumatic cardiopulmonary arrest and found that of the 212 patients who were in asystole, none survived. Fulton and associates²⁷ found that of patients in traumatic arrest, survival was improved when the patients exhibited ventricular fibrillation, ventricular tachycardia, or pulseless electrical activity rather than asystole or an idioventricular rhythm. In another study of EDT for traumatic arrest, asystole, idioventricular rhythm, or severe bradycardia was indicative of poor outcomes or an unsalvageable patient.⁴

The duration of pulselessness prior to EDT has traditionally been used as a decision point. With traumatic injury, survival rates and meaningful neurologic outcomes diminish as the duration of CPR increases. The traditional dogma is that any trauma patient who has undergone CPR for longer than 15 minutes has an exceedingly dismal survival rate and further resuscitation should be considered futile.^{4,6,12,13,27–30} Guidelines from 2013 have questioned the 15-minute dogma and consensus timing on futility of the procedure remains elusive.^{5,31} It is recommended that each institution should develop protocols directing futility decision as it pertains to timing of pulseless activity prior to arrival of the patient in the ED.

Perhaps the most critical determinant of the appropriateness of EDT is whether the patient demonstrates “signs of life.” Signs of life are objective physiologic parameters that are present in patients who survive EDT. They include pupillary response, extremity movement, cardiac electrical activity, measurable or palpable blood pressure, spontaneous ventilation, or the presence of a carotid pulse. The presence of one or more of these indicators has been associated with good neurologic outcomes and increased rates of survival.^{3–11,32}

Although survival remains the ultimate gauge of the effectiveness of EDT, it is also essential to consider quality of life, especially neurologic function of the patient. It is somewhat surprising that survivors of EDT generally have good neurologic outcomes. Rhee and colleagues⁸ reported that 280 of 303 (92.4%) patients discharged after EDT were neurologically intact. It is not possible to accurately predict which patients are likely to survive intact, but the study by Branney and coworkers⁷ demonstrated that all survivors with full neurologic recovery had respiratory effort at the scene, and 75% still had respiratory effort on arrival at the ED. The presence or absence of a palpable pulse was not an absolute prognostic indicator in this study. The first 24 hours after EDT rapidly demonstrates which patients are likely to become long-term survivors. Baker and associates¹⁶ showed that with 168 emergency thoracotomies for mixed trauma, most patients with fatal injuries died within 24 hours. Of patients surviving the first 24 hours, 80% (33 of 41) lived and were discharged from the hospital. Full neurologic recovery occurred in 90% of these survivors. Overall only 2.4% (4 of 168) remained severely disabled or in a persistent vegetative state. Guidelines from 2015 show 90% of penetrating trauma patients surviving EDT were neurologically intact on discharge, although this rate falls to near 60% in blunt trauma.⁵

Cardiac Injuries—Penetrating

Sixty percent to 80% of cardiac stab wounds result in pericardial effusion regardless of the presence of shock.³³ Tamponade can occur if the wound is smaller than 1 cm in size, depending on which chamber is involved. Wounds larger than 1 cm usually

continue to bleed regardless of which chamber is involved. Low-pressure atrial wounds generally form a thrombus before tamponade develops. The thicker-walled left ventricle may spontaneously seal stab wounds up to 1 cm in length. As little as 60 to 100 mL of blood acutely filling the pericardium will impede diastolic filling, reduce stroke volume, decrease cardiac output, and increase release of catecholamine. Catecholamine release may mask the severity of illness because it maintains blood pressure through an increase in peripheral vascular resistance. In penetrating cardiac injury, the right ventricle is the chamber most likely to be involved because of its anterior location, followed by the left ventricle and the atria.^{34,35}

The progression from compensated cardiac function to uncompensated tamponade can be sudden and profound. Although one may suspect tamponade based on well-described signs, clinical diagnosis of pericardial tamponade in an unstable trauma patient is difficult because of the combined effect of hemorrhagic and cardiogenic shock. The classic signs of Beck’s triad (distended neck veins, hypotension, and muffled heart sounds) described in 1926³⁶ have limited diagnostic value for acute penetrating cardiac trauma.³⁷ The most reliable signs of tamponade are elevated central venous pressure, hypotension, and tachycardia.

The advent of ultrasound and the focused assessment with sonography in trauma (FAST) examination has improved the diagnosis of pericardial effusion and tamponade. Findings indicative of tamponade include the presence of pericardial fluid with right atrial or ventricular collapse during diastole (Fig. 18.1). FAST is a rapid bedside screening examination used to detect hemopericardium and hemoperitoneum and is now important in the evaluation of unstable trauma patients.^{38,39} From data collected in 1540 patients, Rozycki and associates⁴⁰ reported 100% sensitivity and specificity in detecting pericardial and peritoneal fluid in a hypotensive, unstable trauma patient.

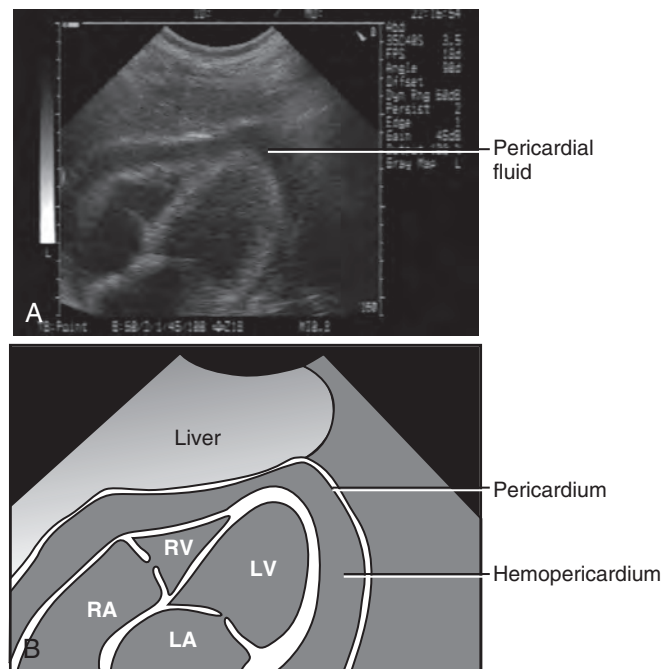

Figure 18.1 A, Bedside ultrasound demonstrating the hemopericardium. B, Artist’s drawing of the chambers of the heart, the pericardium, and the hemopericardium as seen on ultrasound. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Ultrasound can have rare false-negative results when pericardial fluid from a cardiac injury decompresses into the thoracic cavity through a wound in the pericardium.⁴¹ A 2015 study by Inaba and colleagues showed a high sensitivity and negative predictive value of FAST exam in determining which patients will not benefit from EDT.⁴² In this study the likelihood of survival if pericardial fluid and cardiac motion were both absent was zero.

After EDT for penetrating cardiac wounds, survival is also related to the mechanism of injury. Patients with stab wounds fare better than do patients with gunshot wounds. Rhee and colleagues⁸ noted that 16.8% of patients with stab wounds survived to hospital discharge after EDT. Branney and coworkers⁷ reported a 29% survival rate in stab wound patients with tamponade, and a 15% survival rate in those without tamponade.

In contrast, gunshot wounds are often large injuries unable to seal themselves; tamponade occurs in only 20%. Patients with penetrating cardiac injuries from gunshot wounds are more likely to initially be seen with profoundly compromised hemodynamics. In addition, the increasing popularity of larger-caliber weapons has made it more difficult to resuscitate patients with gunshot wounds to the chest. Of 112 patients with gunshot wounds to the heart,⁷ only 2% survived neurologically intact.

Cardiac Injuries—Blunt

Blunt trauma to the heart can range from minor contusion to cardiac rupture. The most common cause of death after nonpenetrating cardiac injuries is myocardial rupture, and in approximately 25% of such patients the ascending aorta is ruptured simultaneously.³³ Branney and coworkers⁷ observed a 2% survival rate in blunt trauma patients resuscitated with EDT. Those who survived had vital signs present in the field. The poor outcomes associated with this type of injury are a result of the poor cardiac function caused by myocardial contusion, even if the hemorrhage has been treated.

Pulmonary Injuries

Pulmonary injuries can be divided into three types: parenchymal, tracheobronchial, and large vessel. Parenchymal and tracheobronchial injuries rarely require EDT because they are either rapidly fatal or treated initially by tube thoracostomy. Tracheobronchial injury is more common in blunt than in penetrating trauma. Bertelsen and Howitz⁴³ reviewed 1128 patients at autopsy and found only three to have this injury. The airway is usually maintained, even with complete transection. The stiff tracheobronchial cartilage tends to hold the lumen open, and the paratracheal and parabronchial fasciae preserve the relationship of the proximal to distal bronchi. Ninety percent of tracheobronchial tears occur within 2.5 cm of the carina and most commonly involve the main stem bronchi. Complete division of the trachea is extremely rare. Depending on the size and location of the injury, patients may have massive hemoptysis, airway obstruction, pneumomediastinum, pneumothorax, or tension pneumothorax. Massive subcutaneous emphysema and pneumomediastinum are usually seen, although up to 10% of patients with this injury have no abnormal findings on the initial radiograph.⁴⁴ If hemorrhage is profuse or if the site of the injury can be determined, use of a bifid endotracheal tube or unilateral intubation of a main stem bronchus will help secure the airway.

Lacerations of the lung parenchyma that are not accompanied by injury to major vessels generally respond to tube thoracostomy. If the initial chest tube drainage is more than 1500 mL or if there is persistent hypotension or cardiac arrest, consider immediate thoracotomy. For pulmonary injuries, survival after EDT is also related to the mechanism of injury. Branney and coworkers⁷ reported a 17% survival rate after pulmonary stab wounds, 3% after gunshot wounds, and 5% after blunt trauma.

AIR EMBOLISM

Air embolism is a complication of pulmonary parenchymal injuries that may require immediate thoracotomy if the patient is hemodynamically unstable. The development of air embolism after penetrating injuries of the lung is often insidious, and the diagnosis is usually made at the time of thoracotomy.⁴⁵ Preoperative and postmortem diagnosis of air embolism is difficult, and it is likely that most air emboli are not detected. Air embolism is confirmed at thoracotomy by needle aspiration of a foamy air-blood mixture from the left or right ventricle or by visualization of air within the coronary arteries.

Air embolism may appear in either the right or the left side of the circulatory system. Involvement of the right side of the circulation is referred to as *venous* or *pulmonary* air embolism. Generally, venous air is well tolerated, but death can occur when the volume of air reaches 5 to 8 mL/kg. The rate at which air moves into the circulation and the body's position are important determinants of the volume that can be tolerated. If the body's position allows dispersion of air into the peripheral circulation, more air can be tolerated, although the damage to peripheral structures and end-organs can be extensive. Rapid death usually results from obstruction of the right ventricle or the pulmonary outflow tract. Injuries to the vena cava or the right ventricle can also create portals of entry into the right circulatory system.

Air embolism involving the left side of the circulatory system is referred to as *arterial* or *systemic* air embolism. The lethal volume depends on the organs to which it is distributed. As little as 0.5 mL of air in the left anterior descending coronary artery can lead to ventricular fibrillation. Two milliliters of air injected into the cerebral circulation can be fatal. The formation of traumatic bronchovenous fistulas creates potential entry points for air to move into the left side of the circulatory system. The only requirement is the formation of an air-blood gradient conducive to the inward movement of air. Although lowered intravascular pressure from hemorrhage is a risk factor, the most important element in all reports of air embolism has been the use of positive pressure ventilation.⁴⁶

In a review of 447 cases of major thoracic trauma, Yee and coworkers⁴⁷ found adequate chart data to suggest the diagnosis of air embolism in 61 patients. Approximately 25% of patients with air embolism have blunt trauma, with associated lung injury secondary to multiple rib fractures or hilar disruption. The overall mortality is higher than 50%.

The diagnosis of air embolism is easily overlooked because the signs and symptoms are similar to those of hypovolemic shock. Two valuable signs that are present in 36% of patients are hemoptysis and the occurrence of cardiac arrest *after intubation and ventilation*. The development of focal neurologic changes, seizures, or central nervous system dysfunction in the absence of head injury is also suggestive of the diagnosis.⁴⁸ Overall, the diagnosis is subtle and must be considered when

there is no evidence of the more common causes of extremis in a trauma patient.

Blunt and Penetrating Abdominal Injury

In the setting of penetrating abdominal injury, thoracotomy with cross-clamping of the thoracic aorta has been advocated as a means of controlling hemorrhage, redistributing blood flow to the brain and heart, and reducing blood loss below the diaphragm. Unfortunately, aortic cross-clamping can also have detrimental effects. Kralovich and colleagues⁴⁹ studied the hemodynamic consequences of aortic occlusion in a swine model of hemorrhagic arrest. There was no difference between groups in return of spontaneous circulation; however, the occluded aorta group experienced statistically greater impairments in left ventricular function and systemic oxygen utilization in the postresuscitation period. Branney and coworkers⁷ found that 8 of 76 patients undergoing EDT for *penetrating abdominal injury* survived neurologically intact. More recently, Seamon and colleagues²⁵ achieved a 16% survival rate with good neurologic outcomes (8 of 50 patients) when EDT was used before laparotomy for abdominal exsanguination from trauma. Of note, none of the survivors in this study were in cardiac arrest at the time of EDT, but they did have severe hemorrhagic shock, and six of the eight had unmeasurable blood pressure. The resurgence of resuscitative endovascular balloon occlusion of the aorta (REBOA) has changed many institutional trauma algorithms dealing with exsanguinating abdominal and pelvic hemorrhage.⁵⁰ Current recommendations suggest that EDT be performed judiciously in patients with abdominal trauma as an adjunct to definitive repair of the abdominal injury.

Open-Chest Resuscitation for Nontraumatic Arrest

At present, less than 6% of CPR attempts conducted outside hospital special care units result in survival.⁵¹ The first case of a human survivor of open-chest cardiac massage (OCCM) was reported in 1901. In 1960, Kouwenhoven and associates⁵² published favorable survival rates with closed-chest CPR as opposed to OCCM. After further refinement by Pearson and Redding, closed-chest CPR gradually became the preferred method of cardiac compression.⁵³

The goal of CPR is to restore coronary perfusion pressure (CPP), which is the prime determinant for return of spontaneous circulation as established in animal models. Paradis and associates⁵⁴ found that humans need a minimal CPP of 15 mm Hg to achieve return of spontaneous circulation. Although a CPP of 15 mm Hg does not guarantee return of spontaneous circulation, there is 100% failure of resuscitation if CPP is below this level. Despite the limited number of human studies on OCCM, its hemodynamic superiority over closed-chest CPR is compelling. Del Guercio and coworkers⁵⁵ measured cardiac output during both closed-chest CPR and OCCM in in-hospital cardiac arrest patients. OCCM produced a mean cardiac index of 1.31 L/min per m² as opposed to 0.6 L/min per m² during closed-chest CPR. Boczar and colleagues⁵⁶ further examined 10 patients who were unresponsive to closed-chest CPR and measured CPP during closed-chest CPR followed by OCCM. Mean CPP in the closed-chest group was 7.3 mm Hg versus 32.6 mm Hg in the open-chest group. All patients achieved a CPP of at least 20 mm Hg at some time during their OCCM phase. This easily surpassed the minimal CPP required for

return of spontaneous circulation. Outcomes after OCCM have not been well established. Animal models suggest not only improved hemodynamic parameters, but also a possible increase in 24-hour survival rates.⁵⁷ However, neurologic outcomes are unknown, and the American Heart Association guidelines for CPR do not promote the regular use of OCCM in patients with out-of-hospital cardiac arrest.⁵¹

At present, the precise indications for open-chest resuscitation after nontraumatic arrest are not well defined, and the procedure is not considered the standard of care. Despite demonstrated hemodynamic superiority in both animal and human models of open-chest versus closed-chest CPR, outcome benefit is lacking. There is a paucity of human data evaluating the window of time during which this treatment can be effective.

Nontraumatic Hypothermic Cardiac Arrest

In the setting of cardiac arrest from hypothermia, one can consider the use of EDT and OCCM. Cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation are the most rapid methods of core rewarming,⁵⁸ but these methods are sometimes not available immediately. Open thoracotomy with mediastinal irrigation has been used successfully in cases of severe hypothermia with cardiac arrest. Brunette and McVaney⁵⁹ reported 11 patients with hypothermic cardiac arrest, 7 of whom underwent EDT with OCCM and mediastinal rewarming. Five patients survived, and all had positive neurologic outcomes despite cardiac arrest times of between 10 and 90 minutes (although one patient died of gastrointestinal hemorrhage and sepsis following resuscitation; the other four patients survived with full neurologic recovery). The other four patients who did not undergo EDT did not survive despite being taken promptly to the operating room for CPB rewarming. Although the number of cases is limited, this study is evidence that OCCM can provide prolonged hemodynamic support and good neurologic outcomes. It should be noted that similar case reports also exist in which closed-chest CPR was maintained for prolonged periods and resulted in successful hypothermic resuscitation.⁶⁰ EDT with mediastinal irrigation can produce core rewarming rates as fast as 8°C/hr, with the heart and lungs preferentially being rewarmed first.⁵⁹ Mediastinal irrigation involves heating sterile saline in a microwave oven to 40°C and then pouring it slowly over the heart and into the thorax. Performing a thoracotomy for hypothermic arrest does not preclude the use of CPB inasmuch as it was subsequently used after EDT in three of the survivors from the Brunette and McVaney study.⁵⁹

EQUIPMENT

Carefully select the instruments to be included in the EDT equipment tray. See Review [Box 18.1](#) for a complete list.

PROCEDURE

Preliminary Considerations

All trauma patients arriving at the ED with hypotension must be assumed to be hypovolemic and should be treated accordingly. Rapidly exclude other causes as well, including tension

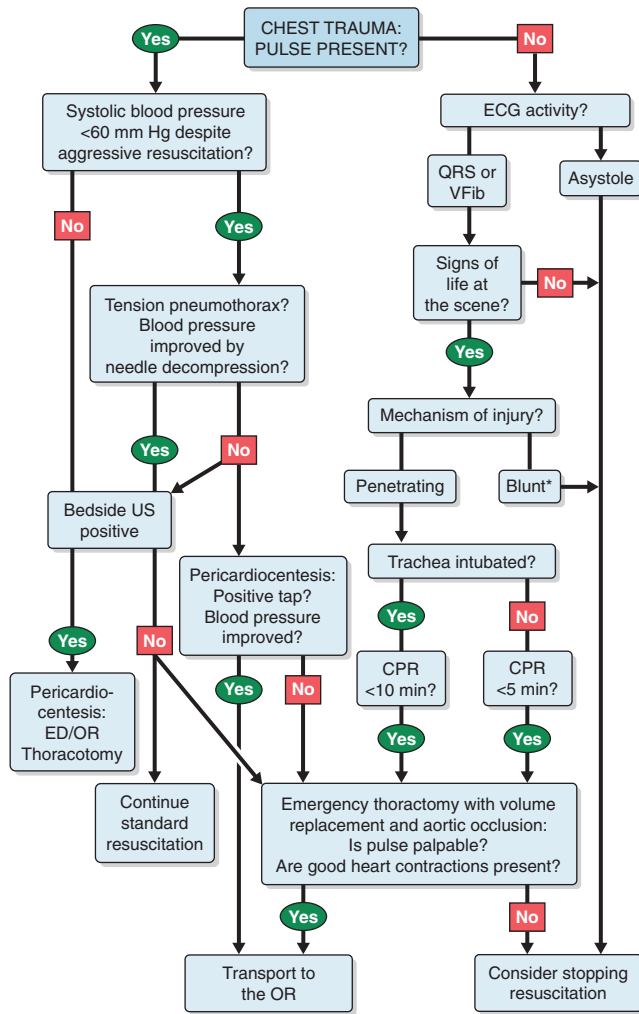

Figure 18.2 An algorithmic approach to chest trauma. *Pulseless blunt trauma management is controversial with some data supporting stopping resuscitation immediately, whereas recent data recommend EDT if CPR has been ongoing less than 5 minutes. QRS, Organized electrical activity; TAP, pericardial tap yielding blood; US, ultrasonography; VFib, ventricular fibrillation.

pneumothorax, cardiac tamponade, air embolism, and neurogenic or cardiogenic shock. A useful algorithmic overview of the approach to chest trauma is presented in Fig. 18.2. The use of autotransfusion, if available, has several benefits, but its use is not widespread or considered standard.⁶¹

Airway Control

Intubate the patient orotracheally, if possible, but be aware that access to the thoracic organs, surgical repairs, or surgical procedures may be hampered by frequent inflations of the left lung. If necessary, selectively intubate the right lung by blindly advancing a standard single-lumen endotracheal tube to a depth of 30 cm (measured from the corner of the mouth) in adult patients.⁶² Although the left lung and the right upper lobe are not ventilated with the tracheal tube in this position, both animal studies and data from humans suggests that selective right lung ventilation provides adequate oxygenation and ventilation for at least 60 minutes.⁶² With the left lung deflated

one can expedite thoracotomy by maximizing space in the left thoracic cavity. Keep in mind that extending the thoracotomy into the right thoracic cavity may necessitate switching to bilateral lung ventilation or left lung ventilation to allow maximum right thoracic exposure.

Anesthesia and Amnesia

Comatose patients undergoing resuscitation may regain consciousness during successful EDT, but this awareness may not be apparent if they are still pharmacologically paralyzed. Anticipate and recognize this phenomenon and administer adequate analgesic, amnesic, and muscle-relaxing agents to a ventilated patient who may also be in shock. No specific regimen has been studied, but ketamine appears to be an ideal agent to use in the ED. It is prudent to administer anesthetic agents routinely if a paralyzed patient demonstrates perfusion during resuscitation. This is not only humane but decreases systemic oxygen consumption.

Anterolateral Thoracotomy Incision

Manually ventilate the patient during the procedure. Ask an assistant to pass a nasogastric tube, which helps differentiate the esophagus from the aorta, but do not allow this procedure to delay thoracotomy. If CPR is being performed, ask an assistant to continue closed-chest compressions up to the point of making the initial incision. Take universal precautions to avoid blood exposure and use a suction catheter to minimize contact with blood. Sterile gloves (consider double-glove protection), gown, mask with an eye shield, and an operative surgical cap are recommended for the procedure.

Prepare the skin of the left anterior aspect of the chest with antiseptic if readily available. Wedge towels or sheets under the left posterior part of the chest and place the patient's left arm above the head (Fig. 18.3A). On the left side of the chest, make an anterolateral incision at the fourth to fifth intercostal space with a No. 20 blade scalpel (Fig. 18.4, step 1). Do not take the time to count ribs; simply estimate the location to be just beneath the nipple in males and at the inframammary fold in females (see Fig. 18.3). It is important to establish wide exposure by beginning the incision on the right side of the sternum and extending the skin incision past the posterior axillary line. Beginning here will save time if the right side of the chest needs to be opened as well. Inadequate exposure, rib fractures, and additional delays occur when the skin incision is too limited. With the first sweep of the scalpel, separate skin, subcutaneous fat, and the superficial portions of the pectoralis and serratus muscles.

Cut the intercostal muscles with scissors to expose the thoracic cavity (see Fig. 18.4, step 2). Use scissors to divide the intercostal muscles because the risk for lung laceration is greater when a scalpel is used. Make the incision just over the top of the rib to avoid the intercostal neurovascular bundle. Just before opening the pleura, stop ventilations momentarily. This will allow the lung to collapse away from the chest wall. Should the internal mammary artery be transected during the procedure, hemorrhage is generally minimal until after perfusion is reestablished, at which time bleeding may be profuse. If actively bleeding, the internal mammary artery should be ligated or clamped. Do not forget to address the internal mammary artery if perfusion is reestablished because this can be a source of significant bleeding.³²

Figure 18.3 Left anterolateral thoracotomy. **A**, Place several towels or sandbags under the left scapula and raise the arm above the head. The patient should be intubated. Insert a nasogastric (NG) tube to differentiate the esophagus from the aorta. Make a left anterolateral submammary incision. **B**, Dashes indicate the incision site in the inframammary fold in women. *ET*, Endotracheal.

Resuscitative Thoracotomy General Technique

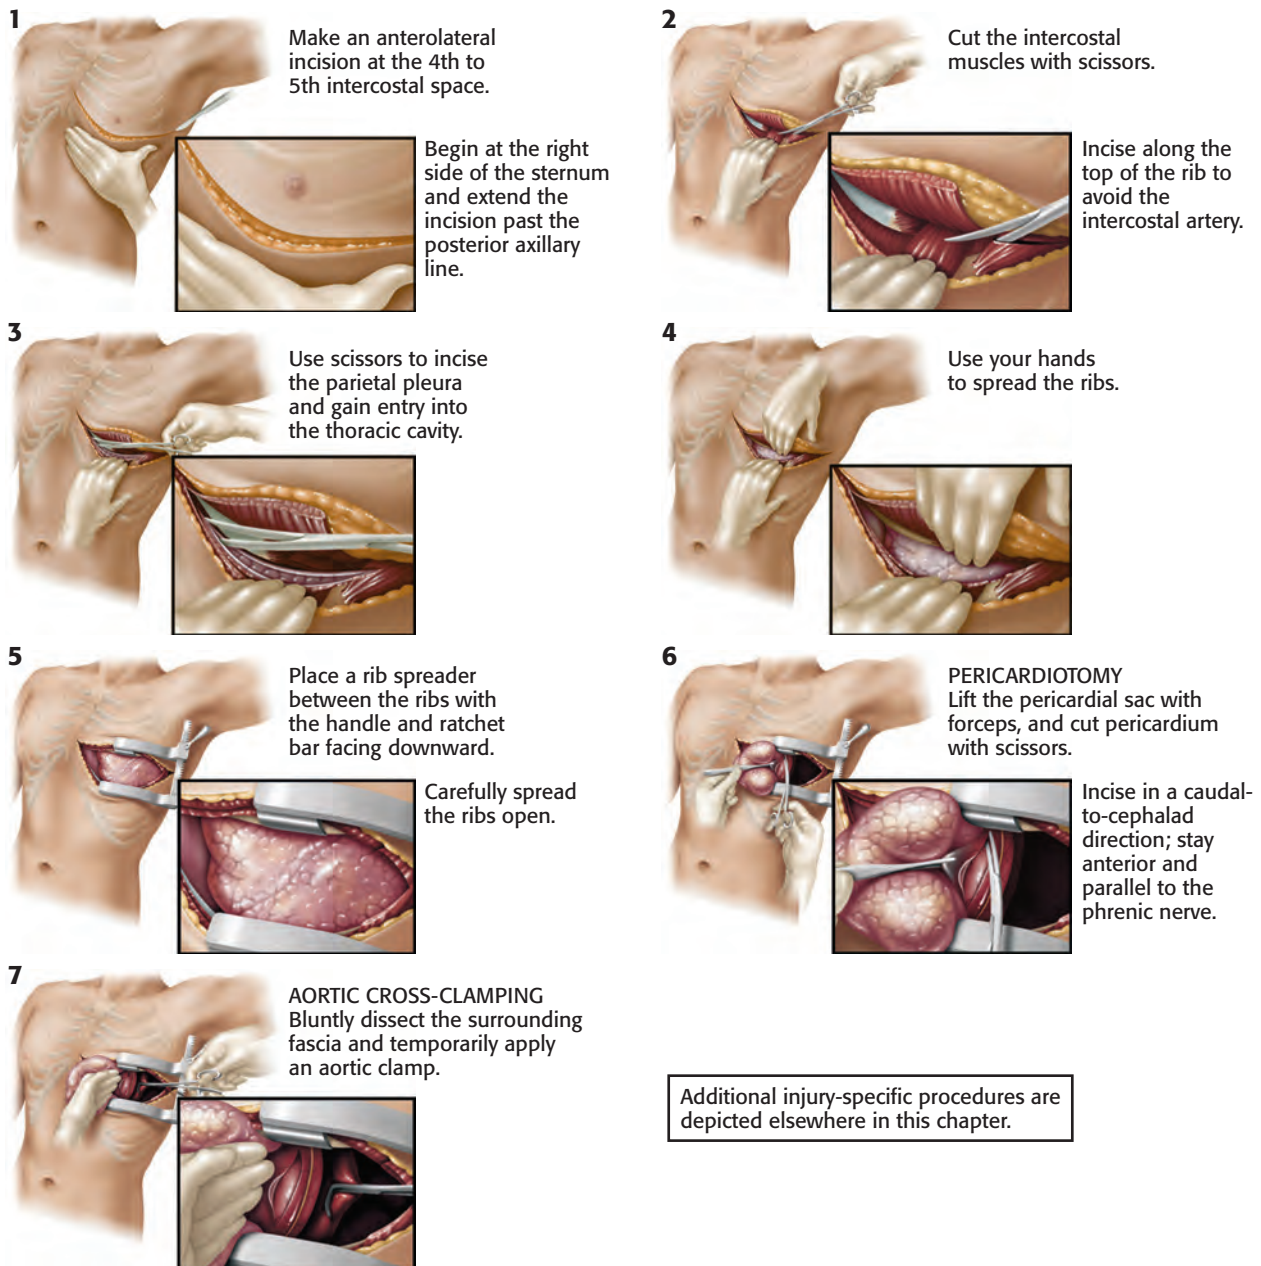

Figure 18.4 Resuscitative thoracotomy, general technique. (From Custalow CB: Color atlas of emergency department procedures, Philadelphia, 2005, Saunders.)

After entering the pleural cavity, gain good exposure. Karmy-Jones and associates⁶³ found that 20% of their patients undergoing EDT via the anterolateral approach needed to have the initial incision extended. To gain better exposure first use your hands to open the chest cavity. Then place a Finochietto retractor (rib spreader) between the ribs with the handle and the ratchet bar directed downward toward the axilla (see Fig. 18.4, step 5). If the retractor were to be placed with the handle up, the ratchet bar would prevent extension of the incision into the right side of the chest. Ribs may be broken during spreading, so be careful to not get cut on the sharp bone edges. If massive hemothorax is encountered, remove the clots manually, suction out the blood, and use towels to absorb any blood spilling from the chest. If the site of injury is to the right of the heart and cannot be reached, extend the incision into the right side of the chest with a Gigli saw, Liebsche knife, sternal osteotome, or standard trauma shears. Before performing EDT it would be prudent to familiarize oneself with the instruments included in the EDT tray, but do not take the time for this during an actual case.

Pericardiotomy

For a patient in cardiac arrest, if there is no other obvious injury in the chest and the myocardium cannot be visualized, open the pericardium. It may be difficult to definitively rule out pericardial tamponade by visual inspection alone. If in doubt, use forceps to elevate a portion of pericardium and carefully incise it to assess for hemopericardium.

If you are confident that there is no pericardial tamponade, leave the pericardial sac closed while you address other life-threatening injuries. Opening the pericardium increases the risk for complications such as delay in the onset of cardiac compressions, damage to the myocardium or coronary vessels, or cutting of the left phrenic nerve. Previous pericardial disease may also have caused adhesions, and if you attempt to separate these adhesions rapidly, you can tear the atria or right ventricular wall. The incidence of traumatic rupture of the atria or the right ventricle during massage is greater when the pericardium is open. Furthermore, with an intact pericardium pressure is distributed over a larger area, and the pericardial fluid seldom allows compressing fingers to remain in one spot for a prolonged period.

Perform pericardiotomy if tamponade is present or suspected. This procedure is performed anterior and parallel to the left phrenic nerve (see Fig. 18.4, step 6). Begin the incision near the diaphragm to avoid injury to the coronary arteries. Lift the pericardial sac with toothed forceps, and use scissors to make a small hole. Extend the incision with scissors in a cephalad direction along the anterior aspect of the pericardium. Extend the incision so that it reaches from the apex of the heart to the root of the aorta. When the pericardium is under tension, it may be difficult to grasp the pericardium with forceps. In this case, use sharp, straight Mayo scissors to divide the pericardium by layers. If the heart is in arrest, speed is important, so use sharp scissors to “catch” the pericardium and start the pericardiotomy. To do this procedure, hold the point of the scissors almost parallel to the surface of the heart and use enough pressure to create a wrinkle in the pericardium to puncture it as the scissors move forward. Apply moderate pressure to puncture the fibrous pericardium. Be cautious because if the point of the scissors is unnecessarily angled toward the heart, the sudden “give” that occurs when you

open the pericardium may result in laceration of the myocardium. Remove clots of blood from the pericardial sac with a sweeping motion using your gloved hand, sterile lap sponges, or gauze pads. If cardiac repair or cardiac compressions are needed, deliver the heart from the pericardial sac. To do this, place your right hand through the pericardial incision and encircle the heart, pull it into the left side of the chest, and place the pericardial sac behind the heart.

Internal Cardiac Defibrillation

It is not uncommon to encounter cardiac dysrhythmias during EDT resuscitative efforts. Recommendations for internal defibrillation are the same as those for external defibrillation: ventricular fibrillation and tachycardia without pulses are immediate indications for defibrillation. With an open chest, internal defibrillation is the procedure of choice.

To perform internal defibrillation, place the *internal paddles* on the anterior and posterior aspects of the heart. The current is delivered through the circular tips of the paddles onto the surface of the heart. There is decreased electrical impedance with direct myocardial contact, and as a result less energy is needed than with standard defibrillation (typically 10 to 50 J). If internal paddles are not available, perform defibrillation in the usual manner with external paddles or electrodes.

Direct Cardiac Compressions

Three techniques for cardiac compression have been described: one-handed compression, one-handed sternal compression, and two-handed (bimanual) compression (Fig. 18.5). To perform the one-handed compression method, place your thumb over the left ventricle, the opposing fingers over the right ventricle,

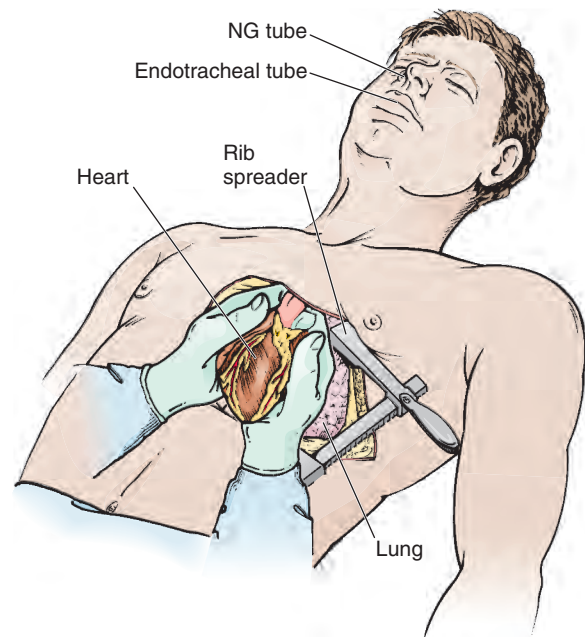

Figure 18.5 Two-handed method of cardiac massage. Compress the ventricles toward the interventricular septum. Note how the hands flank the left anterior descending artery, which overlies the septum. Avoid using excessive fingertip pressure or lifting the heart, which slows ventricular filling by distorting the soft atrial-caval junction. NG, Nasogastric.

and your palm over the apex of the heart. To perform one-handed sternal compression, hold your fingers flat. Keep the fingers tightly together to form a flat surface over the left ventricle and compress the heart up against the sternum with your fingers. To perform two-handed compression, cup the left hand and place it over the right ventricle. Hold the fingers of the right hand tightly together to form a flat surface supporting the left ventricle. Push the flat surface of your right-hand fingers to compress the heart against the cupped surface of the left hand. The bimanual technique has been shown to be consistently superior.⁶⁴

A difference of opinion exists regarding the optimal rate at which the heart should be compressed. Some recommend a rate of 50 to 60 compressions/min; however, no physiologic data support such a recommendation. American Heart Association guidelines for closed-chest CPR recommend a rate of at least 100 compressions/min.⁵¹ It is conceivable that this would also apply to OCCM.

It is important to remember the following points while performing cardiac compression:

1. Use the entire palmar surface of the fingers. Avoid fingertip pressure.
2. For each method, adjust the force of compression so that it is perpendicular to the plane of the septum. The anterior descending coronary artery is located over the interventricular septum, making this a helpful landmark to orient your hand properly.
3. Position your fingers so that the coronary arteries will not be occluded.
4. Venous filling of the heart is especially sensitive to changes in position. Maintain a relatively normal anatomic position of the heart to prevent kinking of the vena cava and pulmonary veins. Do not angle the heart more than 30 degrees into the left side of the chest.
5. It is essential to completely relax the heart between compressions to allow it to refill completely.

Control of Hemorrhagic Cardiac Wounds

To partially control active bleeding from a ventricular wound, place one finger over the wound and use the other hand to stabilize the beating heart. This maneuver buys time while you begin to repair the injury and continue with resuscitation. If the heart is not beating, you may perform closure of the injury before resuscitation and defibrillation, although this is controversial. If you elect to repair the injury before attempting to restart the heart, perform intermittent cardiac massage. Surgical staples can be used to close a ventricular wound and are an extremely rapid method for controlling hemorrhage (Fig. 18.6).⁶⁵ This technique is particularly useful with large or multiple lacerations. Another advantage is that stapling does not expose the operator to the risk associated with needlestick. Macho and coworkers⁶⁶ reported a 93% success rate in temporarily controlling hemorrhage in 28 patients (33 lacerations) with penetrating injuries to both the atria and ventricles by using a standard skin stapler with wide (6-mm) staples placed at 5-mm intervals (Auto-Suture 35W, US Surgical Corp., Norwalk, CT). The rotating long neck of the Ethicon Proximate Quantum Skin Stapler (Model PQW-35, Ethicon, Inc., Somerville, NJ) is helpful in obtaining proper orientation of the staples during placement. The staples can be left in place and reinforced or replaced on further exploration in the operating room.

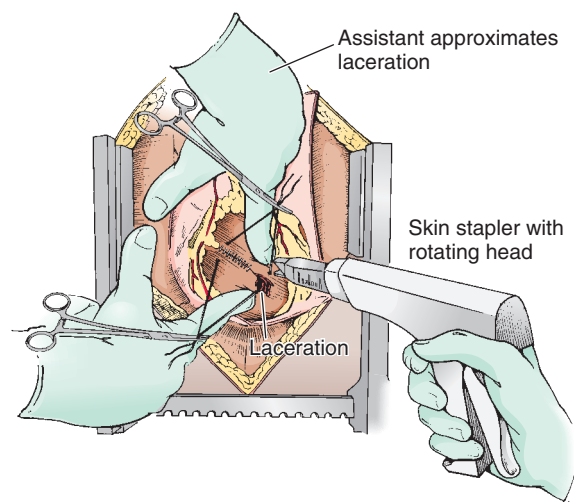

Figure 18.6 Technique of cardiac stapling to temporarily control hemorrhage. Ask an assistant to approximate the tissues with fingertip pressure, or as illustrated, use two half-horizontal sutures to approximate the wound edges and reduce bleeding. Use a skin stapler with wide (6-mm) staples and place them 5 mm apart. This technique may be used for atrial and ventricular lacerations. After stabilizing the patient's condition, revise the wound in the operating room.

Alternatively, repair the wound by placing several horizontal mattress sutures under the tamponading finger (Fig. 18.7). Polypropylene 2-0 or 3-0 monofilament (Prolene) suture is recommended for cardiac repair, but nonabsorbable silk can also be used. Avoid smaller sutures and nylon sutures. If multiple sutures are needed, lay them all in place before they are tied. This allows you to attain equal distribution of wound tension, which prevents tearing of the myocardium.⁶⁷ Alternatively, pass the suture underneath, over, and through Teflon pledgets to prevent the suture from cutting through the myocardium. Pledgets are especially important for reinforcement when the myocardium has been weakened by the blast effect of a bullet,⁶⁸ or when suturing the thinner-walled atria or right ventricle. An alternative to Teflon pledgets is to use small rectangles of pericardial tissue cut from the opened pericardium.

For large wounds that cannot be controlled with pressure, place an incomplete horizontal mattress suture on either side of the wound (Fig. 18.8). Cross the free ends to stop the bleeding. Then the actual reparative sutures can be placed accurately. It must be stressed that suturing the myocardium requires good technique. Excessive tension may tear the myocardium and aggravate the situation. Keys to success include using appropriately sized suture, obtaining a generous “bite” with the needle, and applying only enough tension to control the bleeding.

If exsanguinating hemorrhage is not controlled by the aforementioned methods, temporarily occlude inflow to the heart. Apply inflow occlusion intermittently for 60 to 90 seconds. During occlusion, the heart shrinks, hemorrhage is controlled, and you can place sutures in a decompressed injury. Two techniques that are useful are vascular clamping of the superior and inferior vena cava for partial inflow occlusion,⁶⁹ and the Sauerbruch grip (Fig. 18.9).⁷⁰ The Sauerbruch grip can be performed quickly with the added advantage of cradling and stabilizing the heart while you repair the wounds over either the ventricle or the left atrium. It involves occlusion of the
